The BPNN-based surrogate model for predicting tunnel deformation caused by excavation is more efficient and user-friendly than the FE simulation. Moreover, the computational time of the surrogate model is as fast as microseconds to milliseconds. Simultaneously, accuracy of the surrogate model can predict tunnel deformation with an error of less than 1.5 mm from the measured data of the actual project.

7 CONCLUSION

In this study, we proposed a hybrid FE and surrogate model approach to predict excavation-induced deformation of existing tunnels, with the ultimate purpose of constructing a digital twin of a tunnel–soil–foundation pit system. The following conclusions were drawn:

- (1) A parametric FE model of a shield tunnel during excavation of adjacent foundation pit was established with the ability to simulate different scenarios, such as relative position of the tunnel and foundation pit, soil parameters, geometric parameters, material parameters, retaining structures of the foundation pit, and construction stages. Parametric FE is the data source and foundation due to which surrogate model is physically interpretable.
- (2) The uniform design method shows advantages when faced with complex numerical problems with high dimensions and multiple levels by proposing a surrogate model with high accuracy and low computational cost.
- (3) The BPNN-based surrogate model showed good prediction performance. Considering ± 1 mm error as the accuracy evaluation standard, the accuracy of validation set was $> 91.38\%$, accuracy of the test set was $> 80\%$, error with the measured data from a real project was < 1.5 mm; and the calculation time was milliseconds.
- (4) Even though there is scope for further improvement, the verification results showed that the approach has the potential for generalization and application.

ABSTRACT: In this study, the authors investigate the strain caused by the release of residual stress introduced by welding when fatigue cracks initiate and propagate. The change in the strain under the unloading condition due to fatigue crack initiation and propagation is verified via fatigue tests performed on an out-of-plane gusset joint. Subsequently, to measure and transfer the strain under the unloading condition in actual bridges, the authors create a data logger device using a single-board computer equipped with an Internet-of-Things system. The abovementioned fatigue tests are performed using the developed logger device. The measured strains are transferred via a low-power wide-area network and monitored on an Internet platform. Using the proposed system, the strains can be monitored periodically to capture fatigue crack initiation and propagation via the Internet platform.

1 INTRODUCTION

The initiation and propagation of fatigue cracks are typically encountered on steel bridges. Currently, the number of fatigue cracks in orthotropic steel decks in urban highway bridges is increasing in Japan. Some fatigue cracks in steel bridges have been monitored for crack propagation instead of for crack repair because of the slow growth of fatigue cracks. However, periodic monitoring of fatigue cracks is costly and labor intensive. Therefore, low-cost monitoring systems for fatigue-crack propagation are required.

In fatigue tests, the initiation of a fatigue crack is detected by a decrease in the strain range (or stress range) measured using strain gauges near the welding. This is because fatigue cracks prevent stress transfer at the welded joint. However, this method cannot be applied to actual bridges carrying random-weight vehicles. Meanwhile, researchers reported that different strains were measured under unloading conditions in fatigue tests owing to the initiation and propagation of fatigue cracks (Ishikawa et al. 2022). This is because the residual stress generated near the welded joint was released by fatigue crack initiation. By focusing on the change in residual stress near the weld toe, a method to detect fatigue cracks by measuring the residual stress using X-rays has been proposed (Ishikawa et al. 2017).

In this study, the change in strain under the unloading condition via fatigue crack initiation and propagation was verified based on fatigue tests performed on an out-of-plane gusset joint. Additionally, to measure and transfer the strain under the unloading condition in actual bridges, the authors created a data logger device using a single-board computer equipped with an Internet-of-Things (IoT) system. Fatigue tests under stress ratio $R = -1$ were performed on the out-of-plane gusset joint, and the strain was measured under the unloading condition

using the developed logger device. The measured strains were transferred via low-power wide-area (LPWA) network and monitored on an Internet platform.

2 CONFIGURATION OF STRAIN DATA LOGGER

The main components of the strain logger and data communication system used in this study are shown in Figure 1. The Arduino Uno R3 was used as a single-board computer. A two-channel strain amplifier shield (AD8426) was used for strain measurement. This equipment can measure -2000 to 2000 microstrains. In this study, two strain amplifier shields were used in a cascade configuration to measure four sets of strain data. In addition, a strain gauge bridge was constructed using 120 Ω metal film resistors with a tolerance of +0.1% to connect the strain gauges with the 120 Ω resistors. Power was supplied to the developed logger from a laptop computer. Notably, in field measurements, a strain gauge with a resistance of 350 Ω is preferable for reducing battery consumption.

A Sigfox shield for Arduino (UnaShield V2S) was used to transmit the measurement data for the LPWA. Additionally, Soracom Air for Sigfox (Soracom IoT platform) was used as the web platform to monitor the measurement data, as shown in Figure 1.

Figure 1. Main component of strain data logger and Soracom IoT platform.

3 FATIGUE TEST

3.1 Specimens

The out-of-plane gusset weld joint tested in this study is shown in Figure 2. The material properties and chemical compositions of the specimens are presented in Table 1. The out-of-plane gusset weld joint specimen used in this study comprised a 12-mm-thick, 200-mm-wide main plate, and a 12-mm-thick, 100-mm-high gusset plate. The gusset plate was fillet welded to the main plate via semi-automated CO₂ gas-shielded arc welding. The material used to create the specimen was JIS-SM490Y, whose yield and tensile stresses are 365 and 490 MPa, respectively.

In this study, a plate bending fatigue test machine (Yamada et al. 2007) was used for the fatigue tests, as shown in Figure 3. This plate bending tester has been used in many studies (Baik et al. 2011, Fu et al. 2018, Ishikawa et al. 2017, 2022, Yuanzhou et al. 2016). For the plate bending fatigue tests of the out-of-plane gusset welded joints, the nominal stress range was defined as the average strain range measured by strain gauges B and C (see Figure 2) multiplied by the Young's modulus of steel.

Table 1. Material properties and chemical compositions.

Steel type	Yield stress (MPa)	Tensile strength (MPa)	Elongation (%)	Chemical compositions (%)				
				C	Si	Mn	P	S
SM490Y	431	549	25	0.16	0.28	1.32	0.009	0.004

Figure 2. Out-of-plane gusset specimen, and definition of fatigue crack sizes.

Figure 3. Plate bending fatigue test.

Fatigue tests were performed at a stress ratio of $R = -1$, and the nominal stresses were set at 70, 95, 110, and 150 MPa; the specimens subjected to these stresses were labeled as AW70, AW95, AW110, and AW150, respectively. To monitor the fatigue crack initiation and propagation, shielded copper wires with a diameter of 0.05 mm were adhered onto the weld bead and the surface of the main plate; subsequently, the fatigue lives corresponding to the crack sizes were obtained, as shown in Figure 2. N_{toe} , N_b , and N_{10} were used to denote the crack sizes when a crack initiates at the weld toe, when the crack propagates off the fillet weld toe, and when the crack propagates to 10 mm long, respectively.

3.2 Strain measurement

In this study, uniaxial and biaxial strain gauges with a gauge length of 1 mm (three-wire temperature compensated) were used. The locations of strain gauges A to G are shown in Figure 2. For the strain gauge at CH-A placed near the weld toe, two-directional gauges were used to measure the strain perpendicular and parallel to the fatigue crack. The longitudinal and transverse direction gauges at CH-A was designated as CH-AL and CH-AT, respectively.

To compare the strain measured by the dynamic strainmeter and the developed strain data logger, two strain gauges were adhered to CH-A, -B, -F, and -G at each specified location in the specimen. However, the strain gauges fixed to the dynamic strainmeter and the developed data logger were separated by approximately 5 mm in the transverse direction of the specimen. Every 10–15 min, 4096 data points (approximately 2 s) were recorded at 2000 Hz using the dynamic strainmeter. The strain measured by the developed data logger via the LPWA network was similar to that measured by the dynamic strainmeter, with the maximum and minimum strains measured once every 10 to 15 min.

4 FATIGUE TEST RESULTS AND DISCUSSION

4.1 Fatigue strength

Figure 4 shows the relationship between stress range and the number of cycles for the fatigue life N_{10} obtained from the fatigue tests performed in this study. The figure also includes the reference data (JSSC, 2020). Based on the figure, the fatigue strength of the specimens used in this study was consistent with the fatigue test results.

Figure 4. Fatigue strength N_{10} of out-of-plane gusset specimens.

4.2 Change in strain range

The relationship between the strain range measured by the dynamic strainmeter at each location in Specimen AW95 and the number of cycles is shown in Figure 5. The mean strain at each measurement location is plotted in this figure. Because the fatigue test was conducted at a stress ratio of $R = -1$, the mean strain became the strain under the unloading condition. Additionally, the figures show the fatigue lives of N_{10c} , N_b , and N_{10} .

The strain range measured by CH-AL near the weld toe decreased gradually owing to fatigue crack development, whereas the strain ranges at CH-B and C increased (see Figure 5). This increase was due to the stress concentration at the crack tip approaching the strains at CH-B and C. The strain range at CH-F, which was located at the back side of the main plate, changed owing to fatigue crack development as well. At all locations, the changes in the mean strain were more significant than those in the strain range. This is because the residual stress released by the fatigue crack almost yielded the stress in the tension-introduced area.

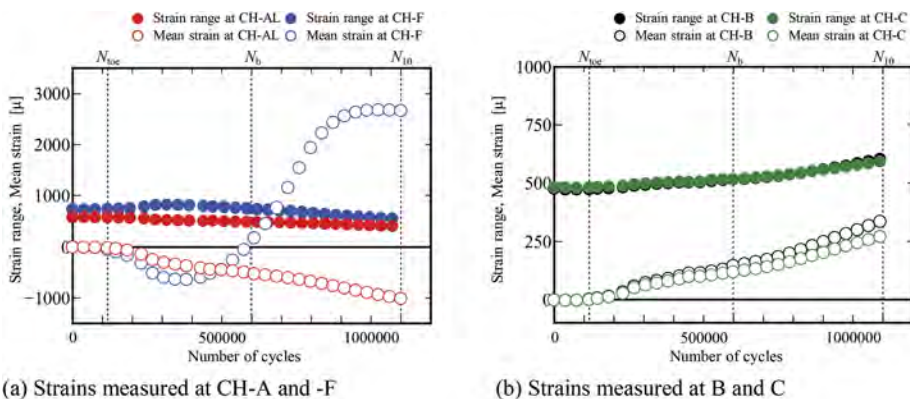

Figure 5. Relationships between strain range and each of mean strain and number of cycles ($\Delta\sigma=95$ MPa).

4.3 Change in mean strain

The relationships between the change in the mean strain obtained from gauges CH-AL, -B, -F, and G in the axial direction of the specimen and the number of cycles based on the fatigue tests are shown in Figure 6. In these figures, the mean strains measured by the dynamic strainmeter and developed data logger are shown. The results for specimens AW150 and AW95 are shown at positions CH-AL, -B, and -F, whereas those for specimens AW110 and AW70 are shown at positions CH-AL, -B, and -G. The fatigue life for each crack length is shown in the figures. As shown in Figure 6, the mean strain at CH-AL, which is in the tensile residual stress region, approached the compressive side, whereas the mean strain at CH-B, which is in the compressive residual stress region, approached the tensile side. The mean strain at CH-F on the back surface of the main plate approached the compressive side and then the tensile side. The mean strain at CH-G at the weld bead decreased at lower cycle numbers compared with that at the other measurement points and then increased. Changes in the mean stress depended on the residual stress condition and crack propagation path. The strain in the tensile residual stress area evolved to compressive strain via crack initiation and propagation, whereas the strain in the compression residual stress area evolved to tensile strain via the crack. Additionally, the strain measured at CH-F and -G near the crack propagation path changed owing to crack propagation and residual stress release.

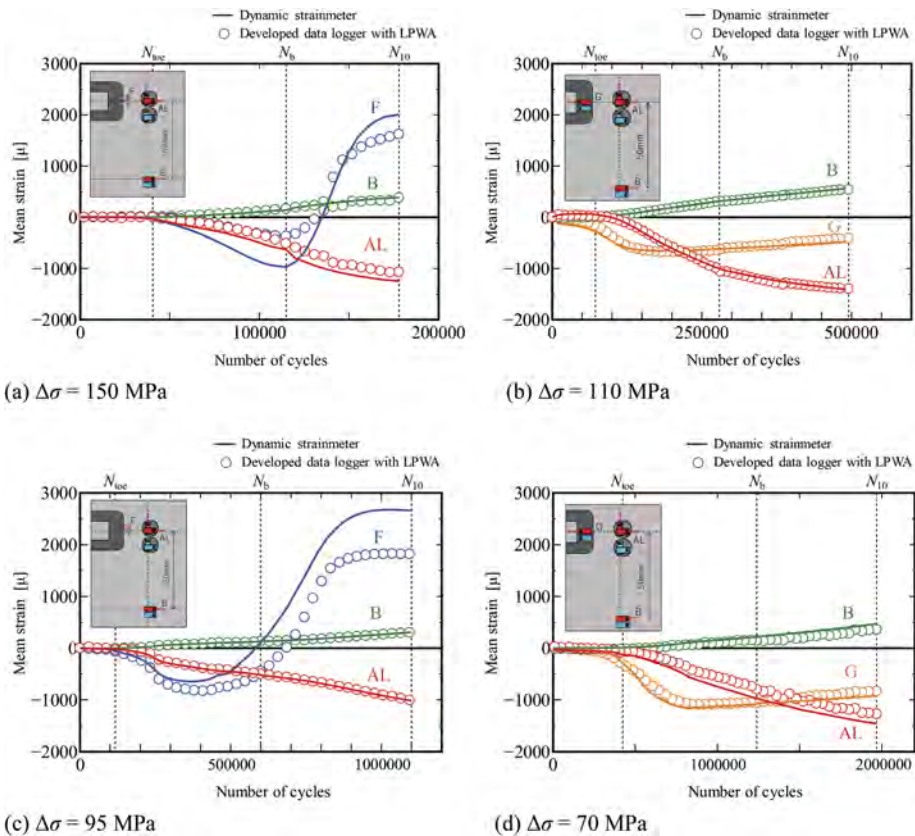

Figure 6. Relationships between mean strains recorded at CH-AL, -B, and -F and number of cycles.

As shown in Figure 6, the mean strain measured by the developed data logger and the dynamic strainmeter show a similar tendency. However, their measurement values differed slightly owing to the difference in the location of the strain gauges. Therefore, the initiation and propagation of fatigue cracks can be evaluated based on the change in the mean strain of the gauges at locations CH-AL, -B, -F, and -G in the axial direction of the specimen.

Figure 7 shows the relationship between the mean strain and number of cycles obtained from biaxial strain gauges CH-AL and -AT near the weld toe in the axial and transverse directions, respectively. The results shows that the mean strain measured by gauges CH-AL and CH-AT decreased and increased, respectively. This occurred because the strain direction of CH-AL was in the tensile residual stress region, whereas that of CH-AT was in the compressive residual stress region.

The measurements in the axial and transverse directions might be distinguishable under the effect of temperature change even at the measurement positions of gauges AL and AT because the decrease/increase in the mean strain can be confirmed.

Figure 7. Relationships between mean strain at CH-AL and AT and number of cycles.

5 CONCLUSIONS

In this study, an IoT strain data logger transmission system using a single-board computer equipped with an LPWA network was developed. Subsequently, the feasibility of using the system to monitor fatigue crack initiation and propagation for out-of-plane gusseted welded joints subjected to plate-bending fatigue tests was clarified. The main conclusions obtained were as follows:

- 1) In the out-of-plane gusset specimen, the fatigue crack initiation and propagation can be evaluated by measuring the strain under the unloading condition (mean strain in this study) near the weld joint using a strain data logger.
- 2) The measurements performed in the tensile and compressive residual stress regions near the welding joint and the strain under the unloading condition in the axial and transverse directions of the specimen can be distinguished under the effect of temperature change.
- 3) The change in strain by the releasing of residual stress is considered to be a suitable index for fatigue crack propagation monitoring using LPWA.

Detection of debonding of CFRP bonded steel members using the AE method

M. Mizutani & T. Ishikawa

Kansai University, Suita-shi, Osaka, Japan

Y. Fujii

Kanazawa Institute of Technology, Nonoichi-shi, Japan

ABSTRACT: In the CFRP bonded repair of steel members, the stress in the steel members is transmitted to the CFRP by the adhesive layer. The debonding of the CFRP should be prevented to sustain the repair effect. Therefore, early detection of CFRP debonding is necessary for the CFRP bonded repair of steel members. This study conducted debonding tests on CFRP bonded steel plates using strain gauges and installed AE sensors. Consequently, elastic waves were detected by the AE sensor at an earlier stage than debonding detection by strain gauges. The position of elastic wave generation during debonding was determined by the AE, and the debonding propagation behavior was compared with that given by the energy release rate. The results indicated that the two trends were almost identical.

1 INTRODUCTION

In Japan, many steel bridges have suffered from corrosion damage. Corrosion countermeasures include repainting for minor corrosion of steel members and bolting the patch plates for corrosion with sectional loss of steel members. Carbon fiber reinforced polymer (CFRP) bonded repair is also a repair method for corrosion-damaged steel members. CFRP is a composite material with excellent material properties such as light weight, high strength, and corrosion resistance. CFRP bonding repair has advantages in terms of workability and corrosion resistance compared with steel patch repair by welding or high-strength bolts.

In CFRP bonded repairs, the stress in the steel members is transmitted to the CFRP by the adhesive layer. Stresses in the adhesive are concentrated at the CFRP end, where the cross section changes. Therefore, when the applied load increases, the CFRP may be debonded. Guidelines for CFRP bonding repairs prescribe the prevention of delamination of CFRP under the design load (Cadei et al. 2004 and JSCE 2018). The guidelines prescribe the maximum principal stress and energy release rate as indices to evaluate CFRP debonding. Currently, CFRP bonding repairs are widely performed on steel members of bridges worldwide (Hollaway and Cadei 2002, Miller et al. 2001 and Sugiura et al. 2009). However, the possibility of debonding of CFRP in in-service still remains for CFRP bonding repair. Therefore, techniques for the early detection of CFRP debonding are necessary to ensure the safety of steel bridges.

Strain gauges are often used to detect debonding in the specimens of CFRP bonded steel members in laboratory tests. Debonding at the location of the strain gauge is determined by the change in the relationship between the applied load and the strain. For the fatigue tests of CFRP bonded steel members, a method of determining the debonding of CFRP and stopping the test at an arbitrary debonding position by electrically detecting the breakage of a thin enameled wire placed on the side of the specimen has also been attempted (Thay et al. 2018). Because these debonding detection methods can only detect debonding at the sensor location, multiple sensors

must be installed to evaluate the progress of debonding. In contrast, the acoustic emission (AE) method is a method to detect delamination from a distant location (Matta et al. 2006 and Zhou et al. 2004). The AE method analyzes brittle fracture phenomena such as adhesive debonding as elastic waves. Elastic waves are transmitted through steel members when adhesives are damaged, and AE sensors can be attached to steel members. In this study, the authors focused on the AE method as a technique for monitoring the debonding of CFRP bonding repairs and conducted debonding tests using strain gauges and AE sensors installed on the specimens.

2 DEBONDING TEST OF CFRP BONDED STEEL PLATES

In this study, two cantilever bending tests were conducted using CFRP at different bonding positions. The test types are shown in Figure 1. The specimens are described in the following section.

2.1 Tests to evaluate initial delamination

The test specimen and setup are shown in Figure 1(a). In the test shown in Figure 1(a), debonding propagates instantaneously. This is because debonding of the CFRP propagates in the direction in which the applied bending moment increases. This test simulates the debonding of the CFRP ends under severe conditions. In this study, the test shown in Figure 1(a) was called the ID test.

The material properties of the steel plates, CFRP, and adhesives used for the specimens in the ID test are listed in Tables 1-3. A CFRP with the fiber direction in the longitudinal direction was used. The steel plate was 50 mm wide and 9 mm thick, and the CFRP was bonded 150 mm from the steel plate end. The CFRP was bonded along the fiber direction of the CFRP, corresponding to the axial direction of the specimen. A two-component epoxy resin was used as an adhesive. After CFRP bonding, the specimens were cured in a room at 20°C for at least 24 h before loading tests were conducted. For the ID tests, half of the CFRP was fixed and the specimen was loaded with a manual jack at 275 mm from the fixed end, as shown in Figure 1(a).

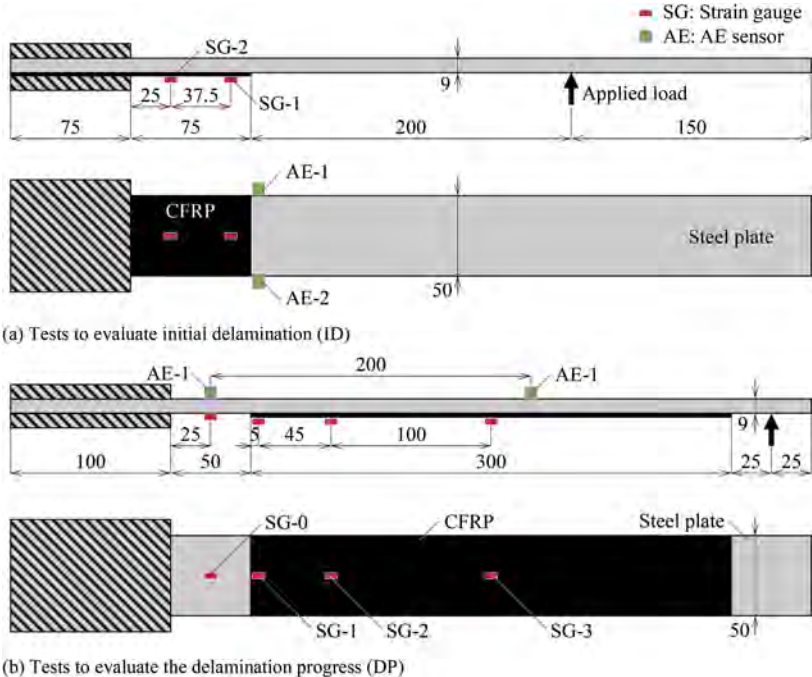

Figure 1. Dimension of specimen and test setup (unit: mm).

Table 1. Mechanical properties of steel plates.

Type	Steel	Thickness [mm]	Yield stress [N/mm ²]	Tensile strength [N/mm ²]	Elongation [%]
ID	SM490Y	9	420	550	25
DP	SM490Y	9	427	553	25

Table 2. Mechanical properties of CFRP.

Thickness [mm]	Tensile strength [N/mm ²]	Young's modulus [kN/mm ²]
2	2,400	167

Table 3. Mechanical properties of adhesive.

Compressive elastic modulus [N/mm ²]	Poisson's ratio	Tensile shear strength [N/mm ²]
2,000	0.38	more than 9.8

Strain gauges and AE sensors were placed on the specimen at the positions shown in Figure 1(a). Two AE sensors were mounted on the side of the specimen at the CFRP end of a CFRP bonded steel plate. The AE sensors had a resonant response at 300 kHz and a good frequency response in the range of 125-750 kHz. The AE sensors had a threshold value of 45 dB and acquired elastic waves at a sampling frequency of 1 MHz.

2.2 Tests to evaluate delamination progress

In the test shown in Figure 1(b), called the DP test, the debonding of the CFRP propagates in the direction where the applied bending moment decreases. Therefore, debonding progresses gradually from the CFRP end toward the center of the specimen. Hence, the propagation of debonding by AE as well as the energy release ratio can be confirmed by the DP test. The materials used for the specimens in the DP test are listed in Tables 1-3. A 300 mm long CFRP was bonded 50 mm from the fixed side. The curing procedure for the specimens in the DP test was the same as that used in the ID test. In this test, the load was applied 375 mm from the fixed end using a universal testing machine with displacement control at a speed of 1 mm/min.

Strain gauges and AE sensors were placed on the specimen at the positions shown in Figure 1 (b). Two AE sensors were mounted on the top surface of the specimen, 200 mm apart, as shown in Figure 1(b). The AE sensor used in this test was the same as that used in the ID test. However, the AE sensor was set to a threshold value of 40 dB and sampling frequency of 5 MHz.

3 TEST RESULTS

3.1 Initial delamination specimens

Figure 2 shows the relationship between the applied load and the strain for the ID test. The vertical axis represents applied load P , and the horizontal axis represents strain ε of SG-1 and SG-2 in the CFRP. The relationships between the applied load and the strain of the CFRP show a linear relationship up to the sudden drop in the strain around applied load $P = 1.0$ kN. This is because the stress is no longer transmitted to the CFRP owing to the debonding. The sudden drop in the strains in SG-1 and SG-2 indicates that debonding of the CFRP

developed simultaneously. Figure 2 shows that the debonding applied load of ID-1 was 1.01 kN and that of ID-2 was 1.02 kN.

Figures 3 and 4 show the AE results for test specimens ID-1 and ID-2, respectively. Figure 3 shows the cumulative counts with respect to the elapsed time and applied load. Figure 4 shows the energies with respect to the elapsed time and applied load. In each figure, the time when the CFRP debonding occurred is indicated by a dashed line.

As shown in Figure 3, the cumulative counts increased when debonding occurred. In addition, the accumulated counts increased before debonding (for example, around 270 s in Figure 3(a)). As shown in Figure 4, more than 30 V·s of energy was generated at the time of debonding. As shown in Figure 4, the energy of approximately 10 V·s was detected at the time when the cumulative counts increased before debonding, as shown in Figure 3. The detection of this small energy suggested that micro-damage occurred to the adhesive prior to debonding.

3.2 Delamination progress specimens

Figure 5 shows the applied load–strain relationship obtained from the DP tests. The filled circles within the experimental values are measured per second. The theory shown in Figure 5 is based on the shear lag theory (Ishikawa et al. 2012) derived by considering the force transfer of the adhesive that was derived for a similar condition in the DP test. As shown in Figure 5, the experimental and theoretical values were in good agreement with each other in the lower applied load range, where the experimental results showed linearity. However, strain gauge SG-1 in DP-1, as shown in Figure 5(a), showed a small response. As shown in Figure 5, as the applied load increased, the values of the strain gauges SG-1 through SG-3 on the CFRP side reached zero. The applied loads when the strain was zero were defined as the debonding loads at each strain location. The debonding loads are listed in Table 4. Figure 5 and Table 4 show

Figure 2. Relationship between the applied load and strains for the ID test.

Figure 3. Counts with respect to the elapsed time and applied load for specimen ID.

Figure 4. Energies with respect to the elapsed time and applied load for specimen ID.

that debonding of the CFRP gradually propagated from the CFRP end on the fixed side toward the center of the specimen as the test load increased. This was because the closer the debonding propagated toward the applied load position, the smaller was the bending moment generated at the debonding tip in relation to the applied load. This was also because the energy release rate per unit load at the debonding tip decreased as the debonding progressed, and the remaining adhesive length of the CFRP became shorter (Ishikawa et al. 2012). In the case of SG-3, where the measured strain gradually decreased after reaching a maximum value, the lag in force transmission owing to the movement of the bonded edge caused by the debonding process might be affected. Compared with DP-1 (Figure 5(a)), the debonding load of DP-2 (Figure 5(b)) was generally lower and the bond strength was weaker.

Figure 6 shows the cumulative counts with respect to the elapsed time and applied load. The drawn AE result is the only event used in the analysis of the source of the elastic wave with the two AE sensors described below. The time of debonding at zero strain at each location is indicated by dashed lines in Figure 6. Notably, the cumulative count of AE increased with the time of debonding at SG-1 to debonding at SG-3. However, as shown in Figure 6(a), for DP-1, the accumulated counts increased even before debonding of SG-1. As aforementioned, the small change in strain in DP-1_SG-1 might indicate that debonding at SG-1 was not accurately estimated. The slope of the cumulative counts for specimen DP-2 (Figure 6(b))

was larger than that for specimen DP-1 (Figure 6(a)). This indicated that debonding propagation was faster for specimen DP-2 than for specimen DP-1.

3.3 Analysis of the debonding evolution of specimen DP

Figure 7 shows the results of the applied load and position of elastic wave generation. The position of the generated elastic wave was linearly evaluated using the time difference between the events when the generated elastic wave arrived at the two AE sensors. The velocity of sound propagating through the steel was assumed to be 5,900 m/s. To reduce the noise in location determination, a filter was applied to modify the threshold value to 50 dB. The solid line in Figure 7 shows the relationship between the debonding load and the debonding length from the CFRP end that is determined by the energy release rate described below.

As shown in Figure 7, as the load increased, the debonding tip location moved from the fixed side to the center of the specimen. Therefore, in conclusion, the debonding propagation behavior was captured by the AE sensors. However, elastic waves were also observed at points where the CFRP was not adhered ($x = -25$ to 0 mm). Therefore, the measurement method must be improved to capture only the elastic waves caused by debonding and evaluate the AE parameters. In addition, it should be noted that only two AE sensors were used in this study; therefore, evaluation in the width direction was not possible. In particular, specimen DP-1 might not debond uniformly in the width direction owing to the relationship between the applied load and the strain and the variation in the results of the AE method.

As shown in Figure 8, considering debonding with a length of l_{cr} from the CFRP end on the fixed side, the energy release rate associated with the progress of debonding is given by the equations below (Mizutani et al. 2022).

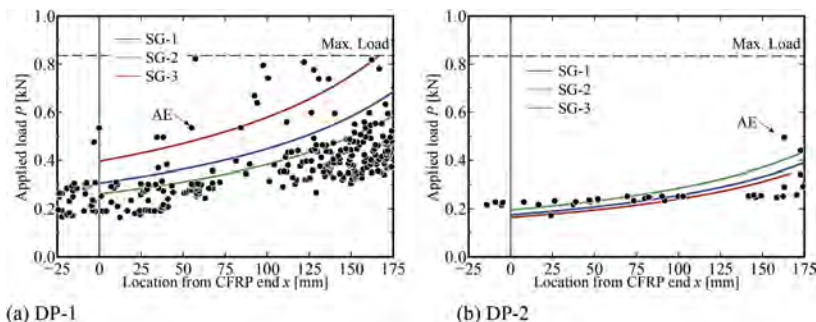

Figure 7. Counts with respect to the elapsed time and applied load for specimen DP.

Figure 8. Modeling of debonding for the energy release rate.

Table 5. Energy release rate for specimen DP (unit: N/mm).

	Reference strain gauges		
	SG-1	SG-2	SG-3
DP-1	0.085	0.062	0.143
DP-2	0.028	0.035	0.025

$$G = \frac{h}{2G_e} \tau_{cr}^2 \quad (1)$$

$$\tau_{cr} = -\frac{cK}{ab_c} \left\{ \frac{L + l_b}{\tanh(cl_b)} - \frac{L}{\sinh(cl_b)} + \frac{1}{c} \right\} P \quad (2)$$

where $c = \sqrt{b_c G_e a^2 / (h E_s I_s K Z_1)}$; $K = 1 / (1 + Z_1 Z_2 r_s^2 / a^2)$; $r_s = \sqrt{I_s / A_s}$; $a = t_s / 2 + h + t_c / 2$; $Z_1 = 1 + I_c / (n I_s)$; $Z_2 = 1 + n A_s / A_c$; $n = E_s / E_c$; G = energy release rate at the debonding tip; τ = shear stress at the debonding tip; l_b = remaining bond length; E_s = Young's modulus of the steel plate; E_c = Young's modulus of CFRP; G_e = shear modulus of elasticity of adhesive; I_s = sectional secondary moments of the steel plate; I_c = sectional secondary moments of CFRP; A_s = cross-sectional area of the steel plate; A_c = cross-sectional area of CFRP; t_s = thickness of the steel plate; t_c = thickness of CFRP; h = thickness of adhesive; b_c = width of CFRP.

The energy release rate is a debonding index used in the Japan Society of Civil Engineers (JSCE) guidelines (JSCE, 2018). Shear stress τ (Equation (2)) was derived based on the shear lag theory. Table 5 lists the energy release rates calculated from the debonding loads at each strain gauge listed in Table 4. The $P - x$ relationships, which were calculated by applying the relationship between debonding length and applied load from Equation (1) by applying the values in Table 5 as the critical energy release rates, are shown in Figure 7. This figure indicates that the evaluation of debonding propagation by the energy release rate has a tendency similar to the results of debonding propagation given by the AE. In particular, the debonding evaluation using the SG-2 results showed good agreement with the AE results.

4 CONCLUSIONS

In this study, to evaluate the debonding of CFRP, debonding tests were conducted on CFRP bonded steel members using strain gauges and installed AE sensors. The cumulative counts and energies associated with debonding of the CFRP were identified from the ID test that evaluated the initial debonding. Consequently, elastic waves were detected by the AE sensor at an earlier stage than the detection of debonding by strain gauges.

The source of the elastic waves could be estimated using two AE sensors from the DP test that evaluated the evolution of the debonding propagation. As the applied load increased, the location of the elastic waves moved from the CFRP end on the fixed side to the center of the specimen. The energy release rate was used to evaluate the debonding propagation, and the results were almost identical to the AE results.

Condition-based maintenance of fatigue-sensitive structures using model predictive control

S. Kong, R. Cao, J. Cheng & Y. Liu

Huazhong University of Science and Technology, Wuhan, China

ABSTRACT: Structural damage such as fatigue cracks can cause the deterioration of structural performance during service life. Condition-based maintenance (CBM) methods are developing rapidly in life-cycle management to address the decision-making of fatigue structural maintenance. In this paper, a new CBM method for deriving the optimal maintenance policy is proposed using Model Predictive Control (MPC). MPC is an optimization-based control method for constrained systems. The control actions are decided by solving a nonlinear programming problem with constraints. A fatigue detail of an offshore wind turbine (OWT) structure is applied to demonstrate the proposed method. The results show that the MPC-based method is feasible to obtain low-cost CBM policies for life-cycle maintenance. Furthermore, the performance of MPC-based method is compared with policies obtained by the time-based cyclic repair approach. The comparison study shows that the MPC policies result in lower life-cycle costs in general.

1 INTRODUCTION

OWT is generally subjected to continuous deterioration during its service life. Structural damage such as fatigue cracking can lead to serious safety issues (Liu & Frangopol, 2019). To maintain an adequate reliability level, repairs should be planned at appropriate times during the lifetime (Cheng et al., 2022). Total life-cycle costs should be considered to decide on an optimal maintenance policy (Frangopol, 2011). Operating and maintenance (O&M) cost accounts for a large portion of the total life-cycle costs of OWT (Turan et al., 2009). Compared to operating costs, maintenance costs are more important in controlling the life-cycle costs of OWT (Ren et al., 2021). Maintenance has a strong influence on downtime duration over the lifetime of an offshore wind turbine and consequently contributes considerably to the total life-cycle costs. Though the performance of OWT degrades over time, reasonable and efficient maintenance strategies and procedures can reduce the downtime caused by aging equipment (Ren et al., 2021). Condition-based maintenance is an advanced maintenance strategy that attracts increased attention in solving maintenance problems. This paper proposes a new framework for deriving the optimal CBM maintenance policy.

Maintenance strategies are typically categorized as corrective (reactive) maintenance, proactive maintenance, and opportunistic maintenance according to when maintenance is conducted (Ren et al., 2021). Nielsen & Sørensen (2011) compared the costs of two distinct maintenance strategies for OWT, namely with and without the inclusion of periodic imperfect inspections. Dao et al. (2021) proposed an integrated maintenance strategy of corrective maintenance, imperfect time-based preventive maintenance and condition-based maintenance for OWT and compared with other traditional maintenance strategies. They evaluated the influence of different important parameters, such as failure rate, reliability of inspections, inspection interval, and the decision rule for repairs.

MPC is an optimization-based control method for constrained systems. Su et al. (2015) used MPC to extend a control system framework for optimal planning of railway maintenance operations. The merit of the MPC-based methodology is that the objective function explicitly captures

the trade-off between maintenance costs and the health condition of the OWT. This is crucial to facilitate the decision-making process. Moreover, other factors concerning the management of OWT like downtime due to maintenance, can also be conveniently added to the MPC optimization problem. MPC provides a promise method to derive the optimal CBM policy.

In this paper, an adaptable MPC-based framework for optimal life-cycle management planning of OWT is proposed. This framework is flexible and can be adapted dynamically considering the measured wind and wave data representative for the location of the OWT. The control actions are decided by solving a finite horizon optimal control problem in real time. A case study on an OWT is applied to demonstrate the proposed framework. This paper compares the maintenance costs using MPC with different horizons. A simple cyclic repair approach with the same objective function is also implemented and optimized for comparison.

2 MODEL DESCRIPTION

2.1 Fatigue degradation progress model

A widely used model for fatigue degradation progress adapted from fracture mechanics is the Paris Law (Paris & Erdogan, 1963). It has been adopted in wind turbine degradation modeling (Zhu et al., 2013). In this research, the OWT component degrades gradually, and its health state is represented by a continuous degradation indicator, D . It is shown in Equation 1.

$$\frac{dD}{dN} = C(\Delta K)^m \quad (1)$$

Where dD is the degradation growth, N is the number of load cycles, Δk is the stress intensity factor depending on the load applied on the component, C and m are material parameters representing material properties of the component.

Generally, the number of operating cycles per unit time is given. The number of cycles per hour is assumed to be constant $dN/dt = 360/h$. The equivalent fatigue degradation growth depending on time is presented as in Equation 2.

$$\frac{dD}{dt} = \frac{dN}{dt} C(\Delta K)^m \quad (2)$$

The continuous degradation indicator D is assumed to be calibrated on a relative scale from 0 to 1 for all components. The degradation $D = 0$ means a healthy component, while $D = 1$ represents a component with a bad state. The initial degradation size $D(0) = D_0$. The D is higher with the more severe degradation of the component. Maintenance makes D lower, which depends on the types of maintenance activity and its effectiveness.

Δk depends on the current damage size D (Nielsen & Sørensen, 2011), and is given by

$$\Delta K = \beta \cdot \Delta s \cdot \sqrt{\pi D} \quad (3)$$

$$\Delta s = H_t \cdot x_s \quad (4)$$

Where β is the geometry factor, and x_s is the proportionality factor of estimating Δs . H_t is the mean significant wave height. The wave height and the wind speed are strongly correlated (Braam & Eecen, 2005). In this paper, the main focus is to model different maintenance activities and to illustrate the benefits of CBM policies derived from MPC. Therefore, the wind speed is assumed as follow.

$$v_t = \alpha H_t \quad (5)$$

The accumulated degradation of the OWT component is updated by Equation 6.

$$D_{t+1} = D_t + \frac{dD}{dt} \Delta t \quad (6)$$

Then the time-dependent degradation D_t is obtained. However, some parameters mentioned before are associated with large uncertainty. For example, the degradation level after replacement depends on how well the replacement has been performed. In this paper, it is assumed to be a stochastic variable D_0 , which is also the initial degradation size. The mean significant wave height is also uncertain. These parameters are assumed to follow the distributions shown in Section 4. Considering the uncertainties, we can obtain the failure rate $P_f(t)$ depending on the current degradation growth D_t .

$$P_f(t) = \frac{N(D_t > 1)}{N_0} \tag{7}$$

Where N_0 is the number of cycles, and $N(D_t > 1)$ is the number of failures in N_0 .

Figure 1. Failure rate curve.

2.2 Maintenance activities and impacts

This paper evaluates three possible maintenance options: (1) to do nothing, (2) repair, and (3) replacement. To do nothing has no effect on the OWT component. A short description of the repair and replacement is given as follow.

- *Repair*: Repair can maintain the degradation level for a constant period T_0 . After this period, the failure rate will develop as before the repair.
- *Replacement*: Replacement is carried out when the condition has worsened, and the failure rate is fairly high. It requires much cost and time, but it can renew the component, which leads to a healthy status for a longer period.

Figure 2. Maintenance activities and impacts.

MPC-based method can be used to observe the probability of failure. It can combine the cost and performance in fixed horizons with the reliability of OWT components to decide what maintenance policies would be adopted at certain points.

3 MPC FOR MAINTENANCE OPERATION PLANNING

3.1 State space model

The failure rate $P_f(t)$ depending on time is shown in Equation 7. The failure rate at real time-step k is denoted by $x(k)$, and the failure rate at degradation time-step i is denoted by $P_f(i)$. Considering an auxiliary variable $\mathbf{P}(i)$ and the input $\mathbf{u}(k)$.

$$\mathbf{P}(i) = [P_f(i+1) \quad P_f(i) \quad 0] \quad (8)$$

$$\mathbf{u}(k) = [u_1(k) \quad u_2(k) \quad u_3(k)]^T \quad (9)$$

The state space model of failure rate at real time-step k is shown as follow.

$$\begin{cases} x(k+1) = \mathbf{P}(i)\mathbf{u}(k) \\ x(k+2) = [\mathbf{P}(i+1)\mathbf{u}(k+1) \quad P_f(i) \quad 0]\mathbf{u}(k) \\ x(k+3) = [[\mathbf{P}(i+2)\mathbf{u}(k+2) \quad P_f(i+1) \quad 0]\mathbf{u}(k+1) \quad P_f(i) \quad 0]\mathbf{u}(k) \\ \vdots \end{cases} \quad (10)$$

With the constraint:

$$M_1 \leq x(k) \leq M_2 \quad (11)$$

The M_1 is the lower bound of the failure rate, and the upper bound is the M_2 .

The input $\mathbf{u}(k)$ is a discrete input representing the three maintenance strategies: to do nothing, repair, replacement. The three control actions are associated with three binary variables $u_1(k)$, $u_2(k)$ and $u_3(k)$. Obviously, $u_1(k) = 1$ means to do nothing, thus $i = i + 1$. $u_2(k) = 1$ represents to adopt repair, and means that degradation time-step i will remain unchanged for a constant period T_0 . Furthermore, replacement would be applied if $u_3(k) = 1$, causing $i=0$. Considering only one of them would be adopted at time-step k , we can add the constraint:

$$u_1(k) + u_2(k) + u_3(k) = 1 \quad (12)$$

3.2 Objective function formulation

The goal of maintenance operations planning is to prevent failure of OWT components and minimize the possible maintenance cost as well as the accumulated energy not supplied.

C_{rpm} is the individual cost per replacement activity, and C_{rpr} is the cost per repair activity. The accumulated energy not supplied can be estimated by maintenance downtime. T_{rpm} is maintenance downtime per replacement activity, and the maintenance downtime per repair action is symbolized by T_{rpr} . The power output of a normal OWT, $P(k)$, is shown as follow (Dao et al., 2021).

$$P(k) = \begin{cases} \frac{1}{2} C_\rho A_r v_k^3 & \text{if } v_{cut-in} \leq v_k < v_{rated} \\ P_{rated} & \text{if } v_{rated} \leq v_k \leq v_{cut-out} \\ 0 & \text{otherwise} \end{cases} \quad (13)$$

Where ρ is the air density; C_ρ is the power coefficient; A_r is the rotor swept area; v_k is the wind speed at time-step k ; P_{rated} is the OWT rated power; v_{cut-in} is the cut-in wind speed; v_{rated} is the rated wind speed; $v_{cut-out}$ is the cut-out wind speed.

Considering the power price b , the cost function $J(k)$ at time-step k as follows.

$$J(k) = \lambda (0 \quad C_{rpr} + bP(k)T_{rpr} \quad C_{rpm} + bP(k)T_{rpm}) \begin{pmatrix} \hat{u}_1(k) \\ \hat{u}_2(k) \\ \hat{u}_3(k) \end{pmatrix} + [\hat{x}(k+1|k)]^2 \quad (14)$$

Where $\hat{u}_1(k)$, $\hat{u}_2(k)$ and $\hat{u}_3(k)$ are the estimated maintenance strategies at time-step k . The weighting parameter λ balances the two conflicting objectives. Denote the estimated state x at

sample step $k + j$ with information available at sample step k by $\hat{x}(k + j|k)$. Let N_p be the prediction horizon, and define:

$$\tilde{J}(k) = J(k) + J(k + 1) + \dots + J(k + N_p - 1) \quad (15)$$

as the objective function at real time-step k .

3.3 MPC controller

This problem is accordingly transformed to be a minimization problem with the objective function $\tilde{J}(k)$ which is shown in Equation 15. And this problem is subject to Equation 8-14.

The modified MPC-based approach is shown as follows.

Initialization: Given the initial state $x(0) = x_0$ and the degradation time-step $i = 0$.

- **Step 1:** Solve Equation 8-15 to obtain the optimal solution $\hat{\mathbf{u}}(k) \hat{\mathbf{u}}(k + 1) \dots \hat{\mathbf{u}}(k + N_p + 1)$.
- **Step 2:** The MPC controller $\mathbf{u}(k) = \hat{\mathbf{u}}(k)$ is applied at the maintenance instant k . The remains of the optimal solution $\hat{\mathbf{u}}(k + 1) \dots \hat{\mathbf{u}}(k + N_p + 1)$ are discarded. The predicted state $x(k + 1)$ can be obtained by applying $\mathbf{u}(k)$ to Equation 10. The actual system state over the next sampling period is updated by $x(k + 1)$.
- **Step 3:** Let $x(k + 1)$ be the initial state for the next predictive horizon $k = k + 1$, and go back to the **Step 1**.

The above MPC algorithm will go over the sustainability period to obtain the optimal control strategy.

4 CASE STUDY

In this section, a case study for an OWT is presented for illustrative purpose. It is a 10-MW OWT with characteristics from (Bak et al., 2013), which is shown in Table 1. The damage parameters in the example are assumed to follow the values and distributions as shown in Table 2. The scale parameter α is assumed to be 5. The lower bound of the failure rate M_1 is assumed to be 0, and the upper bound M_2 is supposed to be 1. Moreover, the mean significant wave height H_1 is assumed to follow Weibull distribution, whose scale parameters is 1.38, and shape parameters is 1.60 (Braam & Eecen, 2005). The cost and time data are presented in Table 3. The constant period of repair T_0 is assumed to be 150 days. The power price b is supposed to be 0.035 £/kWh (Nielsen & Sørensen, 2011).

The MPC controller mentioned before is implemented in Python with the Gurobi Optimizer 9.5.2. The initial condition $x(0) = M_1$, and the sampling time is 10 days. The ratio of C_{rpm} to C_{rpr} is assumed to be 10. We present the simulation results with three different prediction horizons N_p , and three different weights λ .

To be a comparison, a cyclic repair strategy with the same objective function is also optimized. The period for repair T_1 and the period for replacement T_2 should be decided (Su et al. 2015). And the latter is fixed as $T_2 = nT_1 + (n - 1)T_0/step$. All possible combinations of T_1 and n is adopted to obtain the best maintenance plan.

Table 1. Wind turbine characteristics (adopted from Bak et al. (2013)).

Parameter	value
Power rating	10 MW
Rotor diameter	178.3 m
Cut-in wind speed	4 m/s
Rated wind speed	11.4 m/s
Cut-out wind speed	25 m/s
Power factor	0.44

Table 2. Distribution types for damage parameters (Nielsen & Sørensen, 2011).

Symbol	mean	COV	Distribution
m	2	-	Deterministic
β	1	-	Deterministic
C	9.26×10^{-10}	0.2	Lognormal
x_s	11.5	0.1	Lognormal
D_0	0.02	0.02	Exponential

Table 3. The cost and time data (adopted from Dao et al. (2021)).

Symbol	value
C_{rpr}	4.5 (£1000)
C_{rpm}	45 (£1000)
T_{rpr}	11.55 (h)
T_{rpm}	115.5 (h)

The results of the MPC approach are shown in Figure 3-5 and Figure 6 represents the results from the cyclic approach. The results in Figure 3-6 show that a larger weight λ results in higher overall failure rate level. This is because a larger weight λ represents the cost has greater proportion in the objective function. Thus the optimizer tends to decrease cost instead of failure rate level. Figure 4-6 show that the larger weight λ causes later replacement.

Figure 3. Predicted state x for different weights $\lambda = 0.01, 0.05, 0.1$ and a short prediction horizon $N_p = 5$.

Figure 4. Predicted state x for weights $\lambda=0.01, 0.05, 0.1$ and a medium prediction horizon $N_p = 10$.

In Figure 3-5, it is shown that a longer prediction horizon causes a more cautious maintenance plan, which means lower overall degradation level. Because the optimizer will be long-sighted to prevent failure with the increasing of prediction horizon. Furthermore, the effect of increasing prediction horizon is the reverse of increasing weight. In Figure 3-6, The cyclic policy tends to adopt more replacement than MPC-based method with the same weight.

Figure 5. Predicted state x for weights $\lambda=0.01, 0.05, 0.1$ and a long prediction horizon $N_p = 15$.

Figure 6. The effect of the cyclic approach with different weights $\lambda=0.01, 0.05, 0.1$.

The comparison of the MPC method and simple cyclic preventive maintenance approach is given in Table 4, where J is the objective function. In Cases 1-3, 5-7, and 9-11, there is a lower objective function with a longer prediction horizon and the same weight. However, In

Table 4. Comparison of the two optimal approaches.

Case	$N_p N$	λ	number of Repair	number of replacement	Cost (£1000)	J
1	5	0.01	21	7	470.135	6.429
2	10	0.01	26	6	444.303	5.325
3	15	0.01	28	6	454.636	4.942
4	Cyclic	0.01	13	12	687.120	8.170
5	5	0.05	8	7	402.973	66.728
6	10	0.05	25	5	387.474	23.113
7	15	0.05	27	5	397.806	21.692
8	Cyclic	0.05	12	11	630.291	34.393
9	5	0.1	7	7	397.806	119.380
10	10	0.1	25	4	335.811	41.412
11	15	0.1	28	4	351.310	40.119
12	Cyclic	0.1	11	10	573.461	64.650

Cases 2-3, 6-7, and 8-9, we can see the longer prediction horizon doesn't result in lower cost. This is because the optimizer considers not only the cost but also the performance. The objective function is lower although the cost is higher in Cases 2-3, 6-7, and 8-9. Moreover, in Cases 1-4, 5-8, and 9-12, it can be seen that with a long enough prediction horizon, the maintenance plan obtained by MPC always performs better than the plan obtained by the cyclic approach. The cost and objective function of the former are lower than those of the latter.

5 CONCLUSIONS

This paper presents a new MPC-based method for deriving the optimal CBM policy. It can decide on replacement or repair that would be adopted at certain points by considering the cost and performance in fixed predicted horizons. A fatigue detail of an OWT structure is applied to demonstrate this proposed method. The simulation results with different predictive horizons and weights are presented. It is shown that the MPC-based method can balance the cost and performance well. There will be lower cost and objective function by applying the MPC approach with a long enough predicted horizon. The results indeed demonstrate the merits of MPC as an optimization-based approach to aid decision-making in the maintenance of OWT structures. For further research, the ratio of the cost of the two maintenance strategies can be discussed. Furthermore, the cost of inspections can be included in a more comprehensive study.

A deep learning-based corrosion prediction model for paint-coated steel with defects

F. Jiang & M. Hirohata

Graduate School of Engineering, Osaka University, Suita, Osaka, Japan

ABSTRACT: In recent years, numerical analysis of corrosion characteristics to accurately predict corrosion progress has received increasing attention from researchers. In actual construction, steel is mostly treated with coating for corrosion prevention. This study used steel SS400 with two kinds of coating, they were taken from the actual steel bridges. Defects were created artificially on the coating to simulate the corrosion progress when the coating is defective. Corrosion tests were carried out in two corrosive environments. Corrosion data of steel plate surfaces at different stages were used as data sets. In this study, a generative adversarial network (GAN) was used to build a prediction model of the corroded surface. The prediction model could simulate the damage of paint-coating around the defect at various stages and predict the corrosion of the steel plate in the final removal of the coating. Based on comparative results, this corrosion prediction model showed outstanding performance.

1 INTRODUCTION

Steel structures play an important role in modern buildings and facilities, and about 30% of buildings in Japan (in terms of total floor area) are steel-framed structures (Tsuji, M. & Kanno, R., 2016). Among bridges, many are constructed with steel as a major part of the structure. In the United States, more than 30% of bridges are built with steel as the only or major component (ESC Group, 2021). To this day, there are still many pre-1930s steel structures in use around the world (Farhey et al., 1997). As a result, more and more researchers are becoming concerned about the deterioration of steel bridges (Rashidi, M. et al., 2017). Corrosion is one of these important issues. Corrosion poses many hazards to steel structures, it can weaken the structural integrity, increasing the risk of collapse or failure. This can be particularly dangerous in the case of bridges, buildings, and other critical infrastructure, as the collapse of such structures can result in injury or death. It can also reduce the load-bearing capacity of steel structures (Bonopera, M. et al., 2018), making them less able to support the weight and stresses placed upon them. This can lead to the failure of structural components, such as beams, columns, and foundations.

The importance of monitoring and controlling corrosion on steel structures cannot be overstated, as it is essential to preserving the integrity and functionality of these structures. Regular inspection and maintenance of steel structures can help to identify corrosion early on, allowing for timely repairs and preventative measures to be taken. This can help to extend the lifespan of steel structures, reduce the risk of failure, and save money on costly repairs or replacements. Effective corrosion monitoring and control also requires the use of corrosion-resistant materials and coatings, as well as proper design and construction techniques. By considering these factors from the outset, it is possible to mitigate the risk of corrosion and ensure the long-term performance and reliability of steel structures. Therefore, it is important for practical maintenance work if fast and accurate corrosion simulation and prediction models can be developed mathematically. For example, it is possible to assess whether the corrosion

conditions observed during periodic inspections of steel bridges are likely to lead to serious damage before the next inspection. In addition, it is difficult to obtain detailed information on the distribution of corroded surface profiles during normal inspections, but through numerical analysis, the spatial variation of corroded surface profiles can be predicted, making it possible to assess the load-bearing capacity of a structure using methods such as finite element analysis to obtain more accurate information. Therefore, with the development of numerical simulation techniques, more effective corrosion prediction has attracted more and more attention. These new techniques can predict the corroded surfaces of steel structures to save monitoring time and enable early warning of steel repairs.

In recent years, deep learning has shown great potential in many fields. With the development of machine learning and deep learning techniques, they have been widely used in modeling and prediction tasks. Several studies have used SVM (support vector machine) for quantitative assessment of pipe corrosion (Yan, B. et al., 2014). Corrosion of steel structures using weathering steel was studied, and these bridges often suffer severe surface corrosion damage, leading to structural performance degradation. Traditional visual monitoring and classification methods are time-consuming and subjective, and do not provide a valid quantitative evaluation. In a previous study, a deep learning-based method to predict the corroded surface condition of uncoated steel was proposed (Jiang, F. & Hirohata, M., 2022). This method showed excellent performance for corrosion prediction of uniformly corroded uncoated steel. However, these previous studies needed to remove rust from its surface before modeling in order to investigate the actual condition of the corroded surface, which undoubtedly increased the difficulty of practical application. In addition, in actual steel structures, steel is mostly treated with coatings for corrosion protection. Therefore, this study used the corroded surface without rust removal to predict the next stage of corroded surface, and the study was conducted for paint-coated steel, which is commonly used in steel structures. Corrosion of paint-coated steel is a process in which the coating on the surface of the steel breaks down and the steel beneath is exposed to the environment, leading to corrosion. The rate and severity of corrosion can vary depending on a number of factors, including the type of coating, the environment in which the steel is used, and the care and maintenance of the coating. In general, coated steel is less susceptible to corrosion than uncoated steel because the coating provides a barrier between the steel and the environment. However, coated steel is not immune to corrosion, and coatings can break down over time due to a variety of factors.

In this study, adversarial learning was used to simulate future stages of corroded surfaces, with data sets collected from actual paint-coated steel specimens (taken from two actual bridges). Two corrosion tests were conducted, accelerated corrosion test ISO 16539 method B (Jiang, F. et al., 2022), and atmospheric exposure test conducted in Choshi, Japan. Because the purpose of this study is to predict the next stage of corrosion based on the current corrosion and to determine the current corrosion state, generative adversarial network (GAN) was chosen as the model for predicting corrosion. To expand the variety of datasets, Gaussian noise and GAN were used to enhance the datasets, which can improve the accuracy of the prediction model. Together with UNet (Ronneberger, O. et al., 2015), ViT (Dosovitskiy, A. et al., 2020), and Mobilenetv2 (Sandler, M. et al., 2018), the model can be used to predict the next stage of corrosion based on the current corrosion condition. In addition, the model can be used to determine the type of steel coating and to determine the stage of its corrosion. Based on experimental results compared with other models, it was confirmed that the model has good accuracy in predicting the corrosion surface of paint-coated steel. The main contribution of this study is to propose a GAN-based corrosion prediction model, which can predict and simulate the next stage of corrosion based on the current corrosion state of paint-coated steel; the model can predict not only the distribution of corroded surfaces containing rust, but also the actual corrosion (corroded surfaces with rust removal). Compared with traditional methods, the method proposed in this study can predict the corrosion progress faster and more accurately, and this prediction method can save a lot of cost and time for corrosion assessment and maintenance of steel structures using coated steel.

2 EXPERIMENT

2.1 Specimen

Two types of painted SS400 steel were used as specimens. They were designated C1 and C2, respectively, and they were both taken from real bridges. The paint-coated steel C1 was taken from the girders of a highway bridge in Osaka, which served from 1969 to 2002. Paint-coated steel C2 was used for the girders of a railroad bridge in Shimane near the seaside, which served from 1966 to 2019 (Liu, J. et al., 2022). As shown in Figure 1, these specimens were cut into 150 mm × 70 mm × 9 mm steel plates. There were 6 specimens for each type of coating, and a total of 12 specimens were used for corrosion tests. The coated surfaces of the specimens were machined to introduce initial defects of 2 mm in width (brown area in Figure 1), simulating the corrosion of the coated steel surface after damage in a real environment. The back and sides of the specimen were protected with anti-corrosion tape, and the uncorroded part of the edge was used as a reference surface after the corrosion tests (black area in Figure 1). After each stage of the corrosion test, a laser focus measurement system was used to measure the corrosion depth data of the corroded surface in the measurement area (red area in Figure 1). It has a resolution of 0.2 μm and a measurement interval of 0.1 mm.

Figure 1. Dimension and measurement area of the specimen.

2.2 Corrosive environments

In this study, in order to develop a corrosion prediction model for different paint-coated steels under different corrosive environments, corrosion tests were conducted on two kinds of paint-coated steel, C1 and C2, under two corrosive environments. These two environments were the accelerated corrosion test ISO 16539 Method B, and the atmospheric exposure test conducted at Choshi, Japan. There were three specimens for C1 and C2 in each of the two test environments.

ISO 16539 Method B is a new accelerated corrosion test used for steel structures such as bridges, Figure 2 shows its procedure (Jiang, F. et al., 2022). Synthetic seawater with a saturation of 3.5% was sprayed on the surface. The increase in specimen weight after spraying was measured to achieve a target salt content of $28.0 \pm 2.8 \text{ g/m}^2$ per specimen. The drying and wetting process was repeated every 3 hours, with a 1-hour transition process. A cycle of 8 hours consisted of drying, transition and wetting. This cycle was performed 8 times and then the surface of the specimen was cleaned with water. Then synthetic seawater was sprayed on the surface of the steel plates and the drying and wetting process lasted 11 times. Specimens in this corrosive environment were measured by the laser focus measurement system at 0 (initial state without corrosion), 1, 3, and 6 months to obtain corroded surface data including rust. In addition, at 6 months, the rust was removed from the surface of the specimen, and the actual corrosion surface data (without rust) was measured. Therefore, each specimen in this corrosive environment was measured 5 times.

The atmospheric exposure test conducted at Choshi is a corrosion test conducted in a real environment. The location of this test is the Choshi Atmospheric Exposure Center, located at 35°43' N, 140°45' E. The distance from the nearest seashore is 4 km and the height from sea level is 54 m. This site has a general corrosive environment (Kamimura, T. et al., 2006). Because corrosion

progresses more slowly in the atmospheric exposure environment than in the accelerated corrosion test environment, the corrosion test in the atmospheric exposure environment was conducted over a longer period of time. Therefore, specimens in this corrosive environment were measured by the laser focus measurement system at 0 (initial state without corrosion), 3, 6, and 12 months to obtain corroded surface data including rust. In addition, at 12 months, the rust was removed from the surface of the specimen, and the actual corrosion surface data (without rust) was measured. Again, each specimen in this corrosive environment was measured 5 times.

Figure 2. Procedure of accelerated corrosion test ISO 16539 Method B.

3 DATA SET SETTINGS

Table 1 shows the use of 12 specimens for this study. As mentioned in Section 2, the experimental data of each specimen contains corroded surface data for four periods in the status before rust removal and one corroded surface data in the final period with rust removed. Among them, the specimen data numbered 1, 2, 4, 5, 7, 8, 10, and 11 were used as the training set. The specimen data numbered, 3, 6, 9, and 12 were used as the test set. The corrosion prediction model in this study used the corroded surface data from the first three stages as input to predict and generate the corroded surfaces before and after rust removal for the last stage. The prediction results were compared with the real experimental data to obtain the accuracy of the model.

Table 1. Data set settings.

Type	No.	ISO 16539 Method B (month)					No.	Exposure test at Choshi (month)				
		0	1	3	6	6 A*		0	3	6	12	12 A*

* “A” represents the specimen after rust removal.

4 METHODOLOGY

4.1 Model structure

In this study, Gaussian noise and GAN were used to enrich the dataset. UNet + ViT were used as the generator and Mobilenetv2 was used as the discriminator. The generator was mainly used to simulate the next stage of regression of the input data. The role of the discriminator was to determine whether the input data was the data generated by the generator. In addition, the discriminator trained in this model could also be used to determine the type of steel coating and the current stage of the corroded surface. In this model, the adam optimizer was used as the optimizer. Figure 3 illustrates the structure and the procedure of this corrosion prediction model.

4.2 Generative Adversarial Network (GAN)

As a class of deep learning frameworks, generative adversarial network (GAN) can learn from datasets and generate new data with similar statistics. GAN is often used for data augmentation,

especially when the dataset is limited. In this study, because of the long period of corrosion tests, there was very limited data available as the original dataset. Therefore, GAN was used to enrich the dataset and generate new training samples based on the corroded surface data collected from the corrosion tests. GAN and its two variants, Information maximizing GAN (InfoGAN) (Chen, X. et al., 2016) and Conditional GAN (CGAN) (Mirza, M. & Osindero, S., 2014), were used as comparison models for the corrosion prediction model proposed in this study.

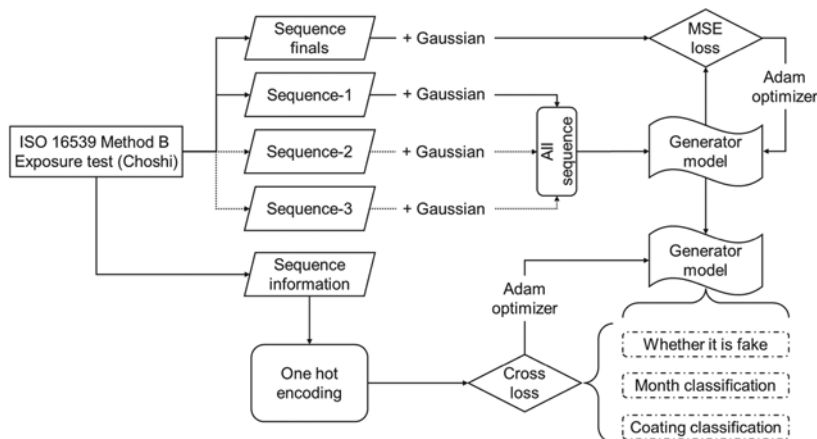

Figure 3. Model structure.

4.3 Generator and discriminator

The corrosion prediction model proposed in this study consists of UNet + ViT as the generator and Mobilenetv2 as the discriminator. UNet was originally designed for biomedical image segmentation. The architecture has two paths. One is a systolic path (or encoder), which is a traditional stack of convolutional and max-pool layers that captures the background in the image. The other path is the symmetric extension path (or decoder), which allows precise localization using transposed convolution. It can handle images of any size, and it is a fully convolutional network (Ronneberger, O. et al., 2015). ViT model, which introduces transformer structure to computer vision. ViT has more similarity between features obtained from shallow and deep layers. Also, it can achieve better performance than CNN on image classification tasks (Dosovitskiy, A. et al., 2020). Mobilenetv2 is an effective model for feature extraction, object detection and segmentation. It is a mobile architecture based on an inverted residual structure that uses deeply separable convolution as an effective building block (Sandler, M. et al., 2018). The model allows the decoupling of the input/output domain from the expressivity of the transform, which provides a convenient framework for further analysis. Its performance has been validated in many missions, such as image classification and object detection. To be more suitable for the discriminator in this study, an additional sigmoid activation function has been added in Mobilenetv2, where 0 is false and 1 is real.

4.4 Model training

The size of the original corrosion depth data of each specimen was 201×581 , and it was scaled to 256×1024 by feeding it in 0 s. A learning rate of 0.0001 and the adam optimizer were used to train the GAN model. $\text{Sigma} = \text{variance}^2$ was used as the sigma activation function. The leaky rate was 0.2. Adam beta values were [0.5, 0.99]. Gaussian noise and the corrosion depth data from the previous stage were used as input to UNet-ViT, and the corrosion depth data from the next stage were used as the target. Mobilenetv2 was used as the discriminator to determine whether the input image was generated by UNet-ViT or the real image, and each step was based on the GAN model for training. At the end of each Epoch, only the UNet-ViT was trained (fine-tuning the difference between the generated and real data).

5 RESULT

5.1 Comparative results

In this study, the accuracy of the different models and their prediction accuracy for corroded surfaces were compared separately for the results. The accuracy of different models is shown in Table 2, the RMSE (Root Mean Square Error) was used as the indicator of the goodness of the model, with lower indicating better accuracy. The results show that the model proposed in this study outperforms other models in all indicators. On the other hand, the prediction accuracy of different models for corroded surfaces is shown in Table 3, because it is to compare whether the predicted corroded surface is close to the real experimental results, not the regression of the model, therefore, the MAE (Mean Absolute Error) was used as the indicator to compare the results, the lower means that the model predicts the corroded surface results closer to the experimental results. The results show that the model proposed in this study has only one specimen whose predicted results are not as good as the other models. In general, the corrosion prediction model proposed in this study was outstanding in predicting the corroded surface of paint-coated steel with defects in the next stage based on former stages.

Table 2. Comparative results of the accuracy (RMSE) of different models.

Model	Discriminator	Prediction	Stage	Coating	Best Epoch
GAN	18.48	8.18	0.69	1.24	20
InfoGAN	3.37	3.37	1.31	1.15	80
CGAN	3.85	3.69	1.01	1.01	40
UNet + ViT	1.63	2.07	0.48	0.83	80

Table 3. Comparative results of the prediction accuracy (MAE) of different models for corroded surfaces before and after rust removal (B represents before rust removal, A represents after rust removal).

Model	No.3 B	No.3 A	No.6 B	No.6 A	No.9 B	No.9 A	No.12 B	No.12 A
GAN	8.43	12.23	7.09	13.78	16.32	16.49	5.34	20.23
InfoGAN	2.29	2.36	1.67	2.19	1.69	1.69	1.60	1.36
CGAN	1.32	1.65	1.41	1.02	1.67	2.18	2.03	2.29
UNet + ViT	0.90	1.17	1.22	1.27	1.38	1.52	1.30	1.30

5.2 Example of corrosion prediction

Figure 4 shows an example of predicting the corroded surface of paint-coated steel by this model. Corroded surface data for 0, 1, and 3 months from specimen No. 3 were used to predict and generate the 6-month corroded surface before rust removal and the 6-month corroded surface after rust removal. (a) and (b) are the predicted 6-month corroded surface before rust removal and 6-month corroded surface after rust removal, respectively. (c) and (d) are the actual 6-month corroded surface before rust removal and 6-month corroded surface after rust removal, respectively. (e) and (f) are the specimen photographs of the actual 6-month corroded surface before rust removal and 6-month corroded surface after rust removal, respectively. The results show that the prediction results are very similar to the experimental results, confirming the validity of the model.

6 CONCLUSION

In steel structures such as steel bridges, paint-coated steel is widely used. Establishing a reliable corrosion prediction method for paint-coated steel is of great importance for maintenance in real facilities. In this study, the corrosion of paint-coated steel with defects was investigated for the case of damage that occurred on the actual coating. An effective corrosion

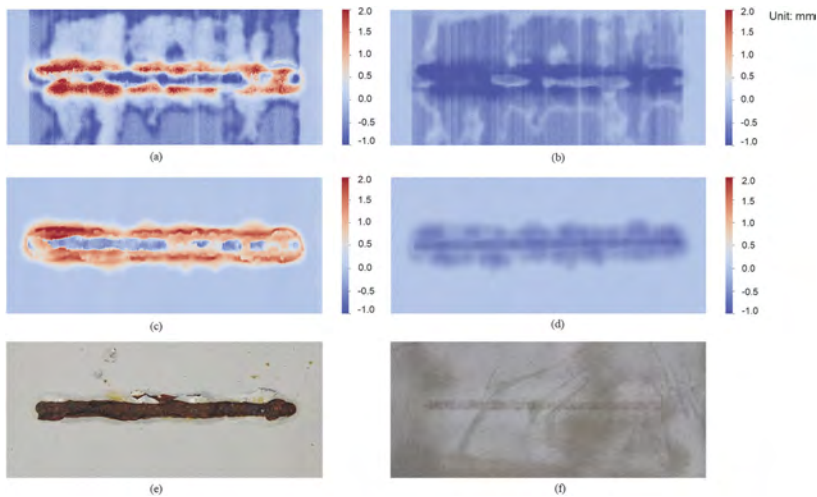

Figure 4. Comparative results of the predicted and experimental corroded surfaces of specimen No. 3. (a) Predicted 6-month corroded surface before rust removal; (b) Predicted 6-month corroded surface after rust removal; (c) Actual 6-month corroded surface before rust removal; (d) Actual 6-month corroded surface after rust removal; (e) Specimen photograph of actual 6-month corroded surface before rust removal; (f) Specimen photograph of actual 6-month corroded surface after rust removal.

prediction model was developed using a GAN-based model trained on the corroded surface data of steel plates obtained from corrosion tests of two paint-coated steels under two different corrosive environments. The model could predict the corroded surface of the next stage based on the previous corroded surface, and also determined the coating type of the steel plate and the current corrosion stage. By comparison, the prediction accuracy of the model proposed in this study was better than other baseline models. This study contributes to simplifying the determination of the corrosion level of paint-coated steel structures and saves time and cost for actual maintenance. In future work, more corrosion cases will be considered. For example, the distinction between the shape of coating defects will be added. The actual paint-coated steel surface is coated with a variety of damaged shapes, it is necessary to investigate how the different shapes of defects affect the corrosion progress.

System identification and damage assessment of benchmark model H

G.S. Wang & C.W. Lo

Chaoyang University of Technology, Taichung, Taiwan

F.K. Huang

Department of Water resources and Environmental Engineering, Tamkang University, New Taipei City, Taiwan

ABSTRACT: Most of the existing buildings available for damage assessment are slightly or severely damaged, and these data may not be sufficient to establish damage indicators. To solve this problem, the experimental method is used to simulate different damage states, followed by identifying the parameters of the associated damaged structure. Consequently, damage indices that describe the degree of damage can be computed using the identified parameters, and then the threshold values of different damage states can be reached afterward. In this paper, the system identification method, called the hybrid genetic algorithm, is used to analyze the measurement from the shaking table test of a series of 3-story steel frame structures, called the benchmark model H constructed in the NCREE. This series of tests tries to simulate different damage states. In fact, structural models are a series of structures simulating various damage states by varying the numbers of diagonal bracings on both sides of x direction. The dimension of the structure is 3m in the longitudinal direction and 2m in the transverse direction. The shaking table test is carried out in the sequence from Full Bracing (FB) in the x direction to the bare frame. From Case1 to Case3, the vertical diagonal bracings of the outer side are removed one by one from the first floor to the third floor in the x direction. In this way, eccentric structures with varying degrees of damage can be simulated. Finally, all diagonal bracings in the x direction are removed, leading to a Bare Frame (BF). With the change in the dynamic parameters of the elastic system under earthquake, the damage assessment method is applied to determine the degree of damage and the location or floor of damage.

1 INTRODUCTION

System identification was first applied to aerospace engineering and mechanical engineering, and later was applied to civil engineering. It is a technique to model the system by analyzing the input and output measurements produced by the system. Most identification methods are calculus-based search methods. A good initial guess of the parameter and the gradient or higher-order derivatives of the objective function are generally required. There is always the possibility of falling to a local minimum. On the other hand, genetic algorithms (GAs) are optimization procedures inspired by natural evolution. They model natural evolutionary processes, such as selection, recombination, and mutation, and work on populations of individuals rather than a single solution. Consequently, algorithms are parallel and global search for techniques that search multiple points and are more likely to obtain a global solution. Many GA applications have been performed on a variety of optimization problems in the engineering area. However, relatively few applications have been made on structural identification. Koh et al. (2003) proposed a hybrid

strategy for exploiting the merits of GA and a local search operator. Two local search methods were studied: an existing SW method and a proposed method called the MV method. The numerical study showed that the hybrid strategy performs better than GA alone. The author (Wang 2005) applied the real-coded GA to structural identification problems. The validity and efficiency of the proposed GA strategy were explored for the cases of systems with simulated input/output measurements. Furthermore, the strategy was also applied to the existing structure. Genetic algorithms (GAs) are global search techniques for optimization. However, GAs are inherently slow and are not good at hill-climbing. In order to accelerate the convergence to the optimal solutions, a hybrid GA identification strategy that employs the Gauss-Newton method as the local search technique, was also proposed and verified by the author (Wang 2009).

In addition to predicting the responses of structures, system identification techniques can also monitor changes in system parameters or characteristics, and can even determine the subsequent step to take, such as repair or retrofit, based on the damage state of the structure. In the past two decades, many scholars have been engaged in research of structural health monitoring. So-called structural health monitoring is the process of comparing the current state of the structure with the undamaged state or the baseline state to determine whether the structure is damaged under the attack of earthquakes or other types of external forces, so as to determine the location and degree of damage.

Buildings are damaged by strong earthquakes, resulting in changes in dynamic parameters. To avoid identifying the nonlinear model of the damage structure, we can analyze the system parameters using the measurements collected from low intensity that occurred before and after the damaged earthquake. According to changes before and after an attack of the strong earthquake, it is possible to carry out the damage assessment. In recent years, many scholars have been engaged in the research of damage indices. The selected damage index must be a physical quantity sufficient to show the degree of damage of the structure. The relationship between the physical quantity and the available structural parameters must be derived. Buildings available for damage assessment have minor or major damage, so the damage indices evaluated accordingly may not be adequate. To solve this problem, the experimental method can be used to simulate various damage states, followed by identifying the parameters of the associated damaged structure. Then, the damage indices that describe the degree of damage can be computed using the identified parameters, and the threshold value of different damage states can be attained.

In this paper, the system identification method, called the hybrid genetic algorithm, will be used to analyze the measurements from the shaking table test of a series of three-story steel frame structures simulating different damage states. The Benchmark Model H was constructed in the NCREE, which is a series of structures that simulate different numbers of diagonal bracings on both sides of the x direction. With the change in the dynamic parameters of the elastic system under earthquake attacks, the damage assessment method will be used to determine the degree of damage and the location or floor of damage.

2 HYBRID GENETIC ALGORITHM AND DAMAGE INDICES

Genetic algorithms are different from traditional optimization methods. It searches for the optimal solution simultaneously by randomly selecting multiple initial points (Holland 1962). Each individual in the population is equivalent to a search point. After generations of evolution, each point moves towards the optimal solution. Due to this characteristic of the genetic algorithm, the chance of reaching the extremum is greatly enhanced compared to other methods. GAs are inherently slow and poor at hill climbing. To compensate for the computational inefficiency in hill-climbing when the solution yielded by GA approaches the optimal value, a local search operator, the Gauss-Newton method is merged with the GA strategy (Wang 2009).

2.1 Genetic algorithm

The genetic algorithm models natural evolutionary processes, such as selection, recombination, and mutation. The algorithms work on populations of individuals instead of a single solution. In

this way, the search is performed in a parallel manner. However, better results can be obtained by introducing multiple subpopulations. Every subpopulation evolves over a few isolated generations (like the single population GA) before one or more individuals are exchanged between subpopulations using the mechanisms of migration and competition. The multi-population GA models the evolution of a species in a way more similar to nature than a single population.

2.2 Gauss-Newton method

The purpose of using the local search method is not for the best solution, but for a better solution in a local area. The global search capability of the local search method is not required to be very efficient. Since the Gauss-Newton method has been demonstrated to be an efficient method in nonlinear least square problems, it is appropriate to use it in the optimization problem of the prediction error in system identification problems. Therefore, the local search method used in this paper is the Gauss-Newton method. For the problem of system identification, an objective function minimized is a sum of square errors as

$$E(\tilde{x}) = \frac{1}{2} \sum_{i=1}^N [f_i(\tilde{x})]^2 = \frac{1}{2} \sum_{i=1}^N [y_i - v_i(\tilde{x})]^2 \quad (1)$$

where \tilde{x} is the vector of the parameters which will yield the least square error between the measured response y_i and the predicted response $v_i(\tilde{x})$, and N is the number of measurement sequences. According to the Gauss-Newton method, a new iterated parameter \tilde{x}_{m+1} can be evaluated in terms of the current parameter vector \tilde{x}_m as

$$\tilde{x}_{m+1} = \tilde{x}_m - [J^T(\tilde{x}_m)J(\tilde{x}_m)]^{-1} J^T(\tilde{x}_m)[f_i(\tilde{x}_m)] \quad (2)$$

where denoting $J(\tilde{x})$ as the Jacobian matrix of $E(\tilde{x})$.

2.3 Hybrid genetic algorithm

The Gauss-Newton method is performed after completing the evolution process of every 10 generations. Accordingly, a new hybridization of a GA with the Gauss-Newton method is formed. Figure 1 shows the structure of this hybrid GA.

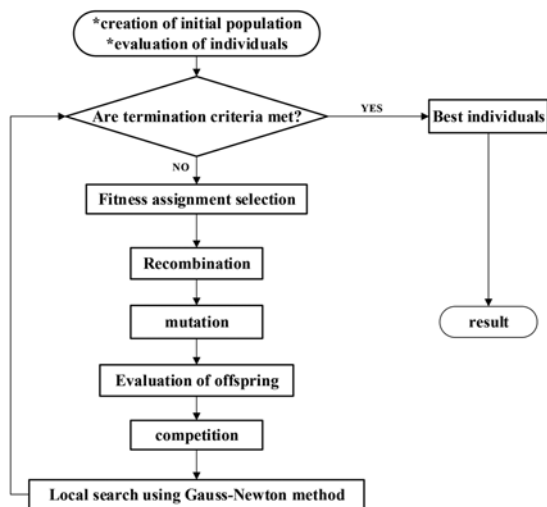

Figure 1. Structure of hybrid GA.

2.4 Damage indices

Damage assessment is a process of determining the location, nature, and severity associated with the target structure. Damage to the structure alters its dynamic characteristics. This change can be characterized by changes in the modal parameter, i.e., modal frequencies, modal damping value, and mode shape associated with each mode. Various damage indices have been proposed to quantify structural damage in structures subjected to seismic excitation. Some of them are reviewed as follows:

Dipasquale & Cakmak (1990) defined the maximum softening index for the one-dimensional case, where only the fundamental modal frequency is considered. The index is given by where T_{und} is the undamaged natural period and T_m is the maximum natural period during the excitation duration. The maximum softening index demonstrates a measure of a combination of both the stiffness degradation and the plasticity effect.

MAC indicates the correlation between two measured mode shapes from two different states (Dipasquale & Cakmak 1989). Let ϕ_A and ϕ_B be the undamaged and damaged mode shapes, respectively, MAC is then defined for modes j and k as follows:

$$MAC(j, k) = \frac{[\sum_{i=1}^N (\phi_A)_{ij}(\phi_B)_{ik}]^2}{[\sum_{i=1}^N (\phi_A)_{ij}^2 \sum_{i=1}^N (\phi_B)_{ik}^2]} \quad (3)$$

where N is the number of coordinates included, and i is the coordinate of column vector associated with the specific mode shape. In other words, $(\phi_A)_{ij}$ denotes the i^{th} coordinate of the j^{th} column (mode) of ϕ_A and $(\phi_B)_{ik}$ the i^{th} coordinate of the k^{th} column (mode) of ϕ_B . MAC values range from 0 to 1, that is, 0 for no correlation and 1 for full correlation (no damage). If the mode shapes ϕ_A and ϕ_B are identical, then the MAC will be 1, indicating full correlation. Therefore, MAC can be used to detect the existence of damage by identifying these values altered from their original values for individual modes, that is, $j = k$.

3 SHAKING TABLE TESTS OF BENCHMARK MODEL H

In December 2005, the National Earthquake Engineering Research Center built three-story Benchmark Models A, B, C, and D for a series of shaking table tests (Lin 2006). Then on 17 September 2008, a series of shaking table tests of the benchmark model H as shown in Figure 1 were carried out. The dimensions of the benchmark structure are 3m in the longitudinal direction (x-axis), 2m in the transverse direction (y-axis), and 3m in the story height, and the total height of the structure is 9m. Two sets of accelerometers are installed in the X and Y directions on the top of the three stories of the benchmark structure as shown in Figure 2 (a). The responses measured by the two parallel sets of sensors are averaged. Two sets of accelerometers in the X direction and Y direction are also installed on the shaking table to measure the input ground motions. Relative acceleration responses can be computed by subtracting the ground motion from the measured absolute response.

This series of tests aims to mimic the damaged state of the structure using the failure of the vertical diagonal bracings. Structure models are a series of structures with different numbers of vertical bracings on both sides of the x direction. The series of shaking table tests starts from the Full Bracing (FB) model with diagonal bracing on both sides of the X direction to the Bare Frame (BF) model with no diagonal bracing on both sides of the X direction. Cases 1 to 3 represent the models in which the vertical diagonal bracings on the rear side are removed one by one from the first floor to the third floor to simulate eccentric structures with different degrees of damage. The final model is the Bare Frame with all the diagonal bracings removed on both sides. Figure 2 (b)~(f) illustrate the undamaged state (FB) and the four damaged states from Case 1 to Bare Frame.

The excitation records are a set of wide-band random noise records and three sets of earthquake records, including the N-S component of the El Centro earthquake in 1940, the N-S components of the TCU076 station and TCU082 station of the Chi-Chi earthquake in 1999.

The above four records are scaled into records with maximum ground acceleration (PGA) equal to 100gal and 200gal, respectively, and these records act on the benchmark structure first in the X direction. In this paper, only the response subject to excitation of the N-S component of the El Centro scaled to PGA equal to 100gal and 200gal in the X-direction will be used for analysis.

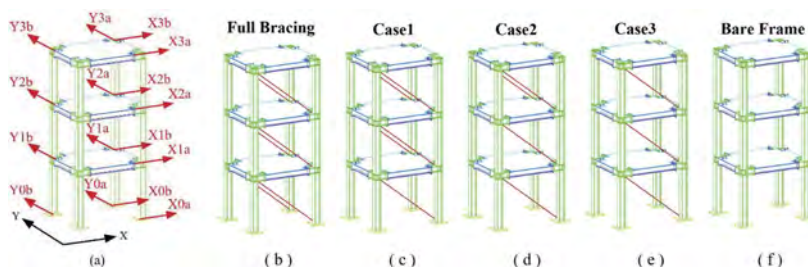

Figure 2. (a) Sensor layout of benchmark model H; (b) Full Bracing; (c) Case 1; (d) Case 2; (e) Case 3; (f) Bare Frame (redraw of Lin 2006).

4 IDENTIFICATION AND DAMAGE ASSESSMENT OF BENCHMARK MODEL H

4.1 Identification model

The motion equation of an MDOF system subjected to a single excitation can be transformed into a modal equation through modal superposition, as

$$\ddot{u}_{sm} + 2\xi_m \omega_m \dot{u}_{sm} + \omega_m^2 u_{sm} = -P_{sm} \ddot{u}_g, \quad s = 1, 2, \dots, n \quad (4)$$

where u_{sm} is the modal displacement in mode m at the s^{th} DOF, and P_{sm} the effective participation factor in mode m at the s^{th} DOF associated with the ground motion \ddot{u}_g . The measurement equation at the s^{th} DOF can be represented as

$$y = \ddot{u}_s = \sum_{m=1}^N \ddot{u}_{sm} = \sum_{m=1}^N P_{sm} \ddot{u}_g - 2\xi_m \omega_m \dot{u}_{sm} - \omega_m^2 u_{sm} \quad (5)$$

where \ddot{u}_s is the relative acceleration at the s^{th} DOF, and N is the total number of modes. $2\xi_m \omega_m$, ω_m^2 , and P_{sm} are the modal parameters to be identified in this case. To assess the accuracy of the proposed identification technique, the error index $E.I.$ is defined as the average of the K measurements as

$$E.I. = \left[\frac{1}{K} \sum_{j=1}^K \frac{\sum_{i=1}^{N_s} (y(i,j) - v(i,j))^2}{\sum_{i=1}^N y(i,j)^2} \right]^{1/2} \quad (6)$$

where N_s is the number of measurement sequences, $y(i,j)$ is the measured relative acceleration response of j^{th} measurement at the i^{th} sampling time, and $v(i,j)$ is the associated estimated acceleration response.

4.2 Results of identification

The hybrid Genetic algorithm is employed to identify the parameters of the benchmark model H under excitations of the N-S component of the El Centro scaled to PGA equal to 100gal and 200gal in the X-direction. The first three modes are identified using excitation and response.

Figure 3 shows the comparison between the estimated response and the measured response on the top floor of the Bare frame under excitations from the El Centro earthquake of PGA equal to 100gal. The error index associated with this floor is 8.64% and this result shows that the searchability of the hybrid genetic algorithm is superior. The hybrid Genetic algorithm can be applied to the parametric identification of the other four cases including Full Bracing (FB), Case 1, Case 2, and Case 3 when subject to excitation with PGA equal to 100 gals. It can also be applied to the parametric identification of the five cases when subject to excitation with PGA scaled to 200 gals. Figure 4 shows the comparison of the parameters identified for all cases with PGA equal to 100 gals and 200 gals. From this figure, it can be concluded that the values of the first modal frequencies will decrease with the removal of more bracing.

Figure 5 shows the comparison of the first effective participation factors of each floor in all cases for the PGA equal to 100 gals and 200 gals. The damaged states of the floors are related to the change of story drifts, while the effective participation factors are related to the mode shapes. Consequently, the damaged state of the floor or the story drift can be observed from the change in the mode shapes of two adjacent floors. From the comparison of the effective participation factors on the first floor, it can be found that the story drift of the first floor of Case 1 is much larger than the story drift of the FB case, indicating that the first floor of Case 1 was damaged. Furthermore, the story drifts on the second and third floors for Case 1 are almost 0 compared to the values of the FB case, indicating that the second and third floors for Case 1 were undamaged. For Case 2, the story drift of the second floor is relatively large, while that of the third floor is almost zero, indicating that the second floor is damaged, but the third floor is not damaged. The drift of the third floor of Case 3 is larger than that of Case 2 and Case 1, implying that the third floor was damaged. In the last case of BF, it can be found that the story drift of each floor increases, so the damage is more severe.

Figure 3. Comparison of measured response with identified response on the top floor of the Bare frame.

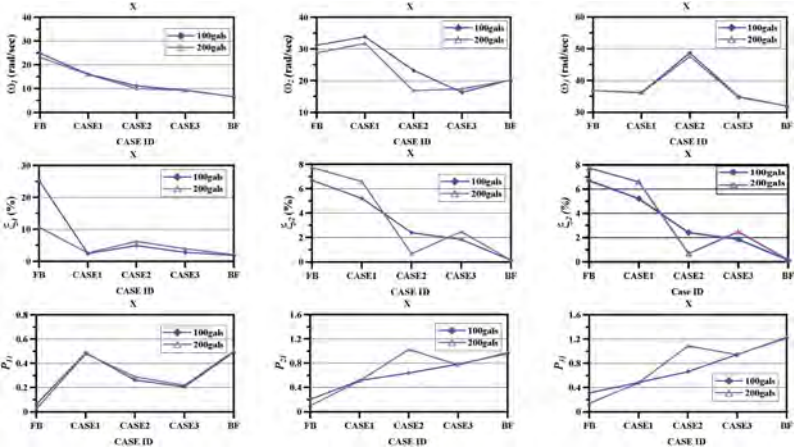

Figure 4. Identified modal frequencies, modal damping ratios, and first modal participation factors.

Figure 5. Comparison of the first modal participation factors with PGA equal to 100gal and 200gal.

4.3 Damage assessment

The results of the maximum damage index in the X direction of each case under the El Centro earthquake scaled to PGA equal to 100gal and 200gal are plotted in Figure 6. The period converted from the first modal frequency of the FB case is used as the undamaged or baseline period. From the first subfigure of Figure 6, it is found that the maximum softening index increases first to 35.243% in Case 1. In Case 2 and Case 3, the indices further increase to 55.266% and 62.712%, respectively. In the last case of BF, the index increases to 73.426%. The damage is getting worse as the braces are removed. From the second subfigure, it can be seen that the maximum softening indices of Case 1 to the BF cases are 59.671%, 56.725%, 31.203%, and 71.661%, respectively, which generally conform to the trend, but the index of Case3 is too low.

By substituting the identified effective modal participation factors into the formula of the MAC index, the results of the first mode can be yielded. Figure 7 shows the results of MAC (1,1) of the five cases under the attacks of the El Centro earthquake scaled to 100 gals and 200 gals. The first modal participation factor identified in the FB case also referred to a baseline value. It can be observed from the two subfigures that the values of MAC(1,1) of the first mode associated with Case 1 dropped to about 0.8. However, the values of Case 2, Case 3, and BF case are larger than that of Case 1 and are all close to 1. In summary, it can be concluded that the MAC index calculated by the effective participation factor of the first mode cannot reflect the actual damage state.

Figure 6. Comparison of the maximum softening indices of the first mode with PGA equal to 100 gal and 200 gal.

Figure 7. Comparison of the MAC indices of the first mode with PGA equal to 100 gal and 200 gal.

5 CONCLUSIONS

In this paper, system identification and damage assessment of the benchmark model H were carried out. The Benchmark Model H was constructed in the NCREE, which is a series of structures simulating different numbers of diagonal bracings on both sides of x direction. The modal parameters were identified by the hybrid genetic algorithm. Then the maximum softening damage indices of the first mode and the MAC indices of the first mode based on the identified modal parameters were used for damage assessment. Therefore, this study draws the following important conclusions:

1. From the comparison of the effective participation factors on the first floor, it can be found that the story drift of the first floor of Case 1 is much larger than the story drift of the FB case, indicating that the first floor of Case 1 was damaged. The story drift of the second floor of Case 2 is relatively large, while that of the third floor is almost zero, indicating that the second floor is damaged. The story drift of the third floor of Case 3 is larger than that of Case 2 and Case 1, implying that the third floor was damaged. In the last case of BF, it can be found that the drift of the story of each floor becomes larger compared to the other cases, so the damage to the entire structure is getting more severe.
2. The results of the maximum softening indices show that the damage is getting worse as more bracings are removed. According to the case study of this benchmark structure, the range of the maximum softening index of the first mode for the slight damage state can be set as 0.2 to 0.4, the range for the moderate damage state can be set as 0.4 to 0.65, and the range for the severe damage state can be set as 0.65 or more.
3. From the results of the MAC indices of the first mode, the value decreased for Case 1 with one bracing removed, but increased instead for Case 2 with two bracings removed and Case 3 with three bracings removed. These results indicate that this index cannot reflect the actual state of damage.

ACKNOWLEDGEMENT

The authors would like to express their gratitude to Prof. C.C. Lin of National Chung-Shin University and Dr. Lin of National Center for Research on Earthquake Engineering, Taiwan for their effort to collect the accelerograms of a 3-story benchmark building structure.

ABSTRACT: The development of an accurate and reliable jack-up model is essential for understanding the hydrodynamic performance of structure, as well as ensuring the structural safety. As part of development of a digital twin, a simplified jack-up numerical model was created based on basin model test. Critical components are the fixity of leg-to-hull connection and spudcan fixity where spring elements were employed. Model updating technique was applied to the measured data to identify the parameters of these fixities. These data, including the hull displacement, leg-to-hull and spudcan moments, were incorporated into the cost function where the difference between model prediction and measured structural responses were minimized. Using the updated model, the predicted responses were consistent with the measured data indicating that the boundary fixities were reasonably estimated. The updated jack-up model can serve as a reliable platform for monitoring and predicting the overall performance of the actual structure.

1 INTRODUCTION

Jack-up structure is a type of mobile platform used for oil and gas exploration and production. It usually consists of a buoyant hull and several movable truss legs. The legs and hull are connected through a rack-chock system, and the bottom of each leg rests on a spudcan footing. These facilitates the operation mode as a fixed platform as well as transit mode as a floating platform. The fixity systems of the leg-to-hull connection and spudcan make the jack-up quite sensitive in terms of dynamic response (Bienen and Cassidy 2009). The basic configuration of a jack-up is a large hull near the top, supported by slender truss legs founded on spudcans, which complicates the structure-wave interaction modelling with respect to hydrodynamic loads. To fully assess a jack-up structure, understanding its dynamic characteristics under different structural configurations and varying load conditions is important and necessary for safe design and maintaining performance (Mirzadeh et al. 2016).

Researchers have focused on analyzing the measurement data in time and/or frequency domain to make quantitative assessments of structural nonlinearity, hydrodynamic characteristics and spudcan fixity. Liu et al. (1991) analyzed laboratory measured data of jack-ups in irregular waves and revealed the influence of nonlinear properties on structural dynamics. The dynamic response of a jack-up moored on the dock under various sea states was also presented (Liu et al. 2015). Such basin models are often based on similarity laws and may not represent of the actual structures accurately. For this reason, in-situ measurement of actual jack-ups has been employed to study the wave kinematics, hydrodynamic loads, global structural response, structural natural period, damping properties and effect of soil-structure interaction (Temperton et al. 1991; Yin et al. 2020). The in-situ measurement under complex environmental conditions provided realistic information for structural health monitoring and gave insight into acceptance criteria of standards.

Numerical analysis of jack-ups serves as a complementary tool to explore the internal forces under different limit states and predict the dynamic response under wave loading. Pisanò et al. (2019) proposed a full continuum nonlinear finite element (FE) modelling framework for jack-up-spudcan soil system to investigate soil-structure interaction effect on response. Although a fully detailed model can simulate the internal force of each member accurately and provide reliable structural analysis, it is quite time-consuming.

In cases where detailed responses or forces are not needed and the prediction of global structural responses is sufficient, simplified jack-up models provide the most efficient tool. Various simplified models, including equivalent 3-leg stick (Liu et al.1991) and sub-structural models (Wang et al. 2014), have been developed. They can be used for overturning checks and reliability analysis. However, such type of model requires calibration due to the highly simplified assumptions, including the fixity of the boundary conditions. This paper presents the development of a simplified model based on the basin test of jack-up modelled at a scale of 1:30, with focus on the fixity of leg-to-hull connection and spudcan fixity. The boundary fixity properties were estimated using model updating technique where the updated results based on power spectral density (PSD) were presented. The calibrated jack-up model can subsequently be used to examine the overturning resistance and assess the dynamic performance under potential future loads.

2 BASIN TEST OF JACK-UP AND STRUCTURAL MODEL

2.1 Basin test

To develop a structural digital twin framework, a generic jack-up model at 1:30 scale was designed and fabricated to comprehend its hydrodynamic performance and gather high quality datasets through basin tests. A sequence of tests based on various wave conditions and operating modes was executed, where a detailed description can be found in Chen et al. (2022). In this paper, the jack-up in its elevated mode was investigated and analyzed.

Figure 1a Shows the time history of hull displacement. The hull displacement was derived from the accelerometers on the hull by double integration. The PSD of the hull displacement is presented in Figure 1b. The first peak is about 0.40 Hz, representing the dominant component of wave load. The second peak coincides at approximately 0.83 Hz, corresponding to the fundamental frequency of the jack-up model.

Figure 1. Comparison of hull displacements: (a) time history, (b) power spectral density (PSD).

The moment at the forward leg-to-hull connection, measured using load cell, is shown in Figure 2. The amplitude of moment ranges from -76 N·m to 92 N·m. From the PSD of the moments shown in Figure 2b, the first and second peaks are at 0.41 Hz and 0.82 Hz, respectively. The frequencies obtained from the moments at the leg-to-hull connection are consistent with those from the hull displacements.

To evaluate the spudcan fixity, the moments at the spudcan were measured using load cells and plotted in Figure 3, where “Fwd”, “Stb” and “Pt” denote the forward, starboard and port legs, respectively. All of the recorded moments have approximately the same amplitude. To quantify the influence of the spudcan moment, Table 1 compares statistics from the time history of the moment at each leg. The moment amplitude of the forward leg is slightly larger than those of the

Figure 2. Comparison of leg-to-hull moment: (a) time history, (b) PSD.

other legs. Given the mean values are close to zero, the positive and negative moment amplitudes would be approximately the same (also indicated by the very low skewness coefficients). Since the spudcan provides some moments, non-zero spudcan moments will lead to a redistribution of the leg bending moments and hence spring elements should be used for the spudcan footing.

Figure 3. Comparison of spudcan moments: (a) forward leg, (b) starboard leg, (c) port leg.

Figure 4 Presents the PSD of the moments at the spudcans, and the first and second peaks of the PSD for all three legs are listed in Table 2. The first PSD peak of the three legs is determined to be at about 0.41 Hz, while the second one is around 0.82 Hz, consistent with those obtained from the hull displacements and the leg-to-hull moments, confirming the wave and fundamental structural frequencies.

Table 1. Statistics from time history of moments at spudcan.

Case	Leg	Maximum	Minimum	Mean	std. devn.
A	Forward	79.64	-72.50	0.066	15.64
	Starboard	76.15	-65.76	-0.188	12.35
	Port	75.42	-62.04	-0.008	12.25

Figure 4. Comparison of moment PSD at legs of spudcan: (a) forward, (b) starboard, (c) port.

Table 2. First two peaks in PSD of spudcan moment (Hz).

Peak	Forward	Starboard	Port
First peak	0.42	0.41	0.41
Second peak	0.81	0.83	0.82

2.2 Structural model

A numerical model of the jack-up based on the basin test results was created as shown in Figure 5. The truss structure of each leg was simplified as an equivalent beam positioned at the geometric center of the leg. The hull was taken a rigid body, modelled with some nodes connected by weightless rigid elements. As the flexibility between the leg and the hull influences the distribution of the leg bending moment and the transfer of the shear force, spring elements were used to model the leg-to-hull connections, as shown in Figure 5b. The spudcan fixity has significant influence on the dynamic characteristic of jack-up. For instance, increased spudcan fixity may increase the natural frequency of the global structure whereas the assumption of zero fixity (i.e. pinned footing) would be very conservative. To estimate the spudcan fixity accurately, it is modelled using spring elements, as shown in Figure 5c.

Figure 5. Schematic diagram of (a) simplified stick model, (b) springs for leg-to-hull connections, (c) springs for spudcan fixity.

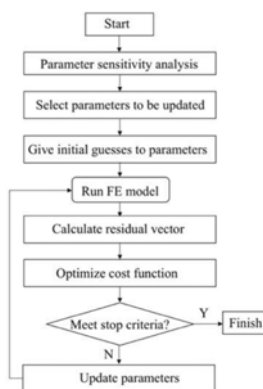

Figure 6. Procedure of model updating.

Rayleigh damping was introduced to simulate structural damping, whose coefficients α and β were determined from two specific modes. For the calculation of wave loading, Morison's equation was employed. It is normally sufficient for dynamic analysis because the horizontal dimension of the leg is significantly smaller than the wavelength.

The aforementioned description is some key features associated with updating the model. An extensive modelling process was presented by Zhang et al. (2022). The equivalent simplified model can efficiently calculate dynamic responses at the expense of model precision, since for each leg, the detailed truss structure replaced by an equivalent beam. Importantly, calculating the fixity of the leg-to-hull connection and spudcan is still a challenging task as the fixity is related to the working condition. Model updating technique serves as an effective tool to calibrate the unknown parameters based measured data.

3 MODEL UPDATING PROCEDURE

The constructed jack-up model can analyze the hydrodynamic performance and response prediction under various load conditions if properly calibrated. In general, the structural response predicted by the FE model may differ from measurement data for reasons such as the fixity of boundary conditions, and variability in material properties. To obtain a good representative

FE model, the measured data are used to update the selected model parameters in the FE model. In essence, FE model updating is an optimization problem to narrow the gap between model prediction and measurement data, which is formulated as

$$\theta^* = \arg \min_{\theta} F(\hat{y}(\theta), y) = \arg \min_{\theta} F(\theta), \quad (1)$$

where θ is a vector of the selected parameters to be updated, $\hat{y}(\theta)$ is the predicted response related to the model parameters θ , y is the measured data, and $F(\cdot)$ denotes the cost function.

There are a variety of alternative formulations for the cost function. One of the simplest indices is the natural frequency, and the other popular index is the mode shape (Guo et al. 2018). However, both indices utilize limited response information, which may not be sensitive to the updated parameters. In this paper, the PSD is taken as a cost indicator, expressed as

$$F(\theta) = \|r(\theta)\|_2^2 = [r(\theta)]^T r(\theta) = \sum_{i=1}^{N_t} r_i^2(\theta), \quad (2)$$

where $r = y - \hat{y}(\theta)$ is the residual vector, N_t is the total number of data points, $\|\cdot\|_2$ denotes the 2-norm of a vector.

In the basin test, various types of data were collected from a heterogeneous set of sensors. For example, the spudcan and leg-to-hull moments were recorded using load cells, and the hull displacement was obtained by integrating the acceleration twice. To accommodate the largest possible amount of measured data, different kinds of measured data were incorporated into a single cost function with different weights. Since different types of measurement data had different magnitudes, ill-conditioning may arise if they were considered in a single cost function. For this reason, data measured from heterogeneous sensors were normalized and the cost function was reformulated as

$$F(\theta) = \sum_{j=1}^{N_s} \sum_{i=1}^{N_t} w_j \bar{r}_{ij}^2(\theta) = \sum_{j=1}^{N_s} \sum_{i=1}^{N_t} w_j (y_{ij} - \hat{y}_{ij}(\theta)), \quad (3)$$

where \bar{r}_{ij} is the normalized residual vector in the i -th row and j -th column, y_{ij} and \hat{y}_{ij} corresponds to measured data from sensors and prediction response from FE models, respectively. Each column j represents data from a sensor at all time, with N_s denoting the total number of sensors. Each row represents a point in time, with N_t as the total number of time steps. The weight factor w_j is generally interpreted as the “confidence” in the j -th sensor data.

According to equations (1) and (3), the optimization problem for model updating can be constructed as

$$\theta^* = \arg \min_{\theta} F(\hat{y}(\theta), y) = \arg \min_{\theta} \sum_{j=1}^{N_s} \sum_{i=1}^{N_t} w_j (y_{ij} - \hat{y}_{ij}(\theta)), \quad (4)$$

Since most of the selected parameters have physical meaning, the solution θ^* should be bounded. For example, Yong’s modulus or stiffness are often nonnegative. Thus, a constraint optimization function for updating model is expressed as

$$\theta^* = \arg \min_{\theta} \sum_{j=1}^{N_s} \sum_{i=1}^{N_t} w_j (y_{ij} - \hat{y}_{ij}(\theta)), \quad (5a)$$

$$\text{subject to } L_{\theta} \leq \theta \leq U_{\theta}, \quad (5b)$$

where L_{θ} and U_{θ} represent the lower and upper limit of the selected parameters.

To solve the optimization problem in equation (5), the `fmincon` solver in MATLAB optimization toolbox is used, where the solver specializes in finding the minimum values of constrained nonlinear problem. Once the update process reaches the functional tolerance or the maximum number of iterations, the parameter values obtained are taken as optimal. Figure 6 summarizes the procedure of model updating. It starts with selecting parameters, where an experienced engineer generally supplies many potential parameters for selection. The sensitivity analysis method is introduced to determine which parameters are to be calibrated. Having selected the parameters to be updated, initial guesses and constraint conditions are assigned to them. The parameters are then fed into the FE model to generate the structural response. By comparing the predicted response against the measured data, the residual vector can be calculated and used to estimate the cost function with the different weights. The optimization

solver is then employed to produce a new set of parameters. The generated parameters are used in the FE model and the procedure is repeated until the stopping criteria is met.

4 MODEL UPDATING OF JACK UP

4.1 Parameter selection for updating

The selected parameters to be updated significantly influence the accuracy and convergence of the model updating. Conceptually, if all physical parameters are selected for tuning, the FE model can model the actual structure fairly well. However, having too many updating parameters may produce an overfitted model, resulting in an unreliable updated model. Choosing an appropriate number of parameters to be updated is crucial.

In the modelling process, an equivalent beam replaced the detailed truss structure of each leg. This means that the representative area (A) and shear stiffness coefficient (ζ) of the section require updating. The equivalent diameter of each leg also affects the hydrodynamic coefficients, while the wave forces are difficult to measure accurately in the basin test. The hydrodynamic coefficients including the drag coefficient (C_d) and inertial coefficient (C_m) were chosen to be updated. Rayleigh damping was assumed for the structure, with coefficients α and β chosen for updating. The two kinds of boundary conditions in the FE model to be updated were the leg-to-hull connections and the spudcan connection as their fixity are difficult to determine. The parameters to be updated are listed in Table 3.

Table 3. Parameters selected for updating.

Parameter label	Description	Notation
P1	Section area of each leg.	A
P2	Shear stiffness coefficient of an equivalent section.	ζ
P3	Spudcan stiffness of forward leg in the x direction.	K_{sfx}
P4	Spudcan stiffness of starboard leg in the x direction.	K_{ssx}
P5	Spudcan stiffness of port leg in the x direction.	K_{spx}
P6	Spudcan stiffness of forward leg in the y direction.	K_{sfy}
P7	Spudcan stiffness of starboard leg in the y direction.	K_{ssy}
P8	Spudcan stiffness of port leg in the y direction.	K_{spsy}
P9	Spudcan stiffness of all the three legs in the z direction.	K_{sz}
P10	Stiffness of leg-to-hull connection for a forward leg.	K_{hf}
P11	Stiffness of leg-to-hull connection for port and starboard legs.	K_{hps}
P12	Hydrodynamic coefficient (drag coefficient).	C_d
P13	Hydrodynamic coefficient (inertial coefficient).	C_m
P14	Rayleigh damping coefficient.	α
P15	Rayleigh damping coefficient.	β

The parameters in Table 3 can be classified into three categories: the first concerns structural properties (A , ζ , and β), the second is the fixity of connections (K_{sfx} , K_{ssx} , K_{spx} , K_{sfy} , K_{ssy} , K_{spsy} , K_{sz} , K_{hf} and K_{hps}), and the third corresponds to hydrodynamic characteristics (C_d and C_m). These parameters in the three categories have coupled effects on the structural response which complicates the model updating process. For example, part of the first category (A and ζ) and the entire second category influence the stiffness matrix; the damping matrix is calculated from structural damping (α and β) and water added damping (C_m).

4.2 Model updating results

Nominal values (if absent, values based on engineering experience) of the parameters were used to start the model updating procedure. Given that the unknown parameters had different amplitudes, they were normalized to unity. Their lower and upper bounds were set to 0.1 and 4, that is within an order of magnitude from the initial values. As mentioned earlier, the `fmincon` solver in MATLAB optimization toolbox was employed and the stopping criteria were set to a tolerance of $1e-5$, limited by the maximum number of iterations of 1500.

Figure 7. Values of normalized parameters with iteration.

Figure 8. Comparison of PSD of structural response: (a) displacement, (b) leg-to-hull moment.

The values of updated parameters with iteration steps are shown in Figure 7, where all parameters converged within 343 iterations. P12 and P14 showed a large jump at the 17th and 244th iterations, respectively. Figures 8 and 9 compare the PSD of the updated results against the test data, which matched fairly well especially at the two peaks. The updated parameters were then used as inputs in the FE model to generate the structural responses. The hull displacements are compared with the measured displacements in Figure 10 showing good match in the overall trend. It showed that the displacement generated at the point level was consistent with the test data. Figures 11 also illustrate the similar agreement for the leg-to-hull moment.

Figure 9. Comparison of PSD of spudcan moment in three legs.

Figure 10. Comparison of hull displacement from 400 to 550 s.

Figure 11. Comparison of leg-to-hull moment from 400 to 550 s.

5 CONCLUSIONS

This work presented the finite element model updating of a jack-up structure based on basin test data. The measured hull displacement, leg-to-hull, and spudcan moments were analyzed in time and frequency domains. The identified fundamental frequency of the jack-up structure was 0.82 Hz while the dominant frequency of the irregular wave was around 0.42 Hz. A simplified jack-up model was created based on the basin test, which considered the fixity of leg-to-hull connection and spudcan fixity amongst other structural and hydrodynamic parameters to be identified. The simplified model with fifteen selected parameters was calibrated by minimizing the cost function represented by the power spectral density of measurement data and the corresponding FE predicted response. Due to the simplicity of the model, noise in the measured data and variability in the loadings, large uncertainties exist in the estimated shear stiffness coefficient, spudcan stiffness in the z direction for all 3 legs, stiffness of the leg-to-hull connections, hydrodynamic drag coefficient and the structural damping coefficients.

ACKNOWLEDGEMENTS

The authors would like to thank the invaluable assistance provided by the TCOMS Ocean Basin Support Team during the ocean basin experiments. This work is funded by the Enhancing Offshore System Productivity, Integrity and Survivability in Extreme Environments (ENSURE) programme. The fund supported by A*STAR under its RIE 2020 Industry Alignment Fund (Grant No: A19F1a0104) is also appreciated.

ABSTRACT: Bayesian updating has been widely used in civil engineering for many different purposes such as parameter identification, model updating, reliability analysis. Bayesian updating usually requires high computation cost, and some methodologies are available to reduce the computational costs. One of the methodologies that has been commonly used for system identification/control in time-series problem includes unscented transformation (UT). In UT, the prior and posterior probability density functions (PDFs) are approximately estimated with $2n + 1$ data points (n is the number of parameters of interest): it means that only $2n + 1$ times simulations are required for Bayesian inference. However, UT assumes that prior and posterior PDFs follow Gaussian PDFs and has limitations for some practical applications. This paper investigates the performance and limitations of UT in Bayesian updating in terms of estimation accuracy of posterior PDFs through synthetic examples. Comparison of UT with Monte Carlo filter (MCF) is also made.

1 INTRODUCTION

Bayesian updating has been widely used in civil engineering for many different purposes such as parameter identification, model updating, reliability analysis. There are many algorithms for implementing Bayesian updating, and Markov Chain Monte Carlo (MCMC, Metropolis et al. 1953) method has been commonly used in civil engineering because of its easy implementation and versatility (e.g., Beck and Au 2002).

In MCMC, samples are directly drawn from the posterior in a sequential way, so one sample after the other, after a burn-in period. The samples are correlated, often 100% when the new sample is not accepted, making them very insufficient in some applications, e.g., the improved performance might not be worth the additional computational costs.

To reduce the computational costs in Bayesian updating, some methodologies are available. One of the methodologies that has been commonly used for system identification/control in time-series problem includes unscented transformation (UT, e.g., Julier and Uhlmann 2004). In UT, the prior and posterior probability density functions (PDFs) are approximately estimated with $2n + 1$ data points (n is the number of parameters of interest): it means that only $2n + 1$ times simulations are required for Bayesian inference. However, UT assumes that prior and posterior PDFs follow Gaussian PDFs and has limitations for some practical applications.

This paper investigates the performance and limitations of UT in Bayesian updating in terms of estimation accuracy of posterior PDFs through synthetic examples. Comparison of UT with Monte Carlo filter (MCF) or particle filter (PF) (Gordon et al. 1993; Kitagawa 1996) is also made.

2 UNSCENTED KALMAN FILTER

An algorithm for Bayesian updating based on UT is called unscented Kalman filter (UKF), and it uses UT to pick a minimal set of sample points (called sigma points) around the mean. The sigma points are then propagated through the nonlinear functions, from which a new mean and covariance estimate are then formed. The resulting filter depends on how the transformed statistics of the UT are calculated and which set of sigma points are used. It should be remarked that it is always possible to construct new UKFs in a consistent way.

For certain systems, the resulting UKF more accurately estimates the true mean and covariance. This can be verified with Monte Carlo sampling or Taylor series expansion of the posterior statistics. In addition, this technique removes the requirement to explicitly calculate Jacobians, which for complex functions can be a difficult task in itself (i.e., requiring complicated derivatives if done analytically or being computationally costly if done numerically), if not impossible (if those functions are not differentiable).

The following subsections briefly describes sigma points and UKF.

2.1 Sigma points

In UKF, n -dimensional random variable \mathbf{x} with mean $\bar{\mathbf{x}}$ and covariance $\mathbf{P}_{\mathbf{xx}}$ is approximated by $2n + 1$ weighted points, which are called *sigma points*, given by:

$$\begin{aligned}\mathcal{X}_0 &= \bar{\mathbf{x}} \\ \mathcal{X}_i &= \bar{\mathbf{x}} + \left(\sqrt{(n + \kappa)\mathbf{P}_{\mathbf{xx}}} \right)_i \\ \mathcal{X}_{i+n} &= \bar{\mathbf{x}} - \left(\sqrt{(n + \kappa)\mathbf{P}_{\mathbf{xx}}} \right)_i\end{aligned}\quad (1)$$

$$\begin{aligned}W_0 &= \kappa / (n + \kappa) \\ W_i &= 1 / (2n + 2\kappa) \\ W_{i+n} &= 1 / (2n + 2\kappa)\end{aligned}\quad (2)$$

where κ is a hyperparameter that controls the location of sigma points, $\left(\sqrt{(n + \kappa)\mathbf{P}_{\mathbf{xx}}} \right)_i$ is the i^{th} column of the matrix square root of $(n + \kappa)\mathbf{P}_{\mathbf{xx}}$ and W_i is the weight which associated with the i^{th} point.

2.2 Unscented filter

The algorithm of the Bayesian updating (filtering) based on UT can be summarized as follows:

1. Define initial mean vector \mathbf{x}_0 and initial covariance matrix \mathbf{P}_0 .
2. Observation update:
 - a) Create a set of sigma points using Equations (1) and (2).
 - b) Transform sigma points via model f .

$$\mathbf{y}_i = f(\mathcal{X}_i), \quad i = 0, 1, \dots, 2n$$

- c) Compute the predicted mean

$$\bar{\mathbf{y}} = \sum_{i=0}^{2n} W_i \mathbf{y}_i$$

- d) Compute the covariance matrices \mathbf{V} and \mathbf{U} .

$$\mathbf{V} = \sum_{i=0}^{2n} W_i (\bar{\mathbf{y}} - \mathbf{y}_i)(\bar{\mathbf{y}} - \mathbf{y}_i)^{\text{T}} + \mathbf{R}$$

$$\mathbf{U} = \sum_{i=0}^{2n} W_i (\bar{\mathbf{x}} - \mathcal{X}_i)(\bar{\mathbf{y}} - \mathbf{y}_i)^T$$

e) Compute Kalman gain \mathbf{K} . and filtered estimate \mathbf{x}

$$\mathbf{K} = \mathbf{U}\mathbf{V}^{-1}$$

$$\mathbf{x} = \mathbf{x} + \mathbf{K}(\mathbf{y} - \bar{\mathbf{y}})$$

3 NUMERICAL EXAMPLE

The performance of UKF to estimate posterior distributions was investigated through a simple numerical test. The following 3rd order polynomial was used as a model f :

$$y = f(x_1, x_2) = 0.02x_1^3 - 0.02x_2^3 \quad (3)$$

where x_1 and x_2 are the model parameters which are assumed to be unknown. The posterior distribution of $\mathbf{x} = [x_1, x_2]^T$ is given by:

$$p(\mathbf{x}|\bar{\mathbf{y}}) \propto p\{\bar{\mathbf{y}}|f(\mathbf{x})\}p(\mathbf{x}) \quad (4)$$

where $\bar{\mathbf{y}}$ is observation. We assumed that $p(\mathbf{x})$ follows the Gaussian distribution defined by

$$N(\mu, \mathbf{C}), \mu = \mathbf{0} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \mathbf{C} = \begin{bmatrix} 1.0 & 0.0 \\ 0.0 & 1.0 \end{bmatrix} \quad (5)$$

Figure 1 shows the prior distribution of \mathbf{x} approximated with 10,000 Monte Carlo samples.

Figure 1. Prior PDF of x_1 and x_2 .

Two types of observation data, $\bar{y} = 0.2$ and $\bar{y} = 0.6$, are considered, and they intuitively correspond to nonlinear and strong nonlinear problems respectively. The observation noise is assumed to follow the Gaussian distribution with $\mu = 0.0$ and $\sigma = 0.1$.

The posterior distributions of x and y were estimated using UKF with different hyperparameters to investigate the effects of the hyperparameters on the estimation. Three different parameter values, which are $\kappa = 0.1, 1.0,$ and $2.0,$ were considered in UKF. Since the target problem is nonlinear, the analytical solution of the posterior distribution is not available. We estimated the posterior distributions using PF with 10,000 samples and assumed the results by PF as “true” or “analytical” solutions to discuss the performance of the UKF.

Figure 2 shows a comparison of posterior PDFs between UKF and PF for $\bar{y} = 0.2$. Although UKF gives analytical form of posterior distributions, the results of UKF are shown as Monte Carlo samples ($N = 10,000$). The result of UKF with $\kappa = 0.1$ is similar to the prior PDF, and the hyperparameter seems to be too small to capture the distribution. The result of UKF with $\kappa = 1.0$ well captures the posterior distribution, and UT can be used in Bayesian updating to reduce the computation cost.

Figure 3 shows a comparison of posterior PDFs between UKF and PF for $\bar{y} = 0.6$. The true posterior distribution is very complex seems difficult to capture UKF. The UKF seems to difficult to capture the complex posterior distribution with high accuracy, but the error between estimated and true distributions by properly tuning the hyperparameter. This study does not discuss the method of hyperparameter tuning, but some authorized methods which are commonly used in machine learning such as cross-validation can be applied in this problem.

Figure 2. Posterior PDF of x_1 and x_2 ($\bar{y} = 0.2$).

Figure 3. Posterior PDF of x_1 and x_2 ($\bar{y} = 0.6$).

Figure 4 shows the comparison of cumulative distribution function (CDF) for y between PF and UKF. When $\bar{y} = 0.2$, the CDF estimated by UKF is similar to true CDF. When $\bar{y} = 0.6$, the CDF estimated by UKF is very different from the true CDF, and it seems difficult to estimate the shape of posterior distribution of y by UKF. These results indicate that UKF can work in weakly nonlinear problems, but not the case in strongly nonlinear problems.

Figure 4. Posterior CDF of y : a) $\bar{y} = 0.2$; b) $\bar{y} = 0.6$.

4 CONCLUSIONS

This study investigated the performance of UT and UKF for Bayesian updating or estimation for posterior distributions through a simple numerical example. When the problem is weakly nonlinear, UT or UKF can reasonably estimate the posterior distributions with low computation cost. However, the problem is strongly nonlinear, it is difficult to capture the shape of the posterior distribution using UKF. In addition, hyperparameter tuning strongly impacts on the estimation, and UKF cannot work when appropriate parameters are not used. How to tune the hyperparameter is left for the future research.

ABSTRACT: Monitoring is becoming increasingly important for the condition assessment of structures, as it allows continuous assessment. The aim is to identify changes in the condition of the structure that cannot be detected by purely visual inspection. In this paper, a typical measurement system used in practice is investigated under laboratory conditions with regard to its temperature dependence. A method for temperature compensation of laser distance measurements is presented and a Bayesian model updating is applied, with which a temperature compensation function over time can be determined semi-automatically. It is shown that the temperature-dependent transfer function should first be generated at the structure in order to perform a reliable temperature compensation. Furthermore, the application of Bayesian Model Updating shows a reliable fit of the temperature-dependent transfer function over time, so that the engineer is provided with a helpful tool for semi-automated temperature compensation in the case of time-variant behavior.

1 INTRODUCTION

For condition monitoring of structures, Structural Health Monitoring (SHM) is becoming increasingly important, as it allows continuous condition assessment of the structure and usefully supplements on-site inspections (Farrar and Worden 2007; Wedel and Marx 2022). The aim of monitoring is to identify changes in the condition of the structure that can only be inadequately detected by the purely visual inspection (Worden et al. 2007), whereby the goal of monitoring can only be achieved by comparing at least two different states: the reference state with the current state (Worden and Tomlinson 2019). For large infrastructures (e.g. wind turbines or bridges), however, the change in condition due to aging is very small (Hübler et al. 2022), so that precise measurements are required to be able to make reliable comparisons. The problem is that not only the behavior of the structure, but also other influences such as temperature affect the measurement signal. The question arises how such influences can be quantified and compensated.

This paper aims to make a contribution to this by investigating a measurement system typically used in practice under laboratory conditions with regard to its temperature dependence and its time-dependent behavior. For this, a method for temperature compensation is presented and Bayesian Model Updating (BMU) is applied, with which a temperature compensation function can be determined semi-automatically. This paper consists of five chapters. In

chapter 2, the measurement principle of the investigated Laser Triangulation Sensor (LTS) is explained and the principle of BMU is described. In chapter 3 the experimental setup with the measurement system used and the exposures are explained. On this basis, the temperature dependence of the measurement signal is analyzed. With the help of time-variant investigations, BMU is applied in chapter 4 and it is shown that a reliable updating of the temperature dependence over time is possible. Chapter 5 concludes with a summary and an outlook.

2 THEORIES AND METHODOLOGIES

2.1 Laser triangulation sensor – measurement principle

In this paper, LTS is used because it enables to investigate a simple measurement principle and it can be used in Offshore Wind Turbine (OWT) or bridge monitoring. The LTS measures the distance to an object surface by calculating the angle and provides a non-contact method of position measurement (Murakami 1994).

Figure 1. Measurement principle of LTS.

A laser beam is projected on the object surface O and a light spot S can be observed on it. The light spot is imaged through a lens with a numerical aperture $\sin(u_i)$ (Dorsch et al. 1994; Berns et al. 2019). The position of the spot image S' is determined with a position sensitive detector called photodiode array (PDA). The PDA is based on the CCD principle (charge-coupled device) and contains light sensitive electronic components using the internal photoelectric effect. From the position of the light spot on the image plane, the position of the measuring object is calculated (Löffler-Mang 2012). For a detailed description of the measurement principle, the reader is referred to Bartels et al. 2023.

2.2 Bayesian model updating – Transitional Markov Chain Monte Carlo (TMCMC)

For engineering problems, mathematical models are typically used to simulate and evaluate the behavior of structures under load conditions. This virtual behavior corresponds only poorly to the real physical structure. To solve this problem, model updating techniques can be applied to update physical input parameters. The parameters then describe e. g. material properties of a structure (Worden and Tomlinson 2019). These parameters are measured on the real structure and are integrated into the mathematical model of the virtual system to be updated, so that the difference between the mathematical model and the real physical behavior of the system is minimized.

The physical behavior of a system is described by a mathematical function $M(x; \vartheta)$, where x defines the vector of unchangeable model parameters and ϑ the vector of changeable model parameters to be updated. The mathematical relationship between the requested quantity

\mathbf{D} (e. g., the output of the measured distance by the LTS) and the mathematical prediction model $M(x; \vartheta)$ is defined by

$$\mathbf{D} = M(x; \vartheta) + \epsilon, \quad (1)$$

where ϵ describes the model or measurement error. The uncertainty in the model parameters ϑ can be accounted for using a probability density function (PDF). These problems are called forward problems because they can be solved analytically or with simple Monte Carlo simulations (Li and Caracoglia 2019). Monte Carlo simulation is used to generate the requested data \mathbf{D} for a known common PDF. The problem in reality is that the best-fit joint PDF is not known, which links the model parameters ϑ to the requested quantity \mathbf{D} . This is called the inverse problem (Lye et al. 2021). The advantage of implementing Bayesian inference in BMU process is that prior information about the requested model parameters ϑ can be combined with the observed data \mathbf{D} . Hence, the stochastic character of the quantity \mathbf{D} to be inferred can be generated. So, if a set of n independent and identically distributed observations ($D_1; D_2; \dots; D_n$) is made, then the pre-information is updated using Bayes' theorem (Mares et al. 2006). This leads to a posterior distribution of the requested model parameters ϑ under the condition of the observations made \mathbf{D}

$$P(\vartheta|\mathbf{D}) = \frac{P(\mathbf{D}|\vartheta) \cdot P(\vartheta)}{P(\mathbf{D})}, \quad (2)$$

where \mathbf{D} represents the observation vector, $P(\vartheta)$ the statistical distribution of the prior, $P(\mathbf{D}|\vartheta)$ the likelihood function, $P(\mathbf{D})$ the evidence, and $P(\vartheta|\mathbf{D})$ the posterior distribution. Instead of the analytical solution, the Monte Carlo method, which is easy to apply, is usually used. To apply the method, samples must be generated, which are performed using the iterative TMCMC sampler. For more detailed information on the TMCMC algorithm, please refer to Ching and Chen 2007.

3 EXPERIMENTAL SETUP AND TRANSFER FUNCTION

For the investigation of the temperature influence on laser measurements, a total of six LTSs within a measuring system is exposed to different temperatures within a climate chamber and analyzed whether and in which way the measurement signal changes.

3.1 Sensors, measurement system and environmental influence

The experimental setup is shown in Figure 2.

The entire measuring system consists of LTS, cable and measuring amplifier. As can be seen in Figure 2, the LTSs are fixed on a base plate with upstand and measure the horizontal distance to the upstand. The special feature: the base plate and the upstand are made of the material Alloy 36, an iron-nickel alloy with a small coefficient of thermal expansion of $\alpha_{T, \text{Alloy36}} = 0.50 \cdot 10^{-6} \text{ 1/K}$. Compared to this material, construction steel ($\alpha_{T, \text{Stahl}} = 13.00 \cdot 10^{-6} \text{ 1/K}$) has a coefficient of thermal expansion more than 20 times higher. With this design, it is possible to attribute changes in the measurement signal to the measurement system, since the influence of base plate strain due to temperature change is negligible. LTSs with a measuring range of 10 mm are tested, which measure within the measuring distances 16 mm to 26 mm. To examine the entire measurement range of the LTS, three initial distances d_{sel} between the sensor and the upstand are selected ($d_{\text{sel}} \approx [17 \text{ mm}; 21 \text{ mm}; 25 \text{ mm}]$).

3.2 Temperature-dependent transfer function

In the climate chamber, temperatures are varied between -10 °C and +50 °C in 10 K steps. The planned temperature curve can be seen in Figure 3.

Figure 2. Experimental setup for the LTS investigation of temperature and time dependence.

Figure 3. Intended temperature regulation for the determination of the temperature-dependent transfer function.

By varying the temperature, a reproducible test of the LTS with respect to the temperature dependence is possible. Each temperature level is kept constant for 4 h and the respective temperature change by 10 K is achieved within 30 min. Keeping the temperature constant for 4 h has two objectives: on the one hand, the temperature inertia of the experimental setup is overcome, so that the temperature can be assumed for the measuring system, the base plate and the ambient temperature. On the other hand, a representative amount of data can be generated over this period. With a sampling rate of 1 Hz, 14,400 measured values are generated over 4 hours. Only the constant temperature and measurement distance ranges are cut and the arithmetic mean is calculated as the expected value.

This procedure is carried out for all temperature levels, so that a total of seven expected values are calculated from -10 °C to $+50\text{ °C}$ in 10 K steps. The values are related to the measured

Figure 4. Temperature dependent transfer function for one LTS.

distance at 10 °C (reference value). This quotient between the measurement distance at a given temperature and the measurement distance at 10 °C is referred to as the transfer factor $H(T)$. The individual transfer factors are approximated by a 2nd degree regression polynomial to the so-called temperature-dependent transfer function (see Figure 4). The detailed description of the procedure for calculating the temperature-dependent transfer function is given in Bartels et al. 2022.

3.3 Time-dependence of the transfer function

With the knowledge of the temperature dependence of the LTS, the time dependence of the transfer function is to be analyzed in the next step. For this, the measurement system is subjected to a modified temperature and humidity curve (see Figure 5) using the same experimental setup as shown in Figure 2.

Figure 5. Intended temperature and humidity regulation for the aging tests.

The temperature and humidity can be divided into four phases, with each phase starting and ending at a temperature of 20 °C. This has the advantage that the measurement signal can be compared with the output signal (also at 20 °C) after each aging phase. In order to be able to record the time variance of the transfer function, the test for determining the temperature-dependent transfer

function according to chapter 3.2 is carried out after each 240-hour aging test and compared with the transfer function from Figure 4. The result is shown in Figure 6.

Figure 6. Investigation of the time variance of the temperature-dependent transfer function.

To enable the humidity to be controlled as well, the experimental setup had to be installed in a different climate chamber that can vary both the temperature and the humidity. At time $t = 0$ h the experimental setup is in the “old” climate chamber, at time $t = 720$ h the experimental setup is in the “new” climate chamber.

It can be clearly seen that the reconstruction of the measuring system has led to a change in the temperature-dependent transfer function. This circumstance means that this transfer function should only be determined in practice after successful installation of the measurement system on the structure when the system is no longer moved. A determination in the laboratory would lead to unreliable and non-reproducible results. After reconstruction the temperature-dependent transfer function does not change much over the considered test period of 1440 h, so that a time-invariant temperature-dependent transfer function can be assumed.

4 BAYESIAN MODEL UPDATING OF TRANSFER FUNCTION

The question arises whether the results from sections 3.2 and 3.3 can also be approximated with BMU. This would mean a partial automation of the measurement data evaluation and accordingly support the interpreting engineer in the quasi-real-time evaluation of the monitoring data. For this, the transfer function from the manual approximation is compared with the one generated by BMU. The result of the BMU is shown in Figure 7.

Figure 7. Transfer function calculated with BMU.

The initial transfer function at time point $t = 0$ h is updated for time point $t = 720$ h. The visual comparison between Figure 6 and Figure 7 shows a good agreement of the transfer functions at time point $t = 720$ h. This finding is quantified in the next step. For this, the mathematical model of the transfer function is important, which includes the parameters ϑ_i to be updated. With equation (3)

$$\hat{h}(T, \vartheta_i) = 1.00096 \cdot \vartheta_1 + (-8.18380 \cdot 10^{-5}) \cdot T \cdot \vartheta_2 + (-1.37294 \cdot 10^{-7}) \cdot T \cdot \vartheta_3 \quad (3)$$

the transfer function for updating is defined at time $t = 0$ h, where T describes the temperature. In the manual approximation of the transfer function at time $t = 720$ h, the parameters of the 2nd degree regression polynomial are determined so that they can be compared with the parameters of the transfer function at time $t = 0$ h. The quotient of the respective parameters results in the fitting factor ϑ_i . For the validation of BMU, the change of the transfer function is considered once between the time points $t = 0$ h to $t = 720$ h and between $t = 960$ h to $t = 1200$ h. The results are listed in Table 1.

Table 1. Comparison of manual approximation vs. BMU (TMCMC).

		ϑ_1	ϑ_2	ϑ_3
t = 0 h to 720 h	2 nd degree polynomial	0.99903	-0.33468	7.52741
	BMU (TMCMC)	0.99901	-0.35000	7.90000
	Error	0.002 %	4.576 %	4.950 %
t = 960 h to 1200 h	2 nd degree polynomial	1.00034	0.60755	0.68738
	BMU (TMCMC)	1.00025	0.65980	0.68000
	Error	0.008 %	8.600 %	1.074 %

It becomes clear that the error between manual approximation and BMU is small. Both in the updating process between strongly varying transfer functions ($t = 0$ h to 720 h) and in the case of similar transfer functions ($t = 960$ h to 1200 h), the procedure is accurate. Nevertheless, the fitting factors in the BMU process are determined with an uncertainty, since an expected value is calculated on the basis of a large number of samples, which is calculated with a standard deviation. In future experiments, it will be investigated how large the standard deviation of the individual parameters can be so that the smallest changes in the transfer functions can be reliably determined and are not lost in the standard deviation of the fitting factors ϑ_i .

5 CONCLUSION AND OUTLOOK

In this paper, a measurement system typically used in practice was tested under laboratory conditions with respect to its temperature dependence and its time-dependence. A method for the temperature compensation of LTSs was presented and furthermore a BMU was applied, with which a temperature compensation function can run semi-automatically over time.

It is shown that the generation of the temperature-dependent transfer function must first be applied on the structure to be monitored in order to perform reliable temperature compensation.

Furthermore, the application of a BMU with TMCMC algorithm shows a reliable fitting of the temperature-dependent transfer function over time. Thus, this procedure providing the interpreting engineer with a helpful tool for semi-automated temperature compensation in the presence of time-variant behavior of the measurement system.

Future studies will address the time variance of the measurement system in more detail. In addition, the uncertainty of the BMU must be taken into account when calculating the transfer function so that marginal change in the measurement system and at the structure can be reliably captured. This is the only way to reliably assess structures using monitoring systems over several years.

ABSTRACT: In stochastic model updating, hybrid uncertainties are typically characterized by the distributional p-box. It assigns a certain probability distribution to model parameters and assumes its hyper-parameters as interval values. Thus, regardless of the updating method employed, the distribution family needs to be known a priori to parameterize the distribution. Meanwhile, a novel class of the random variable, called staircase random variable, can discretely approximate a wide range of distributions by solving moment-matching optimization problem. The first author and his co-workers have recently developed a distribution-free stochastic updating framework, in which model parameters are considered as staircase random variables and their hyper-parameters are inferred in a Bayesian fashion. This framework can explore an optimal distribution from a broad range of potential distributions according to the available data. This study aims to further demonstrate the capability of this framework through a simple numerical example with a parameter following various types of distributions.

1 INTRODUCTION

Model updating has been widely accepted as a fascinating technique to mitigate the discrepancy between model outputs and measurements (Mottershead and Friswell, 1993). The conventional deterministic model updating aims to calibrate model parameters to find their optimal values from a single set of the measurement data. It has been successfully employed in a wide range of practical applications, including the correction of complex finite element models. However, this approach considers the model and measurement data as deterministic, ignoring uncertainties in both modeling and measuring processes.

In contrast, the stochastic model updating aims to calibrate not parameters themselves but their probability distributions, so that corresponding model outputs reproduce the uncertainty characteristics of the multiple sets of the measurement data (Mares et al., 2006). This can be achieved by finding the optimal values of the distribution hyper-parameters that minimize a stochastic distance between model outputs and measurement datasets. Bi et al. (2019) employed the Bhattacharyya distance and developed a Bayesian updating framework that utilizes a distance-based approximate likelihood. The capability of this framework has been demonstrated upon complex applications, e.g., the first edition of NASA UQ problem (Crespo et al., 2014).

More recently, the latest edition of NASA UQ problem (Crespo and Kenny, 2021) has posed a challenge in the stochastic model updating to calibrate the parameter distributions without prior information about their distribution families. Motivated by this, the first author and his co-workers have developed a distribution-free stochastic updating framework, where the parameter distributions

are approximated by staircase density functions (SDFs) (Kitahara et al., 2022a; Kitahara et al., 2022b). SDF is a discrete probability density function (PDF) defined for the staircase random variable (SRV) which has a bounded support set and prescribed values for the first four moments (Crespo et al., 2018). It has no analytical solution but enables to discretely approximate a broad range of distributions by solving moment-matching optimization problem. This distribution-free stochastic updating framework has been demonstrated that it enables to calibrate the parameter distributions with no constraining hypothesis on the distribution formats. However, its capability to estimate various types of distributions has not been thoroughly investigated. Hence, this study aims at further demonstrating the feasibility of this framework through a simple numerical example with a parameter following various types of distributions, including heavy-tailed and multi-modal distributions.

2 OVERVIEW OF DISTRIBUTION-FREE STOCHASTIC UPDATING FRAMEWORK

2.1 *Bhattacharyya distance*

In the stochastic model updating, the stochastic discrepancy between model outputs and measurement datasets needs to be quantified and minimized. Let $\mathbf{Y}_D = \{\mathbf{y}^{(i)}; i = 1, \dots, N_D\}$ be N_D sets of the measurement data $\mathbf{y} \in \mathbb{R}^m$. Let also $\mathbf{Y}_S = \{\mathcal{M}(\mathbf{x}^{(i)}); i = 1, \dots, N_S\}$ be the corresponding N_S model outputs parameterized through a model parameter vector $\mathbf{x} \in \mathbb{R}^n$. In this study, the stochastic discrepancy between \mathbf{Y}_S and \mathbf{Y}_D is quantified as the Bhattacharyya distance, and its theoretical definition is given as:

$$d_B(\mathbf{Y}_S, \mathbf{Y}_D) = -\log \left[\int_{\mathbf{y}} \sqrt{f_{\mathbf{Y}_S}(\mathbf{y})f_{\mathbf{Y}_D}(\mathbf{y})} d\mathbf{y} \right] \quad (1)$$

where $f_{(\cdot)}(\mathbf{y})$ represents the PDF of \mathbf{y} ; \mathbf{y} denotes the support domain \mathbf{y} which comprises the m -dimensional space. Equation (1) indicates that the Bhattacharyya distance measures the degree of overlap between two different distributions. However, the direct evaluation of Equation (1) is generally impractical because the PDF of \mathbf{Y}_D often cannot be precisely estimated due to the very limited number of available measurement datasets. Hence, Bi et al. (2019) proposed the so-called binning algorithm to discretely evaluate the Bhattacharyya distance as:

$$d_B(\mathbf{Y}_S, \mathbf{Y}_D) = -\log \left\{ \sum_{i=1}^{N_{bin}} \sqrt{P_{\mathbf{Y}_S, i} P_{\mathbf{Y}_D, i}} \right\} \quad (2)$$

where N_{bin} indicates the total number of bins; $P_{(\cdot), i}$ represents the probability mass function of \mathbf{y} at the i th bin. N_{bin} is set as $N_{bin} = 10^n$ in this study.

2.2 *Staircase density functions*

Let the model parameters \mathbf{x} be independent random variables having the support set $[\underline{\mathbf{x}}, \bar{\mathbf{x}}]$ and prescribed values for the hyper-parameters $\boldsymbol{\theta}_x = [\boldsymbol{\mu}, \mathbf{m}_2, \mathbf{m}_3, \mathbf{m}_4]$ that consists of the mean vector $\boldsymbol{\mu} \in \mathbb{R}^n$, variance vector $\mathbf{m}_2 \in \mathbb{R}^n$, third-order central moment vector $\mathbf{m}_3 \in \mathbb{R}^n$, and fourth-order central moment vector $\mathbf{m}_4 \in \mathbb{R}^n$. Note that, in practice, the third- and fourth-order central moments are normalized by the variance as the skewness $\tilde{\mathbf{m}}_3$ and kurtosis $\tilde{\mathbf{m}}_4$, respectively, in the updating procedure. Any such variables must satisfy the feasibility conditions $g(\boldsymbol{\theta}_x) \leq 0$ given in Crespo et al. (2018). The realizations of $\boldsymbol{\theta}_x$ that satisfies these conditions constitute the feasible domain $\Theta = \{\boldsymbol{\theta}_x : g(\boldsymbol{\theta}_x) \leq 0\}$.

Let also the support set $[\underline{\mathbf{x}}, \bar{\mathbf{x}}]$ partitioned into n_b sub-intervals with the equal length of $\boldsymbol{\kappa} = (\bar{\mathbf{x}} - \underline{\mathbf{x}})/n_b$, \mathbf{x} can be then considered as SRVs the PDF of which is expressed as:

$$f_X(\mathbf{x}) = \begin{cases} p^j & \forall \mathbf{x} \in (\mathbf{x}^j, \mathbf{x}^{j+1}], \forall j = 1, 2, \dots, n_b \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

where $l^j (= \prod_{i=1}^n l_i^j)$ is the PDF value at the j th bin; $\mathbf{x}^j = \mathbf{x} + (j-1)\boldsymbol{\kappa}$. $n_b = 25$ is utilized in this study, The marginal staircase densities are obtained by solving the optimization problem:

$$\underset{l_i}{\operatorname{argmin}}\{J(l_i) : \mathbf{A}(\boldsymbol{\theta}_{x_i}, n_b)\mathbf{l} = \mathbf{b}(\boldsymbol{\theta}_{x_i}), \boldsymbol{\theta}_x \in \Theta\} \quad (4)$$

where J denotes the cost function; $\mathbf{A}\mathbf{l} = \mathbf{b}$ are moment matching constraints. This optimization problem is convex when the cost function is a convex function. In this study, the cost function is defined as follows based on the principle of maximum entropy:

$$J(l_i) = \kappa_i \log l_i^T \mathbf{l}_i \quad (5)$$

2.3 Approximate Bayesian computation

In the proposed stochastic model updating framework, approximate Bayesian computation (ABC) (Beaumont, 2019) is employed. ABC is based on the well-known Bayes' theorem:

$$P(\boldsymbol{\theta}_x | \mathbf{Y}_D) = \frac{\tilde{\mathcal{L}}(\mathbf{Y}_D | \boldsymbol{\theta}_x) P(\boldsymbol{\theta}_x)}{P(\mathbf{Y}_D)} \quad (6)$$

where $P(\boldsymbol{\theta}_x)$ denotes the prior distribution of the hyper-parameters $\boldsymbol{\theta}_x$ that reflects one's initial beliefs on $\boldsymbol{\theta}_x$; $P(\boldsymbol{\theta}_x | \mathbf{Y}_D)$ is the posterior distribution of $\boldsymbol{\theta}_x$ that represents the posterior state of knowledge on $\boldsymbol{\theta}_x$; $\tilde{\mathcal{L}}(\mathbf{Y}_D | \boldsymbol{\theta}_x)$; is the so-called approximate likelihood function that serves as the connection between the measurement datasets \mathbf{Y}_D and $\boldsymbol{\theta}_x$; $P(\mathbf{Y}_D)$ means the evidence ensuring that the integral of the posterior distribution equal to one.

Given the support set $[\underline{\mathbf{x}}, \bar{\mathbf{x}}]$, the support set of $\boldsymbol{\theta}_x$ can be obtained based on the feasibility conditions as:

$$\Omega = [\underline{\boldsymbol{\theta}}_x, \bar{\boldsymbol{\theta}}_x] = \begin{bmatrix} \underline{\boldsymbol{\mu}}, \bar{\boldsymbol{\mu}} \\ \underline{\mathbf{m}}_2, \bar{\mathbf{m}}_2 \\ \underline{\mathbf{m}}_3, \bar{\mathbf{m}}_3 \\ \underline{\mathbf{m}}_4, \bar{\mathbf{m}}_4 \end{bmatrix} = \begin{bmatrix} \underline{\mathbf{x}}, \bar{\mathbf{x}} \\ \mathbf{0}, \frac{(\bar{\mathbf{x}} - \underline{\mathbf{x}})^2}{4} \\ -\frac{(\bar{\mathbf{x}} - \underline{\mathbf{x}})^3}{6\sqrt{3}}, \frac{(\bar{\mathbf{x}} - \underline{\mathbf{x}})^3}{6\sqrt{3}} \\ \mathbf{0}, \frac{(\bar{\mathbf{x}} - \underline{\mathbf{x}})^4}{12} \end{bmatrix} \quad (7)$$

In this study, the hyper-parameters $\boldsymbol{\theta}_x$ are assumed to be independent each other and the prior distribution is expressed as:

$$P(\boldsymbol{\theta}_x) = U_{4n}(\Omega) I_{\Theta}(\boldsymbol{\theta}_x) \quad (8)$$

where $U_{4n}(\Omega)$ denotes the PDF of $4n$ independent multivariate uniform distribution on Ω ; I_{Θ} denotes the indicator function that equals to one if $\boldsymbol{\theta}_x \in \Theta$ and otherwise equals to zero.

The approximate likelihood function is defined using an arbitrary kernel. The principle behind it is that it should return a high value when the stochastic discrepancy between the model outputs and measurement datasets is small and, conversely it penalizes $\boldsymbol{\theta}_x$ that leads to a large stochastic discrepancy. In this study, the Gaussian kernel is utilized and the stochastic discrepancy is measured by the Bhattacharyya distance. Thus, the approximate likelihood function is defined as:

$$\tilde{\mathcal{L}}(\mathbf{Y}_D | \boldsymbol{\theta}_x) = \frac{1}{\varepsilon \sqrt{2\pi}} \exp \left\{ -\frac{d_B(\mathbf{Y}_S, \mathbf{Y}_D)^2}{2\varepsilon^2} \right\} \quad (9)$$

where ε indicates the scaling parameter which controls the centralization degree of the posterior distribution. A smaller ε provides a more peaked posterior distribution, which is more likely to converge to the true values, but needs more computation burden for convergence. In this study, it is set as $\varepsilon = 0.02$.

The posterior distribution in Equation (6) generally has no analytical solution and thus needs to be estimated using advanced sampling techniques. In this study, the transitional Markov chain Monte Carlo (TMCMC) sampler (Ching and Chen, 2007) is employed. TMCMC is a sequential

approach sampling from a series of intermediate distributions which will progressively converge to the true posterior distribution. The j th intermediate distribution is expressed as:

$$P_j(\theta_x) \propto \tilde{\mathcal{L}}(\mathbf{Y}_D|\theta_x)^{\beta_j} P(\theta_x) \quad (10)$$

where β_j indicates the so-called reduction coefficient. Its value starts from $\beta_j = 0$ in the initial step and gradually increases until $\beta_m = 1$ in the final step. β_j is adaptively computed from the samples of the previous step. Markov chains then propagate new samples starting from the ones in the previous step with higher likelihood values. The reader can refer to Ching and Chen (2007) for details of the TMCMC sampler.

3 NUMERICAL EXAMPLES

3.1 Problem descriptions

The proposed stochastic model updating framework is demonstrated upon a simple three degree-of-freedom (DOF) spring-mass system shown in Figure 1. The stiffness coefficients k_1 , k_2 , and k_3 are supposed to be uncertain with the uncertainty characteristics summarized in Table 1. k_1 and k_2 follow Gaussian distributions, whose hyper-parameters, i.e., means and standard deviations, are not fully determined but fall within given intervals as listed in the third column of Table 1. On the contrary, the distribution family of k_3 is unknown before model updating and only the support set is given as $[5.0, 7.0]$. Hence, it is assumed to be characterized as a SRV and its hyper-parameters are fall within the intervals computed as Equation (7). As a consequence, in total eight hyper-parameters are treated as interval-valued parameters and updated through the proposed procedure. Besides these uncertain parameters, the remaining parameters (i.e., stiffness coefficients k_4 to k_6 and masses m_1 to m_3) are set to be constants with determined values: $k_i = 5.0$ N/m ($i = 4, 5, 6$), $m_1 = 0.7$ kg, $m_2 = 0.5$ kg, and $m_3 = 0.3$ kg.

Figure 1. 3-DOF spring-mass system.

Table 1. Uncertainty characteristics of the model parameters.

Parameter	Uncertainty characteristics		Target values of hyper-parameters
	Distribution family	Support set/ hyper-parameters	
k_1	Gaussian	$\mu_1 \in [3.0, 7.0], \sigma_1 \in [0.0, 0.5]$	$\mu_1 = 4.0, \sigma_1 = 0.3$
k_2	Gaussian	$\mu_2 \in [3.0, 7.0], \sigma_2 \in [0.0, 0.5]$	$\mu_2 = 5.0, \sigma_2 = 0.1$
k_3	Unknown	$k_3 \in [5.0, 7.0]$	Given in Table 2
k_4-k_6, m_1-m_3	Deterministic	–	–

In addition to the prior information on the uncertainty characteristics, target values of the hyper-parameters in k_1 and k_2 are shown in the last column of Table 1. On the other hand, to investigate the capability of the proposed approach calibrating a wide range of distributions without the prior knowledge about their distribution families, five different distributions presented in Figure 2 are

considered as the target distribution of k_3 . Properties of these distributions are also provided in Table 2. The first distribution is a (truncated) Gaussian distribution of which hyper-parameters $\theta_1 = [\mu_{11}, m_{21}, \tilde{m}_{31}, \tilde{m}_{41}]$ are given in Table 2. While the distribution is truncated because the support set of k_3 is a closed interval, its mean and variance are determined such that the support set covers more than the 99.99 % confidence interval of the original Gaussian distribution. The remaining distributions are given by SDFs with the hyper-parameters, $\theta_i = [\mu_{1i}, m_{2i}, \tilde{m}_{3i}, \tilde{m}_{4i}]$, $i = 2, \dots, 4$. The second distribution is a (left) skewed one having a positive skewness. The third distribution is a flat one having a larger variance and smaller kurtosis compared to the Gaussian distribution. The fourth distribution is a heavy-tailed distribution having a larger kurtosis. Finally, the fifth distribution is a bi-modal distribution.

Figure 2. PDF for the target distributions of k_3 .

Table 2. Target distributions of k_3 .

Distribution format	Hyper-parameters
Truncated Gaussian	$\mu_{11} = 6.0, m_{21} = 0.04, \tilde{m}_{31} = 0.0, \tilde{m}_{41} = 3.0$
Skewed	$\mu_{12} = 5.7, m_{22} = 0.06, \tilde{m}_{32} = 0.5, \tilde{m}_{42} = 3.0$
Flat	$\mu_{13} = 6.0, m_{23} = 0.14, \tilde{m}_{33} = 0.0, \tilde{m}_{43} = 2.25$
Heavy-tailed	$\mu_{14} = 6.0, m_{24} = 0.04, \tilde{m}_{34} = 0.0, \tilde{m}_{44} = 4.2$
Bi-modal	$\mu_{15} = 6.0, m_{25} = 0.10, \tilde{m}_{35} = 0.8, \tilde{m}_{45} = 2.0$

The outputs of the system are the three eigen-frequencies f_1, f_2 and f_3 . The measurement datasets consisting of these eigen-frequencies are generated through multiple model evaluations with multiple sets of the model parameters sampled from their target distributions. In this study, the number of datasets are set as $N_D = 1000$. Figure 3 depicts the measurement datasets in the plane of the first and third frequencies for the case where the truncated Gaussian distribution is employed as the target distribution of k_3 . The reference range in the figure means the 95 % confidence interval of the sample distribution. Moreover, 1000 samples of the model parameters are generated by assigning a set of randomly selected initial values of the hyper-parameters, and subsequently 1000 initial model outputs are obtained through the model evaluations. These outputs are also presented in Figure 3. As can be seen, the scatters of the initial outputs are clearly apart from the measurement datasets; thus, model updating is necessary to obtain the model outputs as close as the measurement datasets.

3.2 Model updating results

For the case where the target distribution of k_3 is the truncated Gaussian distribution, totally 17 TCMC iterations are executed to reach convergence. Figure 4 illustrates histograms of

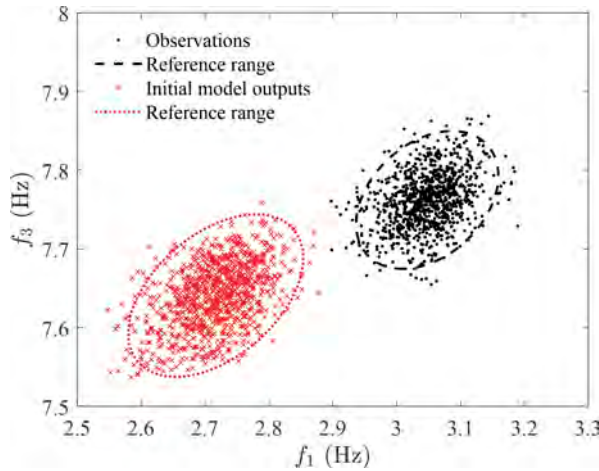

Figure 3. Target relative position of the measurement datasets and initial model outputs.

1000 posterior samples of the eight hyper-parameters, i.e., μ_i and σ_i ($i = 1,2$) as well as θ_1 . The ranges of the horizontal axes are identical to the intervals of the prior uniform distribution. It can be observed that all the hyper-parameters are significantly updated from the prior distribution. The means of the posterior samples are obtained as the posterior estimates of the hyper-parameters and presented in Table 3. The posterior estimates show good agreement with the target values. It should be noted that a relatively large error in m_{21} can be caused due to its very small target value. The updated distribution of k_3 is then obtained as a SDF with the posterior estimates of the hyper-parameters θ_1 . Figure 5 illustrates the updated distribution as the histogram of samples generated from the SDF. As can be observed from the figure, the updated distribution coincides well with the target. Uncastruncated Gaussian distribution.

Figure 4. Posterior distribution of the hyper-parameters in histograms.

Figure 6 shows a relative position of the measurement datasets and updated model outputs. The updated outputs are obtained through the model evaluations with 1000 sets of the model parameters sampled from their updated distributions. Compared to the initial model outputs presented in Figure 3, the updated model outputs fit well with the measurement datasets,

Table 3. Posterior estimates of the hyper-parameters.

Hyper-parameters	Target values	Posterior estimates ^a
μ_1	4.0	4.01/4.00/3.98/4.01/4.04 (1.0) ^b
σ_1	0.3	0.322/0.328/0.329/0.327/0.346 (15.3) ^b

σ_2	0.1	0.100/0.098/0.094/0.098/0.088 (12.0) ^b
$\mu_{11}/m_{21}/\tilde{m}_{31}/\tilde{m}_{41}$	6.0/0.04/0.0/3.0	6.02 (0.3)/0.046 (15.0)/0.05/2.94 (2.0)
$\mu_{12}/m_{22}/\tilde{m}_{32}/\tilde{m}_{42}$	5.7/0.06/0.5/3.0	5.69 (0.2)/0.064 (6.7)/0.402 (19.6)/3.36 (12.0)
$\mu_{13}/m_{23}/\tilde{m}_{33}/\tilde{m}_{43}$	6.0/0.14/0.0/2.25	5.99 (0.2)/0.155 (10.7)/-0.006/2.30 (2.2)
$\mu_{14}/m_{24}/\tilde{m}_{34}/\tilde{m}_{44}$	6.0/0.04/0.0/4.2	6.00 (0.0)/0.045 (12.5)/0.174/4.05 (3.6)
$\mu_{15}/m_{25}/\tilde{m}_{35}/\tilde{m}_{45}$	6.0/0.1/0.8/2.0	6.01 (0.2)/0.106 (6.0)/0.740 (7.5)/2.01 (0.5)

^a Percentage errors compared to the target values in parentheses.

^b Posterior estimates for all the five cases in a row and their maximum percentage errors in parentheses.

which demonstrates that the proposed updating procedure enables to calibrate the model so that its outputs represent wholly the uncertainty characteristics of the measurement datasets.

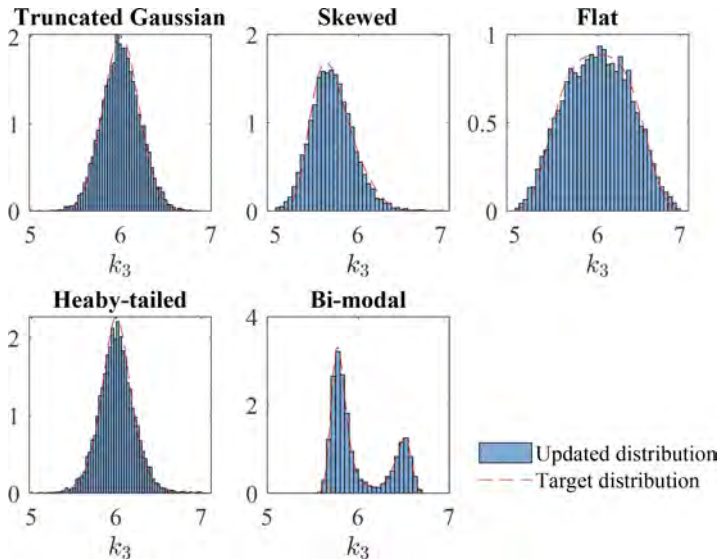

Figure 5. Updated distributions of k_3 .

Similarly, the proposed updating procedure is also performed for the remaining cases with the different target distributions of k_3 . For all the cases, the obtained posterior estimates of the hyper-parameters are summarized in Table 3. All the posterior estimates of the hyper-parameters show good agreement with the target values, including the higher-order moments such as the skewness and kurtosis in the SDFs, and the maximum percentage error compared to the target values is less than 20 %. The updated distributions of k_3 , which assign the posterior estimates of the hyper-parameters are also illustrated in Figure 5 for these cases. It can be seen that the updated distributions coincide well with the target distributions, indicating that the proposed updating procedure can quantify the parameter uncertainty as an appropriate probability distribution including heavy-tailed and multi-modal distributions. Finally, the updated model outputs are obtained through the model evaluations with the updated parameter distributions and compared with the measurement datasets. While relative positions of the updated model outputs and measurement datasets are not further provided for the sake of brevity, it is confirmed that the updated model outputs are properly tuned for all the cases and fit well with the measurement datasets.

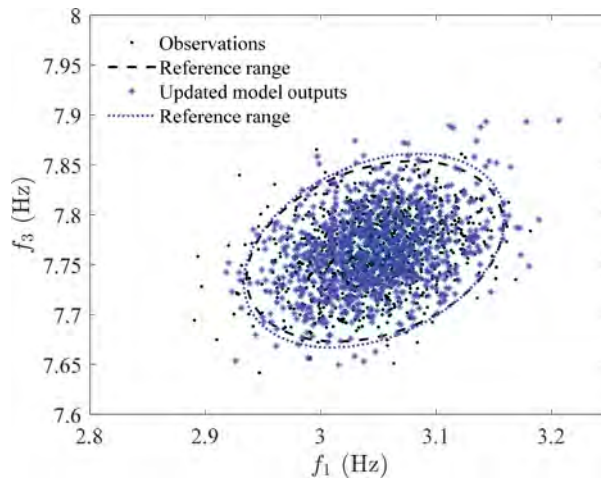

Figure 6. Target relative position of the measurement datasets and updated model outputs.

4 CONCLUSIONS

In this study, we present a distribution-free stochastic model updating framework to quantify the parameter uncertainty that forms a broad range of probability distributions, including heavy-tailed and multi-modal distributions, without the prior knowledge about their distribution families. The unknown parameter distribution is characterized by SDF, and it is assumed that only its support set is known a priori. Its hyper-parameters, i.e., the first four moments, are then inferred through the ABC procedure aiming at minimizing the Bhattacharyya distance between the model outputs and measurement datasets. The proposed updating framework is demonstrated on a simple 3-DOF spring-mass system, in which five different distributions are assumed as the target distribution of a model parameter. The results demonstrate that the proposed procedure has a potential to calibrate the arbitrarily parameter distribution as appropriate so that the model outputs recreate wholly the uncertainty characteristics of the measurement datasets.

ABSTRACT: Accurate parameter estimation is a challenging task that demands realistic models and algorithms to obtain the parameter's probability distributions. The Bayesian theorem in conjunction with sampling methods proved to be invaluable here since it allows for the formulation of the problem in a probabilistic framework. This opens up the possibilities of using prior information and knowledge about parameter distributions as well as the natural incorporation of aleatory and epistemic uncertainties. Traditionally, Markov Chain Monte Carlo (MCMC) methods are used to approximate the posterior distribution of samples given some data. However, these methods usually need a large amount of samples and therefore a large amount of model evaluations. Recent advances in transport theory and its application in the context of Bayesian model updating (BMU) make it possible to approximate the posterior distribution analytically and hence eliminate the need for sampling methods. This paves the way for the usage in real-time applications and for fast parameter estimation. We investigate here the application of transport maps to a simple analytical model as well as a structural dynamics model. The performance is compared to an MCMC approach to assess the accuracy and efficiency of transport maps. A discussion about requirements for the implementation of transport maps as well as details on the implementation are also given.

1 INTRODUCTION

Model parameter estimation is a daily task in many engineering disciplines. In SHM it proved to be very useful to track the changes in a system during its lifetime, thus making it possible to evaluate occurring damage or degradation of components in the system. In applications with uncertainties and stochastic parameters the model updating is usually done by using the Bayesian theorem; however depending on the system at hand the posterior density can not be calculated analytically. For the exploration of the posterior distribution then algorithms based on Markov Chain Monte Carlo (MCMC) are used, since these approaches do not require knowledge about the posterior topology. However, a downside of MCMC is that the convergence can not easily be assessed and sometimes many samples are needed in order to fully reach an adequate result. Some MCMC

algorithms also suffer from burn-in. Recently there have been advances in optimal transport theory (Villani 2009) which were applied in the Bayesian updating context (Parno and Marzouk 2018; Spantini et al. 2018). This opens up the possibility of circumventing some of the issues of MCMC methods, since transport maps provide a means of formulating an analytical relationship between some chosen, easy to evaluate reference distribution and the posterior distribution. Integrals can thus be evaluated on the reference distribution and then be transported to the posterior. In addition, sampling from the posterior becomes a simple evaluation of the map. The problem of finding this map is solved by optimization. Previous works have implemented transport map (TM) approximation in various use-cases, using synergies of this approach with model order reduction techniques to speed up the process (Rubio et al. 2019a,b).

In the following chapters the advantages and disadvantages of the TM approach when compared to an MCMC estimation are investigated. For this purpose we use two academic examples, one exponential function with two parameters and one structural model with three degrees of freedom.

2 PARAMETER ESTIMATION

2.1 Bayesian model updating

Let $\theta \in \mathbb{R}^d$ be a d -dimensional random variable with probability $p(\theta)$ describing uncertain parameters of a model $\mathcal{M}(\theta)$. Given measured data \mathbb{D} the probability of observing θ in $\mathcal{M}(\theta)$ under the condition of can \mathbb{D} be calculated using Bayes' theorem (Beck et al. 1998)

$$p(\theta|\mathbb{D}) = \frac{p(\mathbb{D}|\theta)p(\theta)}{p(\mathbb{D})} \quad (1)$$

where the likelihood $p(\mathbb{D}|\theta)$ describes the probability of observing the data under the assumption of θ and is usually modeled as a stochastic distance between $\mathcal{M}(\theta)$ and \mathbb{D} . One key difficulty in Bayesian model updating (BMU) is the irregular and unknown shape of $p(\theta|\mathbb{D})$ and the fact that it can only be evaluated point-wise. Therefore, MCMC methods are employed to explore the probability space (Beck and Au 2002). The obtained posterior distribution $p(\theta|\mathbb{D})$ is an expression for the updated probability for θ constrained by the observation of \mathbb{D} . $p(\mathbb{D})$ is constant for any given set of model and data so Eq. (1) is also used in the non-normalized form

$$p(\theta|\mathbb{D}) \propto p(\mathbb{D}|\theta)p(\theta). \quad (2)$$

This poses no issue for MCMC methods since the posterior's shape is not affected.

The MCMC algorithm used in this paper is the Transitional MCMC (TMCMC) method (Ching and Chen 2007). The main idea is to introduce an exponent $\alpha_j \in [0, 1]$ to the likelihood

$$p(\theta|\mathbb{D}) \propto p(\mathbb{D}|\theta)^{\alpha_j} p(\theta) \quad (3)$$

and increasing α_j with each level j starting from $\alpha_1 = 0$, which is equal to sampling from the prior density. For $\alpha_j = 1$ Eq. (3) becomes Eq. (2). Values for α_j for the intermediate levels are chosen based on the variance of the drawn samples. After drawing samples from the prior density, the Adaptive Metropolis-Hastings algorithm is used to draw samples for the next level until $\alpha_j = 1$ is reached. The main motivation behind TMCMC is to avoid the problem of sampling from difficult target PDFs but sampling from a series of PDFs that converge to the target PDF and that are easier to sample (Ching and Chen 2007).

2.2 Transport maps

A transport map M is a deterministic coupling between a reference density ρ and the target density π

$$\int f(y)\pi(y)dy = \int (M(x))\rho(x)dx \quad \text{with } Y = M(X) \quad (4)$$

where the target density in the case of BMU is the posterior distribution. The reference density can be chosen freely by the analyst. Common choices are standard normal or standard uniform distributions (Spantini et al. 2018). Any integrals on the target density can thus be calculated on the reference density by use of the map M . Moreover, samples from the target density Y can be drawn by drawing samples X from the reference density and then evaluating the map M . This makes it possible to find an analytical formulation for the posterior density in BMU, which is usually difficult or impossible. The task now becomes to find the map M . A map can be any invertible function $M : \mathbb{R}^d \rightarrow \mathbb{R}^d$, e.g. polynomials or even neural networks (Parno and Marzouk 2018). Using the notation $M_{\#}$ for the push-forward operation the mismatch of the approximation $\pi \approx M_{\#}\rho$ can be expressed with the Kullback-Leibler (KL) divergence

$$\mathcal{D}_{\text{KL}}(M_{\#}\rho|\pi) = \mathcal{D}_{\text{KL}}(\rho|M_{\#}^{-1}\pi) \quad (5)$$

$$= \mathbb{E}_{\rho} \left[\log \frac{\rho}{M_{\#}^{-1}\pi} \right] \quad (6)$$

where the invertibility of the map is used in Eq. (5). With \mathbf{a} as map parameters Eq. (6) becomes

$$\mathcal{D}_{\text{KL}}(M_{\#}\rho|\pi) = \int_X [\log \rho(x) - \log \pi(M(\mathbf{a}, x)) - \log [|\det \nabla M(\mathbf{a}, x)|]] \rho(x) dx \quad (7)$$

Due to optimality and uniqueness properties, maps M were proposed to be monotonic, lower-triangular and constructed from components

$$M^k(\theta_{1,\dots,k}, \mathbf{a}) = f(\theta_1, \dots, \theta_{k-1}, \mathbf{0}, \mathbf{a}) + \int_0^{\theta_k} g(\partial_k f(\theta_1, \dots, \theta_{k-1}, \bar{\theta}, \mathbf{a})) d\bar{\theta} \quad (8)$$

where $f: \mathbb{R}^d \rightarrow \mathbb{R}$ and $g: \mathbb{R}^d \rightarrow \mathbb{R}_+$ so that the resulting map has the structure

$$M(\boldsymbol{\theta}) = \begin{bmatrix} M^1(\theta_1) \\ \dots \\ M^d(\theta_1, \dots, \theta_d) \end{bmatrix} \quad (9)$$

A good approximation of the posterior density results in a small KL divergence, so that Eq. (7) can be transformed into a minimization problem. Note that $\rho(x)$ does not depend on the map parameters and instead of the full posterior $\pi = p(\boldsymbol{\theta}|\mathbb{D})$ the non-normalized form

$$\tilde{\pi} = p(\mathbb{D}|\boldsymbol{\theta})\rho(\boldsymbol{\theta}) \quad (10)$$

can be used. Furthermore, since M consists of analytical functions, the involved integrals can easily be computed by suitable quadrature rules (i.e. Gauss, Monte Carlo etc.). The final minimization problem to obtain the needed map parameters \mathbf{a} is then

$$\min_{\mathbf{a}} \sum_i w_{q,i} [-\log(\tilde{\pi}(M(\mathbf{a}, \boldsymbol{\theta}_{q,i}))) - \log(|\det \nabla M(\mathbf{a}, \boldsymbol{\theta}_{q,i})|)] \quad (11)$$

where $w_{q,i}$ and $\boldsymbol{\theta}_{q,i}$ are weights and integration points for the quadrature rule.

For computations, the framework MParT was used (MParT Development Team 2022). As a basis for the functions f in (8) Hermite polynomials with a selectable degree were chosen. Higher order maps usually are better able to approximate the target function, however since more parameters need to be optimized their computation is also more costly. The maximum map order n can be chosen adaptively, since maps can be combined in the form

$$\mathcal{M}(\boldsymbol{\theta}) = M_n \circ M_{n-1} \circ \dots \circ M_1(\boldsymbol{\theta}) \quad (12)$$

where the subscript denotes the map order and each M_i is of the form (9). If the accuracy of \mathcal{M} after calculation of the i -th component is deemed too low, another component of order $i+1$ can be computed.

2.2.1 Laplace approximation

As a first approximation a map to a Gaussian with mean $\boldsymbol{\theta}_0$ and covariance Σ_0 can be calculated by use of Laplace approximation. $\boldsymbol{\theta}_0$ and Σ_0 are found by solving the optimization problem

$$\boldsymbol{\theta}_0 = \arg \min_{\boldsymbol{\theta}} -\log \tilde{\pi}(\boldsymbol{\theta}) \quad (13)$$

which corresponds to finding the mode of the posterior. Σ_0 corresponds to finding the Hessian \mathcal{H} at $\boldsymbol{\theta}_0$, the final Laplace map thus becomes (Rubio et al. 2019a)

$$L(\boldsymbol{\theta}) = \boldsymbol{\theta}_0 - \mathcal{H}^{-\frac{1}{2}}\boldsymbol{\theta} \quad (14)$$

The Laplace approximation can be used to regularize the problem when combined with (12) to give the final form of \mathcal{M}

$$\mathcal{M}(\boldsymbol{\theta}) = M_n \circ M_{n-1} \circ \dots \circ M_1 \circ L(\boldsymbol{\theta}) \quad (15)$$

Figure 1. Plot of c over t for the analytical exponential model. Blue dots are noisy measurements, red and black lines are outputs of samples taken from TM and TCMC approaches respectively.

Table 1. Number of model, gradient and hessian evaluations for TCMC and both cases of TM approximations.

		Model evaluations
TCMC		45000
TM	1st order	12636
	2nd order	20900
	3rd order	12500
	Total	46036

3 EXAMPLES

3.1 Analytical exponential model

As a simple example we show the application of transport maps to an analytical problem of the form

$$c = A(1 - e^{Bt}) + \zeta \quad (16)$$

with prior distributions $A, B \sim N(0, 1)$, $\zeta \sim \mathcal{N}(0, \sigma_M^2)$, where ζ is a zero-mean Gaussian noise with variance σ_M^2 . The model was taken from (Parno and Marzouk 2018). The parameters to estimate are thus A and B . Data is taken from evaluating Eq. (16) at times $t = \{1, 2, 3, 4, 5\}$ with parameters $A = 0.4$ and $B = 0.2$. Letting c_M be the vector of measurements, $\theta = [A, B]^T$ and $\sigma_M = 0.1$ the problem to solve for obtaining the log-posterior becomes

$$\begin{aligned} \log p(\theta|c_M) &= \log[p(c_M|\theta) \cdot p(\theta)] \\ &= -\frac{1}{\sigma_M^2} \sum_{i=1}^5 (c_{M,i} - [\theta_1(1 - e^{\theta_2 t_i})])^2 - \frac{1}{2} \theta^2 \end{aligned} \quad (17)$$

Note that for the optimization procedure in Eq. (11) the gradient $\nabla_a \mathcal{D}_{\text{KL}}$ is needed, which by applying the chain rule ultimately also needs $\nabla_{\theta} \mathcal{M}(\theta)$. Since this problem is analytical the derivatives are readily available, however special care needs to be taken in situations where this is not the case.

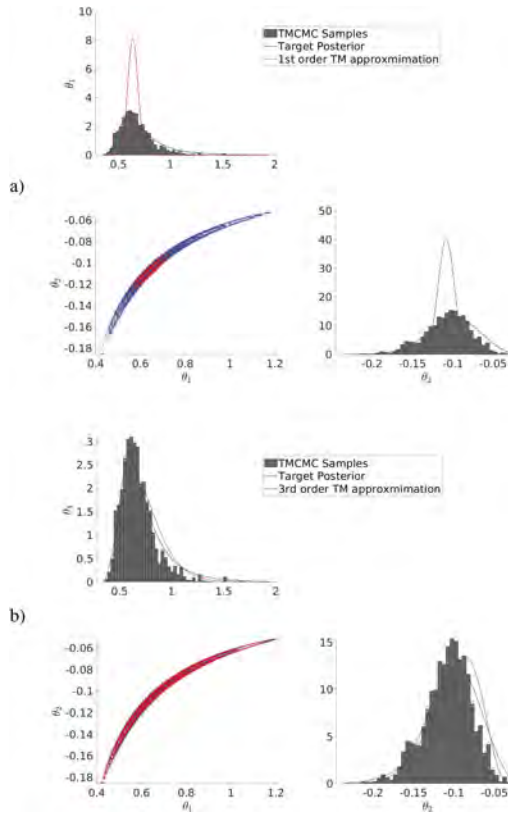

Figure 2. Marginal posteriors for updating results of TMCMC and TM approximations for the analytical exponential system. Figure a) shows a first order map approximation, b) shows a subsequent approximation with a third order map.

Figure 1 shows a result plot with indicated measurements and results taken from samples from transport maps and TMCMC. For TMCMC 5000 samples were taken per level, for the TM approach a MC-integration with 100 samples was used to calculate parameters of subsequent maps up to order 3. The results of the posterior approximation with first, second and third order TM are shown in Figure 2, together with samples taken from TMCMC and the true posterior function. In addition, Table 1 shows the number of model calls for TMCMC and for the calculation of each order of TM, together with the total amount of model calls for all three calculated maps. These results show that the first order map is only able to capture the mean of the posterior and some of its correlation structure, whereas second and third order map are able to make a better approximation. Since a first order map defines a linear relationship between the reference Gaussian and the target density the result can also only be a Gaussian. The computational cost of TM and TMCMC is comparable, however no care was taken to optimize the numerical integration scheme in the TM approach. The results show however some bias in the TMCMC samples which is a common occurrence since the convergence of MCMC methods can not be assessed easily.

Figure 3. 3-DOF system with three masses m_1 , m_2 and m_3 connected by four springs.

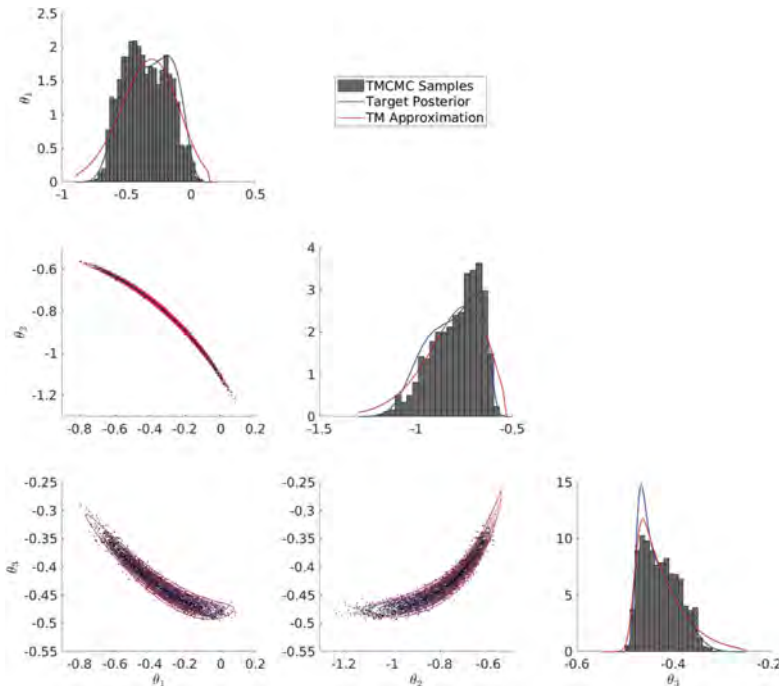

Figure 4. Marginal posterior results for posterior estimation of 3-DOF-system with TMCMC and 5th order TM approach.

Note that after calculation of the map coefficients, a fully analytical expression is obtained which allows for cheap drawing of new samples if needed. Doing the same with MCMC methods would require further model evaluations.

3.2 3-DOF-SYSTEM

For the second example we chose a three degree of freedom system with four springs (see Figure 3) with $m_1 = 100$ kg, $m_2 = 200$ kg and $m_3 = 300$ kg. k_1 , k_2 , and k_3 are uncertain with a prior distribution of $k_{1,2,3} \sim U(100, 3500) \frac{\text{N}}{\text{m}}$. As data we chose the three natural frequencies that can handily be calculated from the system's equations with parameters $k_1 = 1500 \frac{\text{N}}{\text{m}}$, $k_2 = 750 \frac{\text{N}}{\text{m}}$, and $k_4 = 1000 \frac{\text{N}}{\text{m}}$. For regularization purposes $k_1 - k_3$ are transformed to standard normal space using the inverse CDF method (Devroye 1986)

$$k_i(\theta_i) = 100 + (3500 - 100) \Phi(\theta_i), \quad i \in \{1, 2, 3\} \quad (18)$$

where θ_i are the random variables to be updated and Φ is the CDF of the standard normal distribution. With ω_m as the vector of measured natural frequencies the posterior becomes

$$\log p(\boldsymbol{\theta}|\omega_m) = \frac{1}{\sigma_M^2} (\omega_m - \mathcal{M}(\boldsymbol{\theta}))^2 - \frac{1}{2} \boldsymbol{\theta}^2 \quad (19)$$

where $\mathcal{M}(\boldsymbol{\theta})$ is the model to calculate the natural frequencies ω from the system's matrices.

Note that for the optimization the expression $\partial \mathcal{M}(\boldsymbol{\theta}) / \partial \boldsymbol{\theta}$ is needed and the system matrices depend on \mathbf{k} , such that

$$\frac{\partial \mathcal{M}(\boldsymbol{\theta})}{\partial \boldsymbol{\theta}_i} = \frac{\partial \mathcal{M}(\boldsymbol{\theta})}{\partial k_i} \frac{\partial k_i}{\partial \boldsymbol{\theta}_i} = (3500 - 100) \phi(\theta_i) \frac{\partial \mathcal{M}(\boldsymbol{\theta})}{\partial k_i}. \quad (20)$$

where $\phi(\theta)$ is the PDF of the standard normal distribution.

Results of the updating procedures can be seen in Figure 4. For the TM approach a Gauss-Hermite integration of order five was chosen this time and the maximum order of the map was also five. For TMCMC again 5000 samples were used per level.

The target posterior in this example is more complex and shows almost a bi-modal distribution which is more difficult for the TM approach to approximate since higher order maps are needed. The mean and general covariance structure however are nicely approximated. Because of the more complicated shape of the posterior it was found that the TM approximation needed more model evaluations than the TMCMC approach. However the TMCMC samples also again show some bias.

4 CONCLUSION

In this contribution the transport map approach for estimation of the posterior in Bayesian parameter estimation was compared to standard MCMC. Both methods were used on noisy data from an analytical exponential model and a model of natural frequencies of a 3-DOF dynamical system. The TM estimation shows great promise in circumventing some of the problems arising in MCMC sampling, however the implementation and tuning of the parameters in the TM approach require more care. Especially the need to use optimization methods for finding the maps is prohibitive of their use if the problem at hand is too complex and not analytical. While the latter is not generally the case in engineering applications there exist a wide variety of model order reduction methods to replace the original system with a surrogate model that uses analytical functions. In these cases transport maps show great promise since the model becomes differentiable. The result of the transport map approximation is a fully analytic expression of the posterior distribution, allowing for integration and resampling in an efficient way, which is one of the main advantages over MCMC-based

methods. Furthermore, since the KL-divergence is used to optimize the map parameters the convergence between approximation and true posterior is directly evaluated. In MCMC methods the mismatch between approximation and posterior is not quantified which can lead to bias in the drawn samples. Moreover, sequential updating which was not covered here, is naturally possible in the transport map approach by combining multiple maps. Issues with optimization convergence that arise due to the complicated shape of the posterior distribution could be reduced this way, since the change in the approximated posteriors is smaller in the sequential setting when compared to using all data points at once. The usage of transport maps for sequential updating is also interesting for on-line parameter estimation when combined with model-order reduction methods.

Evaluating the minimum cross-section thickness of a conveyor support structure member

Y. Yang, D. Ogawa & T. Nagayama

S. Kato, K. Hisazumi & T. Tominaga

Nippon Steel Corporation, Tokyo, Japan

ABSTRACT: Conveyor support structures are often under a corrosive environment with the accumulation of dust from the conveyor. The corrosive damage may cause severe safety problems. Specifically, the minimum cross-section thickness of each bottom chord member, which determines the ultimate tensile capacity, is important in the safety assessment of the structure. This study develops a strategy for evaluating the minimum cross-section thickness of the member based on the cross-sectional modes (CSMs). Firstly, the member is divided into 10 sections and the average thickness of each section is estimated using a Bayesian model updating method; subsequently, a regression model presenting the relationship between the average cross-section thickness and the minimum cross-section thickness is approximated using real members' thickness distributions; finally, the minimum cross-section thickness is evaluated based on the estimated average thickness and the regression model. The proposed strategy is validated through hammer tests on a real damaged specimen.

1 INTRODUCTION

A conveyor support structure is often exposed to a very corrosive environment because of the dust accumulation on the lower chord members from the conveyor mechanical part above. Traditionally, the health conditions of the members are checked by visual or hands-on inspection. However, these approaches may encounter difficulties in practice, e.g., it is unreliable to visually check the members' conditions from a remote place, and while the risk of entanglement accidents is high when an inspector approaches the structures too close. Therefore, a contactless inspection method is necessary.

In previous research, Rana et al. (2019) showed that the CSMs of the lower chord members which have L-shape cross-sections are localized and the sensitivities of the CSMs to the local damages are high. In addition, the approaches of contactless measurements of CSMs were investigated, and their practical applicability was demonstrated by acoustic excitation experiments (Kato et al. 2018) and operational vibration data (Yang et al. 2021). However, the quantitative evaluations of the damages are still challenging. The lower chord members of a conveyor support structure are of significant focus here because they are highly susceptible to corrosive environments, and their tensile load-carrying capacities are determined by the minimum cross-section thickness.

In the research, a strategy is developed for evaluating the minimum cross-section thickness of the member. The strategy contains three steps: 1) the member is divided into 10 sections and the average thickness of each section is estimated based on the CSM information using a Bayesian model updating method; 2) using real corrosive members' thickness distributions, a regression model which presents the relationship between the average cross-section thickness and the minimum cross-section thickness is approximated; 3) using the estimated average

thickness from step 1), the minimum cross-section thickness of the member is evaluated based on the regression model obtained in step 2). In particular, two approaches to consider the error variances for the Bayesian model updating are investigated in step 1). In the following, the proposed strategy is explained in section 2. In section 3, the strategy is validated through hammer tests on a real damaged specimen. Finally, conclusions are given in section 4.

2 THE METHODOLOGIES OF THE STRATEGY

2.1 Bayesian model updating based on the CSMs

In the study, the Bayesian model updating method is applied. According to Bayes's theorem, the posterior distribution of parameter θ is computed as

$$p(\theta|\mathbf{D}) = \frac{p(\mathbf{D}|\theta)p(\theta)}{p(\mathbf{D})} \quad (1)$$

In equation (1), \mathbf{D} represents the modal information, e.g., modal frequencies and modal shapes; $p(\theta)$ and $p(\mathbf{D}|\theta)$ are the prior distribution and the likelihood function of the parameters respectively; $p(\mathbf{D})$ is the so-called evidence which is a normalization constant. The evidence value does not influence the shape of the posterior distribution, but its evaluation is useful in Bayesian model selection.

When considering the modal information as the available data for Bayesian model updating, it is assumed that the \mathbf{D} consists of N sets of modal information data, i.e., $\mathbf{D} = \{\mathbf{D}_1 \mathbf{D}_2 \cdots \mathbf{D}_N\}$, and each data set includes n extracted modal frequencies $f_{i,j}^m$ and the corresponding incomplete modal shape vector $\Phi_{i,j}^m$ ($i=1\sim N, j=1\sim n$). In practice, the N data sets of modal information can be obtained by processing different measured data sets and using different modal analysis methods.

In the process of the model updating, the corresponding eigen-frequency $f_j^e(\theta)$ and the partial eigen-vector $\Phi_j^e(\theta)$ are calculated from the updated FE model defined by θ . Based on these values, the likelihood functions for the modal frequency $f_{i,j}^m$ and modal shape $\Phi_{i,j}^m$ are written as

$$p(f_{i,j}^m|\theta) = c_{f,j} \exp \left[-\frac{1}{2} \left(\frac{1 - f_{i,j}^m/f_j^e(\theta)}{\varepsilon_{f,j}} \right)^2 \right] \quad (2)$$

$$p(\Phi_{i,j}^m|\theta) = c_{\Phi,j} \exp \left[-\frac{1}{2\varepsilon_{\Phi,j}^2} \left\| \frac{\Phi_{i,j}^m}{\|\Phi_{i,j}^m\|} - \Phi_j^e(\theta) \frac{\Phi_j^e(\theta)^T (\Phi_{i,j}^m/\|\Phi_{i,j}^m\|)}{\Phi_j^e(\theta)^T \Phi_j^e(\theta)} \right\|^2 \right] \quad (3)$$

in which the $c_{f,j}$ and $c_{\Phi,j}$ are the normalization constants of the two likelihood functions respectively, they need to be determined by integrating the corresponding exponential terms; $\varepsilon_{f,j}$ and $\varepsilon_{\Phi,j}$ are the error variances of the modal frequency and shape respectively. The detailed derivations of these equations can be found in Vanik (1997). Assuming that the probabilities of the measured modal information are independent of different orders of modes and the data sets, the overall likelihood function is the product of all the components of modal frequencies and modal shapes as

$$p(\mathbf{D}|\theta) = \prod_{i=1}^N \prod_{j=1}^n p(f_{i,j}^m|\theta) p(\Phi_{i,j}^m|\theta) \quad (4)$$

If the likelihood function and the prior distribution are available, the parameters can be identified by sampling the un-normalized posterior distributions of equation (1). Several sampling approaches can be employed, e.g., MCMC, HMC, and TMCMC. In the study, the prior distribution $p(\theta)$ is assumed as a uniform distribution for each parameter.

2.2 Determination of the weighting of the error variances

In the modal information-based model updating, the relative weighting between the error variances of the modal frequency $\varepsilon_{f,j}$ and the modal shapes $\varepsilon_{\Phi,j}$ should be selected carefully (Goller et al. 2012). In the study, the target member of a conveyor support structure is divided into 10 sections, and the average thickness of each section is to be identified based on the CSM information. Compared with a real damage scenario that is continuous, this simplified model will certainly present some errors in terms of the eigen-frequencies and eigen-vectors. In the study, two approaches are investigated for determining the weightings of the error variances.

In the first approach, the modeling errors are investigated numerically. Specifically, a FE model of the member with continuous thickness reduction is first built using shell elements; correspondingly, a 10-section model with the same dimension is built, in which the thickness of each section is the average value of the same region in the original model; a number of pairs of the models are created in such manner, and the errors of the eigen-frequencies and eigen-vectors between the original and the simplified models are calculated as

$$\tilde{\varepsilon}_{f,j} = \sqrt{\left(\frac{f_j^{orig} - f_j^{simp}}{f_j^{simp}}\right)^2} \quad \tilde{\varepsilon}_{\Phi,j} = \sqrt{\left\| \frac{\Phi_j^{orig}}{\|\Phi_j^{orig}\|} - \Phi_j^{simp} \frac{(\Phi_j^{simp})^T (\Phi_j^{orig} / \|\Phi_j^{orig}\|)}{(\Phi_j^{simp})^T \Phi_j^{simp}} \right\|^2} \quad (5)$$

where the superscript ‘simp’ and ‘orig’ represent the simplified model and the original model respectively; the subscript ‘j’ stands for the j -th mode. Figure 1 presents the thickness contours of a pair of the original and simplified models.

Figure 1. The thickness contour of (a) the original model; (b) the simplified model.

The original model is created randomly, and the thickness distribution of the elements on either flange or web follows a Gaussian process with an exponential quadratic kernel

$$t(x) \sim GP\left(\mu, \sigma_t^2 \exp\left(-\frac{(x_i - x_j)^T (x_i - x_j)}{2\sigma_l^2}\right)\right) \quad (6)$$

in which x represents the coordinate vector of the central point of one element, μ is the mean value and is set as 5 mm; σ_t and σ_l are variance amplitude and correlation length parameters respectively, and they are set as 1.5 mm and 0.06 m. These values are determined based on a real member that has an intact thickness of 6 mm, length of 1.4 m, and flange (web) length of 0.065 m. The FE model of the member is shown in Figure 1.

A total of 3000 pairs of original models and simplified models are created, the eigen-frequency and eigen-vector errors of them are calculated, and they are presented as scattering points in Figure 2.

From the figures, it is observed that: 1) the errors of the three CSMs’ frequencies do not show evident correlations between each other; 2) the correlation between the 1st CSM’s frequencies and modal shapes shows a rough linear tendency, and the errors of the modal shapes

Figure 2. Scattering points of errors of (a) the 1st and the 2nd CSM frequencies; (b) the 1st and the 3rd CSM frequencies; (c) the 2nd and the 3rd CSM frequencies; (d) the 1st CSM's frequency and modal shape; (e) the 1st and the 2nd CSM modal shapes; (f) the 1st and the 3rd CSM modal shapes.

could be much larger than zero even though the frequency errors are about zero; 3) the linear correlations between the 1st CSM modal shapes and the other two kinds of modal shapes are more clear than Figure 2(d), but the dispersions become larger as the errors increase. Based on the numerical results, the relationships between the errors are approximated as

$$\tilde{\varepsilon}_{f,1} = \tilde{\varepsilon}_{f,2} = \tilde{\varepsilon}_{f,3} \quad \tilde{\varepsilon}_{\phi,1} = 0.045 + 0.62\tilde{\varepsilon}_{f,1} \quad \tilde{\varepsilon}_{\phi,2} = 2.35\tilde{\varepsilon}_{\phi,1} \quad \tilde{\varepsilon}_{\phi,3} = 3.63\tilde{\varepsilon}_{\phi,1} \quad (7)$$

In terms of the second approach, following the evidence-based method proposed by Goller et al. (2012), a ratio α between the error variances of the modal shapes and the modal frequencies is assumed, i.e.,

$$\alpha = \varepsilon_{\phi,j} / \varepsilon_{f,j} \quad (8)$$

Based on the α value, the Bayesian model updating is conducted, and the model evidence $p(\mathbf{D})$ is calculated. By implementing the analyses for a series of α values, the model with the largest evidence value is selected as the optimal one.

In the following, the two approaches are employed for identifying the thickness values t_k ($k=1\sim 10$) of the simplified model as well as the modal frequency errors. Based on the results in Figure 2, one error parameter ε_f for the modal frequencies is assumed, and the error parameters for the modal shapes $\varepsilon_{\phi,j}$ can be calculated according to equation (7) or equation (8). Thus, there are 11 parameters to be identified for the model.

2.3 The evaluation of the minimum cross-section thickness

In the previous section, the approach for estimating the average thickness of each section of the member is explained. By using the estimated thickness, a minimum cross-section thickness in the longitudinal direction can be calculated, i.e., $0.5\min(t_1+t_6, t_2+t_7, t_3+t_8, t_4+t_9, t_5+t_{10})$. However, because the estimated thickness is an averaged value, directly using these values will underestimate the true maximum thickness reduction, and further, overestimate the ultimate tensile capacity.

To find the relationship between the average cross-section thickness and the minimum cross-section thickness, the thickness distributions of three real corrosive members are analyzed. They are members A, B, and C in Figure 3. In the figure, the thickness values and lengths of the different members are normalized with respect to 100% and 1 for the conveniences of analyses. The blue, orange, and green lines represent the thickness of the cross-sections, the flange's central lines ($t_1\sim t_5$ direction), and the web's central lines ($t_6\sim t_{10}$ direction) respectively. The blue lines, i.e.,

the cross-section thickness, are calculated as the average values of thickness in one cross-section location, and this data will be used in the following.

First, a 1/5-length region of the member, i.e., section t_1 and t_6 , is selected; by shifting the region from one end to the other in the longitudinal direction, the average cross-section thickness and the minimum cross-section thickness within the region are calculated; for each of the three members, 100 pairs of the data are obtained. Finally, a linear regression model is approximated and shown in Figure 4(a).

Figure 3. The thickness distributions of real corrosive members.

Figure 4. The relationship between the average cross section thickness and the minimum cross-section thickness.

Figure 5. The 12-section model.

It is shown that the linear regression model can reproduce the relationship for members A and C well with an error below 10%. However, the error for member B could be larger than 20%. The outliers are due to the cases where the minimum cross-section thickness exists at the boundaries of the calculation region. Based on the facts, it is considered that by including the thickness values of the adjacent regions, the accuracy of the model can be improved. Figure 4(b) shows the modified regression model where the x -axis is replaced by $\min(T_i, T_{i-0.5}, T_{i+0.5})$. T_i , $T_{i-0.5}$, and $T_{i+0.5}$ denote the average cross-section thickness of the calculation region and those of the regions shifted 1/10-length left and right respectively. Compared with the previous one, the maximum error of the model is reduced to 10%. The formula of the regression model is written in equation (9).

$$\hat{T}_{\min,i} = 1.39 \min[T_i, T_{i-0.5}, T_{i+0.5}] - 38.4 \tag{9}$$

In order to evaluate the minimum cross-section thickness based on equation (9), in addition to the 10-section model in Figure 1(b), the thickness of a 12-section model shown in Figure 5 should also be estimated.

3 EXPERIMENTAL VALIDATIONS

In this section, the thickness of a specimen with real corrosion is estimated using the Bayesian model updating method. In fact, the specimen is member D in Figure 3, of which the real object and the true thickness distribution are shown in Figure 6. The FE model to be estimated is shown in Figure 1(b) and Figure 5 for the 10-section model and the 12-section model respectively. This model is built with 4-node shell elements, which has 700 elements and 4554 DOFs in total. Some of the fundamental information of the model is listed in Table 1.

The hammer tests were conducted with two Laser Doppler Velocimeters (LDVs), i.e., one is set as the reference station and the other is the moving measurement station. The velocity responses of 27 points were measured in 26 cases. The 27 measurement points contain 9 equally spaced points at the corner line and 9 equally spaced points at each outer edge line of the flange and web. They are shown as the ‘b-line’, ‘a-line’, and ‘c-line’ in Figure 6(b). The first three CSMs of the specimen are extracted from the signals; the modal frequencies are 97.5 Hz, 163.8 Hz, and 273.5 Hz respectively. The detailed experiment configuration and the CSM shapes are presented in Figure 7.

Table 1. The fundamental information of the FE model to be estimated.

Length	Flange (web) length	Density	Young’s modulus	Poisson’s ratio
1.4 m	0.065 m	7850 kg/m ³	210 GPa	0.25

Figure 6. (a) The real specimen to be estimated; (b) the true thickness distribution of the specimen.

Figure 7. (a) The experiment configuration; (b) the identified first three CSMs.

The model updating is implemented using the TCMCMC algorithm. The prior distribution of a thickness t_k is defined uniformly between 1 mm and 6 mm, and the range of ε_f is [0.01, 0.1]. The modal information is the first three CSMs’ frequencies and shapes. The data set is one, but it is assumed that 10 data sets with the same results are used in the analysis.

The posterior parameter distributions obtained using approach 1 for the 10-section model are shown in Figure 8. The errors of the parameters are listed in Table 2. In the table, the thickness errors are calculated based on the median values of the sampled parameters. The true value is the average thickness of each section of the real member. The c.s.i stands for the cross-section consisting of t_i and t_{i+5} , and its error is calculated based on the average of the two thickness values. Using approach 1, the log value of the evidence $p(\mathbf{D})$ is 28.3.

Figure 8. The posterior distributions of parameters based on approach 1: (a) t_1 and t_6 ; (b) t_2 and t_7 ; (c) t_3 and t_8 ; (d) t_4 and t_5 ; (e) t_5 and t_{10} ; (f) ϵ_f .

Table 2. The identification errors of the thickness and cross-sections based on approach 1(2).

t_6	t_7	t_8	t_9	t_{10}
2.4% (1.5%)	0.8% (2.7%)	2.6% (3.2%)	41.9% (45.8%)	19.0% (2.2%)
t_1	t_2	t_3	t_4	t_5
3.0% (1.2%)	0.9% (2.9%)	17.6% (34.6%)	28.1% (33.2%)	5.1% (20.4%)
c.s.1	c.s.2	c.s.3	c.s.4	c.s.5
2.7% (0.2%)	0.8% (2.8%)	9.9% (15.2%)	7.7% (7.2%)	8.2% (10.4%)

When applying approach 2, the FE model is updated based on a series of α values. In this case, the α values of 1.0, 2.0, 5.0, 10.0, 20.0, 30.0, 40.0, 50.0, and 100.0 are calculated. The log values of the evidence are shown in Figure 9. It is found that the maximum evidence value, i.e., 36.5, is obtained when $\alpha=30$. Besides, in Figure 9, the log evidence value using approach 1 is also plotted, and this value is equivalent to $\alpha=15$ or 50 in approach 2. The errors in the case are shown in the parentheses in Table 2.

Based on the results, it is found that the estimation error of the average thickness of one section could be as large as about 40%, however, the error is reduced to about 15% when the average cross-section thickness is considered, i.e., the average thickness value of two sections in the same cross-section. The two approaches give similar accuracies while approach 1 slightly outperforms approach 2. It is noted that the log evidence value of approach 1 is smaller than that of approach 2. This phenomenon is probably due to the relatively large inaccuracy of the system model, and it should be investigated in the future.

Figure 9. The log values of evidence based on a series of α values using approach 2.

In terms of the estimations of the 12-section model, the same procedures are implemented. Their results will not be presented here due to the limitation of the space. The minimum thickness of each cross-section and the results of the two approaches are presented in Figure 10 and Table 3,

in which the normalized values are presented. The results of the two approaches are close to each other, and both approaches show that the minimum cross-section thickness occurs at c.s.3 or c.s.4 with about 41% thickness ratio. Compared with the true value, the estimations overestimate the reduction ratio by about 10% which is on the safe side from the engineering's point of view.

Figure 10. The estimations of the minimum cross-section thickness based on approach 1 and 2: (a) c. s.1; (b) c.s.2; (c) c.s.3; (d) c.s.4; (e) c.s.5.

Table 3. The estimated minimum cross-section thickness.

	c.s.1	c.s.2	c.s.3	c.s.4	c.s.5
Approach 1	91.9%	90.2%	41.0%	41.0%	57.5%
Approach 2	94.1%	92.6%	40.6%	40.6%	61.2%
True value	92.0%	90.0%	51.0%	50.0%	60.0%

4 CONCLUSIONS

In this paper, a strategy is proposed to evaluate the minimum cross-section thickness of a lower chord member of a conveyor support structure. The strategy includes estimating the average thickness of the member's sections using a Bayesian model updating method and the CSMs; constructing a regression model for evaluating the minimum cross-section thickness from the average cross-section thickness based on real members' thickness datasets; evaluating the minimum cross-section thickness using the estimated thickness from step 1) and the regression model from step 2). Particularly, in step 1), two approaches to consider the error variances for the Bayesian model updating are investigated.

The method is validated through hammer tests on a real corrosive specimen. The estimation results based on the two approaches are similar. The results show that even though the estimation error of the average thickness of one section could be as large as about 40%, the estimation error of the average cross-section thickness is reduced to 15%. For the tested specimen, the minimum cross-section thickness is underestimated by about 10%, which is on the safe side from the perspective of practical engineering.

Scenario-oriented analysis of bridges subjected to non-deterministic combined seismic actions based on finite element modeling

S. Yamamoto & G. Shoji

University of Tsukuba, Ibaraki, Japan

M. Ohsumi

Public Works Research Institute, Ibaraki, Japan

ABSTRACT: In this study, we proposed the concept of resilience design for seismic damage to infrastructure and lifeline structures by extending the framework of the seismic damage estimation system for infrastructure and lifeline structures proposed in previous studies. Based on the resilience design system, a scenario-oriented analysis was conducted to estimate damage scenarios for road bridges damaged by the 2016 Kumamoto earthquake using three-dimensional finite element analysis. As input actions, surface fault displacement and strong ground motions were used, and damage scenarios were estimated for each seismic action and resilience design for these damage scenarios was examined.

1 INTRODUCTION

Many infrastructure and lifeline structures in a highly seismic hazardous country have been severely damaged by subduction zone earthquakes and inland crustal earthquakes. Seismic damage to infrastructure and lifeline structures in response to anticipated earthquakes is diverse, complex and uncertain because of complex seismic effects such as strong ground motions, surface fault displacement, liquefaction and slope failure. However, from the perspective of infrastructure management and decision-making, road bridge administrators are responsible for identifying probabilistic risks and all possible failure scenarios of road bridges exposed to uncertain seismic actions and for providing earthquake countermeasures that satisfy the needs of road bridge users. Therefore, accurate seismic damage estimation for infrastructures and lifeline structures is required. This seismic damage estimation can contribute to the resilience (Bruneau et al. 2003) and anti-catastrophic capability (Honda 2018) of infrastructures and lifeline structures.

For example, Ichimura et al. (2011), Hori (2018) and Hori et al. (2018) proposed an integrated earthquake simulation using high-performance computing and an automatic construction method of analytical models for urban structures. They have estimated the seismic hazard and damage risk for a hypothetical earthquake by analysing seismic ground motion and the seismic response of urban areas. Decò et al. (2013) proposed a framework to quantify the resilience of bridge structures subject to an extreme seismic ground motion from the perspectives of non-deterministic evaluation. Ohsumi et al. (2021) proposed a scenario design method that considers road-bridge collapse, focussing on the rapid functional recovery of road bridges even if they lose their functionalities because of excess seismic ground motion. Minakawa & Shoji (2022) proposed a framework for a digital twin-based seismic damage estimation system consisting of three subsystems: a seismic action input system, a damage estimation system and an estimation data output system.

By extending the framework of the seismic damage estimation method given by Ref. (Minakawa & Shoji 2022), this study proposes the concept of resilience design for seismic damage to infrastructure and lifeline structures. Additionally, the proposed system evaluates the behaviour of infrastructure and lifeline structures in response to non-deterministic combined seismic actions through multiple trials. Representative examples of the implementation of scenario-oriented analysis for road bridges and specific countermeasures for resilience design are also presented.

2 FRAMEWORK FOR RESILIENCE DESIGN SYSTEM

Figure 1 shows the flowcharts of the resilience design system in seismic disasters. The system considers the interrelationship between physical space and virtual space and consists of three subsystems in each space: a seismic action input system, a damage estimation system and an estimation data output system.

The seismic action input system acquires earthquake-induced actions such as seismic ground motion, liquefaction, slope failure, surface fault displacement and tsunami, which are input to the infrastructure and lifeline structures to be targeted for damage estimation. For example, seismic action data are derived from real-time sensor data and time series data based on observations in physical space. In the virtual space, seismic actions expected to cause damage to the target infrastructures and lifeline structures are determined by numerical simulations. The validity of the estimated seismic action data is ensured by utilising the interrelationship between physical space and virtual space.

The first stage in the damage estimation system is to identify weak points of network properties in the infrastructures and lifeline structures that are exposed to seismic action in each space. This approach is known as 'damage screening'. Using aerial images and visual interpretation, for example, sites at high risk of damage can be retrieved from the physical space. A network model is constructed in the virtual space, seismic actions are input and weak points are extracted by evaluating vulnerability based on the damage function. The second stage involves identifying more specific time series damage scenarios and modes. This approach is known as 'damage focussing'. In the physical space, for example, damage modes are estimated using drones for proximity monitoring. In the virtual space, infrastructures and lifeline structures assumed to be at high risk of damage through damage screening are modeled using a three-dimensional (3D) finite element (FE) method, and by inputting the seismic action data estimated by the seismic action input system, more detailed damage modes of the target structures are estimated.

The estimation data output system provides data collected by drones and images taken by a camera in the physical space, as well as damage information estimated by damage screening and a visualisation of a structure by damage focussing in the virtual space. These outputs are emailed to administrators and users of infrastructure and lifeline structures to mitigate and prevent disasters in an appropriate digital format.

Damage scenarios and damage modes for target structures can be estimated by linking physical and virtual spaces through the system process. A design to improve the resilience of infrastructures and lifeline structures consists of three elements: [1] hardware and software earthquake countermeasures, [2] crisis management immediately after a disaster and [3] emergency recovery after a disaster. In this study, this process is defined as a resilience design. Using road bridges as an example, examples of elements [1] in resilience design include seismic reinforcement of bridge piers, the installation of vibration control dampers in bearings, flexible joints of auxiliary conduits that accommodate power lines and revision of standards for seismic design. In the case of element [2], administrators may include damage information, such as identifying damaged infrastructure and lifeline structures and the presence of secondary disasters, in traffic control. In the case of element [3], restorative materials are warehoused. The restorative materials include temporary vents for emergency restoration work, repair materials to fill cracks in piers, steel support materials to replace broken bearings and sandbags to fill the gap between joints.

In the proposed system, a series of seismic action input system—damage estimation system—and estimation data output system operations are executed in multiple physical and virtual space trials. For example, the physical parameters used in estimating seismic ground motion are changed for each trial in the seismic action input system. From the above multiple trials, it is possible to calculate the simultaneous multi-dimensional probability density of the response of the structure when combined non-deterministic seismic actions are considered. Examples of probability random variables are the displacement of the maximum response and its direction. This probability distribution enables the evaluation of the variability and expected behaviour of damage scenarios. We can select resilience design elements with high accuracy and valid variation, and provide them to administrators and users of infrastructure and lifeline structures, thereby contributing to developing more sophisticated and accurate disaster prevention and mitigation countermeasures.

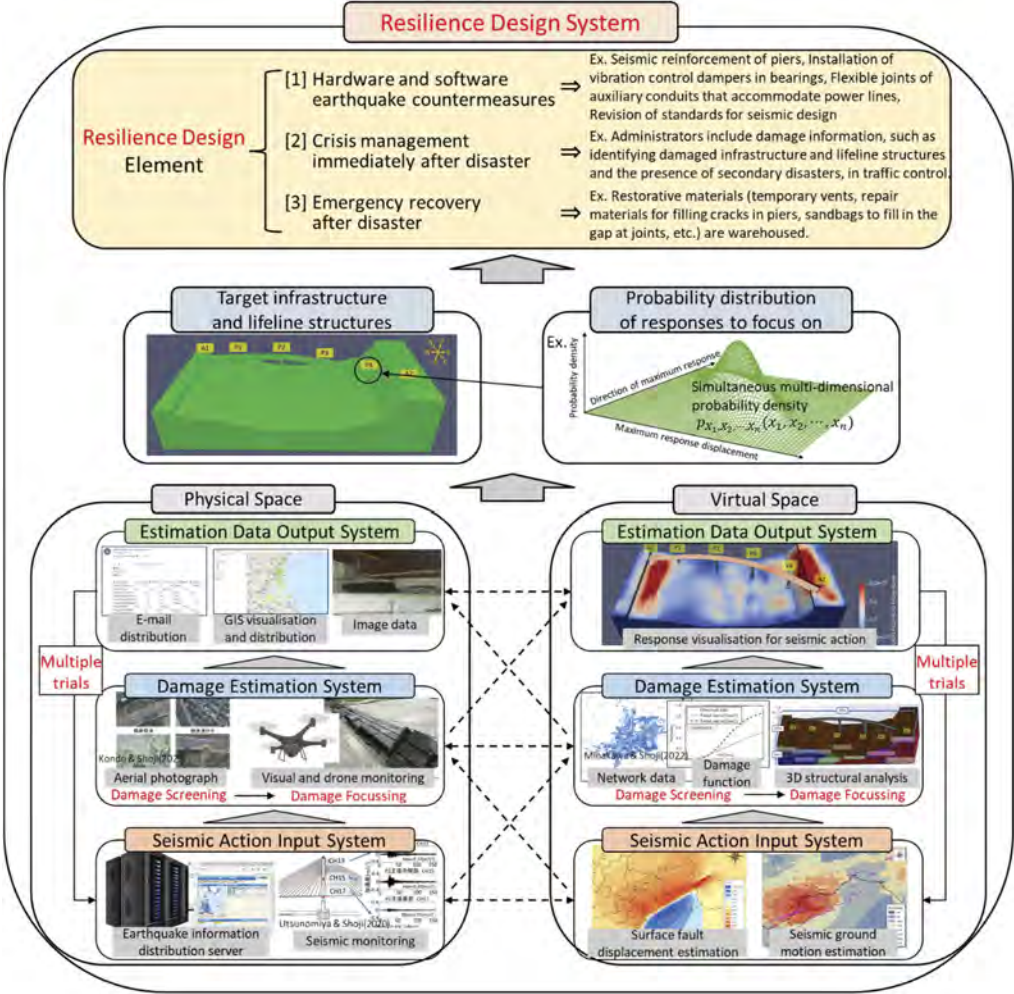

Figure 1. Flowcharts of the resilience design system in seismic disasters.

3 CASE STUDY OF SCENARIO-ORIENTED ANALYSIS

Based on the damage estimation system in the virtual space shown in Figure 1, a scenario-oriented analysis was conducted to estimate damage scenarios by 3D FE analysis for a typical road bridge damaged by the 2016 Kumamoto earthquake. Although the above results are based

on a case study of a damaged bridge, they serve as an example of preliminary damage estimation in virtual space for infrastructure and lifeline structures exposed to seismic hazards.

3.1 Analysis model

Figure 2 shows a 3D FE model of the bridge structure-underground interconnected system that is considered in this study. This model can be constructed in advance in a virtual space based on the design drawings provided by the road bridge administrator. In the target structures, abutments A1 and A2 have reinforced concrete (RC) abutments, and piers P1, P2, P3 and P4 have overhanging RC piers. Laminated rubber bearings are used as bearings. The 3D FE model uses tetrahedral first-order elements to model the abutments, piers and underground. Pentahedral and hexahedral first-order elements are used to model the slabs and laminated rubber bearings. Triangular and quadrilateral first-order shell elements are used to model the girders and auxiliary conduits. The case studies for surface fault displacement and strong ground motions use this model in Figure 2.

Figure 2. 3D FE model of the bridge structure-underground interconnected system.

3.2 Case study for surface fault displacement

The surface fault displacement in the 3D FE model was estimated from the Okada (1985) equation. The boundary conditions were based on those of Habu et al. (2017), where the displacement in the normal direction of the ground side was constrained, and the rest of the boundaries were free boundaries. Linear static analysis was conducted by inputting the amount of surface fault displacement as forced displacement in five incremental steps at intervals of 50 m mesh to the ground bottom. To consider uncertainty in the direction of surface fault displacement, the surface fault displacement estimated from the Okada equation was rotated by 30 degrees for each 50 m mesh on the EW-NS plane, for a total of 12 cases of analysis. When the angle is counterclockwise on the EW-NS plane with the east direction as 0 degrees, the surface fault displacement estimated from the Okada equation is 73 to 84 degrees, which we call Case 1. The conjugate gradient (CG) method was used as the linear solver; in these cases, the symmetric successive over-relaxation (SSOR) method was used as the pre-processing method, and the threshold for determining convergence iteratively was set at 1.0×10^{-6} .

Figure 3 shows the response scenarios to surface fault displacement in Case 1 and the related resilience design. The overall response of the abutments and piers is dominated by the settlement and northeast directions, and joint failure at abutments A1 and A2 is estimated. The response of piers P2 and P3 increases, and significant shear deformation or rupture of the laminated rubber bearings on these piers is anticipated. Therefore, from the viewpoint of element [3] in resilience design, advanced preparation of restoration personnel and materials is necessary. Furthermore, there is a significant differential in displacement between piers P1 and P2, which may induce cracks in the slab and buckling of the bridge girders. Additionally, because the breakage of the auxiliary conduits of the power line attached to the bridge girders is anticipated, countermeasures to make the conduit joint flexible can be considered from the viewpoint

of element [1] in resilience design. Figure 3 also shows histograms of the absolute response displacement and direction of response displacement at pier and abutment tops on the EW-NS plane as variables. For piers P1 and P2, there is variation in absolute response displacement even in almost the same direction of response displacement. Therefore, from the viewpoint of element [1] in resilience design, for piers P1 and P2 in particular, countermeasures such as installing a device to control displacement in the direction where the displacement variation becomes large can be considered.

3.3 Case study for strong ground motions

The strong ground motions input to the 3D FE model were the site-specific waveforms at the location of the target structure, which were estimated using the finite difference method (Yamamoto et al. 2022). Linear dynamic analysis was conducted by inputting these site-specific waveforms as an inertia force to the 3D FE model. Damage focussing, which estimates the detailed damage scenario in Figure 1 in a time-series, necessitates high accuracy and rapid analysis time. In this case, the implicit method was used to solve the equation of motion, the CG method was used as the linear solver, SSOR was used as the pre-processing method and the threshold for determining the convergence iteratively was set to 1.0×10^{-6} .

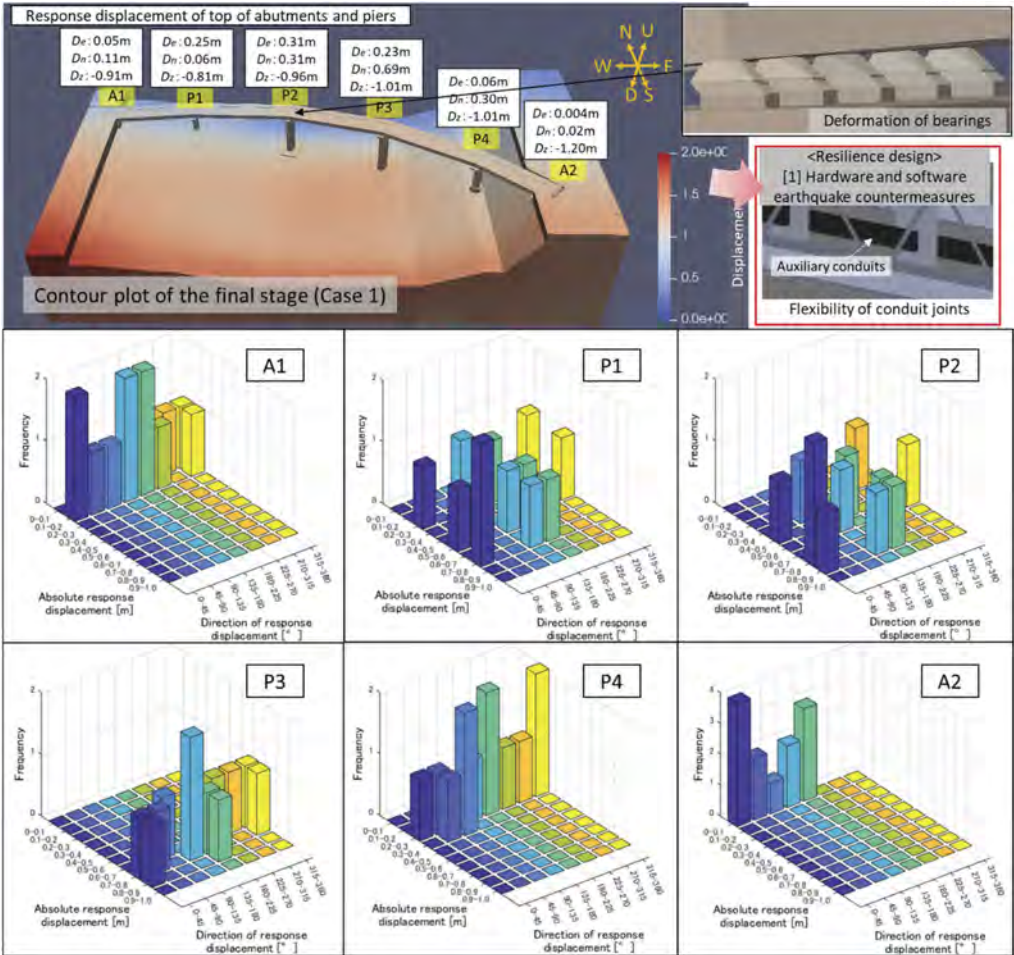

Figure 3. Case study for surface fault displacement.

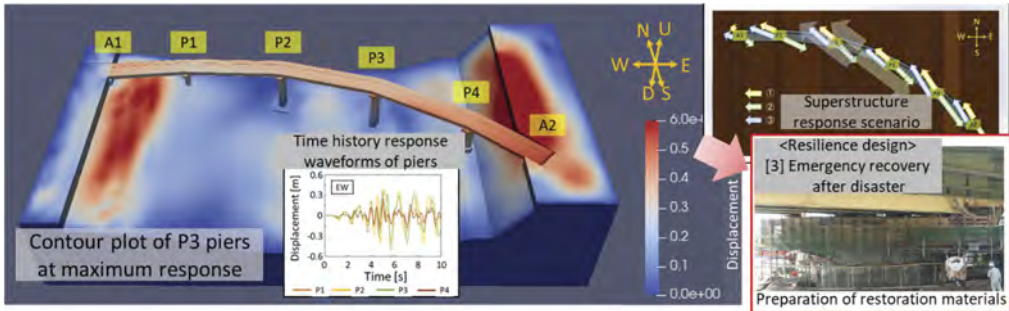

Figure 4. Case study for strong ground motions.

Figure 4 shows the response scenario to strong ground motions and the associated resilience design. Because of the complex behaviour of the superstructure, rupture of the bridge fall prevention cables and failure of the joints are assumed. Additionally, it is assumed that the response of the superstructure causes a rupture region in the laminated rubber bearings on all abutments and piers and that the rupture timing differs as follows: P3B, P4B, P2B, A2B, P1B and A1B (for example, A1B is the rubber bearing on the abutment A1). The response displacement at the top of each pier exceeded 1%, showing that the piers may reach the plastic zone where cracking occurs. Based on the above damage scenarios, it is required to plan to install detour routes and prepare restoration personnel and materials from the viewpoint of element [3] in resilience design.

4 CONCLUSIONS

In this study, we proposed a framework for a resilience design system for seismic damage to infrastructure and lifeline structures. As a representative example of the damage estimation system for resilience design to a road bridge, a scenario-oriented analysis was conducted to estimate damage scenarios for the road bridge damaged in the 2016 Kumamoto earthquake using 3D FE analysis. Strong ground motions and surface fault displacement input actions were used to estimate damage scenarios for each seismic action, and countermeasures for resilience design against the damage scenarios were presented. By repeating the above cases, for example, 1000 times while changing the seismic actions to consider the uncertainty, it is possible to evaluate the variability and expected behaviour of the damage scenarios and carry out a fair resilience design in a non-deterministic approach.

Probabilistic-based model updating on a prestressed concrete box girder

X. Zhou, D. Chen & C.-W. Kim

Department of Civil and Earth Resources Engineering, Kyoto University, Kyoto, Japan

ABSTRACT: The prestressed concrete (PC) bridge is one of the most widely-used bridges. In recent years, their maintenance has become a significant problem in civil engineering. This study aims to investigate the applicability of a probabilistic-based model updating method to the structural health monitoring (SHM) of a PC box girder. The static loading test and vibration measurement were conducted on a PC box girder. A finite element (FE) model was established to reproduce the experiment process. Although the tendency between simulation results and measured data was similar, the discrepancies between them were also observed. To this end, a probabilistic-based model updating method using structural modal properties was used to consider the uncertainties in the system to improve the performance of the simulation. The transitional Markov Chain Monte Carlo (TMCMC) algorithm is taken as a sampler to estimate the distribution of model parameters. The results showed that the discrepancy in the modal properties decreased after updating. The updated FE model was also applied in the simulation of the static loading test, and better fitness in the linear state was observed. However, responses in a nonlinear state did not match well.

1 INTRODUCTION

In Japan, since many bridges were constructed more than 50 years ago during rapid economic growth, the reports of their deterioration and aging were increasing. Therefore, the maintenance and management of such bridges become urgent. Current evaluation methods are largely based on human sensory inspections, such as seeing and touching. However, these approaches are often subjective and need many professional engineers. For example, after the Sasago Tunnel ceiling panel fall accident in 2012 in Japan, local governments in Japan have been required to visually inspect road bridges with a span length of more than 2 m once every five years since July 2014. However, in approximately 20% of local governments, only a limited number of bridges are effectively managed due to a lack or absence of qualified engineers engaged in bridge maintenance work. Therefore, it is necessary to develop a quantitative, simple, and objective non-destructive technology to rationally maintain and manage bridges.

Several technologies have been developed, for instance, using image technology combined with drones to measure the extent of cracks and using infrared and electromagnetic waves to inspect and diagnose the surface and internal condition. The approach based on dynamic properties, such as natural frequencies, and mode shapes, is also widely applied. Dynamic properties can well reflect the change in mass and stiffness of structures and are therefore effective in evaluating structural performance. Moreover, vibration experiments are easy to implement, and particularly acceleration data are easy to acquire (Kim et al. 2016).

In structural engineering, FE models are widely used for structural analysis. Compared with field experiments, FE analysis can save time and costs. However, due to the limited available information and simplification in modeling, uncertainties, such as material properties, geometric properties, boundary conditions, and load conditions, invariably exist in the

system. Model updating methods would calibrate these uncertain parameters in the FE model based on the measurement data.

The Bayesian model updating (Jaynes 2003, Patelli et al. 2017, Zhou et al. 2022) is one of the most popular probabilistic-based approaches. Uncertain parameters are assumed to follow a certain probability distribution based on experimentally obtained data. Beck and Katafygiotis (Beck & Katafygiotis 1998) and Katafygiotis and Beck (Katafygiotis & Beck 1998) comprehensively improved the framework of Bayesian model updating, including model classes for structures and probability models for system errors. The model classes and probability models in the Bayesian model updating are furtherly investigated in many studies (Beck & Yuen 2004, Muto & Beck 2008, Goller et al. 2012). The Bayesian model updating approaches have been conducted for reliability analysis and damage detection on many linear or nonlinear structures in laboratory and actual conditions (Jang & Smyth 2017, Lam et al. 2018, Song et al. 2018, Moravej et al. 2019, Zhou et al. 2022).

Predicting the actual responses by the updated model might be an effective approach for SHM. However, the vibration data is often amplitude-dependent and easily affected by the surrounding environment. Moreover, it is not fully investigated that the accuracy of the simulation of the static loading process by the FE model is updated by vibration data. To acknowledge these challenges, one must investigate the feasibility of SHM by vibration-based Bayesian model updating.

In this study, loading and vibration experiments were conducted on a PC box girder. This process was also reproduced by FE analysis. Then, a probabilistic-based model update using identified dynamic properties was conducted to minimize the discrepancy between the simulation and experiment. The TMCMC (Ching & Chen 2007) method is taken as the sampling method to generate a sample sequence from the posterior distribution. After updating based on the frequency domain, the static loading process simulation is also conducted on the updated model.

2 METHODOLOGY

2.1 Bayesian model updating method

The formulation of the posterior PDF of uncertain parameter vector θ ($\theta \in \mathbf{R}^{N_\theta}$, N_θ is the number of uncertain parameters), under the condition system response D , is given as follows.

$$P(\theta|D) = \frac{P(D|\theta)P(\theta)}{P(D)} \quad (1)$$

where $P(D)$ is the evidence of system response D , and $P(D) = \int P(D|\theta)P(\theta)d\theta$; $P(\theta)$ is the prior PDF; $P(D|\theta)$ is the likelihood function, which donates the conditional probability of D given θ . In the vibration-based model updating process, the likelihood function is given as:

$$P(D|\theta) = c_l e^{-J(\theta)/2\sigma^2} \quad (2)$$

where $J(\theta) = \sum_{i=1}^{N_m} \left(\left(1 - \langle \varphi_i(\theta), \hat{\varphi}_i \rangle \right)^2 + \left(1 - f_i(\theta)/\hat{f}_i \right)^2 \right)$; $f_i(\theta)$ and $\varphi_i(\theta)$ are the i th natural frequency and normalized mode shape vector under the given uncertain parameter vector θ obtained from the FE model while \hat{f}_i and $\hat{\varphi}_i$ are the measured values from the experiments or monitoring; N_m is the total number of modes; c_l is the normalized constant.

2.2 Transitional Markov chain Monte Carlo

Although the Bayesian model updating method can provide a posterior distribution, the complexity of its PDF makes it difficult to generate samples directly from the posterior distribution. Therefore, an efficient sampler is necessary. In this study, TMCMC (Ching & Chen 2007) is used to generate samples efficiently. The essence of TMCMC is to use a series of asymptotic intermediate

distributions, $(P_j(\theta|D), j = 0, 1 \dots m, \theta \in \mathbf{R}^{N_\theta})$, to approach the final distribution. The importance sampling method is used to transfer between the intermediate distributions. With the value of j increasing, the $P_j(\theta|D)$ becomes more closed to the target distribution $P(\theta|D)$.

Figure 1. Specimen drawing.

Table 1. Material properties of specimen.

Compressive strength of concrete	52.7 MPa
Young's modulus of concrete	32.31 GPa
Poisson's ratio of concrete	0.207
Longitude reinforcement ratio	0.3% (web), 0.2% (upper slab), 0.5% (lower slab)
Stirrup reinforcement ratio	0.2%
Prestress	About 1000 MPa
Yield strength of Reinforcing bar	354 MPa
Young's modulus of Reinforcing bar	192 GPa
Yield strength of PC tendon	1600 MPa
Young's modulus of PC tendon	200 GPa

For the asymptotic intermediate distribution $P_j(\theta|D)$, the values of their variances $(\sigma_j, j = 1 \dots m)$ are different, and $P_j(\theta|D)$ is shown as:

$$P_j(\theta|D) = c_j e^{-J(\theta)/2\sigma_j^2} \quad (3)$$

Especially, assuming $P_0(\theta|D) = c_0$ follows a uniform distribution. The adjacent intermediate distributions are connected by importance sampling such as TMCMC. The process that generates sample sequence of $\theta_{j+1,l}$ following the distribution of $P_{j+1}(\theta|D)$ can be described as:

$$\theta_{j+1,l} = \theta_{j,k} \text{ with probability } w_{j,k}^n, \quad k = 1, 2, \dots, N_j, \quad l = 1, 2, \dots, N_{j+1} \quad (4)$$

Therein, weighting $w_{j,k}^n$ is given as:

$$w_{j,k}^n = \frac{e_k}{\sum_{t=1}^{N_j} e_t} \quad (5)$$

where $e_k = \exp\left(-\frac{J(\theta_{j,k})}{2}\left(\frac{1}{\sigma_{j+1}^2} - \frac{1}{\sigma_j^2}\right)\right)$, N_j indicates the number of samples in j th step.

3 EXPERIMENT

3.1 PC box girder test specimen

The test specimen is a 1/2 scale sound PC box girder and more details can be found in Figure 1 and Table 1.

3.2 Static and dynamic experiments

The static loading and vibration experiments are conducted on the test specimen to investigate the static and dynamic responses of the PC box girder. In the static loading experiment, sixteen displacement gauges (SDP, CDP: Tokyo Measuring Instruments Lab) are installed on the lower slab of the PC box girder. The test specimen is subjected to four-point loading by a 30 MN large structural universal testing machine (12 MN for positive bend during testing), as shown in Figure 2. Static loading was applied four times, as Load 1, Load 2, Load 3, and Load 4. Load 1 is 10% higher than the initial cracking load, Load 2 is the shear cracking load, Load 3 is the stirrup yield load (the load when yielding occurs at a certain point among all stirrups), and Load 4 is the ultimate load (crushing of the upper slab). The loading process is shown in Figure 3.

In the vibration experiment, ten accelerometers (NP-2120: Ono Sokki, sampling frequency 2000Hz) were placed on the lower slab of the PC box girder as shown in Figure 1. The impact hammer (8208-Modal, Brüel & Kjær company) was applied on the upper surface of the upper slab right above each acceleration sensor after the unloading of the static test. The same excitation was performed 10 times at each hit point. According to the different steps, they were called St.1, St.2, and St.3.

3.3 Experimental results

3.3.1 Static test

The yield load (F_y) was 1020 kN, and the ultimate load was 2033 kN. In the loading and unloading process, residual deformation can be observed in Figure 4. The load-displacement curve demonstrates that the main girder does not reach the ultimate failure state until the last loading step.

3.3.2 Dynamic test

A total of two modes, the first and second bending modes, can be identified. Table 2 and Figure 5 indicate the natural frequencies and the corresponding mode shapes.

4 MODEL UPDATING

4.1 FE model

The FE model is established by DIANA 10.4, as shown in Figure 6, and the main girder is modeled with solid elements. The horizontal and vertical springs are applied to the support points to qualify the uncertainties in the boundary conditions. The dynamic properties of the

FE model under design values (the same as in Table 1) are shown in Table 2. Compared with the results identified from experiments, the differences in the natural frequencies of both the first and second bending modes are significant, and the difference in mode shapes of the second bending mode is also observed. The static loading process is also applied to the model. Figure 8(a) indicates the load-displacement curve in the midspan, and Figure 8 (b) presents the development of the cracks from FE analysis with a sketch of cracks observed from the experiment for comparison. It is clear that there are differences in the load-displacement curves after the yield point between the simulation and experiment.

4.2 Sensitivity analysis

Before the model updating, a sensitivity analysis was conducted to investigate the effect of each parameter in the dynamic analysis. It was observed that Young's modulus of steel almost has no impact on the eigenvalue analysis. The clear changes in natural frequencies were observed with the fluctuation in concrete density and Young's modulus. The natural frequencies change significantly under both vertical and horizontal springs. Therefore, four types of parameters, including the mass and Young's modulus of concrete, and vertical and horizontal springs, will be considered in the updating process. Some results are shown in Figure 8.

4.3 Model updating process and results

The proposed model updating algorithm is applied to the target structure to improve the performance of the simulation. The results are summarized in Figure 9, Table 3, and Table 4. Figure 9 presents the marginal distribution of each model parameter. Table 4 illustrates the most probable value (MPV) of model parameters. Table 4 indicates the dynamic parameters under MPV of model parameters in Table 3. Comparing Table 4 with Table 2, a significant improvement in the natural frequencies of both the first and second bending modes can be observed. The discrepancy in mode shapes of the second bending mode is also decreased, and the MAC value becomes close to 1. It was confirmed that the updated model is consistent with the experimental data on vibration properties. However, the specific gravity and Young's modulus of concrete exceed the acceptable range in terms of material properties.

Figure 8. Results of sensitivity analysis.

Table 3. MPV of updated model parameters.

	Concrete density (t/m^3)	Concrete Young's modulus (GPa)	Horizontal spring (kN/mm)	Vertical spring (left) (kN/mm)	Vertical spring (right) (kN/mm)
Initial	2.28	34.00	0	∞	∞
Updated	2.50	23.21	$10^{7.36}$	$10^{4.94}$	$10^{4.34}$

4.4 Static simulation by updated model

It is necessary to confirm the performance of the updated model in the static process since the values of the updated Young's modulus of the concrete were far from the design values. This

Table 4. MPV of the updated frequencies and MAC.

		1st bending mode	2nd bending mode
Experiment	Freq. (Hz)	29.27	67.32
	Freq. (Hz)	30.47	63.89
Simulation	Difference of Freq. (%)	4.10	-5.09
	MAC	0.95	0.81

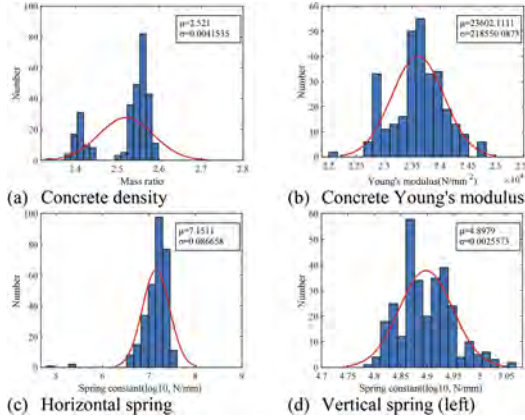

Figure 9. Marginal distribution of updated model parameters.

Figure 10. Simulation for static loading test.

section will discuss the simulation of the static loading process to examine the changes in bridge performance.

Figure 10 (a) shows the load-displacement curve in the midspan from the simulation under updated model parameters, and Figure 10 (b) presents the development of the cracks from FE analysis with an updated FE model with a sketch of cracks observed from the experiment for comparison. In the linear state up to around 1000kN, Figure 10 (a) shows a better fitness than Figure 8(a). However, a significant discrepancy can also be observed in the nonlinear state around displacement of 9mm. Major differences may be rooted in lower Young's modulus identified through the FE model update and the consideration of the longitude spring in support of the updated FE model. Therefore, bending cracks hardly occur in concrete while shearing cracks easily. Considering spring elements at supports is very useful in modal parameter-based FE model updates as the boundary condition is quite sensitive to the frequencies as can be seen in Figure 8 (c). However, for the PC girder, the large horizontal spring could increase prestress effect and may affect the structural behavior of the PC girder. Therefore, as the next step for this study, the following two items will be investigated: one is changing the design of the model parameters in updating process; another is establishing a new objective function, which includes both dynamic and static properties from experiments, for model updating.

5 CONCLUSIONS

This study aims to investigate the applicability of a probabilistic-based model updating method to the structural health monitoring (SHM) of a PC box girder. In the initial model, clear discrepancies in both static loading and vibration processes can be observed. After updating with the dynamic properties, the performance in the vibration and static loading (in the linear state) process is largely improved. The FE model updated by dynamic properties can successfully reproduce the static loading process (in a linear state). It is confirmed that the model updating can improve the accuracy of simulation in both static loading and vibration processes, and is effective for SHM.

However, the distribution of identified model parameters is not in the normal range, and the system responses in a nonlinear state do not match very well. Therefore, the gap between simulation and experiment still exists in a nonlinear state, which means the application of this approach is still limited. Further research considering the nonlinear state is necessary.

Applicable schemes for the Vehicle-Bridge Interaction System Identification method

K. Yamamoto & R. Shin
University of Tsukuba, Japan

ABSTRACT: The VBISI (Vehicle-Bridge Interaction System Identification) method is a drive-by monitoring method that estimates the vehicle's and bridge's parameters and road unevenness simultaneously only from vehicle vibration and position data. The estimation process randomly assumes the mechanical parameters of vehicle and bridge, and solves two processes, namely the IEP (Input Estimation Problem) of the vehicle and the DRS (Dynamic Response Simulation) of the bridge to estimate the road unevenness. It is realized by updating the mechanical parameters by minimizing the residual of the estimated road unevenness. This paper introduces and compares the potential schemes: PSO (Particle Swarm Optimization), NM (Nelder-Mead) method and MCMC (Monte Carlo Markov Chain). The differences between these schemes are also examined numerically in this study. PSO is very efficient but needs large calculation resources, NM is very efficient and shows high accuracy, MCMC is very costly but gives the reliable.

1 INTRODUCTION

1.1 *Research background of this study*

As more bridges are constructed in many countries, the maintenance cost is also expected to be higher. Thus, many researchers in this field are intensively developing technologies for easy bridge inspections. One possible option is DBM (Drive-by Bridge Monitoring).

At the beginning of the development of DBM technologies, Y.B. Yang's Indirect Approach (2004) has inspired many proposed methods. This method uses vibration sensors installed on the traveling vehicle and extracts the bridge natural frequencies only from the measured vertical acceleration vibrations of the traveling vehicle. Yang et al. have verified the applicability of their method analytically (Yang, 2004), numerically (Yang & Chang, 2009) and experimentally (Ling & Yang, 2005). According to the existing studies (Yang & Chang, 2009), the estimation accuracy of the first natural frequency has been improved, but the technical issues remain in the estimation of the second and higher natural frequencies that are expected to be sensitive to bridge damages.

On the other hand, this study focuses on and extends Nagayama's method (Zhao et. al, 2019); (Xue, 2020): Nagayama's method estimates road roughness only from vehicle vibration data. First, they randomly assume the mechanical parameters of the vehicle and compose the Kalman Filter for the equation of motion of the vehicle. The Kalman Filter applied to the vehicle vibration data can estimate the road profiles as the inputs of the front and rear wheels. Spatial-synchronization of the estimated road profiles is expected to return two same road roughness under the condition that the randomly-assumed mechanical parameters match the correct values. The residual between the synchronized road roughness of the front and rear wheels can be used as the objective function to find the correct vehicle mechanical parameters. The combination of the mechanical parameters that gives the smallest residual can be that of the correct values of the vehicle. According to the previous study, the residual can be evaluated in the frequency domain, and the estimation accuracy for road roughness is not bad.

The advantages of Nagayama's method are as follows: 1) the mechanical parameters of the vehicle can be estimated. The inspectors do not need to calibrate the vehicle system in advance. 2) The inputs of the vehicle can be estimated. Even if bridges are on the route, the estimated inputs should include the bridge vibration components. The mechanical parameters of the bridge can be estimated as well as those of the vehicle.

The authors have already proposed the method (Yamamoto et al., 2022), called the VBISI (Vehicle-Bridge Interaction System Identification) method, for estimating all mechanical parameters of a traveling vehicle and a monitored bridge and road roughness by extending Nagayama's method (Xue, 2020). This method is composed of two procedures: 1) IEP (Input Estimation Problem) of the vehicle, and 2) DRS (Dynamic Response Simulation) of the bridge. First, the proposed method randomly assumes the mechanical parameters of the vehicle-and-bridge system. Next, substituting the assumed parameters and measured data of the vehicle acceleration vibrations into IEP and DRS, the road profiles of the front and rear wheels are estimated. Then, the residual between the spatially-synchronized estimated road profiles can be calculated. Repeating these processes from randomly assuming the parameters, the mechanical parameters are expected to converge.

However, examining the optimization methods is still a technical issue in this study. The easiest scheme is the MCMC (Monte Carlo Markov Chain) method (Yamamoto et al., 2022). This method is an idea that assumes many particles at once in the solution space, of which each axis indicates a mechanical parameter, and changes their position slightly to lower residual. The particles would randomly travel in the multidimensional solution space to search for the lowest residual. The MCMC method can consume computation resources.

The second option is the PSO (Particle Swarm Optimization) method (Kennedy, 1995); (Mat-sushita, 2010). This method is also a Monte Carlo-based method, in which the particles travel towards the global and local best points with inertia velocities. The convergence ratio of this method is expected to be much faster than MCMC, but it is necessary to set the hyperparameters.

The third option is the NM (Nelder-Mead) method (Nelder & Mead, 1995); (Gao, 2012). This algorithm is known as a fast and accurate optimization scheme. The particles geometrically search the minimum residual point in a large solution space.

1.2 The purpose and methodology of this study

This paper compares the MCMC, PSO and NM methods and discusses the applicability of these algorithms to the VBISI method. The numerical simulation is also done to obtain the vehicle vibration data as the measured data.

2 BASIC THEORY

2.1 Vehicle-Bridge Interaction system

Consider a vehicle system shown in Figure 1. The vehicle body is modeled as a rigid body with mass m_s and inertia I_s . The suspensions of the front ($i=1$) and rear ($i=2$) axles are respectively composed by springs k_{si} and dashpot c_{si} . The i -th unsprung-mass m_{ui} is connected with the sprung rigid body (m_s, I_s) by the i -th suspension (k_{si}, c_{si}) and with the road pavement by the i -th wheel modeled by spring k_{wi} . Let $x_i(t)$ and $x_G(t)$ be the positions of the front wheel ($i=1$), the rear wheel ($i=2$), and the Gravity center G of the vehicle body, respectively. They are time function but the distance is constant. Letting d_i be the distance from G to axel i , the equation of motion of the vehicle can be expressed as:

$$\mathbf{M}_v \ddot{\mathbf{w}}_v(t) + \mathbf{C}_v \dot{\mathbf{w}}_v(t) + \mathbf{K}_v \mathbf{w}_v(t) = \mathbf{f}_v \quad (1)$$

where

$$\mathbf{M}_v = \begin{bmatrix} \frac{m_{s1}}{d_1+d_2} & \frac{m_{s2}}{d_1+d_2} & \mathbf{0} \\ \mathbf{0} & m_{u1} & 0 \\ 0 & 0 & m_{u2} \end{bmatrix}, \quad (2)$$

$$\mathbf{C}_v = \begin{bmatrix} c_{s1} & c_{s2} & -c_{s1} & -c_{s2} \\ d_1 c_{s1} & -d_2 c_{s2} & -d_1 c_{s1} & d_2 c_{s2} \\ -c_{s1} & 0 & c_{s1} & 0 \\ 0 & -c_{s2} & 0 & c_{s2} \end{bmatrix}, \quad (3)$$

$$\mathbf{K}_v = \begin{bmatrix} k_{s1} & k_{s2} & -k_{s1} & -k_{s2} \\ d_1 k_{s1} & -d_2 k_{s2} & -d_1 k_{s1} & d_2 k_{s2} \\ -k_{s1} & 0 & k_{s1} + k_{u1} & 0 \\ 0 & -k_{s2} & 0 & k_{s2} + k_{u2} \end{bmatrix}, \quad (4)$$

$$\mathbf{w}_v(t) = \begin{Bmatrix} w_{s1}(t) \\ w_{s2}(t) \\ w_{u1}(t) \\ w_{u2}(t) \end{Bmatrix}, \quad (5)$$

and

$$\mathbf{w}_v(t) = \begin{Bmatrix} w_{s1}(t) \\ w_{s2}(t) \\ w_{u1}(t) \\ w_{u2}(t) \end{Bmatrix}. \quad (6)$$

The mass components m_{s1} and m_{s2} are

$$m_{s1} = \frac{d_2 m_s}{d_1 + d_2}, \quad (7)$$

and

$$m_{s2} = \frac{d_1 m_s}{d_1 + d_2}. \quad (8)$$

The loads acting on this vehicle system are produced by the input profile:

$$\mathbf{f}_v = \begin{Bmatrix} 0 \\ 0 \\ k_{u1} u_1(t) \\ k_{u2} u_2(t) \end{Bmatrix}. \quad (9)$$

Figure 1. Vehicle and Bridge model.

On the other hand, as shown in Figure 1, the bridge girder is modeled as an Euler-Bernoulli beam, of which mass per unit length is $\rho A(x)$ and flexural rigidity is $EI(x)$. The following equation can express the equation of motion of a bridge:

$$\rho A \ddot{w}_b(x, t) + \frac{\partial^2}{\partial x^2} \left(EI \frac{\partial^2 w_b}{\partial x^2} \right) = \sum_{k=1}^n \delta(x - x_k) P_k(t) \quad (10)$$

where $w_b(x, t)$ represents deflection of the bridge. In Figure 1, the downward deflection of the bridge is drawn as positive, but note that all mathematical expressions in this paper are written assuming that the upward deflection is positive. $P_k(t)$ is an external force acting on the bridge at $x = x_k$. In this formula, $\delta(x)$ is the Dirac's delta function. Applying FEM (Finite Element Method) to this formula, Equation 2 becomes:

$$\mathbf{M}_b \ddot{\mathbf{w}}_b(t) + \mathbf{C}_b \dot{\mathbf{w}}_b(t) + \mathbf{K}_b \mathbf{w}_b(t) = \mathbf{f}_b \quad (11)$$

where \mathbf{M}_b , \mathbf{C}_b and \mathbf{K}_b represent the mass, damping and stiffness matrices of the bridge, respectively. $\mathbf{w}_b(t)$ is the deflection vector, and $\mathbf{f}_b(t)$ is the external force vector. \mathbf{C}_b is Rayleigh damping ($\mathbf{C}_b = \alpha \mathbf{M}_b + \beta \mathbf{K}_b$). The stiffness of k -th element is given by EI_k . This paper assumes that ρA is constant. In this process, introducing the basis function vector $N(x)$, the bridge deflection can be approximated by $w_b(x, t) = N(x) \cdot \mathbf{w}_b(t)$. Thus, applying the Galerkin method, the Finite Element matrices can be given by:

$$\mathbf{M}_b = \int_0^L N N^T dx, \quad (12)$$

and

$$\mathbf{K}_b = \int_0^L \frac{\partial^2 N}{\partial x^2} \frac{\partial^2 N^T}{\partial x^2} dx. \quad (13)$$

In the VBI system considered in this study, the external forces are only the traffic loads, and the reaction forces acting at the supports. The traffic loads can be given by the following formula:

$$\mathbf{f}_b(t) = \mathbf{L}(t) \mathbf{p}(t) \quad (14)$$

where

$$p_i(t) = k_{ui}(w_{ui} - u_i) = -m_{si}(\ddot{w}_{si} + g) - m_{ui}(\ddot{w}_{ui} + g), \quad (15)$$

$$\mathbf{L}(t) = [N(x_1(t)) \ N(x_2(t))]. \quad (16)$$

The following equation can give the input profiles of the traveling vehicle:

$$\mathbf{u}(t) = \mathbf{r}(t) + \mathbf{L}^T(t) \mathbf{w}_b(t), \quad (17)$$

where $\mathbf{r}(t)$ and $\mathbf{L}^T(t) \mathbf{w}_b(t)$ denote the road profile and bridge profile, respectively. The bridge profile indicates the bridge deflection under the wheels. As the vehicle position changes, the component of the bridge displacement under the wheel $w_b(x_i(t), t)$ is a time function and FEM makes it $\mathbf{L}^T(t) \mathbf{w}_b(t)$. The road profile satisfies that $r_i(t) = R(x_i(t))$, where $R(x)$ is the road roughness as a spatial function.

By solving Equation 1, the dynamic responses of the vehicle and the bridge can be simulated.

2.2 The VBISI method

This study proposes the VBISI method that identifies all mechanical parameters of VBI system: m_s , c_{si} , k_{si} , m_{ui} , k_{ui} , x_i , ρA , EI_k , α , β and estimate the road roughness $R(x)$. The VBISI method solves the vehicle's IEP and the bridge's DRS to estimate road profiles $\mathbf{r}(x)$. The vehicle's IEP can be solved by introducing Kalman Filter, while the bridge's DRS can be solved by the Newmark- β method. Assuming that the mechanical parameters \mathbf{X} can be expressed as:

$$\mathbf{X} = [c_{s1}, k_{s1}, c_{s2}, k_{s2}, m_{u1}, m_{u2}, k_{u1}, k_{u2}, d_1, \rho A, EI_1, EI_2, \dots, EI_{15}, \alpha, \beta], \quad (18)$$

where $d_1 = x_1 - x_G$. Each value of \mathbf{X} indicates each axis of the solution space. The objective function is:

$$J(\mathbf{X}) = \int_0^L (R_1(x) - R_2(x))^2 dx \quad (19)$$

where $R_i(x)$ is the spatial synchronized estimate from $r_i(t)$:

$$R_i(x_i(t)) = r_i(t) \quad (20)$$

As optimization algorithm to change \mathbf{X} to minimize the value of $J(\mathbf{X})$, the MCMC, PSO, and Nelder Mead methods are compared.

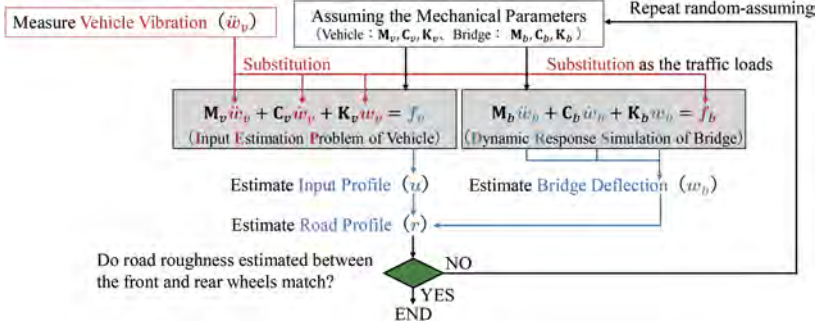

Figure 2. The algorithm of the VBISI method.

2.3 The MCMC method

The MCMC (Monte Carlo Markov Chain) model is called the Random Walk problem. Each particle is put in the space of $(\mathbf{X}^{(i)}, J^{(i)})$ and randomly tries to change the position $\mathbf{X}^{(i)}$. If the next position $\mathbf{X}^{(i)} + \Delta\mathbf{X}$ has a lower height $J(\mathbf{X}^{(i)} + \Delta\mathbf{X}) < J(\mathbf{X}^{(i)})$, the particle $\mathbf{X}^{(i)}$ must move to the next position $\mathbf{X}^{(i)} + \Delta\mathbf{X}$. On the other hand, if the next height is higher than the current height ($J(\mathbf{X}^{(i)} + \Delta\mathbf{X}) \geq J(\mathbf{X}^{(i)})$), it is probabilistically decided whether the particle moves or not. As the number of variables to be identified is large, particles in the latter case never move (Yamamoto et. al, 2022) to converge the process quickly.

2.4 The PSO method

The PSO (Particle Swarm Optimization) method is inspired by the movement of flocks of birds. This method is very similar to the MCMC method, but the position increment $\Delta\mathbf{X}$ is not randomly decided. Each particle $\mathbf{X}^{(i)}$ is set randomly first and moves in the solution space, remembering the best position the particle passes and referring to the best position among all particles. The former and the latter are called “Local Best” $\mathbf{L}^{(i)}$ and “Global Best” \mathbf{G} , respectively. The increment at the k -th step is given by the following formula:

$$\Delta\mathbf{X}_k^{(i)} = \alpha\Delta\mathbf{X}_{k-1}^{(i)} + \beta(\mathbf{L}_k^{(i)} - \mathbf{X}_k^{(i)}) + \gamma(\mathbf{G}_k^{(i)} - \mathbf{X}_k^{(i)}) \quad (21)$$

2.5 The NM method

The NM (Nelder-Mead) method (Nelder & Mead, 1995); (Gao, 2012) is also a kind of Monte Carlo simulation, but the most likely point is searched geometrically. First, several particles are randomly set in the solution space. Next, the NM method evaluates J of the geometric points calculated from the generated particles. The geometric points indicate centroids and internal/external points on the line connecting the tentative optimal point and the next point.

3 NUMERICAL EXPERIMENT

3.1 Vehicle-bridge interaction system model for numerical simulation

The mechanical parameters of the vehicle and bridge models are shown in Table 1. The dynamic simulation of the VBI system with these values is implemented by adopting the Newmark- β method. The road roughness $R(x)$ introduced in this simulation is shown in Figure 3.

Table 1. The mechanical Parameters of the Vehicle and Bridge models for numerical simulation.

Body	Mass	m_s	8310 [kg]	Front Tire	Mass	m_{u1}	469 [kg]
	Front from G	d_1	1.215 [m]		Stiffness	k_{u1}	4,790,000 [kg/s ²]
	Rear from G	d_2	2.175 [m]		Rear Tire	Mass	m_{u2}
Front Suspension	Damping	c_{s1}	24,200 [kg/s]	Mass per unit length	Stiffness	k_{u2}	4,310,000 [kg/s ²]
	Stiffness	k_{s1}	456,000 [kg/s ²]		Flexural Rigidity	ρA	4400 [kg/m]
Rear Suspension	Damping	c_{s2}	29,000 [kg/s]	Rayleigh Damping	EI_i	1.56×10^{11} [Nm ²]	
	Stiffness	k_{s2}	431,000 [kg/s ²]		α	0.7024	
					β	0.0052	

Figure 3. Road roughness.

3.2 Simulated responses

The simulated vibrations of the VBI system are obtained as shown in Figure 4. This study takes the simulated acceleration vibrations of the vehicle, which are shown in Figure 4 (a), as the measured data. By applying the VBISI method to these vehicle vibration data, we can estimate the road roughness and the mechanical parameters of the vehicle and bridge simultaneously.

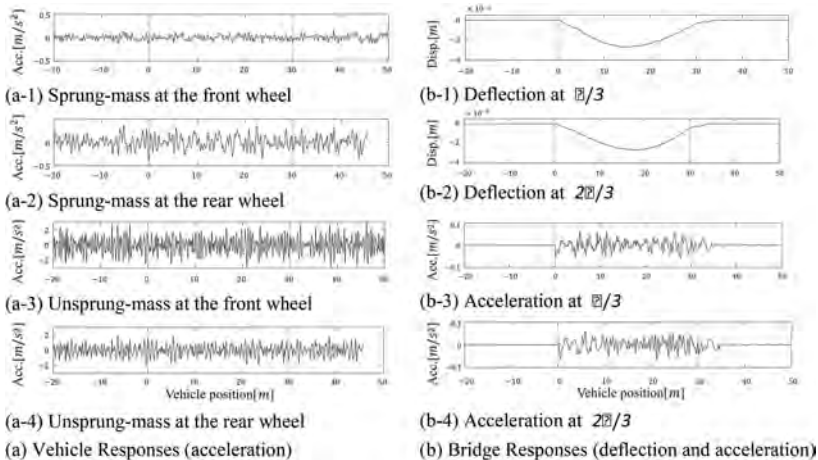

Figure 4. Simulated vibrations.

4 RESULTS AND DISCUSSION

4.1 Application of the MCMC method

The MCMC method for the VBISI method is easy to code but is less computationally efficient and less accurate. This method prepares many particles and lets them search for the optimal combination of the mechanical parameters randomly in the solution space. As the solution space has a large dimensionality, the probability of reaching the optimal solution is expected to be low.

By applying the MCMC method to the measured vehicle vibration data, the result shown in Table 2 is obtained. As the estimated values are normalized by the correct values, 1.0 indicates the correct value. The accuracy of the prior information is 20%, 0.8 and 1.2 indicate that the corresponding parameter cannot be estimated. According to this table, the accuracy of vehicle body mass m_{s1} and m_{s2} is reasonable, while others are not accurate.

Table 2. The estimation accuracy of the VBISI method powered by the MCMC method.

	mean	std		mean	std		mean	std
m_{s1}	0.989	0.025	EI_1	0.998	0.151	EI_{11}	1.010	0.128
m_{s2}	0.973	0.088	EI_2	0.961	0.125	EI_{12}	0.978	0.149
c_{s1}	1.059	0.208	EI_3	1.026	0.170	EI_{13}	1.033	0.150
c_{s2}	1.086	0.265	EI_4	1.021	0.123	EI_{14}	0.950	0.137
k_{s1}	1.103	0.237	EI_5	1.018	0.123	EI_{15}	0.999	0.138
k_{s2}	0.900	0.275	EI_6	1.060	0.146	ρA	0.980	0.132
m_{u1}	1.154	0.225	EI_7	1.018	0.127	α	0.981	0.324
m_{u2}	1.078	0.220	EI_8	0.983	0.136	β	1.063	0.331
k_{u1}	1.188	0.192	EI_9	1.014	0.132			
k_{u2}	1.155	0.265	EI_{10}	1.044	0.111			

4.2 Application of the PSO method

The PSO method is also based on the Monte Carlo algorithm, which is less computationally efficient. The estimation accuracy is expected to depend on the initial particle position; if one particle is generated near the optimal solution in the initial step, the particles can efficiently search for the optimal solution.

The result of the PSO method is shown in Table 3. According to this table, the standard deviation of each parameter decreases from that obtained from the MCMC method. The mean of each parameter is also closer to the correct value. This means that the PSO method can improve the efficiency of the VBISI method.

Table 3. The estimation accuracy of the VBISI method powered by the PSO method.

	mean	std		mean	std		mean	std
m_{s1}	0.989	0.009	EI_1	1.003	0.042	EI_{11}	1.006	0.047
m_{s2}	1.024	0.030	EI_2	1.002	0.056	EI_{12}	1.012	0.041
c_{s1}	1.001	0.085	EI_3	0.987	0.035	EI_{13}	1.007	0.039
c_{s2}	1.009	0.107	EI_4	1.009	0.041	EI_{14}	1.005	0.047
k_{s1}	1.053	0.100	EI_5	0.995	0.053	EI_{15}	0.996	0.046
k_{s2}	0.974	0.084	EI_6	0.998	0.056	ρA	0.995	0.027
m_{u1}	1.040	0.088	EI_7	0.996	0.046	α	0.980	0.135
m_{u2}	0.993	0.089	EI_8	1.007	0.042	β	1.012	0.123
k_{u1}	1.055	0.086	EI_9	1.002	0.046			
k_{u2}	1.020	0.097	EI_{10}	0.998	0.046			

4.3 Application of the NM method

The results of the NM method are also shown in Table 4. The results show that the estimation accuracy for all parameters is superior to the other schemes. The accuracy of the stiffness at both ends of the bridge decreased slightly. This can be due to the small amplitude at the bridge ends.

Table 4. The estimation accuracy of the VBISI method powered by the Nelder Mead method.

	mean	std		mean	std		mean	std
m_{s1}	0.997	0.007	EI_1	1.001	0.100	EI_{11}	0.999	0.008

5 CONCLUSION

This paper applies three different algorithms to the optimization process of the VBISI method: The MCMC method, the PSO method, and the NM method. The best efficient and accurate method is the NM method. The MCMC method is less efficient and less accurate. The accuracy of the PSO method depends on the initial positions of particles. The result of this study indicates that the NM method is the most promising option, but it should be improved.

The VBISI method is an extension of Nagayama’s method for road surface estimation so that it can also identify bridge parameters. The novelty and originality of the VBISI method lie in the ability to inspect the bridge. However, the estimation accuracy of the NM method for bridge parameters is not enough for inspection. An obstacle to improving accuracy is a lack of computational power. If more computational resources are invested, it can be expected that the final result will be more accurate. However, considering that the analysis of big data obtained from many vehicles and bridges is expected in the future, it is unrealistic to increase the number of computational resources to be used without limit. Thus, a quick algorithm, like a non-Monte Carlo optimization algorithm, must be developed.

ABSTRACT: This paper presents a framework to assess the seismic resilience of thermal power plants, which can be applied for power shortage risk analysis during earthquakes and the subsequent recovery process. The key issue of the proposed framework is that in addition to seismic damage and recovery assessment of power plants, we consider operational risk that could cause unscheduled outage of plants. In a situation where multiple power plants are shut down after a catastrophic seismic event, we need to ensure power generation capacity by operating the remaining power plants efficiently and unexpected shut down of plants due to equipment failures could cause power shortage immediately. The effectiveness of the proposed framework is validated throughout the application to an anticipated earthquake scenario.

1 INTRODUCTION

In recent years, due to the increasing complexity of power system and exacerbation of natural disasters, power outage risks have been evolving on an unprecedented scale (Panteli & Mancarella 2015, Bie et al. 2017). In particular, though power plants are generally well-designed against seismic hazards, the shutdown of them due to earthquakes can have a serious impact on the stable supply of electric power because once they suffer from the severe seismic damage, it takes a longer time to resume operations (Karagliannis et al. 2017, Nicolas et al. 2019). Recently, the typical examples have occurred in rapid succession in Japan, namely the 2011 off the Pacific coast of Tohoku earthquake (M_w 9.0), the 2018 Hokkaido Eastern Iburi earthquake (M_w 6.6) and the 2022 Fukushima-oki earthquake (M_w 7.3). These cases gave us some important insights into natural disaster risk of power supply system such as 1) the diversity of both physical damage and recovery process of facilities caused by simultaneous damages over a wide area, 2) the potentiality of cascading failures across the whole power system triggered by some facility damages, and 3) the possibility of compound risks due to superimposition of natural disasters and component failures. In order to understand the complicated impact of such large-scale disasters on power grid and discuss effective countermeasures, it is necessary to develop an integrated risk assessment framework for the entire power system, including both supply (generation, transmission, transformation and distribution facilities) and demand system. Numerous studies have been devoted for this issue as reviewed in Wang et al. (2016) and Bhusal et al. (2020). In this paper, as a contribution to such systemic analysis, we propose a framework for supply capacity evaluation of thermal power plants after a catastrophic seismic event.

Thermal power plants are a stable power source whose importance in ensuring the reliability of the power supply system has been reaffirmed in recent years. This is because they have still maintained their position as the main power source in worldwide (IEA 2021) and are expected to play

a role as a flexible regulator to cope with fluctuations in the output of renewable energy generation, which has increased rapidly in these days (Kubik et al. 2012, Eser et al. 2016). However, while various approaches have been taken to clarify the seismic vulnerability and performance of components and buildings composed of thermal power plant such as field surveys (e.g. Stevenson 1995, Koizumi et al. 2014), experimental tests (e.g. Chiba & Fujita 2004) and response analysis (e.g. Wang et al. 2018), their general resilience as power generation function after a seismic event is not well understood. The one reason for this is that thermal power plants are complex systems consisting of a wide variety of facilities across the fields of civil engineering, architecture, and machinery, therefore, it is difficult to define the fragility of all constitutive components and model the internal logic between the performance of individual components and their power generation functions. For example, Rahman & Edwards (2015) proposed a method for probabilistically predicting the recovery duration of coal-fired power plant after earthquakes by modeling plant system as a network with individual component as nodes and the flow of goods and services among components as links, and then defining fragility and recovery curves for each facility. Hamed et al. (2022) developed a hybrid simulation framework to assess the post-earthquake production capacity of a thermal power plant using system dynamics to assess the production capacity under a certain damage condition of components and agent-based model to evaluate the allocation of resources and recovery process. All of these studies take a so-called “bottom-up approach”, allowing cost-benefit analysis of differences in system configurations and restoration strategies, but on the other hand, they have not been verified using actual earthquake experience data.

In assessing power generation capacity after a seismic event, the primary procedure is to estimate the physical damage and their repair time of individual power plant caused by the earthquake as focused on the previous studies. In addition, in the situation where multiple power plants shutdown simultaneously, power supply and demand balance can become tight and it results in high burden concentration on available power plants, such as those of unaffected or those have been restored earlier. It is pointed out that these heavy reliance on the certain power plants can increase the risk of “unscheduled outage”, which means the unexpected shutdown or output suppression due to component malfunction or emergency repair. Therefore, in order to evaluate the total power generating capacity during the recovery process from immediately after a large-scale earthquake, we need to re-defined the whole process as “compound disaster” where the burden on the “power generation system” consisting of the multiple thermal power plants will increase in a chain reaction triggered by the physical damage caused by the

Figure 1. Post-earthquake power generation capacity and the concept of “compound disaster”.

earthquake (Figure 1). In this study, we propose a framework to assess the total power generation capacity of thermal power plants after a seismic event considering both the direct damage and recovery of power plants due to an earthquake and unscheduled outage risk based on the analysis of the actual operational data after the 2011 off the Pacific coast of Tohoku earthquake.

2 FRAMEWORK

“Resilience triangle” is a concept theorized by Bruneau et al. (2003) to express the quality of infrastructure during and after an earthquake. When we employ the concept to the resilience of thermal power plants, it can be interpreted as the loss and subsequent recovery process of the total power generation capacity of geographically distributed multiple power plants. Figure 2 shows the actual data after the aforementioned 3 recent earthquakes in Japan. The purpose of this study is to develop the framework to estimate those curves under a scenario earthquake, defining as “total power generation capacity curve”. Specifically, as shown in Figure 3, we assume that each thermal power unit can simply take 3 different states: “up (operable)”, “down (shutdown due to an earthquake damage)” and “down (shutdown due to failure)”. The state transitions are ruled by using seismic damage and recovery model (red arrows in Figure 3) and the unscheduled outage model (blue arrows in Figure 3) that the authors developed based on the actual data of thermal power plants.

In the following, we present the models to estimate seismic damage and recovery duration of thermal power plants and the probability of unscheduled outage occurrence in 3.1 and 3.2 respectively. In 3.3, the integrated flow to evaluate the total power generation capacity curve is proposed and it is applied to an anticipated earthquake scenario and the results is summarized in section 4.

Figure 2. Total thermal power generation capacity curves of the recent major earthquakes in Japan.

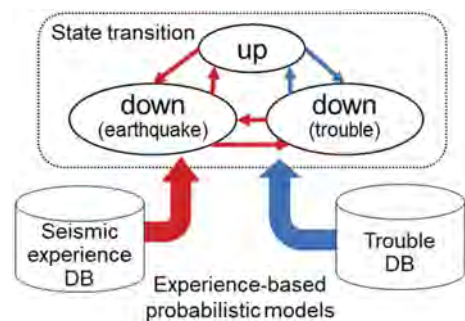

Figure 3. State transitions of thermal power units.

3 MODEL DEVELOPMENT

3.1 Seismic damage and recovery model

The 2 steps probabilistic models developed based on the statistical analysis of experience data from 29 thermal power plants affected by the 2011 off the Pacific coast of Tohoku earthquake by the authors (Yuyama & Kajitani 2014) is used to estimate the recovery time of thermal power plants due to an earthquake.

The first model is the “fragility functions” of each of typical plant sub-system. Fragility curves of each 3 damage rank (severe/ moderate/ minor) were estimated for 9 sub-systems (e.g. boiler, turbine & generator, fuel facilities), respectively. Using these functions, the probability that the damage rank of the s th plant sub-system is k at a certain ground motion level a can be calculated (Equation 1).

$$P_{i,k}(a) = \Phi\left(\frac{\ln a - \mu_{s,k}}{\sigma_s}\right) \quad (1)$$

where $P_{i,k}$ = probability that the damage rank of the i th plant sub-system is greater than or equal to k ; a = peak ground acceleration (PGA) [gal]; $\mu_{s,k}$, σ_s = parameters of fragility functions (Table 1).

The second model is “recovery function” that evaluates the probability that the recovery duration of a thermal power plant whose damage pattern of plant sub-systems is X exceeds the arbitrary value t (Equation 2).

$$G(t|X) = \Pr(T_{rcov}^{EQ} \leq t|X) = \Phi\left(\frac{\ln t - \beta X}{\sigma}\right) \quad (2)$$

where T_{rcov}^{EQ} = recovery duration from seismic damage [day]; X = damage pattern of plant sub-systems (Equation 3); σ , β = parameters of recovery functions (Equation 4).

$$X^T = \{x_{s,k}\} = \{x_{1,C}, x_{2,C}, x_{3,B}, x_{4,C}, x_{5,A}\} \quad (3)$$

where $x_{s,k}$ = binary variable that denotes if the damage rank of the s th sub-system is greater than or equal to k (1) or not (0).

$$\sigma = 0.54 \quad (4a)$$

$$\beta = [1.12 \ 1.22 \ 1.41 \ 1.30 \ 1.74] \quad (4b)$$

The most appropriate combination of sub-system and damage rank was selected using AIC as an indicator through regression analysis of the actual data on the sub-system damage patterns and the required recovery periods.

Using the presented models, this study estimates the recovery duration of a certain thermal power plant after an earthquake as below:

- (1) obtain the ground motion intensity (PGA) at the target power plant location,
- (2) estimates the damage pattern of plant sub-system using the fragility functions,
- (3) evaluates the recovery duration using the recovery function.

Table 1. Parameters of fragility functions.

Sub-system s	1. Water inlet/outlet facilities	2. Power receiving facilities	3. Boiler facilities	4. Flu gas treatment facilities	5. Service buildings
$\mu_{s,A}$	—	—	—	—	—
$\mu_{s,B}$	5.89	5.94	5.39	6.26	—
$\mu_{s,C}$	5.50	5.59	4.87	6.02	—
σ_s	0.65	0.34	0.58	0.20	—

* “—” indicates that parameter estimation did not occur due to the lack of observations.

3.2 *Unscheduled outage model*

In order to evaluate the probability of unscheduled outage of thermal power plants, we employ the experience-based models developed by the authors. The models we use in this paper are updated from the original ones (Yuyama et al. 2018) by using some additional operational data of thermal power generating units during 2011 and 2012 summer in Japan. In the paper, four models were constructed according to the type of power generation method (Conventional (abbreviated as Conv)/ Combined Cycle (CC)) and the experience of unscheduled outages during the season (First accident during the season (abbreviated as 1)/ Two or more accidents during the season (2)). The relationship between the operating period and the

probability of unscheduled outages was modeled based on the theory of survival analysis. Suppose the operational time to failure of a thermal power generation unit is D^{Acc} , the probability that a target unit has not experienced failure at the arbitrary time t is defined as Equation 5.

$$S(t) = \Pr(D^{Acc} > t) = 1 - F(t) \quad (5)$$

where $S(t)$ = a survival function; $F(t)$ = a cumulative distribution function of the failure time.

The probability that an unscheduled outage occurs at t after surviving by t is as below:

$$h(t) = \frac{f(t)}{S(t)} \quad (6)$$

where $h(t)$ = a hazard function; $f(t)$ = a probability density function of the failure time.

In addition, a proportional hazard model (Equation 7) is introduced to consider the characteristics of each unit such as age, power generation capacity and fuel type.

$$h(t) = h_0(t) \cdot r(y, \beta) \quad (7)$$

where $r(y, \beta)$ = a function of explanatory variables y and parameters β .

In the paper, $F(t)$ is assumed to be either Weibull, lognormal, gaussian, logistic or exponential distribution. Weibull distribution (Equation 8) is selected as appropriate model for Conv1, lognormal distribution (Equation 9) for Conv2, CC2 and exponential distribution (Equation 10) for CC1 using AIC.

$$F(t|\beta) = 1 - \exp\left(-\left(\frac{t}{\varphi}\right)^\gamma\right) \quad (8a)$$

$$\varphi = \exp(y'\beta) \quad (8b)$$

$$F(t|\beta) = \Phi\left(-\frac{(\ln t - y'\beta)^2}{2\sigma^2}\right) \quad (9)$$

$$F(t|\beta) = 1 - e^{-\lambda t} \quad (10a)$$

$$\lambda = \frac{1}{\exp(y'\beta)} \quad (10b)$$

The maximum likelihood estimation is adopted to determine the parameters and the results are shown in Table2.

Table 2. Parameters of unscheduled outage models.

variables x	explanations	β			
		Conv1	Conv2	CC1	CC2
Intercept		8.009	3.540	7.057	14.428

LN(PWR)	generation capacity [MW]	-	-	-1.125	-4.042
Age		-0.024	-	-	-
LN(Age)	age	-	-	0.587	1.323
Oil	fuel dummy for oil	-0.909	-	-	-
Oil_LNG	fuel dummy for combination of oil & LNG	-	-	-	-
LNG	fuel dummy for LNG	-	-	2.109	4.055
Gas	fuel dummy for gas	14.637	-	19.272	-
LN(σ)		-	0.741	-	0.458
LN($1/\gamma$)		0.288	-	-	-

As for the simulation of the recovery time after the failures, a non-parametric resampling approach is adopted and the actual recovery time records in the same database collected for the estimation of unscheduled outage probability is used. More details are described in Yuyama et al. (2018).

Using the models and simulation method presented above, the occurrence and recovery of a certain thermal power generating unit after an earthquake is simulated as below:

- (1) obtain the characteristics of the target power generating unit,
- (2) estimates the operational time to failure using the unscheduled outage model,
- (3) evaluates the recovery duration based on the resampling of the actual recovery time records from the database.

3.3 Simulation of total power generation capacity

Figure 4 shows the flowchart to simulate the power generation capacity of a target thermal power plant unit under a scenario earthquake, combining the model described in section 3.1 and 3.2. The “total power generation capacity curve $C(t)$ ” of multiple thermal power plants (units) is calculated by the summation of the power generation capacity of all units whose status is “up” at time t .

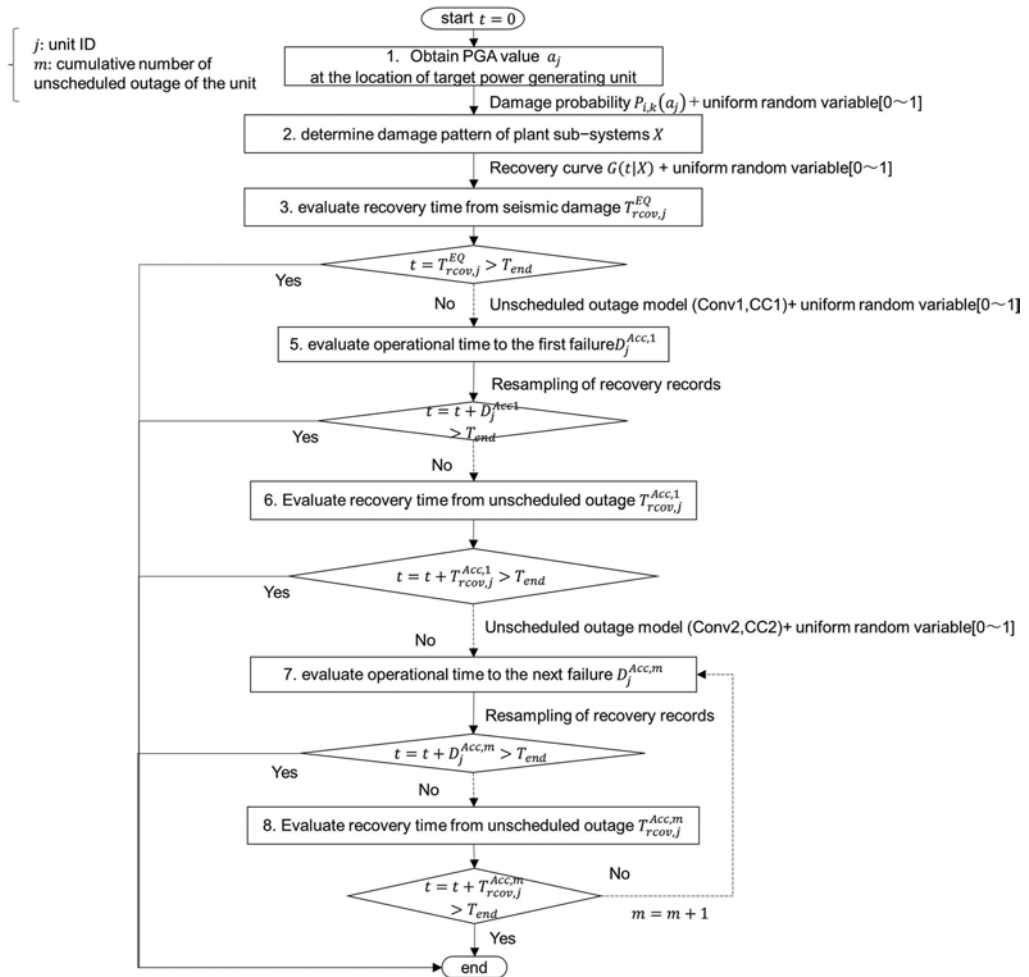

Figure 4. Flowchart to simulate generation capacity of a thermal power unit after a seismic event.

4 CASE STUDY

In this section, we simulate the total power generation capacity curve of thermal power plants after an anticipated earthquake scenario, anticipated Tokyo Metropolitan earthquakes. Figure 5 shows the distribution of seismic ground motion and the location of thermal power plants. 17 plants 92 units (total 44,330MW) located in Kanto area are included in this case study. Figure 6 shows the simulated average, maximum and minimum potential power generation curves (1,000 simulations) of the cases where only seismic damage is considered (EQ) and both the seismic damage and unscheduled outages are included (EQ+Acc). In the case considering only earthquake damage, the supply capacity immediately after the earthquake dropped to about 9,700 MW (Δ 78%) on average and it takes 77 days to secure 50% of the initial capacity (22,152MW) and 185 days for 80% . Figure 7 shows the results of evaluating the maximum difference in supply capacity for each simulation case when only earthquake damage is considered and when both seismic damage and unscheduled outages are included. In this simulation, the maximum loss of supply when multiple units experience unscheduled outages simultaneously is approximately 17% (7645MW) of the total capacity of the power plants. This suggests that the occurrence of unscheduled outages may pose an additional risk in the operation of power plants during the recovery process after an earthquake.

Figure 5. Distribution of ground motion intensity and the location of thermal power plants. Figure 6. Simulated power generation curves.

Figure 7. Maximum differences in supply capacity in each simulation.

5 CONCLUSIONS

In order to evaluate the resilience of thermal power plants to a large-scale complex disaster, this study developed a framework to simulate the potential supply capacity of thermal power plants after a scenario earthquake by integrating various models such as 1) seismic fragility

curves to predict physical damage of constitutive components in plants and 2) seismic recovery function to estimate recovery time based on the information of component damage patterns and 3) unscheduled outage model to estimate operational time to unscheduled outage, which are developed based on the damage and restoration data of thermal power plants caused by 2011 off the pacific coast of Tohoku earthquake and the operational records of thermal power plants during the subsequent high demand seasons. The application of this framework enables to evaluate various damage and restoration patterns of thermal power plant and their frequency of occurrence.

Non-deterministic seismic damage detection of road infrastructure analysing image training database

R. Kondo & G. Shoji

University of Tsukuba, Ibaraki, Japan

ABSTRACT: In this paper, we visually deciphered the damage to road structures in 25 aerial photographs which were taken after the 2016 Kumamoto earthquake and detected these damage modes according to the image training database of seven damage modes: road surface cave-in, road surface liquefaction, road surface cracks, road surface collapse, road surface steps, falling rocks and landslides and building debris on road surface. Specifically, texture analysis produced a histogram of six feature values: contrast, variance, skewness, kurtosis, energy and entropy, and a threshold were set to detect damage. The results presented that the coefficients of variation of kurtosis and entropy were small and effective for damage detection.

1 INTRODUCTION

The Kumamoto earthquake, which struck on April 14 and 16, 2016, severely damaged road structures. In order to prompt lifesaving and restoration activities, technology is required in identifying widespread earthquake damage for infrastructure quickly. In the detection of earthquake hazards, such as slope failure and liquefaction, Midorikawa and Miura (2010) extracted the areas of slope damage caused by the 2008 Iwate-Miyagi Nairiku earthquake from high-resolution synthetic aperture radar (SAR) images, and Rathje et al. (2017) measured the horizontal displacement owing to the liquefaction which was caused by the 2011 Canterbury earthquake from satellite images. The displacement was measured from satellite images taken before and after the earthquake using light detection and ranging (LiDAR) and optical image correlation. In terms of detecting surface faults, Gori et al. (2018) conducted field mapping from images taken by LiDAR and unmanned aerial vehicles (UAVs) during the 2016 earthquake in central Italy.

In terms of detecting damage to buildings and civil engineering structures as a result of slope failure, liquefaction, and surface fault displacement, which include seismic motion, Matsuoka and Yamazaki (2004) focused on the backscattering characteristics of the affected area in the 1995 Hyogo-ken Nambu earthquake and evaluated damage to buildings by using European Remote-Sensing Satellite (ERS) images before and after the earthquake. In terms of detecting damage to buildings, Miura et al. (2016) conducted a texture analysis by using high-resolution SAR images taken during the 2010 Haiti earthquake. A linear discriminant function based on the difference and correlation coefficient was calculated from the images taken before and after the earthquake in detecting collapsed buildings. As an example of a study focusing on earthquake damage to road surfaces, Maruyama et al. (2006) identified damage to expressways from aerial photographs taken during the 2004 Mid Niigata prefecture earthquake. Sezaki et al. (2017) attempted to automatically detect road damage from images taken by a vehicle-mounted camera during the 2016 Kumamoto earthquake. Yoshinari and Shoji (2020) identified damage to road structures from satellite images taken after the 2018 Hokkaido Iburi eastern earthquake. Kondo and Shoji (2022) attempted to identify damage to road surfaces according to the texture analysis by using aerial photographs taken during the 2016 Kumamoto earthquake.

Figure 1. The spatial distribution of the aerial photographs.

Figure 2. Definition of damage modes of road surfaces.

There are various modes of seismic damage to road surfaces, and even image analysis using aerial photographs, which is more accurate, can be difficult sometimes even though many studies on the application of image analysis to earthquake damage to buildings have been conducted recently. Therefore, in this study, we examined the damage caused by the 2016 Kumamoto earthquake, attempted to detect various modes of seismic damage to road surfaces on a set of high-quality aerial photographs and discussed the accuracy of the detection.

2 AERIAL PHOTOGRAPHS AND DAMAGE MODES FOR ANALYSIS

2.1 The aerial photographs

Twenty-five aerial photographs which were taken by the Geospatial Information Authority of Japan (GSI) were used for the survey of Mashiki Town, Kashima Town, Mifune Town and Kosa Town in Kamimashiki County, Kumamoto Prefecture, which were particularly damaged by the Kumamoto earthquake. Aerial photographs were taken on April 15, 16, 20, 29 and 22 July 2016, using Ultra Cam X, Ultra Cam Xp and Digital Mapping Camera equipment. Aerial photography was taken at altitudes ranging from 1,396 to 3,366 m. The images have a resolution of 1,200 dpi and a scale of 1/10,000; thus, the length of one pixel on the ground is about 20 cm.

Figure 1 shows the spatial distribution of the aerial photographs to be analysed. There are eight aerial photographs of Mashiki Town, five of Kashima Town, two of Mifune Town and ten of Kosa Town. They have been system-corrected and ortho-rectified following the acquisition of these photographs. These corrections are made to compensate for distortions caused by the coordinates measured at the time of acquisition, distortions caused by the sensor structure, and distortions caused by height differences in topography, buildings, and other factors.

The 25 aerial photographs were used in performing a visual interpretation of road surface damage modes. Seven damage modes were defined as follows: road surface cave-in, road surface liquefaction, road surface cracks, road surface collapse, road surface steps, falling rocks and landslides, and building debris, based on the analyses of Shoji and Sakurai (2011) and Kondo and Shoji (2022). Figure 2 shows the damage modes. Cave-in is a partial collapse of the road surface that occurs primarily at the shoulder. Liquefaction is a condition in which the entire road surface sinks which results in sand and water fountains. Cracks are relatively large fractures in the road surface that can be identified from the aforementioned 1 pixel 20 cm equivalent aerial photographs. Collapse is a condition in which, in addition to road surface damage, the shoulder or slope has collapsed beyond the width of the road. Steps vary in height by 10 cm or more at expansion joints between the road and bridge girders at the abutment of bridges. Rockfall and landslide is a situation in which a road is completely or partially blocked by falling rocks or soil. Building debris is a situation in which buildings facing the road are damaged to the extent that they are completely or partially destroyed, and debris is scattered to the extent that road traffic is obstructed.

The total number of damaged locations in the 25 aerial photographs is 171. Liquefaction was the predominant damage mode at 77 locations, followed by cracks at 33 locations, steps at 26 locations, collapses at 19 locations, building debris at 10 locations, cave ins at 3 locations and rockfall and landslides at 3 locations. Figure 3 shows the visual readings of the damaged areas for CKU-2016-27_C9-6.tif, CKU-2016-27_C7-9.tif and CKU-2016-27_C5-37.tif. In a town-by-town comparison, Mashiki Town, which is closest to the epicentre, suffered the most damage. Liquefaction was the most common cause of damage for road surfaces in urban areas, while rockfall and landslides were relatively common in mountainous areas.

Figure 3. Visual detection for damage modes of road surfaces.

3 TEXTURE ANALYSIS

3.1 Process of construct data

The process of generating data for image analysis from aerial photographs is shown as (1) affine transformation is used in correcting the geometry; (2) rubber sheet is used to correct the positions of the aerial photograph and road edge data; (3) raster transformation is used to correct the slope of the image; (4) the aerial photograph is converted into polygons; (5) the polygons are divided into meshes that correspond to the number of pixels in the aerial photograph. From the viewpoint of the aforementioned 1-pixel accuracy, the sizes of the polygons are approximately 20 cm square. (6) By using the road edge data, the polygons of the aerial photograph are cut and divided into the road and non-road portions to obtain polygon data for the road portion only. (7) The meshes created in (5) and the polygons created in (6) are overlaid to obtain the meshed polygon data of only the road section. (8) By using the damage database created in the previous section, polygons of the damaged area are created. (9) By superimposing the road mesh created in (7) on the polygons of the damaged area created in

Figure 4. Monochromatized image for road surface collapse.

(8), meshed polygon data of the damaged area is created. The mesh data created in (7) and (9) are used to extract pixel data from aerial photographs for analysis.

3.2 Method of texture analysis

The monochromatized images shown in Figure 4 are considered more accurate in the detection of the various damage modes on the road surface shown in Figure 2 although the aerial photographs are RGB colour images.

$$I = 0.3R + 0.59G + 0.11B \quad (1)$$

where I is the luminance value in 256 levels as a measure of brightness, and R , G and B are the pixel value in the Red, Green and Blue channels, respectively. In order to extract damaged areas of road surfaces with high accuracy, six characteristic values, contrast (CNT), variance (VAR), skewness (SKW), kurtosis (KRT), energy (EGY) and entropy (EPY), were selected based on the findings of Yoshinari and Shoji (2020) and Haralick et al. (1973), as shown in the following equations.

$$CNT = \sum_0^{255} l^2 \cdot P(l) \quad (2a)$$

$$VAR = \sum_0^{255} (l - MEN)^2 \cdot P(l) \quad (2b)$$

$$SKW = \frac{1}{VAR^2} \sum_0^{255} (l - MEN)^3 \cdot P(l) \quad (2c)$$

$$KRT = \frac{1}{VAR^3} \sum_0^{255} (l - MEN)^4 \cdot P(l) \quad (2d)$$

$$EGY = \sum_0^{255} P^2(l) \quad (2e)$$

$$EPY = - \sum_0^{255} P(l) \cdot \log_N P(l) \quad (2f)$$

An approximation of the probability density of luminance values, $P(l)$, is used in calculating the characteristic values. $P(l)$ is represented by the histogram $H(l)$ of luminance values ($l=0\sim255$) for each pixel divided by N , the total number of pixels in the window, where MEN denotes the mean value of l . In this study, a window of height and width of 27 pixels * 27 pixels is used, so N is 729. Figure 5 shows the analysis results for the aerial photograph CKU-2016-27_C6-21.tif. The left figure shows the spatial distribution of each feature in the road area, and the right figure shows the histogram of each feature in the road area.

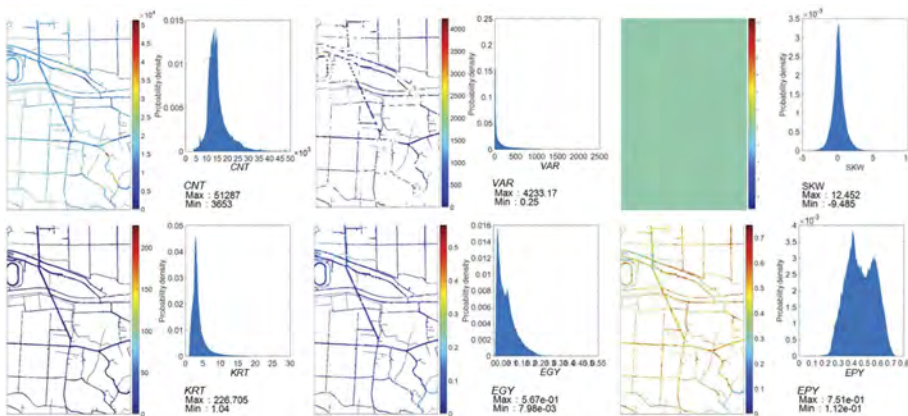

Figure 5. Spatial distribution and histogram of each characteristic value for the aerial photograph CKU-2016-27_C6-21.tif.

CNT is a quadratic moment around the origin and is considered to be effective in distinguishing damage in cases where the luminance values are low in comparison to the surrounding road areas, such as cracks and cave-ins. *SKW* represents the distortion of the distribution; however, it is unlikely to be an effective feature, and it is presented here for comparison with other characteristic values because the distortion of the histogram is not large in this analysis. *KRT* is the fourth-order moment around the mean, which represents the sharpness of the probability density function and takes a large value when the distribution is concentrated near the mean. Although *EPY* shows the opposite tendency to *EGY*, it can distinguish liquefaction damage from the same viewpoint as *EGY*.

4 CALCULATION OF THRESHOLD AND DAMAGE DETECTION

4.1 Calculation of threshold

Threshold values are calculated according to the least-squares method from the characteristic values in the damaged area of aerial photographs as follows.

$$d_i = c_t - c_i \quad (3a)$$

$$D = \sum_{i=1}^N d_i^2 \quad (3b)$$

A provisional threshold c_t is determined by using Equation (3a), and for every 1~Nth damaged road pixel in the damaged area, the difference d_i between the provisional threshold and the characteristic values c_i is calculated. The threshold value is the feature value which is obtained when the sum of the squares of the differences D is the smallest for all damaged road pixels. For each characteristic value, 25 aerial photographs were used in calculating the threshold value, and the threshold value with guaranteed accuracy was adopted. Table 1 shows the mean, standard deviation (SD), and coefficient of variation (COV) of the threshold value for each feature. Table 1 shows that the coefficients of variation of *KRT* and *EPY* are 0.1838 and 0.1148, respectively, which are smaller than the coefficients of variation of 20% of other features, which indicate that these features are effective in distinguishing damage.

Table 1. Mean, standard deviation (SD) and coefficient of variation (COV) of the thresholds.

	<i>CNT</i>	<i>VAR</i>	<i>SKW</i>	<i>KRT</i>	<i>EGY</i>	<i>EPY</i>
Mean	13280	504.2	0.233	3.89	0.0381	0.572
SD	4783	341.4	0.475	0.715	0.0180	0.066
COV	0.3602	0.6772	2.0427	0.1838	0.4723	0.1148

4.2 Method of damage detection

We discuss the valid features and ranges of damage detection by using the average values of the thresholds shown in Table 1. Damage detection is performed by identifying pixels within the range of the damaged area in the following four cases assuming a coefficient of variation of 0.05 and 0.1: (1) 10% positive and negative, (2) 10% positive, (3) 10% negative, and (4) 5% positive and negative.

4.3 Consideration for result

Damage detection was performed on 25 aerial photographs, and the accuracy was checked visually. In cases (2) 10% positive and (4) 5% positive and negative, 22 of the 25 images produced

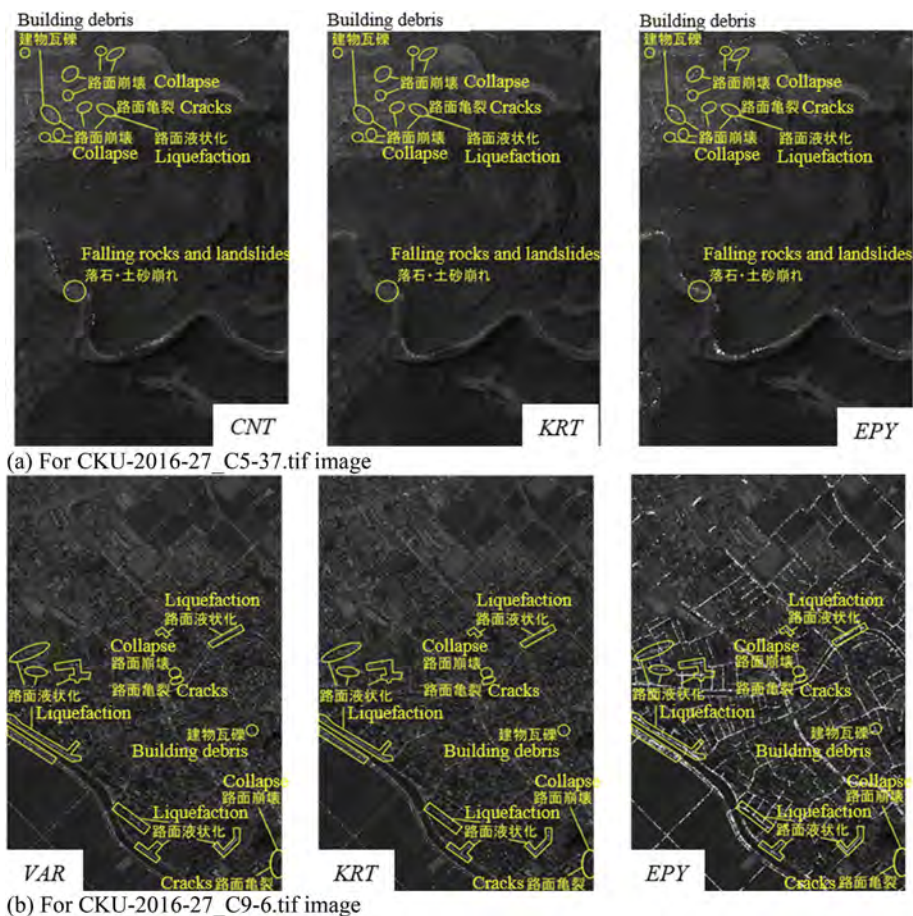

Figure 6. Damage detection result for each characteristic value.

good results with few false positives. Among them, the damage detection results for CKU-2016-27_C5-37.tif and CKU-2016-27_C9-6.tif are shown in Figure 6, and the histogram of features and damage detection range for each image are shown in Figure 7.

The damage caused by liquefaction was detected by *VAR*, *EGY* and *EPY* as shown in Figure 6(a); damage caused by cracking was detected by *KRT* and *EGY*; damage caused by collapse was detected by *VAR*, *KRT*, and *EPY*; damages caused by rockfall and landslide were detected by *KRT* and *EPY*; damage caused by building debris was detected by *CNT* and *EPY*.

KRT and *EPY* were the most common features in the extraction of these damage modes, and *KRT*, a fourth-order moment around the mean, may have discriminated well by emphasising variation in the brightness of the damaged area. The *EPY* showed better detection results for damage caused by liquefaction. This is because road liquefaction results in sand and water fountains, which darken the damaged area, so *EPY*, which shows larger values with smaller pixel luminance, is considered effective. However, in the case of road surface cracks, *EPY* was not a suitable feature because false positives were frequently observed for the area of damage. In the case of road surface collapse, *EPY* was a suitable feature because it was effective in detecting areas which appeared darker in relation to the road surface, as was the case with the road liquefaction described above.

In Figure 6(b), the damage caused by road liquefaction was detected by *CNT*, *VAR* and *KRT*; damage caused by road surface collapse was detected by *VAR* and *EGY*; damage caused by building debris was detected by *CNT* and *KRT*; however, there were no good

Figure 7. Histogram of each characteristic value and damage detection range.

indicators for detecting damage caused by road surface crack. In Figure 6(a), *KRT* and *EPY* were dominant, whereas in Figure 6(b), *KRT* was dominant. The reason is that road liquefaction was the outstanding damage mode in terms of both the number of damaged areas and the area of damaged regions. In addition, *VAR* showed good detection results for all damage modes, including road liquefaction and road collapse. There are many false positives in *EPY* for all damage modes as shown in Figure 6(b). This could be because, in urban areas, shadows of buildings and vehicles are reflected on the road, and the brightness values are not uniform even on undamaged road areas, resulting in false detection of damaged areas.

VAR was the common feature in the two images for road liquefaction. In contrast, *KRT*, which was not a good feature in Figure 6(a), showed good results for road surface liquefaction. This could be because *KRT*, which more strongly reflects differences in luminance, showed better results due to the large variation in luminance values in the road area described above. *KRT* was effective for detecting road surface cracks in Figure 6(a), but it could not detect them in Figure 6(b). Comparing the damaged areas of both road surface cracks, the damaged area in Figure 6(a) appears darker, which could be because the area in Figure 6(b) is outside the range of the damage detection threshold. In Figure 6(b), the road surface collapse was detected by *VAR* and *EPY*, whereas in Figure 6(a), it was detected by *VAR*, *KRT* and *EPY*. *VAR* was detectable in both images. The reason why *KRT* was unsuitable for detecting road surface collapse in Figure 6(b) is that the threshold value of CKU-2016-27_C9-6.tif is about 26% larger than the average value, and the area of the road surface collapse is not as large as the area of the road. The road surface collapse area was considered to be outside the range of the threshold value for damage detection because of the large difference in brightness between the road area and the collapse. In contrast, the reason why *EPY* was a suitable feature for detecting road surface collapse in Figure 6(b) is that it has a complementary relationship with the *EPY* index, which could have resulted in more areas being detected as false positives, but in Figure 6(b), suitable results were obtained, and the reason for this is a subject for future study.

5 CONCLUSION

Seismic damage modes of road surfaces were extracted in terms of six characteristic values according to the texture analysis of 25 aerial photographs which were taken after the 2016 Kumamoto earthquake. The coefficients of variation of kurtosis (*KRT*) and entropy (*EPY*) were smaller than those of other features, and they were found to be effective features for damage detection in terms of the threshold values. In terms of the damage discrimination range, 10% of the positive and 5% of the positive and negative values from the threshold showed good results, which had a relatively small area of false positives. Variance (*VAR*) and *KRT* were relatively common features that are suitable for detecting each damage mode, particularly for road liquefaction. *KRT* was also effective for detecting road surface crack damage, but it may not be possible to distinguish between it and other features which depends on the quality of the aerial photograph. *KRT* and *EPY* were the most effective features for detecting rockfall and landslides, and *VAR* was the most effective feature for detecting road surface collapse.

Life-cycle assessment of cold formed steel buildings: Main influential materials and parameters

O. Iuorio

University of Leeds, Leeds, UK
Politecnico di Milano, Milan, Italy

A. Gigante

University of Sannio, Italy

ABSTRACT: Reducing the carbon footprint of the built environment is a duty to achieve the target of the 2030 Urban agenda. The built environment is, indeed, responsible for about 42% of the EU total energy consumption and about 35% of the greenhouse gases emissions. One of the challenges in reducing the impact of building on the environment is in quantifying them, with a good degree of accuracy. To this end, over the last decades, life cycle methodologies and metrics have been developed for the assessment of green-house gases impacts of material, products, and components, that can be applied by academics and professionals. However, the quality of the assessment relies on the quality of data related to the amount of materials used for the studied building or component, and the corresponding adopted embodied carbon coefficients. This paper aims to shed light on this two key aspects investigating the cradle – to – gate life cycle impacts of a cold formed steel building, for which high accuracy is provided in terms of amount of materials and for some of the embodied carbon coefficients. The results will provide a useful benchmark for the wider academic community in terms of environmental impacts of cold formed steel structures, which is still a under-investigated field, and shed lights on the uncertainties generated by the selection of embodied carbon coefficients.

1 INTRODUCTION

Prefab systems, also known as offsite constructions, are today at the forefront for the development of low carbon construction systems. Prefab systems includes a large family of systems that according to the level of prefabrications can be defined as stick-built (when single components are produced in factory and then assembled on site with mechanical fasteners), panelized (when full walls or floor panels are realized in controlled environment and connected together on site, and volumetric (when fully tridimensional pods, or rooms are realized in factory and brought to site to be vertically and horizontally connected). Prefab systems, after having historical mix fortune, are today widely spreading for the realization of high standards long-terms construction systems. They are indeed very often associated to new energy-efficient buildings (Gervasio et al 2018, Iuorio et al 2019). Among prefab system, cold-formed steel (CFS) construction systems are becoming popular systems for the speed of production, the quality of final products and the structural efficiency.

1.1 *The contributions of the work*

This paper aims to investigate the environmental impacts of a cold-formed steel building, discuss the main contributing components and to critically analyze how the adoption of a variety

of databases for the calculation of the embodied carbon (EC) can provide significant differences in the obtained results.

2 CASE STUDY

This research examines a CFS school built in Italy in 2009. The school comprises 6 joint one storey stick-built CFS buildings of about 4 m height. The school has been designed for a grade 2 seismic zone according to the Italian classification OPCM 2006 and was designed and built to achieve the best energy class. All walls and roofs comprises CFS components and are designed according to sheathing braced methodologies, which accounts for the collaborations between steel profiles and sheathing panels, to achieve the required racking capacity (Iuorio, 2009). All steel components (i.e. wall studs, tracks, and rafters, as well as roof joists, tracks and blockings) are made of steel grade S320, which are zinc coated and dip – hot galvanized, and have thicknesses ranging between 1.5mm to 3.0mm. The structural sheathing panels are made by 9mm thick type 3 Oriented Strand Boards (OSB). The definition of the functional “packets” and technological choices visible in Figure 1c aimed to the eco-efficiency of the building in its life-cycle, and included wood wool panels (CELENIT) and hemp fiber as thermal insulation material for walls and roof, and gypsum based panels for fire resistance. All the sections of walls and floors are discussed in detail in Iuorio et al 2023.

Figure 1. British Force School (BFS): a. general view; b. typical wall; c. external wall stratification.

3 METHODOLOGY

One of the most complete and accurate methodology for the environmental assessment of the environmental impacts of a construction system is the life cycle analysis, which can be carried out in accordance to the ISO 14040/44 standard. In this paper, a cradle-to-gate LCA methodology of the BFS school is analysed, to understand the impacts of the structural and non-structural components of a CFS building, for which the bill of material is defined with high accuracy, because retrieved by official design and construction documents. Later in section 5, the results of the LCA study for the main structural components will be compared to those attainable from a simplified approach.

3.1 LCA of the BFS building

In his study the LCA boundaries include only the production stage (A1–A2–A3). Modules A1, A2 and A3 are indicated as a single aggregated module which includes all the steps from the cradle-to-gate (raw material supply, transport impacts and manufacturing) of the building components adopted for the case study construction. The total GHG emissions deriving from phases A1 to A3 represent the embodied emissions of the building. The life cycle analysis is developed with the use of One Click LCA automated life cycle assessment software (One Click), according to the requirement of the (EN 15978) standard, which is in line with the (ISO 14040/44) standard. As reported in Table 1, six standard impact categories are considered in this study.

Table 1. Impact categories considered.

Impact Category	Abbreviation	Unit
Global warming potential	GWP	kgCO ₂ -eq
Acidification potential	AP	kgSO ₂ -eq
Eutrophication potential	EP	kgPO ₄ -eq
Ozone depletion potential	ODP	kgCFC ₁₁ -eq
Formation of ozone of lower atmosphere	POCP	kgC ₂ H ₄ -eq
Total use of primary energy	TUPE	MJ

According to the LCA methodology, the bill of materials has been calculated for each examined building component, and then for each material the corresponding cradle-to-gate impacts have been evaluated on the basis of the corresponding EPD, retrieved in the One Click databases.

3.2 Life cycle inventory

In order to analyse the environmental impact of the case study, the following Table 2 show the quantities of materials used for the walls (both load-bearing and non load-bearing walls) and roof of the BFS School, making the distinction between materials for structural and non-structural components.

Table 2. Bill of materials.

	Construction Material	Quantity (Density)	Struct./ Non-Struct.
Foundation	Concrete (12/15 MPa)	199 m ³ (2400 kg/m ³)	Non-Struct.
	Concrete (30/37 MPa)	424 m ³ (2200 kg/m ³)	Struct.
	Rebar	18.3 ton (7850 kg/m ³)	Struct.
	Cold Formed steel (CFS)	44.6 ton (7850 kg/m ³)	Struct.
	OSB panels	52.6 m ³ (617 kg/m ³)	Struct.
	Wood wool panels—CELENIT N 25	28 m ³ (460 kg/m ³)	Non-Struct.
Load-Bearing Wall	Wood wool panels—CELENIT N 50	56 m ³ (360 kg/m ³)	Non-Struct.
	Fibre-cement panels	8.9 m ³ (1850 kg/m ³)	Non-Struct.
	Gypsum fibreboard—Knauf Vidifire	106 m ³ (1180 kg/m ³)	Non-Struct.
	Hemp Fibre insulation	300 m ³ (35 kg/m ³)	Non-Struct.
Non-load Bearing Wall	Cold Formed steel (CFS)	6.4 ton (7850 kg/m ³)	Non-Struct.
	Mineral fibre insulation	46 m ³ (56 kg/m ³)	Non-Struct.
	Gypsum fibreboard—Knauf Vidifire	46 m ³ (1180 kg/m ³)	Non-Struct.
	Cold Formed steel (CFS)	50.9 ton (7850 kg/m ³)	Struct.
	OSB panels	45 m ³ (617 kg/m ³)	Struct.
	Wood wool panels—CELENIT N 25	126 m ³ (460 kg/m ³)	Non-Struct.
Roof	Hemp Fibre insulation	252 m ³ (35 kg/m ³)	Non-Struct.
	Corrugated galvanized steel	2524 m ² (13.95 kg/m ²)	Non-Struct.

4 RESULTS

Table 3 indicates the overall GHG impacts of the BFS school according to the six impact categories. The results shows that the EC of the building amounts to approximately 606 tons of

CO₂e. As shown in Figure 2, about 70% of these GHG emissions are due to the materials and quantities used in walls (load-bearing and not-load-bearing walls) and roof, while 24.1% is due to the foundations. Among the other analysed impact categories, the contribution of the materials included in the wall mainly covers the impacts quantified in EP, ODP and TUPE with percentages equal to 62%, 54% and 44%, respectively. The roof components are primarily responsible for the observed AP and POCP impacts, with percentages incidence of 47% and 51%, respectively. The foundation are primarily responsible for 24.1% of GWP and for 20% of the AP, plus about 14% on average for the remaining impact categories.

Table 3. Global LCIA results.

	GWP tonCO ₂ -eq	AP tonSO ₂ -eq	EP kgPO ₄ -eq	ODP kgCFC11-eq	POCP kgC ₂ H ₄ -eq	TUPE MJ
Total	606	1.8	370	40 × 10 ⁻³	152	8'090'092

Figure 2. LCIA results: incidence percentages in each impact category.

In terms of percentage incidence of the individual materials within each building component, Table 4 and Figures 3 report the LCIA results for the foundations. The main responsible of the quantified impacts for foundations is the concrete C30/37. In terms of GWP, this material accounts for 70.5%, with about 130 tons of CO₂e. The steel reinforcement for concrete (C 30/37) has the greatest impact in terms of POCP (about 31.9%) while it has a very low impact in terms of GWP and AP, with incidence percentages of 5.5% and 3.5% respectively. The Lean concrete (C 12/15) has lower impact the C 30/37 both because it is present in a smaller quantity and because it has a lower carbon factor (ECC). In particular, from the EPDs, concrete C30/37 and concrete C12/15 have emission factors of 294 kgCO₂e/m³ and 217 kgCO₂e/m³, respectively.

Table 5 and Figure 4 show the LCA results for the CFS structural walls. The structural components (CFS and OSB panels) are responsible for 9.44×10^4 tonCO₂-eq that correspond to 51.5% of the total GWP of the load-bearing walls. In particular, CFS profiles show a predominant EC (80%) with respect to OSB panels (20%). The non-structural building materials cause an overall EC of about 8.9×10^4 tonCO₂-eq. Among them, the three thermal insulation panels cause about 18.1% of the GWP of the walls. Natural hemp fiber insulation is present in greater quantities but is much more sustainable than wood wool insulation panels. Instead, the fibre-gypsum board and the fibre cement panel are responsible for 14.5% and the 16% of EC, respectively. As for the other considered impact categories, the structural CFS is the most impacting building material in terms of AP (31%), followed by the fibre-gypsum board (26.8%). In addition, the fibre-gypsum board involves 67% of the EP of the walls. In terms of ODP, OSB panels and fibre-gypsum board are the most impacting materials, with percentages of 43.8% and 30.1%, respectively. Furthermore, the insulating panels in wood wool (CELENIT N 50 and CELENIT N 25) are responsible for 30.1% of the photochemical ozone creation potential of the structural walls. At the same time, structural materials (structural CFS and OSB) account for about 43.7% (28.7% and 15%, respectively) in the POCP

indicator. The materials that involve the greatest total use of primary energy are the structural CFS and the fibre-gypsum boards, respectively, with percentages of 32.9% and 25.7%. In this case, the percentage of incidence of non-structural materials is approximately 58.3%.

Table 6 and Figure 5 show LCA results for non-load-bearing walls. It is observed that, in all analysed impact categories, the least sustainable material is the fibre-gypsum board (responsible for 44.8% of the total GWP), followed by the non-structural CFS (responsible for 41.9% of the total GWP). The mineral fibre insulation panel is the most sustainable material.

Table 4. LCIA results: Foundation.

Material	GWP kgCO ₂ -eq	AP kgSO ₂ -eq	EP kgPO ₄ -eq	ODP kgCFC11-eq	POCP kgC ₂ H ₄ -eq	TUPE MJ
Structural	1.41×10^5	2.70×10^2	4.12×10	4.28×10^{-3}	1.78×10	8.6×10^5
Non-structural	4.45×10^4	9.38×10	1.23×10	1.30×10^{-3}	3.98×10	2.50×10^5
Total	1.85×10^5	3.64×10^2	5.35×10	5.58×10^{-3}	2.18×10	1.11×10^6

Figure 3. Percentage incidence of building materials in LCIA results: Foundation.

Table 5. LCIA results: Load-bearing Walls.

Material	GWP kgCO ₂ -eq	AP kgSO ₂ -eq	EP kgPO ₄ -eq	ODP kgCFC11-eq	POCP kgC ₂ H ₄ -eq	TUPE MJ
Structural	9.44×10^4	1.66×10^2	2.14×10	8.42×10^{-3}	2.10×10	1.29×10^6
Non-structural	8.86×10^4	3.53×10^2	1.55×10^2	1.08×10^{-2}	2.69×10	1.80×10^6
Total	1.83×10^5	5.19×10^2	1.76×10^2	1.92×10^{-2}	4.79×10	3.09×10^6

Figure 4. Percentage incidence of building materials in LCIA results: load-bearing walls.

Table 6. LCIA results: Non Load-bearing Walls.

	GWP kgCO ₂ -eq	AP kgSO ₂ -eq	EP kgPO ₄ -eq	ODP kgCFC11-eq	POCP kgC ₂ H ₄ -eq	TUPE MJ
Total	2.60×10^4	9.89×10	5.65×10	2.85×10^{-3}	5.36	5.64×10^5

Figure 5. Percentage incidence of building materials in LCIA results: Non Load-bearing Walls.

Finally, Figure 6 shows the results for the roof. In this case, the structural components are responsible for 10.25×10^4 kgCO₂-eq (Table 7) and cover 47.8% of total GWP. The materials that most affect the embodied carbon are the CFS (40.2%), CELENIT N 25 (29.9%) and corrugated galvanized metal sheets (19.3%). As in the case of the walls, the hemp fiber insulation has lower impact than CELENIT N, involving just 3% of the GWP. Regarding AP, the percentages are equal to 45.1%, 26.8% and 21.8% for the corrugated galvanized metal sheets, CELENIT N 25 and CFS, respectively. In terms of TUPE, the CFS and the OSB account for 34.2% and 6.9%, respectively. Among the non-structural materials, CELENIT N 25 show a greatest impact (34.7%).

Table 7. LCIA results: Roof.

Material	GWP kgCO ₂ -eq	AP kgSO ₂ -eq	EP kgPO ₄ -eq	ODP kgCFC ₁₁ -eq	POCP kgC ₂ H ₄ -eq	TUPE MJ
Structural	10.25×10^4	2.23×10^2	2.26×10	7.31×10^{-3}	2.19×10	1.40×10^6
Non-structural	11.25×10^4	6.22×10^2	6.42×10	5.39×10^{-3}	5.59×10	1.99×10^6
Total	2.15×10^5	8.45×10^2	8.68×10	1.27×10^{-2}	7.78×10	3.39×10^6

Figure 6. Percentage incidence of building materials in LCIA results: Roof.

5 COMPARISON BETWEEN DIFFERENT LCA DATABASES

As discussed the GWP is key environmental impact to evaluate the EC of a building/construction. The key variables that drive the definition of EC are the amount of material per unit of the building and the Embodied Carbon coefficient (ECC) in terms of kgCO₂e per kg of material. While, as seen, the first variable is closely dependent on the analyzed project, instead the evaluation of ECC is certainly more complex, since, the environmental profiles of the materials used in constructions are rarely available. To understand how much the definition/selection of ECC can influence the total EC results, here a simplified methodology (De Wolf et al 2014) is applied for the evaluation of the EC of the main structural components/materials and for the evaluation of the ECCs, two databases, namely ICE (Hammond & Jones 2010) and AMECO were considered. In particular, the ICE has been published by the University of Bath, and presents ‘cradle-to-gate’ data for carbon and energy impacts of primary building materials, mainly focused on the UK market. However, since in many cases the production of energy to manufacture a process is the dominant carbon impact and therefore this data can be extrapolated to different markets with different energy sources. The database presents some of the background for the data sources enabling the user to infer data quality. The AMECO Software calculates environmental impacts of buildings and bridges made of steel and concrete. Table 8 shows the obtained results. Please note that the quantities of concrete and CFS refer only to the structural components. The quantities of OSB and rebar are the total quantities calculated for the BFS. The ECCs from the two external databases are higher in all cases, with the exception of steel. In the case of concrete, the values are highly comparable while both in the case of OSB and steel reinforcement the ICE and AMECO coefficients are more than double those from One Click LCA. Clearly these differences are reflected in the calculation of the GWP. However, the total values calculated for the structural materials considered are comparable and equal to about 328 tons of CO₂e and 333 tons of CO₂e respectively with the ECCs coming from One Click LCA and those provided by the two external databases. As can be seen in Figure 7, the use of ECCs from different databases leads to a different percentage incidence of structural materials compared to the total GWP they generate. In fact, according to the LCA conducted using One Click LCA (Figure 7a), steel represents the most impactful structural material in terms of GWP (51.5%), while in the second case (Figure 7b) concrete accounts for 40.3 % of the total GWP of structural materials and steel accounts for 36.1%.

Table 8. BFS: Global Warming evaluation with different databases.

Material	kg	EC (ICE/AMECO) [kgCO ₂ e/kg]	GWP (ICE/ AMECO) [kgCO ₂ e]	EC (One Click LCA) [kgCO ₂ e/kg]	GWP (One Click LCA) [kgCO ₂ e]
Steel	95500	1.24 ²	118420	1.77	169035
OSB	60219	0.99 ¹	59617	0.45	27099
Concrete	1017600	0.13 ¹	132288	0.12	122112
Rebar	18317	1.24 ²	22713	0.55	10074

1 Coefficients evaluated on the basis of ICE (ICE 2010)

2 Coefficients evaluated on the basis of AMECO

6 CONCLUSION

This study analyses the LC impacts of a CFS building built in Italy. The LCA is developed according to a cradle-to-gate approach, investigating the impacts of both structural and non structural components. The study demonstrates, when the building is a single story building, as for the investigated case, the GWP is nearly equally shared between walls, roof and

Figure 7. Percentage incidence on total structural materials GWP: a) ECCs from One Click LCA; ECCs from ICE & AMECO.

foundation (see Figure 2). But when the materials are analysed, it is clear the strong incidence provided by the CFS structural members, followed by OSB panels (for a total combined incidence of 80% of structural walls GWP). Among the insulations, the hemp fibre is that with lower incidence. While for the foundation, the impacts are primarily driven by the C30/37 concrete. Therefore, these results restate the utmost importance and necessity to optimize the structural system, and that future code allowing the dissipative design of CFS system could have a significant impact also on the environmental profile of this prefab system. Finally, section 5, shows how EC results are strongly dependent on the ECCs considered, with the simple example showing how the percentage incidence can be flipped by considering a different variety of ECC database. Therefore, the continue development of EPDs for current and future building materials will be the most appropriate approach to develop reliable assessments.

The new construction products regulation: Opportunity or barrier for reused constructional steel?

P. Hradil, L. Fülöp & M. Wahlström

VTT Technical Research Centre of Finland Ltd., Espoo, Finland

C. del Castillo

European Convention for Constructional Steelwork, Brussels, Belgium

ABSTRACT: This paper discusses the implication of the new provisions of the proposed Construction Products Regulation on the constructional steel reuse. The regulation extends its scope to products either previously placed on the EU market or installed in the EU, but at the same time provides guidance how to treat used, remanufactured or surplus products and a possibility to derogate from the full Declaration of Performance rules for products that have been previously assessed. The requirements include stable material properties, safety, durability and exclusion of overloaded components assessed by de-installer or pre-deconstruction auditor. The technical guidance and protocols for structural steel reuse are developed as Annex to EN 1090-2 in the CEN/TC 135. In our study, we provide an example of such process applied on the components recovered from a single-storey industrial hall that are offered for reuse in another building project.

1 INTRODUCTION

Constructional steel components are the best suitable building elements for reuse. In most cases already designed with bolted connections, their deconstruction is usually reversed assembly process with some minor modifications. This approach can significantly improve sustainability of the constructional steelwork (Ungureanu et al. 2019), but at the same time, the reliability and resilience of steel and steel-based structures should not be compromised. For instance, the elements recovered from aged structures, demolition or post disaster recovery are significantly more challenging to reuse than relatively new components maintained in a good condition. Despite these challenges, there are some successful examples of reusing elements from such buildings. To date, the primary motivation for reusing structural steel has been economic benefits of the specific project (Balcar, 2005, Kuhnhenne, 2018). However, it is important to note that successful reuse cases in Europe are also limited due to various legislative barriers.

The upcoming environmental regulations, e.g.; the EU Taxonomy (EU 2020), Environmental Performance of Buildings Directive, EPBD (EU 2021), and the different national regulations, will set stringent embodied carbon thresholds. Compared to primary steel, reused steel production carbon emissions are significantly lower. The first Environmental Product Declaration, EPD, available for reused section claims Global Warming Potential values for the production stage of reusable steel under 50 kgCO₂e/t (EPD International 2022). Reused steel can therefore become a cost-effective near zero emissions construction material. In addition, the consideration of reuse as the End-of-Life option for primary steel elements provides environmental benefits beyond the current lifecycle. Hence, steel reuse will become a more common practice in the future.

Our survey (Hradil et al. 2014) identified missing legislation and standardization as one of the greatest obstacles to the structural components reuse already in 2014. The situation has

changed since then and new regulations, technical specifications, industry guides and standards were released in support of circular economy of building products, many of them specifically for constructional steel.

The constructional steel products covered by the European harmonization are so-called constituent products (e.g. sections, sheets or bars) and assemblies or specific structural elements fabricated from those constituents (called structural steelwork). The harmonized European Standard EN 1090-2 (CEN 2018) provides requirements for execution of structural steelwork, and since 2018 it allows use of constituent products that are not covered by the relevant harmonized standards if their properties are specified (clause 5.1 of EN 1090-2). This can be interpreted as the possibility to reuse non-CE marked steel products and then provide CE marking of the steelwork according to this standard (Widenoja et al. 2018, Wahlström et al. 2019). The amendment to the new version of EN 1090-2 is being drafted by CEN/TC135 with the rules for quality assessment of used steel sections and fabricated structural components. This will allow manufacturers and reuse operators to declare consistently performance of such products. The testing methodology is based on the testing protocol from PROGRESS project (Pimentel et al. 2020) and on the Swedish guidance for structural steel reuse (MVR 2021).

A new annex to EN 15804 (CEN 2019) was released in 2019 with the rules for calculation of environmental impacts of materials beyond the system boundary when more than one recycling route is used. This is important especially for steel as the part of end-of-life material not suitable for reuse will be always recycled. The methodology is consistent with PEF rules (Eurometaux 2019) and our findings from PROGRESS project (Ungureanu et al. 2019). The complementary rules specific for steel structures were published in 2021 as prEN 17662 (CEN 2021) by CEN/TC 135/WG 17. Declaration of environmental impacts is becoming very important as many European countries are adapting requirements and limits for such impacts in the new construction projects (Kuittinen 2019).

Finally, the designers will receive guidance on the calculation of structural resistance, stability and serviceability of existing load-bearing structures and components in the new generation of the Eurocodes. The technical committee CEN/TC 250/WG 2 published technical specification TS 17440 (CEN, 2020b) with general principles of assessment and retrofitting of existing structures and is currently preparing rules specific for steel structures (CEN 2020a).

2 CONSTRUCTION PRODUCTS REGULATION

The European market of constructional products is regulated since the release of the Construction Products Directive (EU 1989). The purpose of the Directive was to remove technical barriers to trade in construction products between different Member States. It established a system of harmonized technical specifications, attestation of conformity, a framework of notified bodies, CE marking of construction products and list of six essential requirements to be satisfied in order to place the product on the market. The Directive was replaced by the Construction Products Regulation (CPR) in 2011 (EU 2011) which came into full force on 1st July 2013 for the supply of structural steel products. The CPR provides further clarification of the established rules and responsibilities of the actors, introduces the need to issue declaration of performance (DoP) as a basis of CE marking and lists seven essential basic requirements for construction works (BRCWs) based on the essential requirements from the Directive. The new BRCW no. 7 “Sustainable use of natural resources” states that the construction works must be designed, built and demolished to ensure the reuse or recyclability of the construction works, their materials and parts after demolition. Unfortunately, the CPR does not contain any guidance how to declare performance of reused building products in order to place them on the European Union market.

This issue has been addressed in the proposal for a new Construction Product Regulation (EU 2022a) adapted in 2022. The proposal widens the scope of the CPR to reused and 3D-printed products and pre-fabricated single family houses as well as to products not only put on the market, but also those installed in the European Union. Both changes are important for the circular economy of steel products because the products are often reused without placing on EU market (e.g. as a result of direct contract between the parties or internally within

different facilities owned by the same company). The number of BRCWs is extended to eight with hazardous emissions separated from BRCW no. 3 as BRCW no.7 and the sustainable use of natural resources moved to the last position.

2.1 Modified declaration of performance for used, remanufactured and surplus products

The Article 12 of the CPR proposal (EU 2022) lays down conditions for simplified procedure to declare performance of recovered building products from construction, demolition or renovation works if they were previously assessed (and their original DoP is available) or they are going to be used for decoration purposes. Such solution might be attractive in near future when the owners of buildings constructed after 2013 (when CE marking of steel products became compulsory) will strive to reuse steel sections as constituent products or the whole steelwork.

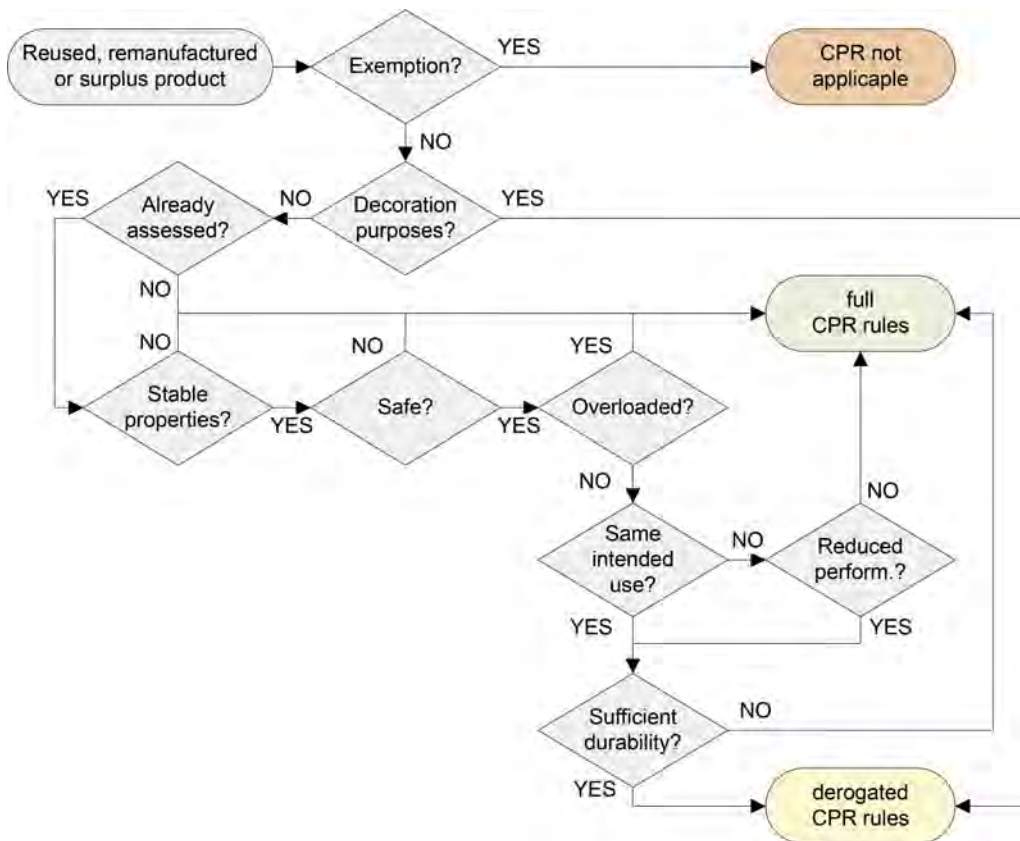

Figure 1. Procedure to reach derogated CPR rules according to the article 12.

To satisfy the requirements for the simplified CPR assessment, the product (constituent product or steelwork) shall fulfill the following criteria (see Figure 2):

- (1) It has been already assessed and its properties are known. The authorities may also require Digital Product Passport according to the Ecodesign Directive (EU 2022b) including appropriate labeling and traceability system (Hradil et al. 2023).
- (2) It has stable properties for the intended new use and is not affected by degradation. In the case of steel, a proper inspection of the coating and corrosion damage should be performed during the pre-deconstruction audit.

- (3) It is safe to use. This means the toxicity of the coatings and integrity of the connections should be checked during the audit. However, the CPR does not specifically allocate the responsibilities on the stability of chemicals and mechanical properties for the new intended use and neither the health and safety considerations that seem to be responsibility for the later user or owner. Moreover, there is not any existing recommendation for weld inspections of reclaimed structural elements.
- (4) It is not overloaded and no plastic deformation is registered. This requirement is in line with the proposed annex to EN 1090-2 (CEN 2018). In particular, the CPR allocates member states the responsibility to define stresses that render the product unsuitable and to demonstrate that the product has not been subjected to such stresses according to the protocol established by the de-installer in accordance with Article 29 and the documentation on the conditions of a certain building, so-called “building log-book” (Hradil et al. 2023).
- (5) It has the same intended use or different use with reduced performance. In our interpretation it means that it is covered by the same harmonized standard as the existing DoP and it is either used in the same building design (including wind, snow and seismic loads) or the reduced performance is confirmed by the corresponding structural calculation according to the Eurocode 3 (CEN 2005).
- (6) It has sufficient durability. Durability is declared in design according to the Eurocode 0 (CEN 2002) and the service life is typically 50 years for buildings. Therefore, the product can be reused with the original design up until the remaining service life or its service life extension has to be supported by the relevant structural checks with possibly modified safety factors and/or additional reinforcement.

2.2 Harmonization of rules for execution of steel structures from reused elements

The reuse of structural steel from existing buildings is currently possible due to clause 5.1 of EN 1090-2. Despite no protocols are defined in the current EN 1090-2 versions, different industry standards are available and the recommendations and testing methodologies from PROGRESS project (Pimentel et al. 2020) and on the Swedish guidance for structural steel reuse (MVR 2021) can be currently followed. Some member states are also working on the development of national standards on steel reuse. However, there is a need for developing a family of harmonized standards at EU level.

CEN/TC 135 has received the mandate to develop a technical standard on the “Reuse of Steel”. The mandate includes Execution Classes 1, 2 and 3. The first version of the standard is expected to be published as an EN 1090-2 Annex and will be likely released during 2024. Based on both PROGRESS project and the MVR 2021 recommendations, the new CEN/TC 135 Technical Standard on steel re-use will for the first time set protocols for the re-qualification of steel within an EN normative

The Technical Standard will provide specific testing protocols for constituent products depending on the date of production and the documentation available. These protocols include a specific protocol for steel manufactured after 1970’s when certificates are available. The protocol is simple and accurate and will likely meet the CPR requirements for the lower execution classes in new buildings. So, member states should adopt this standard and its future developments as reference to define the stresses that render the products unsuitable and how to certify that reclaimed products has not been subjected to stresses that makes it unsuitable for the new intended use.

In addition, this protocol and other included in the TS will provide the necessary tools to enable the re-use of reclaimed steel when DoP are not available.

The first version of the Technical Standard will be limited in scope and will not cover all the stresses that make a reclaimed product unsuitable for the new intended use, but it is expected that future work will extend the different testing protocols in the standard to cover weld inspections, fatigue design or seismic loads covering EXC1, EXC2 and EXC3 fabricated and constituent products.

3 REUSE OF CONSTRUCTIONAL STEEL FROM SINGLE STOREY HALL

The demolition of the year prize in Finland was awarded in 2022 for deconstruction of the steel hall which was fully documented and its structural members were included in the electronic traceability system with RFID tags and cloud-based information database (Hradil et al. 2023) developed and demonstrated in EU ICEBERG project. The demolition area in Lämminpää district of Tampere, Finland contained in total 15 buildings constructed between 1928 and 2016, four of them deconstructed for future reuse (see Figure 2) by the demolition contractor and partner in the project, Purkupiha Group Oy. Purkupiha arranged the standard pre-demolition inspection, developed deconstruction plan and executed the disassembly of the steelwork (see Figure 3), VTT and other partners from ICEBERG project then assisted with additional inspection work such as 3D scanning and installation of RFID tags for the cloud-based traceability system (Hradil et al. 2023).

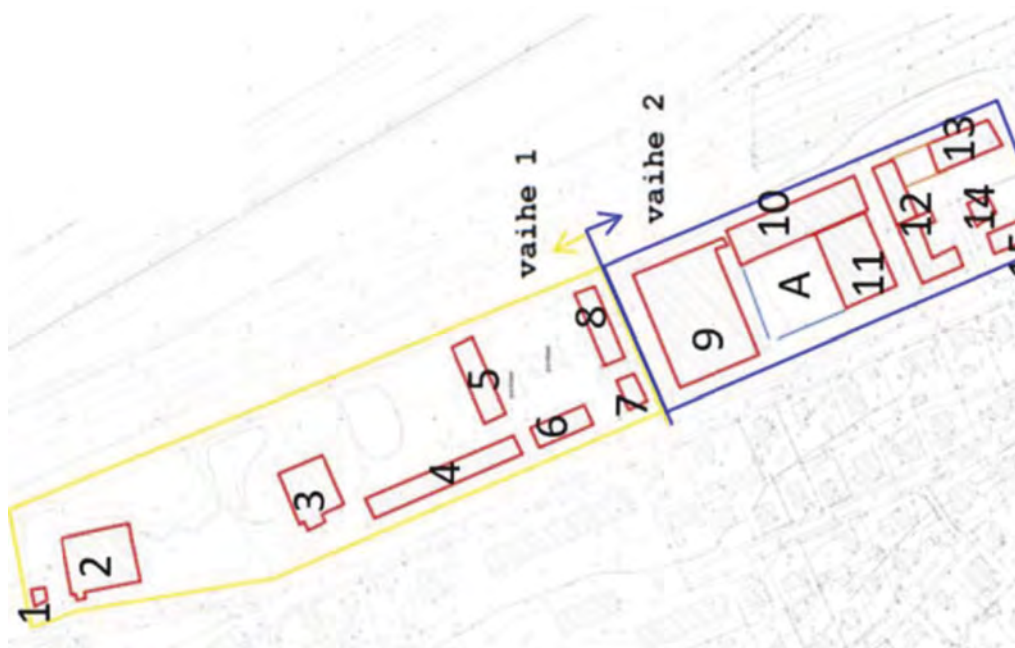

Figure 2. Buildings in the area of Tampere, Lämminpää demolished and deconstructed in two stages (vaihe 1 and 2) in 2022.

The contractor is then arranging a direct sale between the previous and new owner of the building elements. Some of them can be also sold on the company's own online sales platform (Purkupiha Group Oy 2022). We will use this example as a background for several hypothetical case studies to compare current requirements of the existing CPR (EU 2011) and EN 1090-2 (CEN 2018) to the possible future scenarios with the proposed CPR (EU 2022) and annex to EN 1090-2 for reuse of steel sections. The comparative study includes two different steel halls:

- **A:** Old building (typically constructed before 2013 with no CE-marking) without any existing documentation and CE marking,
- **B:** New building (constructed after 2013) with existing design documentation and CE-marking of the individual steel sections according to EN 10025-1 (CEN 2004) and the whole steelwork according to EN 1090-2 (CEN 2018).

Figure 3. Steel hall in Lämminpää district, Tampere, Finland (left) and its deconstruction (right).

The following most common business models in steel reuse (Ungureanu et al. 2020, Sansom et al. 2020) are considered in the study:

- Direct reuse of the whole steelwork when the owner of the building remains the same (typical case of building relocation) or agrees with the new owner directly without putting the deconstructed steelwork on the market,
- Sale of the steelwork when the building is deconstructed and offered for sale for instance on online market such as Purkupiha Group Oy (2022),
- Sale of sections deconstructed and separated from end-plates and other welded attachments for instance following the business model of Cleveland Steel & Tubes Ltd (2022).

The requirements for CE marking and material testing are summarized in Table 1.

Table 1. Comparison of the scenarios with deconstructed old steel hall (A) and new steel hall (B).

Case	Direct reuse		Sale of steelwork		Sale of sections	
	A	B	A	B	A	B
<i>Current requirements (CPR from 2011, EN 1090-2:2018)</i>						
New CE marking of sections	no ¹⁾	no ¹⁾	no ¹⁾	no ¹⁾	no ¹⁾	no ¹⁾
New CE marking of steelwork	no ²⁾	no ²⁾	yes ³⁾	yes ³⁾	-	-
Testing of reclaimed material	not clear ⁴⁾	no	yes ⁵⁾	no	yes ⁵⁾	no
<i>Future requirements (proposed CPR from 2022, EN 1090-2:2018 + annex about reuse)</i>						
New CE marking of sections ¹⁾	Yes ⁶⁾	no ⁷⁾	Yes ⁶⁾	no ⁷⁾	not clear ⁸⁾	no ⁷⁾
New CE marking of steelwork	Yes ⁶⁾	no ⁷⁾	Yes ⁶⁾	no ⁷⁾	-	-
Testing of reclaimed material	yes	no	yes	no	yes	no

- 1) Reused sections are not covered by any harmonized standard
- 2) Products not placed on Union market are not in the scope of the current CPR
- 3) Clause 5.1 of EN 1090-2 allows use of constituents not covered by harmonized standards
- 4) Testing is not required by standards or regulations, but may be required by building authority
- 5) Clause 5.1 of EN 1090-2 requires specification of material properties
- 6) The new CPR covers also products installed in the European Union
- 7) CE marking may be based on the original DoP according to Article 12 of the proposed CPR
- 8) It is not clear if EN 10025-1 will be considered as relevant harmonized standard for reclaimed sections when the testing rules from the proposed annex to EN 1090-2 will come into force

In our study, we identified two situations when the current and planned regulation is not clear about the required procedure:

- (1) The requirements for testing of materials reused directly without CE marking are not specified in any EU regulation or standard, and therefore may be subjected to the decision of

the local building authority. For instance, the building control in Finland may require testing of materials of unknown origin according to the recommendation from the Finnish Ministry of the Environment.

- (2) At the moment the interpretation of the scope of harmonized standard EN 10025-1 (CEN 2004) is that it does not cover reclaimed steel sections (Widenoja et al. 2018, Wahlström et al. 2019) because it does not provide any relevant testing protocol. However, the testing protocol will be described in the annex of EN 1090-2 (CEN 2018), and therefore the future interpretation might be different. In such case, the Clause 5.1 of EN 1090-2 will be irrelevant. It should be noted that the knowledge of material properties is required in any case, and therefore material testing cannot be avoided.

4 SUMMARY AND CONCLUSIONS

The proposed CPR brings additional administrative burden for materials and structures reused directly without putting them on EU market. They will require corresponding DoP according to the harmonized standards. The derogated CPR procedure according to the Article 12 is only relevant to the products with existing assessment (produced after 2013), design documentation and functional product passport with traceability system. Most of the buildings constructed up to date might not qualify for this procedure. However, the implementation of the proposed CPR may not in general cause additional costs for testing of materials.

We acknowledge that the proposed CPR clarifies the certification process of reclaimed structural steel products and lays down rules for improved harmonized standards, but its implementation for the current building stock will be difficult and may create additional barriers for the circular economy before the digital product passports will be in use and the buildings already assessed by the current CPR will come to age and will be subjected to deconstruction and possible reuse.

We recommend that the building authorities in EU Member States adapt rules for building products traceability as soon as possible to be able to approve the conformity of the new declared certification to the corresponding products at the time of their future deconstruction. This will remove the most severe barriers of the proposed CPR to the structural steel (and possibly other materials) reuse.

ACKNOWLEDGEMENTS

The research presented in this paper was supported by the EU project ICEBERG. This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 869336.

ABSTRACT: Upon recognition of the advantages of composite steel-concrete structures, solutions that integrate built-up cold-formed steel sections have become more prevalent in the last few decades. Some of the reasons for the increased interest in composite steel-concrete structures are that components of such systems are easy to manipulate, transport, and erect due to reduced weight. These advantages can be even more significant if the system is designed for demountability, reflecting the environmental impacts at the end-of-life of the system. This paper deals with a cold-formed steel-concrete composite floor system as part of the LWT-FLOOR project at the Faculty of Civil Engineering, University of Zagreb, Croatia. Cold-formed steel elements are built-up beams with back-to-back profiles such as flanges and corrugated webs. Cold-formed steel elements are connected by fast and productive spot-welding technology, while composite action between steel and concrete is realised through innovative demountable shear connections with structural bolts. The LWT-FLOOR system has numerous potential benefits, which will be investigated through experimental, numerical research with the support of probabilistic methods and, of course, life cycle analyses. This paper presents a practical application of integrating environmental impacts associated with the mentioned LWT-FLOOR system and the traditional composite structural floor system with hot-rolled steel beams. A comparative Life Cycle Assessment (LCA) of structural composite steel-concrete floor systems along with a Life Cycle Cost (LCC) are given. Impact analyses at different levels such as production and end-of-life were performed. This research reflects what makes a sustainable design with an example of a cold-formed steel-concrete composite system, which addresses the need for improved awareness of materials.

1 INTRODUCTION

The interaction between steel and concrete has been widely used in structural engineering due to the multiple benefits that result from combining the desirable mechanical properties of each material. The advantages of structural steel are high tensile strength and ductility, while concrete ones are high stiffness and high compressive strength (Androić et al. 2012). In recent years, different solutions with cold-formed steel elements and lightweight concrete were investigated to find better behaviour over traditional solutions with hot-rolled steel elements and concrete slabs (Lukačević et al. 2022).

Based on built-up cold-formed steel beams with corrugated web, which show excellent behaviour throughout experimental (Benzar et al. 2015; Ungureanu et al. 2018b, 2018a) and numerical research (Ungureanu et al. 2021, 2019b, 2019a), it was possible to develop a new composite floor

system with the integration of concrete slab over built-up steel elements. LWT-FLOOR system represents innovation that maximises the values of each building component and used materials. This system has been investigated within the research project LWT-FLOOR at the University of Zagreb, Faculty of Civil Engineering, Croatia (Lukačević et al. 2022).

The proposed structural system is formed of built-up cold-formed steel beams and cast-in-place concrete slabs that are interconnected using an innovative type of shear connection.

The LWT-FLOOR project integrates fast and productive spot welding technology and innovative cold-formed steel-concrete composite solutions proposing a new construction method as a combination of built-up cold-formed steel members and cast-in-place concrete slab. This potentially cost-effective and sustainable floor system could offer vital benefits in a high degree of prefabrication, reusability, and suitability for larger spans. The LWT-FLOOR system has numerous potential benefits, which will be investigated through experimental, numerical research with the support of probabilistic methods and of life cycle analyses.

This paper presents a practical application of integrating environmental impacts associated with the LWT-FLOOR system mentioned and the traditional composite structural flooring system with hot-rolled steel beams. A comparative Life Cycle Assessment (LCA) of the structural composite steel-concrete floor system and traditional beam systems along with a Life Cycle Cost (LCC) was performed. The environmental impact analyses were carried out for different levels, such as production and end-of-life stages. This research reflects what makes a sustainable design with an example of a cold-formed steel-concrete composite system, which addresses the need for improved awareness of materials.

2 COMPARISON OF LWT-FLOOR SYSTEM WITH TRADITIONAL SYSTEMS

2.1 General

Considering the benefits of applying cold-formed steel (CFS) profiles in structures, the comparison of LWT-FLOOR steel cross-sections and traditional hot-rolled cross-sections is shown. LWT-FLOOR steel cross-section is formed of four C profiles connected in one unit with a corrugated web, and the beam is reinforced at the ends with shear plates. To make an appropriate comparison with the traditional system with hot-rolled sections, several criteria are observed:

- steel beam height, h ,
- cross-sectional area, A ,
- moment of inertia, I_y ,
- steel beam mass, m .

Based on the mentioned criteria, the profiles with the same or similar characteristics were searched among hot-rolled sections.

Analysed LWT-FLOOR steel cross-section has an overall height of 400 mm, and the length of the beam is 6 m. The steel beam is built-up of four C profiles whose height is 120 mm and the thickness is 2.5 mm. The mass of each profile is 4.61 kg/m, and the cross-sectional area is 600 mm² for each profile. All four cold-formed C120/2.5 profiles have a mass of 110.64 kg and a cross-sectional area of 2400 mm².

Considering that the corrugated web is not extended from end-to-end of the beam, its length is 5622 mm (unfold length is 6783 mm). The thickness of the analysed corrugated web is 1.0 mm, and the height is 400 mm. All mentioned leads to the corrugated web mass of 21.3 kg.

Four shear plates that reinforced the LWT-FLOOR steel beam are 400 mm high and 870 mm long. The thickness of shear plates is 1.0 mm. The mass of all four shear plates is 10.9 kg.

Based on mentioned geometry and arrangement of steel elements in the cross-section, the moment of inertia for the LWT-FLOOR steel beam is calculated with a value of 5063.7×10⁴ mm⁴. Based on this value, the hot-rolled profile will be searched for the same/similar moment of inertia criterion. Considering that cold-formed steel profiles are usually class 3 or 4, effective W_y values will be used to calculate the beam's bending resistance. In the following sections, a comparison based on mentioned criteria is shown. All steel elements are steel grade S350 GD.

2.2 Steel beam height and cross-sectional area

The height of the LWT-FLOOR steel beam is 400 mm. The same height has a hot-rolled steel profile IPE 400. The sectional area of IPE 400 is 1643 mm^2 , and the mass is 66.3 kg/m . This means that the steel beam IPE 400, with a length of 6 m, has a mass of 397.8 kg . The moment of inertia of IPE 400 is $23130 \times 10^4 \text{ mm}^4$.

In Figure 1a), the comparison between the LWT-FLOOR steel beam and IPE 400 is shown based on the same steel beam height. Based on shown values in Figure 1a), it is possible to see that the LWT-FLOOR steel beam has approximately four times reduced mass, cross-sectional area and moment of inertia.

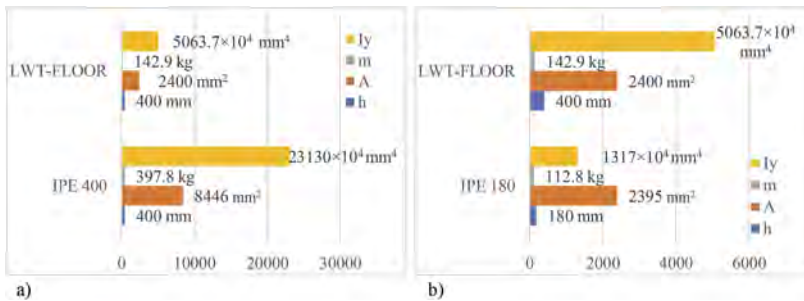

Figure 1. Comparison of beams a) with same steel beam height and b) with a similar cross-sectional area.

Considering the cross-sectional area of the LWT-FLOOR steel beam, the hot-rolled profile, IPE 180, which has a similar value of the cross-sectional area as the LWT-FLOOR steel beam, is chosen. The cross-sectional area of the LWT-FLOOR steel beam is 2400 mm^2 , while that of IPE 180 is 2395 mm^2 . The difference is negligible. The total mass of the IPE 180 beam is 112.8 kg , while the moment of inertia is $1317 \times 10^4 \text{ mm}^4$.

In Figure 1b), the comparison between the LWT-FLOOR steel beam and IPE 180 is shown based on a similar cross-sectional area. In Figure 1b), it is shown how beams with a similar cross-sectional area can have a height difference of up to 50%. Also, it is possible to see how a beam with a similar cross-sectional area can significantly differ in the moment of inertia.

2.3 Moment of inertia and steel beam mass

Considering the criterion of the moment of inertia, the LWT-FLOOR steel beam is compared with two hot-rolled profiles: IPE 240 and IPE 270. Mentioned profiles are chosen because the value of the moment of inertia of the LWT-FLOOR steel beam is in the range of moments of inertia of IPE 240 and IPE 270. The values and comparison of all other criteria for mentioned profiles are shown in Figure 2a).

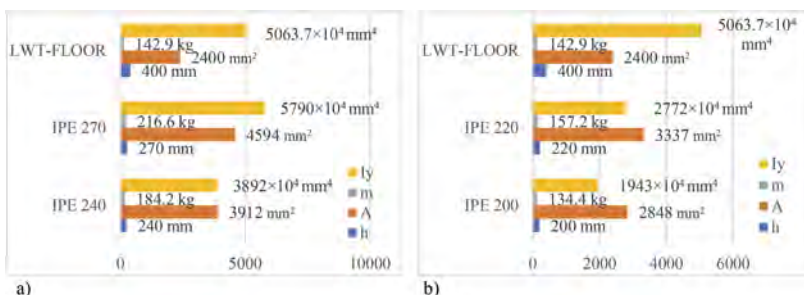

Figure 2. Comparison of beams a) with a similar moment of inertia and b) with a similar mass.

In Figure 2a), it is shown how beams, despite the similarity in a moment of inertia, have different cross-sectional areas. Also, the LWT-FLOOR beam has reduced mass compared to IPE 240 and IPE 270. On the other side, the height of the LWT-FLOOR beam is greater than it is for chosen hot-rolled profiles.

Based on the mass similarity, the profiles compared with the LWT-FLOOR beam are IPE 200 and IPE 220. These two profiles are compared because the value of the mass of the LWT-FLOOR beam is between the masses of IPE 200 and IPE 220. The comparison is shown in Figure 2b).

Figure 2b) shows a comparison of the LWT-FLOOR beam with two other steel beams composed of hot-rolled sections with the same mass. It is possible to see how steel beam height can be doubled for a similar value of mass and have a greater moment of inertia which will be important for the bending resistance of the beam. Furthermore, the LWT-FLOOR steel beam has a greater height, but a lower cross-sectional area compared to sections IPE 200 and IPE 220.

2.4 Bending resistances of analysed beams

In order to improve the application of the LWT-FLOOR beam, the bending resistance between different composite steel-concrete beams is compared. In previous paragraphs, the comparison between steel beams is shown. Now, the metal deck and concrete slab are positioned on each mentioned beam. For establishing the shear connection, bolts M12 with a height of 85 mm and quality 8.8 are used. The overall height of the concrete slab is 120 mm, and the used concrete class is C25/30. The height of the metal deck rib is 60 mm. The axial distance of metal sheet ribs in the longitudinal direction is 240 mm. The effective width of the concrete slab is 1500 mm. The LWT-FLOOR beam is designed as simply supported.

After creating composite beams, the calculation of bending resistances for full shear connection and in the case when shear connectors are positioned in pairs is shown. It is necessary to emphasise that for calculating the bending resistance of the composite LWT-FLOOR beam, the effective moment resistance, $W_{y,eff}$ is used because of the slender cross sections.

Figure 3 shows the comparison of bending resistances for full shear connection and when shear connectors are positioned in pairs.

Figure 3. Bending resistance for composite steel-concrete beams.

It is very important to say that a full shear connection is not possible to achieve by arranging the shear connectors because the ribs of the metal deck determine the arrangement of shear connectors. Full shear connection is possible only by tie constraint in the numerical model, which will eliminate the slip between steel and concrete elements. For that reason, only the case when shear connectors are arranged in pairs will be discussed. Also, the longitudinal distance between bolts is defined by the axial distance of metal deck ribs and amounts to 240 mm. At the analysed shear length, nine bolt pairs are positioned, and an equal number of bolt pairs are positioned on every analysed beam.

Considering that position of the neutral axis for composite beam IPE 400 is in the steel part of the composite section, the bending resistance for the mentioned beam is calculated with W_y ,

while for other composite beams made of hot-rolled steel profiles $W_{y,pl}$ is used because the neutral axis is in the concrete slab. The bending resistance for the LWT-FLOOR beam is calculated as it is explained in the paper (Lukačević et al. 2022). Based on the results shown in Figure 3, it is concluded that the LWT-FLOOR beam has very good bending resistance among all analysed composite beams. IPE 400 beam has the greatest bending resistance, as expected. LWT-FLOOR composite beam has a bending resistance similar to IPE 240. Another beam with higher resistance than the LWT-FLOOR beam is IPE 270. Taking into account the cross-sectional area and weight of beams that have greater bending resistance than the LWT-FLOOR beam, it is concluded that mentioned beams have greater cross-sectional area than the LWT-FLOOR beam, which also leads to greater mass. Considering all mentioned, the LWT-FLOOR beam can be considered as a potentially good candidate for buildings of business or residential purposes. The next section will provide the LCA analysis results, which will show the environmental impact of the proposed LWT-FLOOR system compared to the traditional steel-concrete composite floor systems previously analysed in this paper.

3 LIFE CYCLE ASSESSMENT

The LCA carried out presents the environmental impact of each composite floor system discussed earlier in the paper, from cradle-to-gate with modules C and D. In the analysis was considered the Production stage phases (A1, A2, A3) and End-of-life (C1, C2, C3, C4), in conjunction with Potential environmental loads and benefits (D), under EN 15643-1:2012 and EN 15804:2012+A2:2019, using GaBi database and LCA software (Sphera Solutions GmbH 2021). The declared unit in the analysis is one composite floor system with a length of 6000 mm.

In the production stage (modules A1-A3) it was considered the extraction and processing of raw materials, as well as energy consumption, the transportation of the raw materials to the manufacturers or to the ready-mix plant (the model includes road transportation of each raw material using Euro 5 articulated lorries transport (16 t payload capacity), the manufacture of products, packaging, the energy consumption and the waste generated at the production plants, the water during the concrete manufacturing process.

In a normal-use scenario, we assumed that no maintenance (B2), repair (B3), replacement (B4), nor refurbishment (B5) is needed. Therefore, the assessment does not specify values for module B.

In this assessment, the end-of-life scenario for each one of the seven composite floor systems studied involved an instance of “demolition and recycling”. Module C1 includes the use of diesel fuel used by work machines during the demolition process, and module C2 includes the transport to waste processing (a conservative assumption of 50 km by lorry 16t payload capacity was used). For modules C3 and C4, the scenarios included are representative of one of the most probable alternatives: 90% of steel is transformed into secondary material in a recycling plant (based on the European average), and 10% of the steel is assumed to be landfilled while the concrete is 50% recycled and 50% landfilled.

Module D reflects the avoided burdens considering the potential recycling of the construction materials after the end-of-life stage of the composite floor systems. The scrap content in the steel components (steel profiles, corrugated steel sheet, bolts) has been acknowledged. Only the mass of primary steel in the components was considered to provide a benefit to avoid double counting. For the concrete, the avoided product is considered crushed aggregate.

4 RESULTS OF LCA AND ECONOMIC IMPACT

This paper presents a practical application of integrating environmental impacts associated with the LWT-FLOOR system mentioned and the traditional composite structural flooring system with hot-rolled steel beams. The research reflects the benefits of a sustainable design with an example of a cold-formed steel-concrete composite system, which addresses the need for improved awareness of materials.

Tables 1, 2, and 3 outline the greenhouse gas (GHG) emissions for each case scenario. As the results show (see Table 1), in the production stage (A1-A3), the emissions reflected by the Global

Warming Potential-total (GWP-total) indicator are up to 34% smaller when LWT-FLOOR is used in comparison with the traditional steel-concrete composite floor systems based on the IPE 220 - IPE 400 steel beams. Only the steel-concrete composite floor systems based on beams with a similar cross-sectional area (IPE 180) and on beams with a similar moment of inertia (IPE 200) record smaller emissions in the GWP-total, in the production stage, than the LWT-FLOOR.

For the end-of-life stage (C1-C3), the results show (see Table 2) that the emissions in the GWP-total are all smaller with 9-19% for the traditional steel-concrete composite floor systems based on hot-rolled steel profiles than the LWT-FLOOR, except for the steel-concrete composite floor system based on the IPE400 steel beam, which indicated 10.46% more emissions in the GWP-total than the LWT-FLOOR.

Table 3 shows the potential benefits and loads beyond the system boundaries reflected by each type of composite floor system analysed through the considered recycle scenario of the LCA. The LCA potential savings are reflected as negative values, while positive values define potential burdens of material utilisation.

For the GWP-total indicator, the results show that beyond the system boundary, in the scenario where LWT-FLOOR is used, the potential savings are 83%-141% higher than in the scenarios where traditional steel-concrete composite floor systems were considered. Figure 4a) shows the total LCA results of the scenarios in terms of GWP - total, including loads and benefits beyond the system boundary.

Table 3. LCA results for the potential environmental benefits of the assumed scenarios.

For the economic impact of the assessed steel-concrete composite floor systems, it was considered the financial cost of the analysed scenarios associated with the Production stage. The prices considered in the analysis represent the prices of construction materials listed on the Romanian market in December 2022 and do not include VAT. Figure 4b) shows the total production cost of each scenario, in terms of euro+VAT/steel-concrete composite floor considered in the analysis previously presented in the paper.

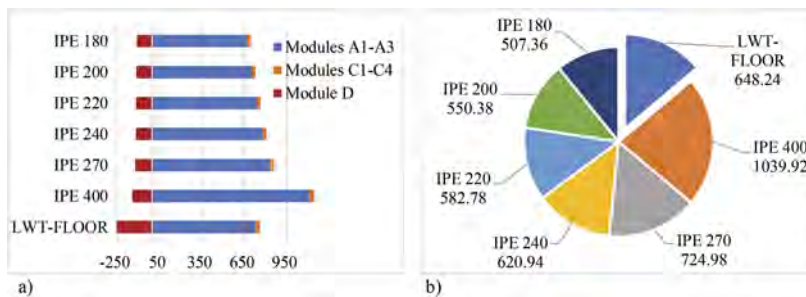

Figure 4. Total LCA results and production costs of the steel-concrete composite floor systems a) environmental impact: GWP - Total [kg CO2 e] and b) production cost [Euro + VAT].

As the results of the economic impact show, in the production stage (A1-A3), the costs of the LWT-FLOOR are above the costs of the production of the traditional steel-concrete composite floor systems based on the IPE 180 - IPE 240 steel beams, but with 37.6% smaller than the solution based on IPE 400 steel beam.

5 CONCLUSIONS

The present assessment considered different case studies of steel-concrete composite floor systems based on hot-rolled beams and the LWT-FLOOR system, an innovative

demountable composite floor system developed at the University of Zagreb, Faculty of Civil Engineering, Croatia.

The system is based on cold-formed steel elements, which are built-up beams with back-to-back channel profiles and corrugated web, connected by spot-welding technology and cast-in-place concrete slabs that are interconnected using an innovative type of shear connection.

In the first part of the paper, by comparing the geometrical characteristics of different composite beam configurations, it is concluded that the LWT-FLOOR beam has good bending resistance with low material consumption.

The LCA and LCC assessment in the second part of the paper focused on the structural feasibility, environmental benefits, and economic savings of the LWT-FLOOR system set side by side with the traditional steel-concrete composite floor systems. The results showed that in the production stage, the environmental impact (reflected by the GWP-total indicator) is up to 34% smaller when LWT-FLOOR is used in comparison with the traditional steel-concrete composite floor systems based on the IPE 220 - IPE 400 steel beams, while the costs of it are smaller with 10-37% compared to steel-concrete composite floor systems based on the IPE 270 - IPE 400.

On the other hand, in terms of environmental impact, the GWP-total indicator shows that the potential savings by recycling the materials at the end-of-life of the composite floor systems are 83%-141% higher in the scenario where LWT-FLOOR is used than in the scenarios where traditional steel-concrete composite floor systems were studied.

ACKNOWLEDGEMENTS

This research was partially funded by the Croatian Science Foundation, grant number UIP-2020-02-2964 (LWT-FLOOR project - Innovative lightweight cold-formed steel-concrete composite floor system), project leader: Ivan Lukačević and by a grant of the Romanian Ministry of Research and Innovation, CCCDI-UEFISCDI, project number PN-III-P2-2.1-PTE-2021-0237-Wellformed-Frames.

Politehnica University of Timisoara, Timisoara, Romania

ABSTRACT: In the first part of the paper, three examples of sustainable mixed building technologies are presented, which, for the main frame, combine cold-formed with hot-rolled steel sections, using timber for floor joists and cladding studs. In the second part of the paper, two examples of single-family houses made of cold-formed steel wall studs sheathed with OSB are detailed. The buildings are located in moderate seismic regions. The paper presents aspects related to design and detailing, including aspects of structural features. For structural design, a prescriptive method was applied, based on the test results on full-scale shear wall panels made of cold-formed steel profiles and OSB panels, under monotonic and cyclic loads. The results of life-cycle analyses of these constructions, compared with various traditional solutions, are also presented.

1 INTRODUCTION

In recent years, users, architects, and engineers have all been searching for the most economical building systems for dwellings. In this context, steel-framed houses have become a choice in many European countries, including Romania. The mechanical properties and lightweight of cold-formed steel profiles make them suitable for use in areas with low and moderate seismic risk. That is the reason why the new European Design Code for Seismic Resistant Buildings - Eurocode 8, still in the inquiry phase, has explicitly included design provisions for such structures (Landolfo et al. 2022). Light steel frame (LSF) structures of thin-walled cold-formed steel (TWCFS) wall studs and joisted floors are gaining growing popularity in modern construction practise worldwide, both in new developments and as a cost-effective and low-carbon solution for the vertical extension of existing buildings. The ease of off-site manufacturing using LSF structures offers many benefits compared to traditional methods, including: (a) improved quality and productivity, reduced material use, less waste, and savings of 30-50% in total construction time and associated costs; (b) flexibility for more customised design solutions complying with the Design for Manufacture and Assembly approach; and (c) scalability of automation technologies in the construction industry.

However, the current use of LSF structural systems is limited due to critical drawbacks such as the low local buckling resistance of TWCFS elements, the low lateral stiffness, and robustness of typical LSF systems and the limitations of current design and optimisation approaches to exploit their full capacity. Mixed technologies, also called hybrid construction, combine thin-walled cold-formed steel profiles with thicker hot-rolled steel profiles and/or with timber, to increase the stiffness and resistance, in the end improving the robustness and durability of building structures (Mortazavi et al. 2018). Lightweight cold-formed composite steel-concrete structural systems have continuously been increasing within the field of structural engineering due to efficient material usage, particularly noticeable when using cold-formed built-up sections and the innovative types of shear connections (Lukačević et al. 2022).

Compared with ordinary steel moment resisting frames or with cold-formed steel wall stud systems, the economic assessment demonstrates that hybrid framed structures can save up to

23% in framing costs. On the other hand, hybrid framed structures can lead to less environmental impact than previous two systems (Usefi et al. 2021). These buildings have great potential for prefabrication, making hybrid framed structures a better option with respect to many social compact indicators such as noise, air, vibration and dust pollution and traffic.

2 EXAMPLES OF RESIDENTIAL BUILDING HYBRID STRUCTURES

2.1 *Urban villa*

The structure is a block of flats built in 2007 in Timisoara, a moderate seismic zone, with a temperate continental climate, in Romania (Ungureanu et al. 2011a). The keys to this kind of structure are built-in flexibility and energy efficiency. The main structure is made of steel profiles with light floors. Column-free and free floor slabs were the optimum answer to allow users to optimally reconfigure internal areas and this generally means long-span solutions. Some innovative design solutions have been used in this project, i.e. thermo-energetic cladding system, gas-electric energy supply system etc. Several types of cladding systems have been analysed, and for the chosen solution, data related to the performance of the cladding system have been collected during the 2008/2009 autumn/winter season. Figure 1 presents architectural views, the structure during erection, and the final view of the building.

Figure 1. Urban Villa. Hybrid structure: hot-rolled steel main frame, cold-formed steel wall-studs, cladding and OSB shear panels, light concrete composite floor slabs.

An intensive study has been carried out to choose the correct cladding solution (Mutiu 2011). Given the wide variations in seasonal temperature levels, as described above, and the cumulative effects of (1) overheating of the south and west facades in summer and (2) heat loss due to the effect of the wind chill on the north/northwest sides of the facade in winter, special attention was paid first of all to passive energy savings measures. Consequently, the envelope design was directed to achieve three main objectives: (1) to minimize heat loss through the envelope; (2) to ensure high levels of physical wellbeing; (3) to equip the building with an energy saving heating system.

2.2 *Traditional family house*

This is a single-family private house built in 2006 in Timisoara, Romania. The main structure is made of steel profiles, while the floor and roof are made of timber elements. The building combines modern and traditional materials and techniques (see Figure 2) to obtain a typical Transylvanian village house (Mutiu 2011).

Figure 2. Traditional family house. Hybrid structure: hot-rolled steel for the main steel skeleton, timber rafters, supporting floor and roof, and timber wall stud claddings.

2.3 Modern family house

This single-family private house, with courageous architecture, was built in 2010 in Resita, South-West of Romania, in a low seismic but quite windy zone. Architectural and structure views during construction are presented in Figure 3 (Mutiu 2011). In terms of flexibility in layout, the use of hot-rolled steel framing presents several advantages, such as longer spans and large wall openings.

In addition, architectural expression can be pushed to the limit through cantilevers and roof overhangs. To support an envelope, a secondary structural system (wall structure) is required. Such structures are usually made of lightweight studs and constitute the frame on which the successive envelope layers are fastened. Extended use of OSBs on the upper floors provides stiffness and high shear strength, allowing them to behave as rigid boxes (see Figure 3).

Figure 3. Modern family house. Hybrid structure: hot-rolled steel for the main frame, OSB-sheathed cold-formed steel wall studs, composite light concrete and cold-formed steel trapezoidal sheeting.

3 CASE STUDY

3.1 Sustainable detached family house

The first case study presents an innovative structure-envelope solution, enabling flexible floor plan and modular construction, faster fabrication and erection times and high solution diversity for flooring and envelope (Dubina et al. 2010). The architectural concept is based on the development of a rectangular footprint of 5.60 m × 13.40 m, which gives a first module of 75 m², for a one-level unit. The dwelling is a two-storey building, with a terrace roof, with a gross built area of 150 m² and a usable area of 124.41 m². Figure 4 presents the 3D view of the house. A further development of the house is possible by adding a new module by horizontal addition, extending in this way the living area.

Figure 4. 3D view of the house: (a) architectural layout; (b) structural layout.

The proposed construction system, as shown in Figure 4, consists of: (1) hot-rolled steel framed structure; (2) secondary structure is composed of cold-formed steel studs (or wood studs); (3) various envelope systems; (4) floor structure - light concrete topping on trapezoidal steel deck; (5) double-glazed loggias with PVC or aluminium frames; (6) foundations and slab/cast in place reinforced concrete; (7) terrace roof or pitched roof. The achievement of thermo-energetic efficiency was another goal set by the design team. Several factors were considered: (1) indoor temperature and air quality; (2) thermal insulation; (3) moisture protection; (3) different heating and cooling systems; (4) passive ventilation and shading; (5) glazed terraces act as a buffer zone; (6) skylights will be used to improve cross ventilation for the one-level house.

The main steel structure is a two-storey portal frame structure in the transverse direction, while longitudinal shear walls are used to resist horizontal forces from the wind and earthquake. The columns are made of hot-rolled steel profiles and are rigid at the base in the transverse direction and pinned in the longitudinal direction. The transversal girders are made of hot-rolled steel profiles with semi-rigid beam-to-column connections, while the longitudinal girders are pin-ended. To take over horizontal longitudinal loads, shear walls made of cold-formed steel studs sheathed with 10 mm OSB on both sides are used.

The structure is designed considering the climatic and seismic conditions of the city of Timisoara, Romania. The loads used for the design of the structure are taken according to Romanian codes, aligned with the relevant Eurocodes. To control floor vibrations, a deflection of $L/350$ was considered reasonable for a family house. In terms of seismic response, the performance of the shear walls is crucial. The results of the full-scale wall panels test, made with a cold-formed wall-stud skeleton and different cladding arrangements, commonly used in residential buildings, tested at the Politehnica University of Timisoara (Dubina et al. 2010), have been used as reference values to check the available shear strength of walls.

The shear resistance of cold-formed steel wall stud panel specimens sheathed with 10 mm OSB under cyclic loads was found to be 69844 N, as shown in Figure 5 (Dubina et al. 2010). For a panel length of 3.6 m, this leads to a value of 19.40 kN/m.

Based on experimental results, a very simple method can be applied to calculate the efficiency of shear wall panels. Due to the fact that the structure is very regular, with planes of symmetry on both axes and distinct load path, the analysis can be divided following the two principal directions, i.e. transversal and longitudinal ones. In the transverse direction, the seismic action is resisted by the portal frames, while longitudinally by the shear walls. Finally, the lengths of walls necessary to provide the shear capacity were calculated.

The design approach also included information about the environmental impact of the building (Dubina et al. 2010). For this purpose, the next step in design is a comparative life-cycle analysis of the house described above for various solutions.

Figure 5. Design assisted by testing. Experimental curves for wall panels sheathed with OSB.

For this purpose, the building was designed in four different solutions, each of them having its own structural system, as follows: (1) hot-rolled steel framing, the innovative structure; (2) cold-formed steel framing; (3) wood framing and (4) masonry. *Hot-rolled steel frames*: moment resisting frames in transversal directions, while in longitudinal direction the structure is stiffened by cold-formed shear walls sheathed with OSB. The floor structure is made of light concrete topping on a trapezoidal steel deck. The infrastructure is made up of an isolated foundation connected to the foundation beams. *Cold-formed steel framing structure*. In this case, the construction system consisted of: (1) isolated foundations under columns linked by foundation beams and a concrete floor slab; (2) cold-formed steel profiles for the framed skeleton structure (C150 cold-formed sections); (3) secondary structure made of cold-formed steel studs (C150 profiles spaced at 600 mm) on which OSB is laid interior and exterior, in order to stiffen the steel framing for lateral loads, including wind and seismic loads; (4) floor structure made of OSB on trapezoidal steel deck; (5) envelope system and double-glazed loggias with aluminium frames; (6) flat roof (thermal and hydro-insulations) laid on trapezoidal steel sheeting. *Wood framing structure*, which is carried out on the same principle as the cold-formed system. In this case, the wood skeleton extends to the roof. The secondary structure and envelope are built on the same principle as in the case of the cold-formed house. *Masonry structure*. This is the classic

Romanian solution of dwelling, with 25 cm thick hollow brick walls and thermal insulation of polystyrene. The infrastructure system is ensured by continuous foundations under the walls and a solid concrete slab. The flooring and roof are also a 13 cm reinforced concrete slab.

Besides the life-cycle analysis at the level of structural skeletons, studies regarding the cladding solution, versatility and adaptability on the four structural skeletons are integrated. Several aspects are presented in turn, in order to underline the impact for different stages during the life-cycle: (a) construction stage only; (b) construction stage and final disposal of materials; (c) construction stage, disposal and maintenance. Figure 6 presents the scoring of all stages of the life-cycle of buildings (single score) as a direct sum of the construction stage, the maintenance of the building for a 50-year service life period of and the disposal at the end-of-life for the constitutive materials.

Figure 6. LC comparison on environmental impact for construction, including maintenance and end-of-life.

In a single score analysis and considering the boundary conditions, i.e. all identical components are left out of the comparison (see Dubina et al. 2010), the steel houses (6096 and 6481 eco-points, respectively) present an important advantage in front of masonry house (7192 eco-points), while the score for the wood house is about the average value corresponding to the impact of the other three solutions. Of course, many parameters (such as national or regional peculiarities, climatic zones, or distance from the material distributors) can affect these results. From this point of view, one has to observe the trends and not the values given by the analyses.

In addition to this, the following advantages of this structural system can be underlined: (1) functional and aesthetic architecture; (2) modularity and adaptability; (3) improved structural performance, particularly for seismic action; (4) cost-effective.

The analyses performed show the following aspects: (1) steel framing solutions (both hot-rolled and cold-formed framings) represent a good alternative to the classic masonry house, both from safety and sustainability points of view; (2) all framing solutions present a better environmental impact for construction stage and life-cycle analyses on building materials compared to the classic masonry house; (3) the maintenance process of steel and wood solutions is more complex than that of a masonry house. Furthermore, it could be easily observed that maintenance plays a major role in terms of environmental impact.

3.2 *TWCFS shear wall studs OSB-sheathed family house*

The structure for this single-family house was built in 2005 in Ploiesti (Ungureanu et al. 2011b), in a zone of higher seismic risk ($a_g = 0.35g$). There are two main characteristics of the built house, namely the lightweight-steel framing and the architectural solution constrained by the shape of the site (see Figure 7). From an architectural point of view, the main challenge of the project was to fit this private house on an irregularly shaped lot of only 168 m². The resulting cube-shaped building was measured at the end of 84 m² of built area on each of the two floors.

Due to the proximity of the buildings on adjacent properties, the next difficulty consisted of finding the balance between the right amounts of views, natural light, and privacy. Because the building seats in the property limit, it was impossible to provide window openings on that side. This was also one of the reasons for the roof to have a single slope, the height of the building ranging from 9 to 10.5 m. Each floor has approximately 2.75 m height with a roof slope of 30°. Two skylights located above the staircase and the hallway were placed to provide a light shaft to enhance the centre.

Figure 7. (a) 3D view of the house; (b) steel skeleton; (c) skeleton with structural OSB sheathing.

The structural skeleton is made of light-gauge C-shaped profiles (C150/1.5) spaced at intervals of 600 mm, with a thickness of 1.5 mm, fixed with self-drilling screws of 4.8 mm diameter (see Figure 7b). The height of the cross-section of profiles is 150 mm, which governed the thickness of the walls. To withstand horizontal actions and to provide stiffness and strength, the walls were stiffened with 12 mm thick OSB provided on both sides of the structural walls (see Figure 7c).

The load bearing beams in the slab are C200/1.5 profiles disposed at 600 mm intervals, this distribution resulting from the condition of controlling the vibrations of the floor rather than from strength conditions. Roof purlins were obtained as Z150/1.5 profiles spaced at 1200 mm intervals.

The floor diaphragms were designed to be based on the same principle of covering with OSB. No concrete was used on the slab. The isolated foundations under the columns were connected by foundation beams. The floor at ground level (a 10 cm concrete slab) was carried out over a dense soil bed and a layer of compacted gravel.

In terms of seismic response, the methodology presented in Section 3.1 was applied, in which full-scale shear wall panels made with a cold-formed wall stud skeleton and different cladding arrangements were tested (Ungureanu et al. 2011b). On the basis of experimental results, the methodology presented above can be applied to calculate the efficiency of shear wall panels, the structure being divided in two principal directions, i.e. transversal and longitudinal ones. Finally, the length of walls necessary to provide the shear capacity were calculated.

For 3D analysis, the rigidity induced by the sheathing has been replaced by equivalent cross bracings and considering the frame to be pinned. Rigidity criteria and test results on wall specimens have been used to calibrate the area of equivalent braces. The structure is subjected to torsion during an earthquake because some walls are fully sheathed, while others accommodate all the openings. The maximum shear force in this wall was 43 kN (12.8 kN/1m).

The total length of the shear wall panels that compose the analysed TWCFS structure, for the ground and first floors, both in the transverse (TV) and longitudinal (LG) direction are: (1) for the transverse direction, ground floor 21.55 m and first floor 17.12 m; (2) for the longitudinal direction, ground floor 17.22 m and first floor 12.42 m.

The masses were calculated from the earthquake combinations ($1 \times$ self weight + $0.4 \times$ live load + $0.4 \times$ snow load) according to Romanian standards. The first three vibration modes of the structure have been simulated using FE analysis, and the corresponding periods of vibration are the following: $T_1 = 0.38$ s, $T_2 = 0.35$ s and $T_3 = 0.26$ s.

In a first step, the total mass of the structure is evaluated, at the level of the first floor and at the roof level, taking into account the loads and safety coefficients considered for the special combination of seismic action:

$$\sum_{j=1}^n G_{k,j} + \gamma_I A_{E,k} + \sum_{i=2}^m \psi_{2,i} Q_{k,i} \quad (1)$$

where: $A_{E,k}$ – characteristic value of seismic action; $\psi_{0,i}$ – factor for combination value of the variable action i ; Q_i – 0.4 for snow load and live load.

It results: (i) the total mass at the floor level $M_{\text{floor}} = 23.07$ t and (ii) the total mass at the roof level $M_{\text{roof}} = 11.71$ t. Accordingly, the total seismic force applied to the structure is:

$$S_e(T) = \gamma_I \cdot a_g \cdot \beta(T) \cdot g \cdot M = 1 \cdot 0.28 \cdot 2.75 \cdot 9.81 \cdot (23.07 + 11.71) = 262.72\text{kN} \quad (2)$$

Considering that the deformation is linear in terms of height, the horizontal load is distributed to both levels as follows:

$$S_1 = S_r \cdot \frac{z_1 \cdot G_1}{\sum (z_j \cdot G_j)} = 262.72 \cdot \frac{3 \cdot 23.07}{(3 \cdot 23.07 + 7 \cdot 11.71)} = 120.27\text{kN}$$

$$S_2 = S_r \cdot \frac{z_2 \cdot G_2}{\sum (z_j \cdot G_j)} = 262.72 \cdot \frac{7 \cdot 11.71}{(3 \cdot 23.07 + 7 \cdot 11.71)} = 142.45\text{kN} \quad (3)$$

The total seismic force corresponding to both levels are:

$$T_{ground\ floor} = S_1 + S_2 = 262.72\text{kN} \text{ and } T_{first\ floor} = S_2 = 142.45\text{kN} \quad (4)$$

Based on experimental work, for the analysed shear wall panels, the shear capacity under cyclic loadings was found to be 69844 N (Ungureanu et al. 2011b), which means for a length of 3.6 m of the tested panels an experimental reference capacity of 19.40 kN/m.

Finally, the length of walls necessary to provide the shear capacity results as:

$$L_{ground\ floor} = \frac{T_{ground\ floor}}{P_{calc}} = \frac{262.72}{19.40} = 13.54\text{m} < 21.55\text{m(TV)}; < 17.22\text{m(LG)} \quad (5)$$

$$L_{first\ floor} = \frac{T_{first\ floor}}{P_{calc}} = \frac{142.45}{19.40} = 7.34\text{m} < 17.12\text{m(TV)}; < 12.42\text{m(LG)}$$

Examples of shear walls in the transversal and longitudinal directions are presented in Figure 8.

Figure 8. Examples of shear walls on transversal and longitudinal directions (Ungureanu et al. 2011b).

To have a complete study, the integration of environmental impact was performed in the design of the buildings. The case study compares the environmental impact of a single-family house, designed in two different situations: the existing thin-walled cold-formed house and the same house designed in masonry solution, the so-called traditional house. Impact analyses were performed at different levels: (i) construction, (ii) construction and end-of-life, (iii) life cycle including maintenance and, (iv) life cycle including maintenance and consumable goods (Ungureanu et al. 2011b). The structural system of the masonry house was made up of 25 cm masonry walls, a concrete floor, continuous foundations and a wooden roof structure. Due to the different thicknesses of the walls used in the two solutions, the main preoccupation was to obtain the same interior volume for all rooms. The design considers the same location of the building and the same imposed and climatic loadings. The details of the environmental impact comparison were presented in detail by Ungureanu et al. (2011b). Both solutions were designed for a service life of 50 years.

In a single score representation (see Figure 9), and considering the boundary conditions (all identical components are left out of the comparison, i.e. windows, doors etc.), the metallic house (2750 eco-points) presents an important advantage in front of the traditional home (4220 eco-points). Of course, many parameters (such as national or regional peculiarities, climatic zones, or distance from the material distributors) can affect these results.

The main conclusion of the study highlights that steel dwellings with cold-formed structural elements represent a good alternative to masonry houses, not only with respect to structural requirements but also considering the environmental impact assessment.

Figure 9. Life-cycle comparison on environmental impact for the metallic and traditional house (single score) for construction, including maintenance and end-of-life.

4 CONCLUDING REMARKS

The five examples summarised in the actual paper represent a complete sustainable technology of high-performance thermos-energetic materials for cladding and finishing and use productive and qualitative technologies both for fabrication and erection. It enables one to obtain flexible partitions and allows for further upgrade, easy modifications and/or development.

All buildings are located in moderate-to-high seismic regions. Compared to traditional housing technologies, steel frame houses, in addition to their technical advantages and improved quality of both structure and finishing, are also cost-effective. The hybrid structures of the mainframes of these buildings have proven their advantages compared to the traditional solutions.

Another important aspect to be highlighted for this type of structures is the end-of-life of construction products that plays an important role, considering the circular economy, as buildings have a long intended life span and require a significant amount of material resources. To maintain circularity, these resources must be kept in use through modularity, reuse, reclaim, or recycling. The end-of-life credentials of structural materials vary due to their inherent properties. Therefore, the reuse of steel is a viable solution to meet the criteria of the circular economy and reduce energy demand.

Influence of fastening systems on the ultimate capacity of steel-faced sandwich wall panels under transverse loads

F. Dinu, C. Neagu & S. Lindiri

Politehnica University Timisoara, Romania

M. Senila

Technical University of Cluj-Napoca, Cluj-Napoca, Romania

ABSTRACT: Light weight sandwich wall panels are largely used for different kind of commercial or industrial buildings. They are typically designed from the weather/climate related conditions of the site (wind action, thermal comfort). Despite their low weight, they have adequate load carrying capacities under transverse (out of plane) loads, e.g., wind loads. However, under extreme loading conditions, like external explosions, such walls can be heavily damaged or destroyed, either under positive or negative pressure phases. The study presented in the paper describes the results obtained on wall sandwich panel elements tested for transverse loading until complete failure. The panels are arranged as single span systems supported on side rails and loaded at the mid-span using a quasi-static monotonic loading protocol. After an initial quasi-linear response, the maximum bending strength is reached. Then, due to a local buckling of the top face at mid-span, a sudden drop in load capacity is recorded, followed by a second increase in capacity due to development of catenary forces. If the end fasteners have adequate resistance, the ultimate capacity in the catenary stage can be significantly higher than the peak flexural capacity, which is generally used in the design. For small edge distance, the failure takes place due to the pull over of the fastener head through the top face of the sandwich panel and tearing of the bottom face around the fasteners. For large edge distances, the failure is due to the excessive deformations of the supporting rails. The increase in the ultimate panel capacity by means of adequate fastening and supporting enhances the robustness and reduces the risk for the occupants, all at a small increase in costs.

1 INTRODUCTION

Sandwich panels are largely used for modern wall systems in building constructions, particularly in commercial and industrial buildings. They are composed of two faces connected by a low-density material core. Such an example is the PUR steel sandwich panel, which is composed of two thin steel faces connected by a low-density polyurethane foam layer. The two faces may be also made from composite materials, e.g., glass fiber reinforced plastic, GFRP. For wall applications, the two walls are generally flat or lightly profiled (Davies 1993). Walls made from sandwich panels are light, low-weight systems, typically designed from the weather/climate related conditions of the site (wind action, thermal comfort), with or without limited in-plane axial loads. The determination of the load-bearing capacity required for the design of sandwich panels is based to a large degree on test results (ECCS 127 2009), (Georgescu & Ungureanu 2014, Georgescu et al. 2014). In case of extreme loading conditions, like the ones generated by external explosions, the pressure exerted on the wall elements significantly exceeds the wind pressures used in the initial design of the walls and can heavily damage or destroy the closing walls (UFC 3-340-02, 2014). As a result, the shock wave or fragments that are projected at high speed can injure the building occupants or cause further structural damage at the interior (WBDG 2019), (FRAMEBLAST 2018). For such extreme cases, it can become uneconomical to adopt the traditional design based on flexural capacity, because, combined with the small mass of the wall, a significant strengthening may be required. In such cases, the ultimate capacity may be increased by allowing the development of catenary forces in the panels using appropriate end

restraints, i.e., connections with the support structure. Even several test programs on the response of wall sandwich panels under transverse (out of plane) loading were developed, they were mostly used to determine the flexural strength and deformation, which is mainly governed by the local buckling (wrinkling) of the panel face in compression (ECCS 127 2009), (Pokharel & Mahendran 2005), (EN 1993-1-3 2006), (Pokharel & Mahendran 2003). The local buckling (wrinkling), and consequently the flexural strength and stiffness, is also influenced substantially by the core density, i.e., soft cores make the panel more vulnerable to localized effects under concentrated loads, and inwards wrinkling of the compression face (Sharaf et al. 2010). A test program on sandwich panels was done by Chong and Hartsock (Chong & Hartsock 1993). They evaluated the ultimate flexural buckling failure of foam-filled sandwich panels with light gauge cold formed metal faces.

Five types of panels with three face configurations and four kinds of rigid urethane foam were subjected to center point loading, and the results were compared with mathematical derived solutions. An experimental program devoted to the evaluation of the mechanical characteristics and load (Kuhnhenne et al. 2020) bearing capacity of sandwich panels used for roofs and walls was conducted by Vayas et al. (Vayas et al. 2010). The four-point bending tests on three simply supported panels showed a similar response, with a quasi-linear behavior up to the attainment of the maximum load, followed by a fast drop in capacity. The test program was limited to the evaluation of the flexural peak capacity, without any consideration of the post-flexural response. The results indicated that, after the peak ultimate flexural capacity is reached, the resistance is steadily decreasing. In a recent experimental program conducted by Kuhnhenne et al. (Kuhnhenne et al. 2020), used sandwich panels, which were in service for over 14 years, were tested to check if they still comply with the actual strength and stiffness requirements. Four types of tests were performed, including bending tests. The research also investigated the effect of perforations due to end fasteners and the feasibility of a new clamping system to provide the fixation of the sandwich panel on the building substructure without any penetration.

The study presented in the paper investigates the ultimate capacity and failure mode of PUR sandwich panels with steel faces under quasi-static transverse loading. Eight double hinged specimens were tested, four with the span of 1.9 m and four with the span of 2.5 m. For reference, two additional bending tests were performed on simply supported specimens, one of 1.9 m span and one on of 2.5 m span, respectively. These two tests aimed to evaluate the response in the absence of any in-plane axial restraint (flexural response only). The panels were supported by cold formed lipped channels. Such sections are commonly used in practice as side rails for sandwich panel walls. The experimental tests were performed within SAFE-WALL project (*SAFE-WALL* 2020), which included similar tests on liner trays (Dinu et al. 2022), but also near field blast tests on a full-scale steel frame building with walls from same sandwich panels (Dinu et al. 2022) and liner trays, but the results are not reported here.

2 DESCRIPTION OF THE EXPERIMENTAL PROGRAM

The panels investigated in the test program are polyurethane foam sandwich panels with 0.4 mm thick steel faces and $t_p = 100$ mm thick core (noted PUR 100/0.4). The panels are 1000 mm wide and are supported by cold formed lipped channel side rails (section C150/2 mm) spanning $L_{SR} = 4.5$ m. The geometric and material characteristics of the panels and side rails are presented in Table 1.

Table 1. Geometric and material characteristics of panels and side rails.

Element	Steel grade	Yield strength f_y	Tensile strength f_u
		N/mm ²	N/mm ²
Side rail C150/2	S350GD-275Z	350*	420*
PUR/0.4	S250GD	303	330

*Values presented in the table are nominal values

The experimental program included ten tests, see Table 2. Eighth specimens were tested for double hinge condition, while two reference specimens were tested for simply supported

condition. The test set-up is shown in Figure 1 and Figure 2. The double-hinged panels were connected to the side rails using six self-drilling screws 5.5/6.3 at each end, while the side rails are connected to the support structure using UPN65 stubs and three bolts M12x35 mm, class 8.8, see Figure 2c. Note that the two reference specimens tested for bending had fasteners at one end, only. To prevent the loss of capacity of side rails by out-of-plane bending and lateral-torsional buckling, lateral restraints were provided as follows (Figure 1a):

- On the areas outside the width of the sandwich panel, the rails were supported at the top flange using 3 studs made from cold formed lipped channels on each side.
- On the areas inside the width of the sandwich panel, the rails were supported at the level of the web using two pairs of round steel rods.

It should be mentioned that in a real structure, the wall panels act as lateral restraints to the side rails for inward deflections, but the level of restraining is only verified for flexural stage (or small deformations). The parameters considered in the experimental program are the panel span, the type of the fastener washer, and the edge distance of the fasteners. For the panel span, two distances were used, i.e., 1.9 m and 2.5 m, respectively. It is expected that the increase of the panel span to thickness ratio, L_p/t_p , will favor the development of the catenary response due to higher flexibility. For reference, additional bending tests were performed on simply supported specimens to evaluate the flexural response in the absence of any in-plane axial restraint. As for the washers, excepting a single 1.9 m span specimen, for which self-drilling screws with standard EPDM washers were used, for the rest of the specimens, additional steel washers with a diameter of 27 mm and a thickness of 2 mm were added. The additional washers (see Figure 2b) increase the contact area with the sandwich panel and reduce/prevent the pull-over effect through the top (external) steel face. This is generally required when higher load bearing capacity of panel fastenings is required. As for the edge distance of the fasteners, e_1 (Figure 1b), it was 50 mm and 125 mm, respectively. Note that the minimum edge distance is typically defined by the panel manufacturer (EN 1993-1-3 2006). Also, if the edge distance is smaller than 45 mm, the pull-over resistance derived from the test results must be reduced (ECCS 127 2009). It is therefore expected that the increase of the edge distance of the fasteners will lead to larger catenary forces and higher ultimate capacity.

The load was applied at the middle of the panel, using a transversal steel beam to distribute the load force along the panel width. The test was quasi-static, with the load incremented up to the failure of the specimen using displacement control. Because the stroke of the hydraulic jack was not sufficiently long, several stops were made to allow the addition of some spacers. During these stops, the force was reduced to zero. However, the unloading and reloading intermediate phases were removed from the force-displacement curves.

Table 2. Description of the specimens.

Specimen	Span L_p m	Edge distance e_1 mm	Washers
SP-1.9 -50	1.9	50	EPDM
SP-1.9 -50-W/1	1.9	50	EPDM + W*
SP-1.9 -50-W/2	1.9	50	EPDM + W*
SP-1.9 -125-W	1.9	125	EPDM + W*
SP-2.5 -50-W/1	2.5	50	EPDM + W*
SP-2.5 -50-W/2	2.5	50	EPDM + W*
SP-2.5 -125-W/1	2.5	125	EPDM + W*
SP-2.5 -125-W/2	2.5	125	EPDM + W*
SP-1.9-bending**	1.9	125	EPDM
SP-2.5-bending**	2.5	125	EPDM

*EPDM - ethylene propylene diene monomer (EPDM) washers

W - steel washer with 27 mm diameter and 2 mm thickness

**For bending tests, end fasteners were used for one end only, and the other end was free to slide

Linear variable differential transformers (LVDT) were used to measure the displacements at several locations in the panel and side rails, see Figure 1b. Digital image correlation system

VIC-3D was used to measure the longitudinal strains at several locations in the top and bottom steel faces. The VIC-3D system was positioned near one of the panel supports, where bending moment is negligible, thus indicating the possible development of the catenary force in the panel during post-flexural deformation stage (Figure 1b).

Figure 1. Test set-up and instrumentation: a) isometric view; b) longitudinal view.

Figure 2. View with test setup: a) overview of the experimental setup and a panel ready for testing; b) end fasteners with additional steel washers connecting the panel to the side rail; d) side rail connections to the support structure.

3 EXPERIMENTAL RESULTS

Figure 3a and b show the force-displacement curves for the 1.9 m and 2.5 m span specimens, respectively, while Figure 4 shows the global view of a specimen after test and the detailed view of the typical plastic mechanism at the midspan. The vertical forces corresponding to the maximum flexural capacity (F_f) and to the ultimate stage (F_u) and the associated displacements (D_f and D_u) are presented in Table 3. Note that the vertical displacement contains only the displacement of the panel, without considering the contribution from the side rails. As seen from Figure 3, the behavior of the panels tested for double hinge conditions is characterized by three distinct zones. First, there is a quasi-linear elastic behavior up to the attainment of the maximum flexural capacity - point A on the curves. After point A, the panels have a sudden drop in capacity, associated with a local dynamic instability of the top face in compression – point B on the curves. After point B, a second increase in capacity is observed, and, for all specimens, the force corresponding to the ultimate capacity, F_u (point C on the curves), is higher than F_f , excepting the specimen SP-1.9-50-W/2, where the test was stopped before reaching the ultimate capacity due to technical issues (see Table 3).

*The residual flexural capacity for simply supported specimens was considered constant till failure

For the specimens tested for simple supported conditions, after the attainment of the maximum flexural capacity, the panel have a similar drop in capacity due to the local dynamic instability of the top face in compression and remains almost constant until the end of the test. Note that, for each span, the „residual “flexural capacity, $F_{f,r}$, of simply supported specimen and double hinge specimens is very close. Based on the observations made during each test, three failure modes were identified, see Table 3. They are influenced by the type of washer and edge distance, but also by the flexural capacity (in plane and out of plane) of the side rails supporting the panels. Thus, Mode 1 is characterized by a pullover of the fasteners through the top steel face combined with the tearing and buckling (folding) of the bottom steel face (see Figure 5). This failure mode takes place only for specimen SP-1.9-50, where the fasteners have standard EPDM washers only. Once additional larger steel washers are used, the pull-over of the fasteners through the top steel face is prevented, and failure takes place due to the tearing and buckling (folding) of the bottom steel face, which is identified as Mode 2 (see Figure 6). The angle between the two rupture lines is approximately 30° (see Figure 5c). One may note that similar failure mode may be also seen in spot welding of thin steel plates (Dubina et al. 2012). Mode 3 represents the failure of the side rails due to a combination of in plane and out of plane bending, but without the failure of the end connections (in Mode 1 or Mode 2) (see Figure 7a, b). The larger the edge distance, the larger the

Figure 5. Mode 1 of failure, with pull-over of fasteners through the top steel face (a), bottom steel face teared and buckled (folded) (b), and close-up view of the rupture lines (c).

Figure 6. Mode 2 of failure, with pull-over of fasteners through the top steel face prevented (a) and bottom steel face teared and buckled (folded) (b).

Figure 7. Mode 3 of failure, with failure of the side rail (a), bottom steel face teared and buckled (folded) (b), and close-up view of the rupture lines and folding area (c).

folding zone (see Figure 7c) and, consequently, the ultimate resistance is not given by the fasteners but by the supporting rails. Note that side rails were designed to resist the design loads applied on the panels at the Ultimate Limit State.

Figure 8 shows the contribution of catenary action to total load resistance for two specimens, i.e., SP-1.9 -125-W and SP-2.5-125-W/1, respectively. Note that the catenary action was obtained by subtracting the bending resistance (quasi-constant after point B) from the total resisted load. As may be seen from Table 3, except for the specimen SP-1.9 -50-W/2 (in whose case, the test was stopped before reaching the ultimate capacity due to technical issues) and the specimen SP-1.9-50 (standard

Figure 8. Contribution of catenary action to total load resistance: a) specimen SP-1.9 -125-W; b) specimen SP-2.5 -125-W/1.

EPDM washers only), for all the other specimens, the catenary action that developed during large deflection stage increased the load capacity significantly. It is also important to note that, even the flexural capacities are larger for shorter spans, the ultimate loads at failure are very similar.

To evaluate the development of the catenary force in the panels and the contribution of the two steel panel faces, the longitudinal strains measured with VIC-3D system were employed. As seen from Figure 9, up to point B, the strain measurements at the bottom face indicate a small variation with the increase of the applied force. Then, because the supports restrain the horizontal displacements of the panel end, catenary action develops in the panel. This development is indicated by the continuous increase of the strains (elongations) up to the attainment of the ultimate capacity (point C). From Figure 9, it may also be seen that the elongations, and therefore the tensile forces, are not constant along the panel width, but decrease from the longitudinal edge (extensometer E0) to the middle of the panel (extensometer E10). This also suggests that the contribution of fasteners in resisting the catenary forces and, ultimately, the contribution to the ultimate capacity, F_u , varies along the panel width. Also, because the end fasteners are flexible when loaded by in plane axial force, the catenary force is transferred almost entirely through the bottom face. This may be seen from the very small deformations of the top steel face around the screw head at the end of the test, see Figure 10, with no visible elongations.

4 CONCLUSIONS

Sandwich wall panels are largely used for different kind of commercial and industrial buildings. Despite their low weight, sandwich panels have high load carrying capacity under transverse loads. However, under extreme loading conditions, like near field explosions, the panels can be destroyed

or severely damaged, either under positive or negative pressure phase. The traditional design based on flexural capacity becomes uneconomical and may prohibit the use of sandwich panels when resistance against such high pressures is intended. The ultimate capacity can however benefit from the development of the catenary response, which is significantly higher than the flexural response if appropriate end fastenings (number of screws, edge distance, larger washers) and supporting restraints are provided. The increase in the ultimate panel capacity by means of adequate fastening and supporting enhances the robustness and reduces the risk for the occupants, all at a small increase in costs. Even if the in-plane forces in the fasteners at ultimate stage are not evenly distributed along the panel width, the ultimate capacity increases proportionally with the number of fasteners. When end distance increases from 50 mm to 125 mm, the ultimate capacity increases, in average, by more than 30% for 1.9 m span panels, and by more than 90% for 2.5 m span panels. This increase is conditioned by the use of additional larger washers to prevent the pull-over failure (noted as Mode 1). The ultimate capacity of the panels can be also increased by strengthening the side rails, as catenary forces can induce significant in-plane and out-of-plane bending moments. The ongoing research focuses on optimizing the number of fasteners and improving the local detailing to enhance the catenary response of the wall panels. Near field blast tests on a full-scale steel frame building with sandwich wall panels and improved fastenings and local detailing are also in progress.

Simplified assessment of the cyclic performance of steel constructions in aggressive environments

A. Milone & R. Landolfo

University of Naples “Federico II”, Naples, Italy

ABSTRACT: Owing to their peculiar destination of use, steel constructions such as bridges or offshore constructions are often placed in aggressive environments. In such cases, the combined action of cyclic loadings and material degradation can lead to sudden corrosion fatigue (CF) collapse if structures are not properly protected. In the present work, a simplified technique to assess the cyclic performance of steel constructions located in aggressive environments is introduced. The presented methodology relies on the concept of “critical corrosion degree” η^*_{Rd} , i.e. the minimum rate of corrosion which induces fatigue collapse for a given target service life t^* . Accordingly, CF checks can be hence expressed in a “demand vs. capacity” form more in line with principles of performance-based engineering. An existing railway riveted bridge located in Italy is hence selected as a case-study to provide a first application of the presented procedure with regards to a full-scale existing structure. Finally, parametrical analyses are presented in order to highlight the sensitivity of predicted cyclic performance to physical and mechanical variables governing corrosion fatigue phenomenology.

1 INTRODUCTION

After the second half of XXth century, fatigue performance of new and existing steel structures became a relevant civil engineering topic due to major fatigue-related failures (Anderson, 2017).

When dealing with existing steel structures, fatigue damage can be coupled with another relevant source of damage, i.e. material degradation, mainly in the form of metallic corrosion (Milone et al., 2022). Corrosion involves a progressive material loss due to electrochemical processes which are extremely sensitive to local environmental conditions (i.e., humidity, salinity, temperature). Hence, both time- and space-depending evolution of corrosion can sensibly vary during service life, leading to phenomena such as pitting (i.e. localized) corrosion or sudden changes in rate of corrosion in time.

When corrosive processes occur in conjunction with cyclic loads, corrosion damage is not merely summed to fatigue damage; namely, the two processes influence each other due to multiple factors (Milone et al., 2022):

- On one hand, fatigue cracking creates preferable spots for corrosion development, as the cracks can penetrate through protective layers (i.e. zinc coatings, ducts. . .), if present;
- On the other hand, corrosion induces a reduction of the resisting cross-section, resulting in stress amplifications which accelerate fatigue cracking.

In light of the above, it is clear that phenomenology of corrosion fatigue in steel structures is a complex topic to be addressed and it is still an open field of research at the present time (Cascini et al., 2008).

The present work attempts at providing a unified and simplified methodological approach for the fatigue assessment of steel structures in aggressive environments. This purpose is

addressed by introducing a “critical corrosion degree” η^*_{Rd} associated to an assigned fatigue life t^* , which allows carrying out fatigue checks in an explicit “demand vs. capacity” form.

This paper is mainly divided in three parts. In the first part, each step of the procedure is presented. In the second section, an application of the presented methodology is reported for a corroded riveted bridge located in Italy. Finally, parametrical analyses are performed in the third part with regard to most critical members.

2 OUTLINE OF THE PRESENTED PROCEDURE

The proposed methodology for the simplified corrosion fatigue assessment of steel structures in aggressive environments is based on the well-known Miner’s rule for damage cumulation, which is already codified in EN1993:1–9 (CEN, 2005) within the framework of the Damage Tolerant (DT) approach.

Nevertheless, in this work, fatigue checks will be presented in a more direct “capacity vs. demand” approach in line with performance-based engineering. This aspect is addressed by introducing the concept of “critical corrosion degree” η^*_{Rd} for an assumed target fatigue life t^* .

2.1 Step 1: Definition of corrosion trend

As highlighted previously, corrosive phenomena are highly sensitive to local boundary conditions. In general, in years immediately after the construction time, corrosion is limited due to the presence of preventive measures. Once the protection layer is worn, the corrosion process sharply accelerates. Finally, after significant superficial corrosion products have already formed, the corrosive process usually slows down, approaching a stabilized rate (Figure 1, dashed curve).

Compliantly, and according to ISO 9224 (ISO, 2012) recommendations, in the presented approach the corrosion development is approximated by a polyline with two branches (Figure 1, solid polyline). The slopes ratio among the two branches is equal to C: 1, with $C = 1 \div 5$ depending on the corrosivity category as defined in (ISO, 2012).

Figure 1. Qualitative (black dashed curve) and assumed (red solid polyline) trends for corrosion development for the proposed methodological approach.

The knee point of the bi-linear curve is assumed to occur $\Delta t = 10$ years after construction time. The corrosion degree η is assumed null for $t = t_0$. Conversely, for $t = t^*$ (target fatigue life) a “critical corrosion degree” η^*_{Rd} is introduced, i.e., the minimum corrosion degree which induces corrosion fatigue collapse for $t = t^*$.

The selection of a proper value for t^* has to be intended as a designer’s choice, which depends on the expected influence of fatigue and material degradation on structural performance. The corrosion degree at a given time $\eta(t)$ is hence expressed by Equation 1a-b:

$$\eta(t) = \begin{cases} \dot{\eta}_0(t - t_0) & t \leq t_0 + \Delta t \\ \frac{\dot{\eta}_0}{c}(t - t_0) + \Delta t \dot{\eta}_0 \left(1 - \frac{1}{c}\right) & t_0 + \Delta t < t \leq t^* \end{cases} \quad (1a)$$

$$\dot{\eta}_0 = \frac{\eta_{Rd}^*}{\Delta t \left(1 - \frac{1}{c}\right) + \frac{t^*}{c}} \quad (1b)$$

in which η_0 represents the corrosion rate assumed for the first branch of the polyline. Equation 1a-b holds true for an arbitrary value of η_{Rd}^* , the actual value of which will be derived in Step 4.

2.2 Step 2: “Unaltered” structural analysis

According to (ISO, 2012), the expected amount of material loss due to corrosion do not exceed few $\text{mg}/(\text{year} \cdot \text{m}^2)$ even in the case of extremely aggressive environments. Hence, global stiffness reduction due to corrosion can be initially neglected, performing structural analysis on the “unaltered” structure.

In this way, extreme values of the stress characteristics ($S_{0,\min}$; $S_{0,\max}$) can be determined only once. Influence of corrosion will be later accounted in terms of local stresses amplifications.

2.3 Step 3: Evaluation of “real” load spectrums

After estimating “unaltered” stress characteristics $S_{0,\min}/\Delta S_0$, “unaltered” local stresses $\sigma_{0,\min}/\Delta \sigma_0$ can be determined using expressions from the theory of elasticity. Hence, introducing appropriate stress magnification factors (SMFs), “real” corrosion-depending stresses $\sigma_{\eta,\min}/\Delta \sigma_{\eta}$ can be evaluated.

At least two sources of amplification have to be accounted for, i.e., local erosion of the resisting cross-section and the presence of mean tensile stresses $\sigma_{0,m} > 0$ (Goodman, 1899). Corrosion-induced amplification can be modelled by means of an SMF (SMF_{η}), which is a function of (i) cross-section properties in pristine conditions X_0 ; (ii) cross-section properties reduction ΔX_{η} ; and (iii) the type of corrosive process (CP). In the simplest case (uniform corrosion), SMF_{η} can be expressed as follows (Equation 2):

$$SMF_{\eta,uniform} = \left(1 - \frac{\Delta X_{\eta}}{X_0}\right)^{-1} \approx \frac{1}{1 - \eta} \quad (2)$$

Non uniform corrosion (“pitting”) can be modelled by scaling $SMF_{\eta,uniform}$ by means of a non-dimensional function $f(t, CP)$ defined case-by-case. Indeed, when relevant, pitting can be modelled by means of equivalent notches inducing local stress amplifications (Berto et al., 2014). To this end, multiple expressions for $f(t, CP)$ functions can be found in Peterson et al. (1997).

“Real” corrosion-depending stresses $\sigma_{\eta,\min}/\Delta \sigma_{\eta}$ are hence derived as follows (Equation 3a-b):

$$\sigma_{\eta,min} = SMF_{\eta} \sigma_{0,min} \quad (3a)$$

$$\Delta \sigma_{\eta} = SMF_{\eta} \Delta \sigma_0 \quad (3b)$$

In case of complex stress histories, “real” stress histories are expressed by means of “real” oscillograms, in which each point $\sigma_{\eta}(t)$ is derived by magnifying SMF_{η} times the related “unaltered” stress $\sigma_0(t)$.

Hence, cycle counting is performed considering only the fluctuating part of amplified stresses (e.g. with Rainflow method – CEN, 2005). Cycle counting yields an approximated “real” load spectrum ($\Delta \sigma_{\eta,i}$; n_i). The equivalent fatigue demand accounting for mean stress effect $\Delta \sigma_{eq,i}$ is hence estimated (Equation 4):

$$\Delta\sigma_{eq,i}(t) = \Delta\sigma_{\eta,i}(t) \cdot SMF_{Eq}(t) \quad (4)$$

where SMF_{Eq} is an equivalent magnification factor accounting for the mean stress effect. According to consolidated practice, Goodman (1899) model is selected to deal with pulsating stress histories. It should be remarked that SMF_{Eq} implicitly depends on $\Delta\sigma_{\eta,i}$, as Equation 5a-b holds:

$$SMF_{Eq}(t) = \frac{1}{1 - \frac{\sigma_{m,i}(t)}{f_u}} \geq 1 \quad (5a)$$

$$\sigma_{m,\eta,i}(t) = \sigma_{\eta,min,i}(t) + \frac{\Delta\sigma_{\eta,i}(t)}{2} \quad (5b)$$

with f_u being the ultimate tensile strength (UTS) of structural steel. The evaluation of $\Delta\sigma_{eq,i}$ is performed for each stage of the structural service life, thus obtaining $(t^* - t_0)$ “equivalent” load spectrums, which represent the overall fatigue demand on the analyzed structure (Figure 2).

Figure 2. Estimation of “real” load spectrum from aperiodic stress histories.

2.4 Step 4: Estimation of critical corrosion degree

Using Miner’s rule for damage accumulation, the actual value of the critical corrosion degree η^*_{Rd} can be estimated by imposing that total damage D_{TOT} reaches unity for $t = t^*$ (Equation 6):

$$f(\eta^*_{Rd}, t^*) = 1 - D_{TOT}(\eta^*_{Rd}, t^*) = 1 - \sum_{t=t_0}^{t^*} \frac{n_i}{N_i(\Delta\sigma_{eq,i}(\eta^*_{Rd}))} - 1 = 0 \quad (6)$$

Evaluation of the number of stress cycles up to failure N_i has to be performed using a S-N- η fatigue strength domain to account for fatigue strength reduction due to material degradation (Equation 7a-b – Adasooriya et al., 2020):

$$\log \frac{5 \times 10^6}{N_i} = m_{1,\eta} \log \left(\frac{\Delta\sigma_{D,\eta}}{\Delta\sigma_{Eq,i}} \right) \quad (7a)$$

$$\log \frac{N_i}{5 \times 10^6} = m_{2,\eta} \log \left(\frac{\Delta\sigma_{Eq,i}}{\Delta\sigma_{D,\eta}} \right) \quad (7b)$$

with $\Delta\sigma_{D,\eta}$ being the modified constant amplitude fatigue limit (CAFL, $N = 5 \times 10^6$) for the selected element, accounting for the effect of corrosion, and $m_{1,\eta}/m_{2,\eta}$ being the corrosion-depending inverse slopes of LCF/HCF branch of the S-N curve, respectively.

According to Adasooriya et al. (2020), modified CAFL can be derived assuming that the stress range $\Delta\sigma_{10000}$ inducing collapse for $N = 10^4$ does not depend on η . Thus, $\Delta\sigma_{D,\eta}$ can be calculated starting from the “pristine” detail class ($\Delta\sigma_c$, $N = 2 \times 10^6$ – Equation 8a-b):

$$\Delta\sigma_{D,\eta} = \frac{\Delta\sigma_{10000}}{(5 \times 10^2)^{\frac{1}{m_{1,\eta}}}} \quad (8a)$$

$$\sigma_{D,10000} = (2 \times 10^2)^{\frac{1}{m_{1,0}}} \cdot \Delta\sigma_C \quad (8b)$$

with $m_{1,0}$ being the inverse slope of the LCF branch according to EN1993:1-9 (CEN, 2005) in pristine conditions.

Consistently with Adasooriya et al. (2020), the inverse slopes are assumed to linearly reduce as η increases (Equation 9a-b):

$$m_{1,\eta} = m_{1,0} - \frac{\eta}{\eta_{ref}} \Delta m_{1,\eta} \quad (9a)$$

$$m_{2,\eta} = m_{2,0} - \frac{\eta}{\eta_{ref}} \Delta m_{2,\eta} \quad (9b)$$

in which $m_{1,0}/m_{2,0}$ are the inverse slopes of the S-N curve in pristine conditions, respectively; $m_{1,\eta}/m_{2,\eta}$ are the corrosion-affected inverse slopes and $\eta_{ref}/\Delta m_{1,\eta}/\Delta m_{2,\eta}$ are experimental parameters expressing the influence of corrosion on fatigue behavior.

In this work, $\eta_{ref} = 0.2$, $\Delta m_{1,\eta} = 0.375 m_{1,0}$, and $\Delta m_{2,\eta} = 0.375 m_{2,0}$ are assumed compliantly with experimental results reported in Adasooriya et al. (2020).

Conservatively no endurance limit is assumed (that is, $m < \infty$ independently from the assumed stress range). The resulting shape of S-N- η domains is depicted in Figure 3 for increasing values of corrosion degree η .

Figure 3. Assumed shape of S-M- η domains for corrosion fatigue analyses.

2.5 Step 5: Corrosion fatigue checks

Once η_{Rd}^* is known, corrosion fatigue checks can be performed by controlling that “corrosion demand” at a given time $\eta_{Ed}(\bar{t})$ does not exceed the “corrosion capacity” $\eta_{Rd}(\bar{t})$ for the same \bar{t} (Equation 10):

$$\eta_{Ed}(\bar{t}) \leq \eta_{Rd}(\bar{t}) = \eta_{Rd}^* - \frac{\eta_{Rd}^*}{\Delta t(C-1) + t^*} (t^* - \bar{t}) \quad (10)$$

Based on Equation 10, three different structural damage stages can be identified, namely:

1. For $0 < \eta_{Ed}(\bar{t}) < \eta_{Rd}(\bar{t})$, the structure can be safe with regard to corrosion fatigue failure;
2. For $\eta_{Rd}(\bar{t}) < \eta_{Ed}(\bar{t}) < \eta_{Rd}^*$, the necessity of maintenance measures emerges as values of $\eta > \eta_{Rd}^*$ are expected to be attained for $t < t^*$;
3. For $\eta_{Ed}(\bar{t}) > \eta_{Rd}^*$, the structure quickly requires safety measures against corrosion fatigue collapse, which is indeed predicted to occur.

3 CASE STUDY

The presented procedure is hence applied with reference to an existing riveted railway bridge located in Italy (bridge over “Gesso” torrent, Montecalvo Irpino, Italy). The structure was erected during 1960s to replace a former masonry bridge damaged by 1962 Irpinia earthquake.

Four existing masonry piles were preserved, while the deck was rebuilt by means of three identical 29 m long 3D truss steel bays (see Figure 4a).

Steel members were realized by coupling hot-rolled and/or welded profiles by means of riveted battens. 22 mm hot-driven rivets were also implemented for connecting members via gusset plates. Namely, chords have an inverted Π section made of battened angles and plates.

Figure 4. (a) View and (b) modelling of the selected case study (railway bridge over “Gesso” torrent).

H-shaped welded profiles were used for vertical struts, while diagonals were made by battening two C profiles. Due to Italian Railway Network Management (RFI) provisions (RFI, 2011), no zinc coating was applied to protect members and connections from ongoing corrosion.

“Unaltered” global analysis accounting for “real” train loads as defined in RFI (2011) was performed using SAP2000 v.23 (CSI, 2021) (Figure 4b). All members were modelled by means of equivalent mono-dimensional frame elements. According to the original design report (Landolfo et al., 2010), an Fe 50.2 steel grade ($f_u = 500 \text{ N/mm}^2$) was assumed for all elements. The number of passages per year was assumed based on data provided by RFI (Table 1).

Table 1. Train loads for the selected case study according to RFI indications.

Train Type [-]	Total Load [kN]	Total Length [m]	Velocity [km/h]	Passages/Day [1/d]
3	9400	385.5	250	7
4	5100	237.6	250	6
8	10350	212.5	100	1
9	2960	134.8	120	1

In order to reproduce the actual phenomenology of corrosion, a progressive thickness reduction for elements on the bottom was assumed. Indeed, due to stagnation of meteoric waters, degradation phenomena are highly promoted in the inferior portion of the 3D truss. Moreover, owing to the structural scheme, lower steel members were considered as more prone to fatigue damage due to significant mean tensile stresses.

For the sake of brevity, only corrosion fatigue analyses for most critical elements are reported, i.e. *i*) the mid-span segment of lower chords, *ii*) tension diagonals closest to supports and *iii*) vertical struts located at mid-span. Figure 5a shows geometrical features and “unaltered” load spectrums for the considered members.

Critical corrosion degree was estimated considering a C3 exposition class ($C = 2.5 - \text{ISO}, 2012$) for all the elements (Figure 5b-c). According to Italian Ministry of Transportations (MIT) provisions for bridges (MIT, 2018), $t^* = 100$ years was set as target fatigue life, while a detail class $\Delta\sigma_C = 71 \text{ N/mm}^2$ for connections was selected compliantly with EN1993:1-9 (CEN, 2005).

It can be noticed that estimated values of η^*_{Rd} are rather variable for investigated members ($\eta^*_{Rd} = 50.7\%, 80.1\%$ and 27.5% for the lower chord, the diagonal and the vertical strut,

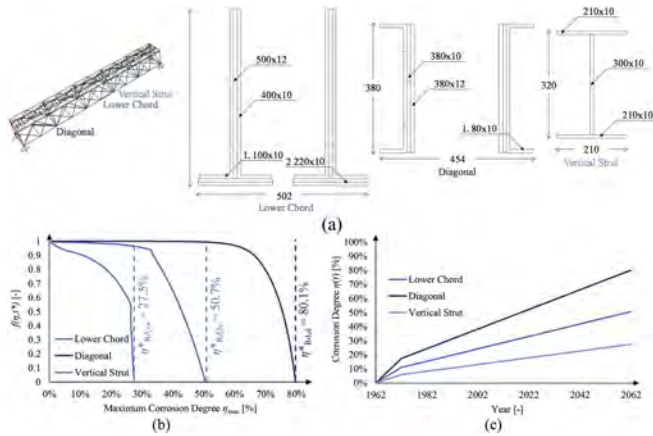

Figure 5. (a) Main geometrical features, (b) damage functions $f(\eta, t^*)$ and (c) critical corrosion trends for each considered critical element, e.g., lower chords, diagonals and vertical struts.

respectively). Indeed, while a significantly high critical corrosion is derived for both lower chords and diagonals, in case of vertical struts the effect of corrosion is more pronounced.

This outcome depends on the small cross-section of struts, which lead to high stress ranges even for low values of corrosion degree η . Appreciable damage arise also in lower chords for $\eta \geq 30\%$. Conversely, diagonals always show a significant range of safety against corrosion fatigue failure.

3.1 Parametrical analyses

In order to investigate the influence of physical/mechanical variables on the corrosion fatigue performance of structural members, parametrical analyses were conducted varying the

Table 2. Assumed values of parameters for parametrical analyses.

Parameter	Reference Value	Range of Variation
CX [-]	C3	C1 ÷ C5
f_u [N/mm ²]	500	340 ÷ 600
t^* [years]	100	50 ÷ 150
R [-]	0.3 (Lower Chord), 0.4 (Diagonal), 0.0 (Vertical Strut)	0.0 ÷ 0.5

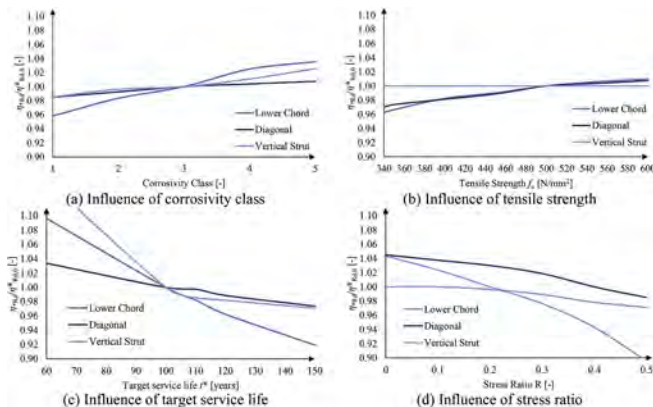

Figure 6. Results of parametrical analyses on investigated elements.

following parameters, namely: *i*) corrosivity class CX , *ii*) tensile strength f_u , *iii*) target service life t^* and *iv*) stress ratio R (Table 2).

Results of parametrical analyses are reported in Figure 6. One can notice that, as expected, the diagonal is less sensitive ($\pm 4\%$) to boundary conditions variations due to the negligible impact of corrosion fatigue on its service life. Conversely, lower chord displays a more significant sensitivity with respect to varied parameters.

Namely, increasing t^* or R a significant increment of damage is predicted, with a variation $\Delta\eta^*_{Rd} \approx -10\%$ with respect to the reference value in both cases (Figure 6c-d, dark blue plots). Finally, vertical strut is highly sensitive to t^* ($\Delta\eta^*_{Rd} = -15\%$ for $t^* = 60$ years), while other parameters do not appreciably affect the value of η^*_{Rd} . It should be noted that, as compressive mean stress arises in such element due to permanent loads, f_u has no effect on η^*_{Rd} .

4 CONCLUSIONS

A simplified methodology for the corrosion fatigue assessment of steel structures in aggressive environments was presented. The proposed method was hence applied with reference to an existing riveted bridge located in Italy. In light of the results, the following conclusions can be drawn:

- The proposed method for the corrosion fatigue analysis of steel structures is based on the concept of “critical” corrosion degree η^*_{Rd} , which is derived for a selected target fatigue life t^* ;
- The selected case study has a good performance against corrosion fatigue failure (i.e., $\eta^*_{Rd} = 50.7\%$, 80.1% and 27.5% for the lower chord, the diagonal and the vertical strut, respectively).
- Vertical struts are the most exposed elements due to their reduced pristine cross-section;
- Parametrical analyses showed how target fatigue life t^* and stress ratio R are the most influent parameters for the corrosion fatigue performance of the selected case study;
- Further studies on different full-scale steel structures located in aggressive environments will be conducted to prove the reliability of the presented simplified procedure.

Multi-hazard robustness assessment of seismic resistant multi-story steel frame buildings

D. Dubina, F. Dinu & J. Dominiq

Politehnica University Timisoara, Romania

Romanian Academy, Timisoara Branch, Romania

ABSTRACT: Buildings designed and constructed in accordance with the today code provisions are expected to withstand frequent hazards without structural damage and to prevent collapse under rare events (e.g., strong earthquakes). However, there are also situations where multiple or cascading hazards can occur, e.g., earthquake aftershocks or fire after earthquake. In such cases, even if the structure survives the first event with minimal damages that do not affect the global stability, the subsequent events can severely damage critical members and potentially cause extensive damages or even failures. The study presented in the paper investigates the response of a typical steel frame structure under cascading scenarios that involve damage to both lateral and gravity load resisting systems. The parameters considered in the study are the initial design conditions (level of overstrength in members), load scenarios (single/multi hazard events), and residual capacity after first event. Numerical models were calibrated against relevant test data. Results indicated appropriate resistance for single and multi-hazard loading scenarios. Even the structure showed adequate progressive collapse resistance, the internal column loss scenarios drawn attention, as they led to extensive damage in the perimeter moment resisting frames, which were still undamaged after the earthquake. It is expected that the multi-hazard design can be used to obtain more robust building structures against extreme loading events and improve the life-cycle performance of built infrastructure.

1 INTRODUCTION

Structural robustness and prevention of progressive collapse of building structures are specific safety conditions required by modern codes and standards, including Eurocodes (EN 1990 2002). The successful application in practice of this policy requires special attention not only from construction industry specialists (structural engineers, architects, builders) but also from authorities and insurance companies. The importance of design for robustness became evident following tragic events, such as the collapse of the Twin Towers in New York following the September 11, 2001, attacks, which led to the need for more elaborate design provisions (Demonceau et al. 2021). The design for robustness of building structures can be done considering either the direct effects of an extreme action or a certain extension of the damage following an unknown/unforeseen event using the Alternate Path method ((DoD 2009) (EN 1991-1-7 2006)). The methods in the first category require clear identification and definition of the accidental action. Typical examples are fire, gas explosion, or impact. In some cases, the development of local damage may be allowed, but not to a disproportionate extent to the original cause ((Demonceau et al. 2021), (EN 1991-1-7 2006)). However, in certain circumstances, accidental actions may exceed the conditions considered in the codes, or cannot be defined with sufficient accuracy, for example in cascading load scenarios, e.g., earthquake after earthquake, fire after earthquake or fire after explosion. One such example is the Christchurch (New Zealand) earthquake series of 2010-2011. First, it was not the strongest motion, i.e., 2010 event with magnitude 7.1, to cause the most losses (economic costs, fatalities) but the smaller 2011

aftershock (magnitude 6.3), which was responsible for 185 fatalities and more than 40 billion US \$. So, the new earthquake models should probably include the cascading effect of earthquake aftershock sequences (Bruneau & MacRae 2017). Second, the post-earthquake reconstruction process, which brought to surface the urban resilience as a main goal. So, even the concept was not necessarily new (Bruneau et al. 2003), it was probably the first time it was considered on such a large scale. The reconstruction favored the use of several innovative and emerging structural systems to make the new buildings of Christchurch more seismically resilient, e.g., low damage/replaceable technology construction. The advantages of such approaches have been also documented in (Dubina et al.2008; DUAREM 2015; Dubina et al. 2020, 2021; Jakab et al. 2022). Thus, it is becoming more widely accepted that preventing loss of life and reducing the damages due to single strong hazards (which are the main aims today) are simply not sufficient for a good modern structure and a resilient environment, but we need also to consider that:

- At smaller scale, buildings should be better prepared for unforeseen hazards - robust systems.
- At larger scale, built infrastructure should be less vulnerable and easier to repair to large scale single or multi hazard events – more resilient systems.

So, to be resilient, a structural system needs the capacity to resist the hazard, or robustness, and the ability to recover from the hazard in a timely and cost-effective manner. But these two components are very much dependent on the design concept and structural requirements for single and multi-hazard loading scenarios. During the past decade, a significant number of research projects related to the structural response of steel and composite buildings under various exceptional loading situations (impact, fire, explosion, ...) have been carried out (*ADBLAST* 2015; *CODEC* 2016; *FRAMEBLAST* 2018). Outcomes of these recent scientific actions included new design approaches to mitigate progressive collapse accounting for the full potential of materials used in steel or steel-concrete composite structures. Of particular importance is the *FAILNOMORE* project entitled “Mitigation of the risk of progressive collapse in steel and composite building frames (Demonceau et al. 2021). The project aimed at consolidating the existing knowledge and transform it into practical recommendations and guidelines. The output included design guidelines for steel and composite structures subjected to identified and unidentified threats, such as impacts, explosions, fires, and earthquakes, but also detailed worked examples. The examples give information about the design of steel and composite steel-concrete structures considering single hazards (e.g., explosion) or multi-hazard events (e.g., column loss following strong earthquake). In what concerns the column loss events for bare steel frame structures, results indicated that, even the seismic resistant systems perform better than non-seismic ones, they remain vulnerable to columns loss scenarios affecting parts designed for gravity loads only. Thus, when the column loss affects the internal structure with pinned beam ends, the damage propagates, and the progressive collapse develops on the entire affected area. The pinned connections cannot resist the large axial force demands resulted from the column loss. To limit the damage and prevent the progressive collapse, the alternatives to the pinned connection strengthening (which may be difficult to attain) are the use of moment resisting connections instead of pinned connections (redesign), or use of composite action of the beam with the concrete slab (Demonceau et al. 2021). The case-study building presented in the paper was initially designed for the ultimate limit state (ULS) and serviceability limit state (SLS), with additional requirements for damage limitation state (DL) in case of seismic action. Then the structure was tested for cascading hazard scenarios that involve a strong ground motion, followed by the loss of a column. In the first step, the structure is subjected to a design earthquake and the response is calculated using push-over analyses and the N2 method (EN 1998-1 2004). In the second step, the structure already tested for design earthquake is investigated for column loss scenarios using the alternative load path (ALP) method and nonlinear dynamic procedure (NDP), in accordance with the UFC 4-023-03 guidelines (DoD 2009). Several locations are considered for column loss

scenarios, which are assumed to be lost one at a time. They include only columns that are part of the seismic load resisting system.

2 DESIGN OF THE STRUCTURE

The isometric view of the structure is shown in Figure 1a. The main structural system consists of a dual system made of an internal V-braced cores and perimeter moment resisting frames (MRFs). The beam grid with main and secondary beams are designed to resist gravity loads (Figure 1b).

The structure has 6 stories of 4.0 m high each, 6 bays of 8.0 m in the longitudinal direction, 3 bays of 12.0 m in the transversal direction – internal, and 6 bays of 6.0 m in the transversal direction – perimeter. The design used S355 steel for all members, excepting non-dissipative beams in the braced frames, which were made of S460 steel grade. H sections were used for all steel elements. The joints were designed according to the EN 1993-1-8 provisions (EN 1993-1-8 2011), with additional requirements for seismic resistant systems in terms of minimum capacity (EN 1998-1 2004). The actions that were used in the design of each structural typology are:

- Dead load: $g_k = 5 \text{ kN/m}^2$ on floors, and $g_k = 4 \text{ kN/m}^2$ on the façade
- Live load for office buildings: $q_k = 3 \text{ kN/m}^2$
- Wind pressure: $q_b = 0.4 \text{ kN/m}^2$
- Snow load: $s_k = 1.5 \text{ kN/m}^2$
- Seismic action: Type 1 response spectrum, ground type B, $a_g = 0.25g$, $q = 4.8$ (EN 1998-1 2004).

Combination of actions for ULS and SLS were considered in compliance with EN 1990. Additionally, according to EN 1998, DL requirements were considered. The structural analysis was carried out using 3D models and linear elastic analyses. The calculations were performed using the SAP2000 software. For the seismic design, a modal response spectrum analysis was conducted. Also, the plastic mechanism and seismic response by means of non-linear static analysis procedure (push-over analysis) was evaluated using the N2 method. The output of the design is presented in Table 1. More details about design are given in (Demonceau et al. 2021).

Figure 1. Geometry of the structural system: a) isometric view; b) plan view with spans and bays and position of lateral load resisting system (MRF + CBF) (Demonceau et al. 2021).

3 DEFINITION OF HAZARD SCENARIOS AND ANALYSIS PROCEDURES

The main objective of the study is to evaluate the robustness of the structure following two extreme events that can affect the structure one upon another. The two cascading hazards refer to a strong earthquake that can damage the main lateral load resisting system, followed by a column loss, either due to the indirect effects of the seismic action or due to other causes (e.g., localized fire).

In the first step, the seismic response of the structure is analysed using the N2 method (EN 1998-1 2004). This method combines the nonlinear static (pushover) analysis of a multi-degree of freedom model with the response spectrum of a single degree of freedom system. The distribution of the lateral loads along the height followed two patterns, i.e., one uniform (uniform response acceleration) and one as an inverted triangle (similar to the first mode shape). However, only the first distribution is presented, as it brings higher demands. Two performance levels (or limit states) were used in the analysis, i.e., DL and ULS.

Table 1. Sections for beams, columns and braces (Demonceau et al. 2021).

Element	Direction	Story	Section
Perimeter beams	X	1-6	IPE550
	Y	1-6	IPE600
Interior beams	X	1-6	IPE550
	Y	1-6	IPE550
Inner core beams	X	1-3	H800*
		4-5	HEM800
		6	HEM700
	Y	1-3	HEM500
		4-6	HEB500
		1-6	HE550B
Corner columns		1-6	HE550B
Perimeter columns		1-6	HE500B
Inner core columns		1-6	HD400X463
Brace	X	1-3	HEA320

		5	HEA220
		6	HEA200
		1-3	HEA320
		4-5	HEA260
	Y	6	HEA220

* H800 is a built-up section with $h = 814\text{mm}$, $b = 380\text{mm}$, $t_f = 50\text{ mm}$, and $t_w = 30\text{ mm}$

In the second step, the structure, damaged due to earthquake, is investigated for column loss scenarios using the alternative load path (ALP) method and nonlinear dynamic procedure (NDP), in accordance with the UFC 4-023-03 guidelines (DoD 2009). Several critical locations are considered for column loss, which are assumed to be removed one at a time, see Figure 2. Note that the removal scenarios include only columns that are part of lateral load resisting system. Also, if a column has vertical braces attached, they are also removed. As reported in (Demonceau et al. 2021), the loss of columns from gravity load resisting area may be also of interest, because the beams attached to the columns are generally connected using simple connections. The ALP method ascertains the capacity of a structure to resist the loss of a critical load-bearing element without causing disproportionate collapse. In the NDP, first, the gravity load is calculated with Equation (1) and applied on the structure using a static analysis:

$$G = [DL + 0.5LL] \quad (1)$$

where G is the increased gravity load on floors, DL is the dead load and LL is the live load.

Then, in the second stage the column is removed almost instantaneously (i.e., 0.001 seconds) to account for the dynamic effects.

Both the nonlinear static analysis and column loss analysis were done using the plastic hinge concept. Columns were modeled using discrete plastic hinges, located at both ends, of axial-moment interaction, type P-M2-M3, defined according to ASCE/SEI 41-13 provisions (“ASCE/SEI 41-13” 2014). For beams however, plastic hinges were modeled using flexural moment hinge type (M3-type), defined also according to (“ASCE/SEI 41-13” 2014) but calibrated against relevant test data obtained within the framework of the “Structural conception and collapse control performance based design of multi-story structures under accidental actions CODEC” research project (CODEC 2016), (Dinu et al. 2016). The test setup is illustrated in Figure 3a, while Figure 3b shows the detailed numerical model developed with the SAP2000 software. In the test, the vertical load was applied quasi-statically at the top of the central column using a displacement control protocol and

Figure 2. The column removal locations.

was gradually increased until the failure of the specimen. The ultimate vertical load capacity of the numerical model was obtained by carrying out a displacement controlled dynamic pushdown analysis, but with a low speed, similar with the experimental one. The numerical model consists in beam elements with nominal specimen geometry, material properties based on the material tests, and P-M2-M3 hinge types, assigned at both ends of the main beams and columns (Marginean et al. 2019). Figure 4 shows the vertical force versus vertical displacement curves at the central column. The numerical results show a very good correlation with the experimental ones.

Figure 3. Geometry of test specimen (a) and SAP2000 numerical model (b).

Figure 4. Force-displacement curves, experimental vs. numerical.

4 RESULTS

To evaluate the seismic demands at ULS, the structure is pushed sideway to its top target displacement D_t using a monotonically increasing uniform pattern of lateral forces.

Figure 5 shows the capacity curves for transversal and longitudinal directions and the target points for ULS and DL. Figure 6 shows the plastic mechanisms for transversal and longitudinal directions corresponding to target displacement D_t at the ULS. No plastic hinges develop in perimeter moment resisting frames in neither X nor Y direction at ULS, but only in the braced frames.

Figure 5. Seismic analysis: a) push-over curve with the position of the target point, X direction; b) push-over curve with the position of the target point, Y direction.

Figure 6. Seismic analysis: a) plastic mechanism corresponding to target displacement D_t at ULS, interior transversal frame; b) plastic mechanism corresponding to target displacement D_t at ULS, interior longitudinal frame.

Figure 7. Vertical displacement in time for the considered removal scenarios.

After the damage state following an earthquake is evaluated, alternate load path method is applied for all removal scenarios, all located at the ground floor. The scenarios involve columns on the short and long sides of the façade but also interior columns from the braced spans. Figure 7 shows the history of vertical displacement above the removed column for the column removal scenarios, and indicates the progressive collapse is prevented in all cases. The plastic mechanisms presented in Figure 8 show that, for each scenario, the level of damage is moderate. For interior column removal scenarios affecting the braced spans (cases C3 and C6), the results indicate a possible hazardous situation. Thus, if we use a detailed view of the structure and separate the internal structure from the perimeter frames (see Figure 9), it may be seen that plastic deformations spread also in the perimeter MRFs, with plastic hinges both

in beams and columns. Note that after the seismic action ends, there are no residual deformations in the perimeter MRFs, and plastic hinges are only the results of column removal in the braced spans. This is explained by the smaller tributary area for gravity loads, but also by the large level of flexural overstrength in beams resulted when the contribution of the perimeter MRFs is checked, i.e., the duality should be checked by verifying that the MRFs carry at least 25% of the seismic force.

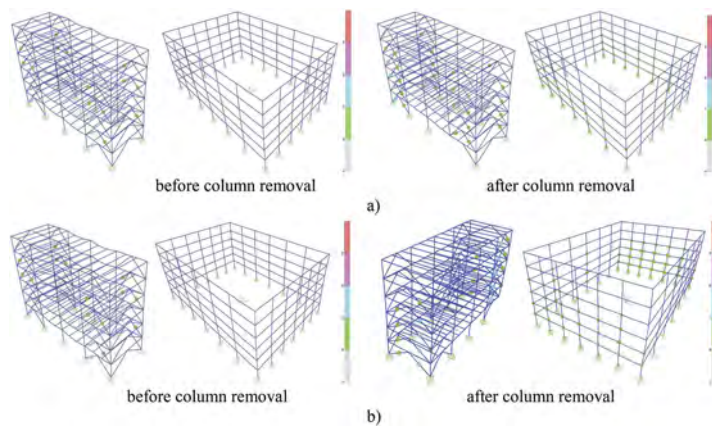

Figure 9. Plastic mechanisms following seismic event, before and after interior column loss: a) scenario C3; b) scenario C6.

5 CONCLUSIONS

Earthquake engineering and seismic design and practice have seen significant developments in the last decades. However, with all these developments, the potential for losses and extensive disruption of social and economic life due to seismic events remain high. One reason is the effect of multiple hazards occurrence, e.g., earthquake aftershocks, fire after earthquake, or fire after explosion. In such cases, even the structure survives the first event with damages that do not affect the global stability, the subsequent events can severely damage critical members and potentially cause extensive damages or even failures. The case study structure was initially

designed for the ULS and SLS requirements, with additional requirements for DL in case of seismic action. The response in case of column loss following an earthquake was investigated using the APM and nonlinear dynamic procedure. Even the structure showed adequate progressive collapse resistance, the internal column loss scenarios drawn attention, as they led to extensive damage in the perimeter moment resisting frames, which were still undamaged after the earthquake. It is expected that the results of the study can be used to design more robust building structural systems against extreme loading events and improve the life-cycle performance of built infrastructure.

Laser scanning technology for the evaluation of damage in complex building envelopes after extreme load events

P.C. Zdrenghia, F. Dinu, S. Herban & C. Neagu
Politehnica University Timisoara, Romania

ABSTRACT: Deformations and displacement measurements of structural/non-structural components of a building are often required during its design life, and several instruments and technologies are available (e.g., displacement transducers, total stations). However, this task can become very challenging for complex environments and/or when large deformations or displacements are expected, e.g., large building facades or large deformations under extreme loading. For such applications, terrestrial laser scanning (TLS), or Topographic LiDAR (Light Detection and Ranging), can be employed. Such systems provide high accuracy and high resolution measurements, and therefore can be used for complex loading environments, which can be otherwise difficult to perform using traditional methods. The paper presents the application of a terrestrial LiDAR system for deformation measurements of a lightweight façade made from wall liner trays, installed on a full-scale steel frame building model. The tests involve the detonation of several high energy explosive charges in the proximity of the building. The surface approximation is captured by TLS precise solutions, transformed into colored point clouds and then to 3D models. The results can be further used to calibrate advanced numerical models or to make rapid damage assessments and optimization of the recovery activities.

1 INTRODUCTION

For a community to be resilient, it requires robust infrastructure that can withstand hazards (single/multiple-exceptional threats) and demonstrate sufficient residual capacity, and rapid recovery after disruptive events (Figure 1). Developing appropriate tools and intervention procedures and optimizing allocation of resources help creating more disaster resilient communities. The loss of functionality due to insufficient robustness and or insufficient residual capacity can be alleviated if preventive rehabilitation strategies are employed. On the other hand, the rapid loss and damage evaluation, taking into consideration the evolution in time, can significantly shorten the recovery time. It is therefore necessary to increase the emergency preparedness and response capacity to effectively respond to a disaster.

Post-event information gathered through monitoring, sensing, and other field measurements helps the rapid damage assessment and the recovery activities. Aerial and digital technologies can also be used for damage assessment following major disasters, e.g., unmanned aerial vehicles (UAV) for post-disaster assessment and response; remote sensing techniques, such as interferometric synthetic aperture radar; improved location intelligence, early warning and relief response via social media and crowdsourcing.

Generally, damage assessment is focused on the information required to restore the facility to its pre-disaster condition. The inaccurate damage assessment (underestimated, overestimated) may lead to wrong decisions. Rapid (local) and comprehensive damage assessments are therefore critical. First, local damage assessment is used to determine if the damages resulting from the hazard can be addressed by existing resources. Then, comprehensive damage assessment activities focus on the damage assessment for buildings and infrastructure to establish the causes/levels of damage and to provide the most cost-effective solution/recommendation (repairing/strengthening/demolition).

Figure 1. Resilience concept, adapted from (Bruneau et al. 2003) and (McDaniels et al. 2008).

According to EN 1991-1-7 (EN 1991-1-7 2006), structural robustness is the ability of a structure to withstand extreme events like fire, explosions, impact or the consequences of human error, without being damaged to an extent disproportionate to the original cause. Generally, buildings are not designed for loading conditions generated by explosions, excepting the facilities designed to resist such actions (e.g., blast resistant buildings) or buildings where gas is burned or regulated EN 1990 (EN 1990 2002). Thus, when buildings are subjected to such extreme loads, they may sustain extensive damages (Demonceau et al. 2021).

The paper presents the application of a terrestrial LiDAR system for deformation measurements of a lightweight façade made from wall liner trays installed on a full-scale steel frame building model. The tests involve the detonation of several high energy explosive charges in the proximity of the building. The surface approximation was captured by TLS precise solutions, transformed into colored point clouds, and then to 3D CAD models. The results were further used for the calibration of numerical models. Damage levels based on maximum mid-span deformations were also proposed. Such results can be employed in damage assessment and recovery activities. The results were obtained in the framework of SAFE-WALL research project “Safety of building walls and claddings against accidental explosions” (SAFE-WALL 2020).

2 TEST SET-UP AND INSTRUMENTATION

The object under investigation is a full-scale 3D steel frame building structure. The steel frame structure has two spans of 4.5 m each, two bays of 3.0 m each, and two stories of 2.5 m each (Figure 2a). More details may be found in (FRAMEBLAST 2018). The structure is designed for persistent and seismic design situations (EN 1990 2002).

On one side, the building has a façade made from steel-based wall panels. The panels were assembled in two configurations, i.e., right hand side span with standard wall layers – system S1 (inner metal liner, thermal insulation, outer weather cladding), and left hand side with inner metal liner only – system S2, see Figure 2b. The liner trays are MBS KS100/600 type panels with 0.88 mm thickness, S320 GD steel (see (EN 10326 2013) for Technical delivery conditions). Liner trays are placed horizontally and fixed to the supporting steel columns using six 5.5 mm S-MD55Z self-drilling screws at each panel end.

The model was tested under increasing blast loads until complete failure of the wall panels. The blast charges were placed at a height of 1.5 m from the ground and 1.5 m from the wall, first at right midspan, then at left midspan. The charges were positioned normal to the 3rd liner tray (from the ground). The laser measurements were done on the initial undeformed walls, then for the following tests:

- Test RT1: right span, charge weight of 1.144 kg
- Test RT2: right span, charge weight of 2.288 kg
- Test LT1: left span, charge weight of 0.572 kg
- Test LT2: left span, charge weight of 1.144 kg

The tests were done at the INSEMEX blast testing facility in Petroșani, Romania, and used different instrumentation, i.e., high-speed cameras, pressure sensors, strain gauges, displacement transducers, and Z+F IMAGER 5010C type terrestrial laser scanner (see Figure 3).

Figure 2. General view of the building structure (a) and steel based faced during construction (b).

Surveying methods based on laser scanning are very effective to obtain accurate data about the response of the structural and non-structural elements, including the residual panel deformations and displacements. The Z+F IMAGER 5010C (M.S. Quintero et al. 2008) is a static ground scanner mounted on a rigid tripod and has a fixed position during the data acquisition process. It also belongs to the category of active scanners, which emit controlled radiation in the form of a laser wave and determinate the position of the laser point on the scanned object using the built-in camera. The scanner has an integrated HDR (High Dynamic Range) camera, with a resolution of 60 megapixels, and it is appropriate for capturing high-resolution, high-quality images. This type of scanner has also a dynamic compensation, which is designed to provide the position correction so that the instrument does not suffer any offset during successive measurements (Figure 4). The position has been constantly corrected, so that the maximum offsets did not exceed $\pm 2^\circ$, thus resulting in very high accuracy holds.

Figure 3. General view of the building, with the LIDAR system installed on position.

To determine the coordinates of the points, the scanner uses the time-shift principle, making it ideal for lens scanning due to the speed of the scan and the higher resolution compared to the scanners based on the time-of-flight method. The time-shift method is often used in wave measurements. This method is used in both total stations using the laser function for distance measurements and in active laser scans. It involves the measurement of a phase difference between transmitted and received waves.

Figure 4. Detected tilting changes between two low encoder positions ($< 0.007^\circ$).

The maximum data acquisition of the device could reach 1.016.000 points per second, but the actual measurements were made at lower rates. Furthermore, due to the relatively large number of people involved in the site testing (and implicitly during the scanning process), the use of this type of laser was found more appropriate as it has a wavelength of $1.5 \mu\text{m}$ (laser class 1, (EN 60825-1 2014)) and the laser beam is rated harmless.

Paper targets were used as landmarks and were placed at different locations around the building. These paper targets are made of two black triangles attached to the center of the paper, which is the reference point in the post-processing stage. Considering the particularity of the blast test conditions, i.e., the pressure propagates at large distance from the source, the location of the paper targets has been carefully considered. They have a critical role in aligning the point clouds and coordinate systems in consecutive scans (before and after the explosion). The minimum requirement is that there are at least three common targets between scanning stations (i.e., before and after the test). If the targets are located too far, the accuracy is low, while if they are too close to the blast, they could be destroyed or they can change the position, which means the measurements are compromised.

Each scan series consisted of two separate scans, i.e., an initial scan to capture the initial shape of the wall panels, and a second one performed after the test to determine the deformations caused by explosion (Figure 5). Seven paper targets were used in average and were placed at distances ranging between 10 and 70 meters from the scanning stations. Although the paper targets were placed at a relatively large distance from the center of the explosion, three targets were affected by the pressure wave, as they were moved from the initial position. Also, one target proved to be too far to provide satisfactory accuracy.

To determine the optimal position of a scan station, it is important to consider the range of the scanner, the maximum distance to which the scanner ensures maximum accuracy, and coverage. To optimize the number of scan stations, the distance between them was adjusted to reduce the points overlapping (the same points seen on several stations). It is also necessary to determine the positions that are providing the largest coverage area of interest, without any obstruction on the laser beam path. Therefore, the scanner position was chosen such that the emitted laser beam intersected the scanned surface as much as possible in a perpendicular direction.

To process the results and obtain the point clouds of the façade system, test data were first exported using the Z+F Laser control program. The accuracy obtained in the alignment of the point clouds was very high and showed an average error of only 1.7 millimeters.

Initially, the point cloud is in grayscale (Figure 6), but during the post-processing phase each point is colored by using panoramic images which are taken by the camera incorporated in the laser scanner (see Figure 7). The larger the point cloud, so is the computational demands. Therefore, some points were considered redundant and removed from the point cloud, because they referred to objects that are not of interest (e.g., trees, terrain). The cleaning process was done with the CloudCompare program (see Figure 8).

Figure 5. View with undeformed wall panels (a), view from exterior with wall panels damaged due to blast (b), and view from interior at the end of the tests (c).

Figure 6. The initial point cloud is in grayscale.

Figure 7. Uncleaned point cloud of the facade before the explosion (a) and after the explosion (b).

3 RESULTS AND DISCUSSIONS

To obtain accurate results, the scans taken before and after the explosion had to have the same coordinate system. Therefore, the coordinates of the paper targets used in the first scan (initial shape) were used as baseline for the second scan (final shape). Post-processing done using CloudCompare software reduced the number of points from an initial 2.7 million to 300.000 points. This step allowed us to reduce the thickness of the point cloud and to obtain the deformed shapes of the panels with accuracy.

Figure 8. Cleaned point cloud of the facade before the explosion a) and after the explosion b).

The deformations could be seen directly from the CloudCompare software (Figure 9), which presents the residual deformations after the tests RT1 (on S1) and LT2 (on S2). It may be seen for a charge of 1.144 kg, the deformations of S1 panels are moderate compared with S2, which has one panel completely failed. However, due to the limitations of the software in handling the results, they were exported in a more general CAD format (i.e., DXF) (see Figure 10).

Figure 9. Top view of the cleaned point cloud of the deformed shape after the tests RT1 (on S1) and LT2 (on S2).

Figure 10. Final point cloud of the deformed shape in DXF format: a) front view; b) top view.

Figure 11 presents the residual deformations for the two wall systems, S1 and S2. Due to some technical issues, for S2 system only the scan after LT2 test provided accurate result. The deformation reported here for LT1 has been measured only at the midspan using a ruler. For S1, there were two valid scans, one for RT1 and one for RT2. As may be seen, for the same blast parameters in RT1 and LT2, i.e., 1.144 kg TNT and stand-off distance $R = 1.5$ m, panels in S2 attains the ultimate capacity and fails, while panels in S1 suffer extensive deformations but the failure is prevented. S1 system steel demonstrate some residual capacity even at a much powerful blast, i.e., 2.288 kg TNT (same stand-off distance $R = 1.5$ m).

Damage levels of wall components under blast loads can be defined by reference to a range of ductility, μ , and support rotation values, θ (Hoffmeister et al. 2015). Some guidance on response limits for structural components of steel-based walls can be found in (DoD 2020) and (DoD 2008). Table 1 shows typical values for cold formed corrugated thin wall members (DoD 2020) and experimental values for the two wall systems presented in Figure 11. For ease of use, Figure 11 presents the panel chord rotation, in degrees, but also the deformation-to-span ratios,

which are more common in the design practice. Note that, the maximum transient deflection limit used in steel-based liner tray design against wind is $L/150$. This limit is associated with elastic design, without any residual deformations of the panels.

Figure 11. Residual deformations in the 3rd panel from the ground row, comparison between the two façade systems, S1 and S2.

Table 1. Response limits for cold formed structural steel members in terms of chord rotation, θ (DoD 2020).

Element	Damage level:	Moderate	Heavy	Hazardous
			Moderate-to-Heavy	Heavy-to-Hazardous
<i>Corrugated panel</i>	Full tensile membrane capacity	3°	6°	12°
	<i>Some tensile membrane capacity</i>	1°	4°	8°
	No tensile membrane capacity	1.3°	2°	4°
Liner tray, system S1		3.2°		5.9°
Liner tray, system S2		1.0°		8.8°

As seen in Table 1, for system S1, the panel behaviour is dominated by flexural response with some tensile membrane capacity, and the two damage levels can be associated with moderate-to-heavy and heavy-to-hazardous responses, respectively. For system S2, which is made of inner metal liner trays only, rotation for LT1 indicates a moderate damage, while the maximum chord rotation is larger than the hazardous response limit ($\theta > 8^\circ$).

For both systems, higher response limits can be achieved (i.e., full tension membrane) if the premature failure of the end connections in shear is prevented. Also, even the unprotected liner trays in system S2 demonstrate a larger deformation capacity than S1, the panels fail at smaller blast pressures due to a lack of interaction between adjacent panels (they work more like 2D systems) and more concentrated blast pressure around midspan.

4 CONCLUSIONS

Terrestrial Laser Scanning can be effectively used for gathering valuable information in the aftermath of an extreme event, e.g., strong earthquakes, extreme weather events, or accidental explosion. They can be installed at certain range from the objective, with minimum on site

demands. The results can help providing a rapid damage assessment and optimize the recovery activities. They are particularly efficient for complex environments, e.g., building facades, where other more traditional techniques may be difficult to apply and with less accurate results.

The results presented in the paper showed the application of laser scanning technique to assess the residual deflections in wall panels mounted on a 3D steel frame building. To reduce the size of the point cloud, results were filtered, without a significant impact on the accuracy. The complex deflected shape of the panels were represented with high accuracy and will be used to calibrate numerical models which under development. The results were also used to propose preliminary damage assessment criteria using predefined chord rotation values, suggesting terrestrial laser scanning represents an effective method that can be used to make a rapid damage assessment and optimizes the recovery activities.

Design strategies for reusable structural components in the built environment

F. Kavoura & M. Veljkovic

Delft University of Technology, The Netherlands

ABSTRACT: The technical solutions for deconstruction are reviewed and investigated in the building sector as this is an expected trend under the sustainability requirements set in the EU Commission's "Green Deal" towards net zero greenhouse gas emissions by 2050. Two of the main research areas for efficient deconstruction strategies are; i) the behavior of multi-material structural components (hybrid structures) that combine the advantages of mechanical properties and architectural appearance of different construction materials, and ii) the techniques and mechanical properties of connections between structural components which allow deconstruction and reuse. However, there is a very limited number of studies and methods into specific demountable and hybrid structural systems, and even fewer focus on their practicability and feasibility. Since these systems have the potential to reduce construction waste, encourage resource efficiency and reduce embodied carbon impacts, it is expected that they will contribute immensely to a sustainable built environment. This paper focuses on technical solutions of the design strategies that currently have been developed for hybrid and steel reusable structural systems, and proposes an approach on implementing structural floor systems designed with the linear approach to a circular building environment.

1 INTRODUCTION

1.1 *Re-use of steel structural components*

In response to the sustainability requirements set in the EU Commission's "Green Deal" (European Commission, 2018) towards reduction of the greenhouse gas emissions, it is estimated that the structural design for deconstruction (leading to structural components' reuse) is going to contribute considerably to the sustainable development of the built environment (Brambilla et al., 2019). The construction sector is responsible for a big percentage of the annual resource consumption, of construction and demolition waste, and of total energy consumption. The preferred strategy in order to achieve a sustainably built environment is to design for demounting, and reuse of the structural components before thinking about repair, remanufacturing, or recycling following Cramer's (Cramer, 2015) scheme on how a circular economy can be incorporated for sustainable construction. Demountability and reuse are the main focus areas in the construction sector since they allow for value retention of the structural members, the potential for cost reduction in extended life cycles, a smaller environmental impact and consequently enhancing sustainable construction.

The idea of reusing steel structural elements is developing through the years. Even if it is still in primitive application in practice, it is highly supported by approaches addressing nowadays the reusability of buildings like "Donorskelet" (Terwel & Korthagen 2021), bridges like the "Nationale Bruggenbank" (2023) or platforms that create digital databases on reclaimed steel structural elements like the "Circulair Bouwen in 2023" (2023). Also, recommendations for the reuse of steel structures have been made stating that any sign of plastic deformation is a reason for rejection and presenting a strategy to support reuse (SCI 2019, Progress 2020). Even if broad concepts on the reusability of structures have been discussed and developed in the aforementioned concepts, very few have presented extended processes to successfully implement the concept in real-life structures. An overview of the reusability of steel and steel-concrete hybrid floor systems is discussed in the next Sections.

1.2 Steel-dominated hybrid demountable structures

Current developments of the steel and steel-dominating hybrid structures underline their advantages with respect to their speed of construction, optimum material use, and consequently decrease in floor weight and the self-weight of the structure while achieving larger floor span when compared with other types of structural systems (e.g. reinforced concrete, timber) (Ahmed et al, 2019). The skeleton of these steel-dominating hybrid structures is made mainly of steel structural components where nearly one hundred percent of the steel is recycled or reused while they can be easily mounted, demounted, and reused with the use of bolted connections. So, as the demand for new structures and the need for reusing existing ones are increasing due to the growing pace of urbanization, there is no doubt that the selection of steel-dominating hybrid structures can have an immense contribution to the sustainable development of the built environment.

Hybrid structures as defined in this paper, consist of floor systems with hybrid beams (steel structural components and multi-material floor and deck systems) that exhibit excellent structural characteristics, in terms of their stiffness and strength, when compared with steel or reinforced concrete beams. The reason is that they combine the advantages of mechanical properties of different construction materials (e.g. concrete in compression and steel in tension). When it comes to the connections of their floor systems with the steel beams, the demountable shear connectors have shown that they can play a significant role in the deconstructability of these systems (Pavlovic et al. 2013, Nijgh et al. 2018).

So, through the transition from a linear economy to a circular one for steel-dominated hybrid structures, a few proposed solutions are summarized in Figure 1. Specifically, through research developments of the last few years the conventional constructional method of the steel-concrete composite floor systems, the steel beams are connected with welded headed studs which are encased within the concrete slab in order to achieve the necessary shear connection. Through developments, this construction method can be transformed into a demountable structure which could lead to a sustainable built environment. This could be achieved through the use of “green” concrete materials [e.g. geopolymers (Liu et al. 2015, Ataei et al. 2016)] the reuse of the structures’ components through the use of demountable connectors (Pavlovic et al. 2013, Nijgh et al. 2018, Odenbreit et al. 2019), and the optimum material use through the use of tapered and high strength steel beams (Nijgh et al. 2018) and composite slabs (Gritsenko et al. 2019).

Figure 1. Development of a sustainable solution for a hybrid floor system through research developments focusing on optimum material utilization and floor system deconstruction and reuse (though demountable connectors).

2 REUSE OF STEEL-DOMINATED HYBRID STRUCTURES

2.1 Reuse of steel structural systems

Design for deconstruction of one-story steel buildings has been presented in detail in the RFCS project Progress (2020) where the in-situ and relocated reuse scenarios are examined thoroughly. The overall same approach for the reusability of reclaimed steel structural components is also adopted by SCI (2019). Accordingly, the process for the reuse of reclaimed steel structural elements is described in Figure 2. The three main phases for the reuse of a structural component and its implementation in the circular building environment include a) the pre-deconstruction audit and assessment for reuse, b) sampling and testing, and c) design for reuse.

The first phase of the pre-deconstruction audit and assessment for reuse includes the preliminary assessment for the evaluation of the feasibility of reclaiming and reusing the existing steelwork. A preliminary overall visual inspection (e.g. identifying problems such as excessive corrosion, excessive/plastic deformation of the structural elements, etc.) and quantitative/empirical evaluation and reporting (e.g. dimensions of joints and their connectors, etc.) of the existing steelwork are undertaken within this phase. The second phase of sampling and testing includes techniques that quantify the material properties and verify the structure. The testing programs include a range of destructive (DT) and non-destructive (NDT) tests. Non-destructive tests (NDT) do not damage the structure and can be useful to locate and/or measure the size of the defects. Some examples are hardness tests, positive metal identification (using X-ray Fluorescence and optical emission spectrometry), and small punch testing. Destructive testing (DT) techniques require extracting (by cutting or drilling) small samples from the existing structure following the EN 10025 (2004) standards. Destructive testing (DT) techniques include tensile testing, chemical composition analysis, Charpy impact test, and metallography. Last, the design for reuse phase includes the design considerations for achieving a reliable structure with reclaimed steel elements and the structural analysis principles according to EN 1993 provisions.

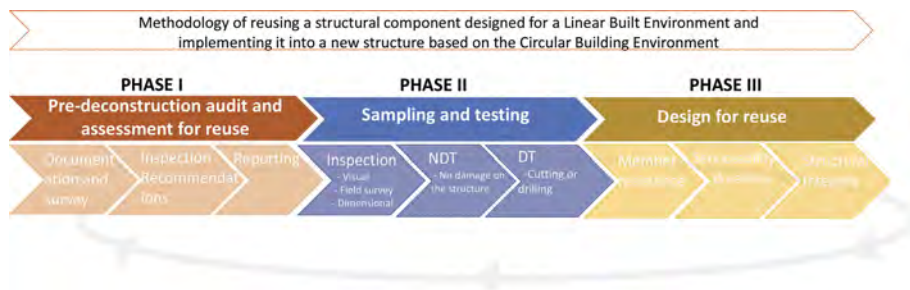

Figure 2. Methodology of reusing a structural component designed for a linear built environment and implementing it into a new structure based on the circular building environment according to the RFCS project Progress (2020).

2.2 Case studies

The idea of reusing steel structural elements is highly supported by approaches addressing nowadays the reusability of buildings like “Donorskelet” (Terwel et al. 2021) (see Figure 3), bridges like the “Nationale Bruggenbank” (2023), or platforms that create digital databases on reclaimed steel structural elements like the “Circular Bouwen in 2023” (2023). Additionally, projects worldwide have proved that reuse of the old steel structure was more feasible than designing and erecting a new steel structure with the same dimensions and functionality (Wakefield 2017, Snyder 2022). Several case studies are presented in detail in the RFCS project Progress (2020) and illustrate the use of reclaimed steel structures in various EU countries and some of the technical issues that were overcome. It is underlined that the case studies and consultations with the supply chain, confirm the technical viability of the reuse of steel reclaimed elements. The additional time/program and cost of using reclaimed steel have been identified as significant barriers across the supply chain. However, the structural design using reclaimed steel elements has shown environmental and economic benefits. These benefits are discussed in Section 3.1.

Case studies using reclaimed steel elements taken from stocks and digital databases on truss bridges (van Lookeren Champagne 2022) and frame structures (Rademaker 2022) have been studied recently. These studies support the design by considering that not all profiles, lengths, and dimensions are available at all times when having such databases (Gorgolewski 2008, Bukauskas 2020). Also, reclaimed elements often lack information about material properties and the used standards when being manufactured. For this reason, the need for a standardized process for the reuse of steel elements is underlined. Countries like the Netherlands, are in the process to standardize the procedure to guarantee the material properties by

Figure 3. Construction of Biopartner 5, whereby steel elements are used from the neighboring Gorlaeus-building (Terwel et al. 2021).

NEN-EN 1993-1-1 for new structural steel for reclaimed steel profiles. The goal is then that the required information about the reclaimed steel element will be included in a material passport, which will be presented in the digital database.

3 DEMOUNTABLE STRUCTURES AND CONNECTORS

3.1 *Demountable and reused floor systems – environmental impact assessment*

The sustainability potential of demountable-reused structures has been assessed by several studies through a Life Cycle Assessment (LCA). The LCA is an internationally used technique that aims at the analysis and evaluation of the environmental aspects and impacts of a product from the procurement of raw materials to the end-of-life stage which can consist of reuse, recycling, or disposal (International Organization for Standardization, 2006). Then different types of emissions are unified into several environmental impact categories which all together determine the total impact. The total impact may be expressed in the functional unit €, which describes the cost society is willing to pay for measures to achieve each emission target. In the Netherlands, this value is called MKI-value or shadow cost. The information obtained from the LCA results concludes a more comprehensive decision process, including quantitative information about the total environmental impact of the structure (International Organization for Standardization, 2006).

Through LCA it has been evaluated that a demountable steel-dominated hybrid structure could reduce considerably the amount of environmental footprint (Brambilla et al. 2019, Bohlen 2021, van Maastrigt 2019). The demountability and consequently the reusability of these systems are supported by the use of demountable shear connectors which allow for the assembly and disassembly of the systems. A detailed list and discussion about types and the structural performance of demountable connectors through the years are given in Section 3.2.

3.2 *Demountable connectors*

The key structural component for achieving a demountable and reusable structure is the type of shear connectors used for the connection between the steel beam and the floor system (for cast-in-situ and prefabricated slabs) (Kavoura et al. 2022a). One of the first types of demountable connectors introduced in the literature is the friction-grip bolt (see Figure 4a). These pre-loaded bolts have been tested in the late 1960s, through push-out and beam tests (Dallam 1968) in order to evaluate if full interaction occurs between the concrete slab and the steel beam within the serviceability limit states. It was reported that friction-grip bolts are demonstrating higher fatigue strength than conventional welded shear studs.

Another type of demountable connection that has been investigated experimentally and analytically in the literature is the bolted shear connectors with embedded nuts (see Figure 4b) (Kwon et al. 2010, Pavlovic et al. 2013). Push-out experiments and detailed FE models have been investigated on prefabricated concrete slabs with single-nut bolt shear connectors (Pavlovic et al. 2013).

They have demonstrated a reduced stiffness of 50% at service loads when compared with headed studs but they could achieve approximately 95% shear resistance (Pavlovic et al. 2013). Post-installed double-nut bolt connectors were used in an investigation of the strengthening of existing bridge girders (Kwon et al. 2010). Static experiments on post-installed double nut bolt connectors showed that they have lower shear strength and ductility when compared with post-installed friction-grip bolted shear connectors but they exhibit high stiffness in the elastic range.

The behavior of bolted shear connectors with a coupler system (see Figure 4b) has been recently studied experimentally on push-out and beam tests (Kozma et al. 2019, Nijgh et al. 2018, Nijgh et al. 2019, Gritsenko et al. 2019). This connector consists of a coupler welded on a steel L-shaped profile on top of the steel beam in which two bolts are connected. One bolt is embedded in the slab and a second removable bolt is placed from below the steel beam flange. In this concept of shear connectors, the coupler has higher strength than the bolts, so damage related to the overloading of the shear connector accumulates in the external bolt, rather than in the embedded coupler. In this way, in a subsequent life cycle, the external bolt can be replaced and the concrete deck is fit for use (Nijgh et al. 2019).

In subsequent studies, injected bolted shear connectors with a coupler system (see Figures 4 c and d) were tested in push out and beam tests on prefabricated slabs (Nijgh et al. 2018, Nijgh et al. 2019) and composite slabs with profiled steel sheeting (Gritsenko et al. 2019). After the injection and curing, the epoxy resin acts as a load-bearing element, and its resistance is substantially higher than its uniaxial compression strength due to the natural confinement provided by the bolt hole (Nijgh 2021). The injected bolted shear connectors allow for oversized holes which can account for the fabrication and execution tolerances and consequently improve the execution efficiency. Even if the increased bolt-to-hole clearance causes a decrease in the effective shear connector's stiffness (Yang et al. 2018), injecting the remaining bolt-to-hole clearance with an epoxy resin has the potential to mitigate this decrease in stiffness (Nijgh 2021). Last, these injected demountable connectors with a novel injected steel-reinforced resin have demonstrated high stiffness when compared to the conventional injectant bolted connections under different deck applications (e.g. concrete and FRP) and consequently confinement conditions (Kavoura et al. 2022b).

Figure 4. Types of demountable bolted connectors a) friction grip bolts, b) double-nut, c) coupler system connectors, d) injected bolted shear connectors with a coupler system.

3.3 Demountable and reused floor systems – structural behavior

In this paper, the developments on the reuse of steel reclaimed elements and the technical solutions for reusing a steel-nominated hybrid floor system are discussed. Several research has been conducted on these two thematic areas but up to now there is a research gap on how these could be combined. In the general theoretical framework of reusing a structural component designed for a linear built environment and implementing it into a new structure based on the circular building environment, the reuse of steel structural components is well-investigated and implementations are attempted through standardization processes (Progress, 2020). However, when it comes to the reuse of hybrid floor systems research and real-life applications still need to be developed.

A first attempt at the analysis of floor systems designed with the linear approach is realized in this paper through a case study. A conventional floor system with continuous beams and a corresponding

demountable solution are analyzed in the program Midas (2011) for comparing their structural performances. The two structural systems are explained in Figure 5 along with their dimensions.

The main concept of this short case study is to evaluate modeling techniques and results by implementing demountable connections between composite beams and slabs created with the linear built approach. These connections are modeled as spring elements between the two structural components with the shear and tensile mechanical characteristics of a bolt connected at the locations of zero bending moments of the continuous beam. The vertical displacement and bending moment contour maps are shown in Figures 6 and Figure 7 respectively. It is observed that in the case of the demountable floor system, the maximum deformations occur close to the end supports. This behavior is caused by the semi-rigid connection between the hybrid beam and the concrete slab implemented as spring elements. The alternation of the bolted demountable connector which is commonly used as a shear connector in hybrid beams (presented in Section 3.2) to another type of connector more suitable for these applications or the implementation of more rigid connectors, could result in a slab behavior closer to the conventional one. Even if technical solutions for connecting hybrid beams with a slab have not yet been developed, this is a research area with great potential and contribution to the sustainable building environment.

4 CONCLUSIONS

This paper presents an overview of the most recent developments regarding the efficient strategies for the reuse of reclaimed steel elements and multi-material structural components (hybrid structures), and the types and properties of connections between structural components which allow deconstruction and reuse. The main conclusions of this paper are summarized below:

- The idea of reusing composite structural elements has been developing through the years. Even if it is still at the initial stage of application in practice, it is highly supported by guidelines and recommendations in addressing the reusability of buildings.
- The three main phases for the reuse of a structural component and its implementation in the circular building environment include a) the pre-deconstruction audit and assessment for re-use, b) sampling (in terms of grouping) and certification of structural components, and c) design for reuse as instructed by well-developed guidelines (SCI 2019, Progress 2020).
- Through LCA it has been evaluated that a demountable steel-dominated hybrid structure could considerably reduce the amount of environmental footprint.
- The reuse of hybrid floor systems and their implementation into a circular building environment, even if they were created with the linear execution approach, has not been developed and needs further investigation. A first attempt at implementing the connection between the hybrid beams and the concrete slabs shows that maximum deformations occur close to the end supports rather than at the midspan of the slab. This behavior will eventually require more sophisticated modeling and implementation of connections between the two systems, in order to capture the real behavior of the system in the vertical and horizontal directions.

A computer vision-based identification of natural frequency of a pole structure and damage detection

D. Kawabe

Graduate School of Global Environment Studies, Kyoto University, Kyoto, Japan

C.-W. Kim

Department of Civil and Earth Resources Engineering, Kyoto University, Kyoto, Japan

ABSTRACT: This study aims to investigate a way of estimating natural frequencies and detecting damage of a full-scale pole structure by means of video footage as a preliminary investigation. The accuracy of estimated frequency from a processed video are compared with the identified results by accelerometers installed on the structure. Furthermore, loosening states of the anchor bolt as a damaged scenario are also recorded for the assessment of damage detection. A phase-based motion magnification method is used for visualizing the mode shapes of the target pole. Then, its vibration is extracted using the Kanade-Lucas-Tomasi Tracker that is one of the optical flow method to track the featured points from the processed video. Changes in estimated natural frequencies at all damaged data were observed, which shows the possibility of the proposed approach for damage detection of the target pole although the accuracy of estimated natural frequencies needs improvement.

1 INTRODUCTION

There are many pole structures such as lighting poles and traffic sign poles, along the road. Periodic inspection is crucially important to prevent them from being collapsed. Since it is time-consuming and labor-intensive to conduct the visual inspection of pole structures due to a large number of such structures, infrastructure asset owners are looking to develop a quick and cost-effective anomaly detection method.

One innovative idea is in utilizing sensing equipment installed inside the inspection vehicle and obtaining the information on the road, which is called the drive-by inspection method. For example, the identification of road roughness and bridge damage from the accelerometer installed on the car has been studied as a cost-efficient method (Gonzalez et al. 2008, Harris et al. 2010). Focusing on the information from in-vehicle footage, detecting corrosions or concrete cracks of the target structures by means of artificial intelligence (AI) has been studied following the improvement of image processing technology nowadays (Petricca et al. 2016, Kim et al. 2017).

The causes of the collapse of the pole structure are basically inside corrosion at the basement of the main poles, fatigue cracks at the base welding location because of the maximum bending moment, or anchor bolts' loosening in the basement. As they are located in the basement of the structure, it is difficult to detect such damage visually from the inspection car. As an alternative way to the visual inspection, vibration-based structural health monitoring focusing on changes in frequency, damping ratio and mode shapes is an effective method for damage detection (Doebling et al. 1996). For example, the changes in natural frequency due to fatigue cracks of a truss bridge are correlated to the reduced stiffness of the structure (Chang & Kim 2016).

The aim of this study is, therefore, to obtain the modal information on the target pole structure from video footage and detect the severity of the damage before collapse among the large

volume of pole structures. This study attempts to extract the modal information of the target pole structure from the video footage at a fixed point. Since information except the target pole structure exists in the recorded video, it is necessary to identify the area of the specific pole from the entire angle of the view. Digital image correlation (Chu et al. 1985) is one of the basic methods to obtain the modal information from the video, but the drawback is the necessity of installing the marks beforehand. In this study, we investigate the application of the phase-based motion magnification method (Wu et al. 2012, Wadhwa et al. 2013), which magnifies slight movements in the video footage. The phase-based motion magnification method first processes the whole angle of view so as to emphasize the target vibration mode of the structure by magnifying the featured bandwidth in the recorded video footage. The tracks of displacement of the target pole structure are extracted using processed video and natural frequencies are estimated. Furthermore, this study measures the video when one anchor bolt is completely loosened as a damaged scenario and investigates the changes in estimated frequencies.

A laboratory experiment for a full-scale pole structure is carried out. Five tri-axial accelerometers were installed for the purpose of identifying true modal parameters such as frequencies and mode shapes. Next, the vibration of the pole is recorded by a commercially available digital camera but high framerate setting. The phase-based motion magnification is applied to the video footage, and wave patterns of the pole are extracted using the Kanade-Lucas-Tomasi Tracker (hereafter “KLT Tracker”) (Lucas & Kanade 1981) that is one of the optical flow methods to track the featured points in the processed video.

2 MODAL CHARACTERISTICS OF THE TARGET POLE

2.1 Laboratory experiment

The steel hollow pole structure for a full-scale laboratory experiment is shown in Figure 1, whose height and diameter of the pole are 5.9 m, and 190.7 mm respectively, and the length of the beam is 2.9 m. The beam and the pole are fixed with four bolts as shown in Figure 1. The baseplate is welded at the basement of the main pole and is reinforced with six triangular ribs (Figure 1). The pole is connected to floor through a base concrete block fixed by four anchor bolts (Figure 2).

For the purpose of identifying natural frequencies and mode shapes of the target structure, Figure 1 also shows the locations of tri-axial accelerometers (shown as solid red circles), five of which are installed in the pole to clarify mode shapes, while one of which is on top of the base

Figure 1. The target full-scale pole structure and the locations of the tri-axial accelerometer. Therein solid red circles denote the location of the accelerometers.

Figure 2. The size of the baseplate of the pole and the states of the anchor bolts at INT and Damaged scenarios.

concrete block to check the movement of the base concrete block. This experiment measures its vibration when the human-induced impact is conducted at a meter height from the baseplate. Twenty impact vibrations, performed at 30-second intervals in each scenario, were acquired, and the average value was used as the true value of the structure. The sampling frequency was 200 Hz.

This study also discusses the feasibility of detecting anomalies caused by anchor bolt loosening. Healthy condition (hereafter called INT) measures its vibration when all anchor bolts are tightened, while a damaged scenario (hereafter called Damaged) denotes the state of one anchor bolt being completely loosened. Figure 2 shows the size of the baseplate and the location where the anchor bolt loosens.

2.2 Modal parameter identification

Natural frequencies and mode shapes of the pole were identified by means of stochastic subspace identification (VanOverschee & DeMoor 2012). Identified frequencies and mode shapes of the pole are summarized in Figure 3. Since this study intends to use the video footage recorded in a driving vehicle, the 1st bending mode of the pole in the Y axis (Figure 3a) is selected for further consideration.

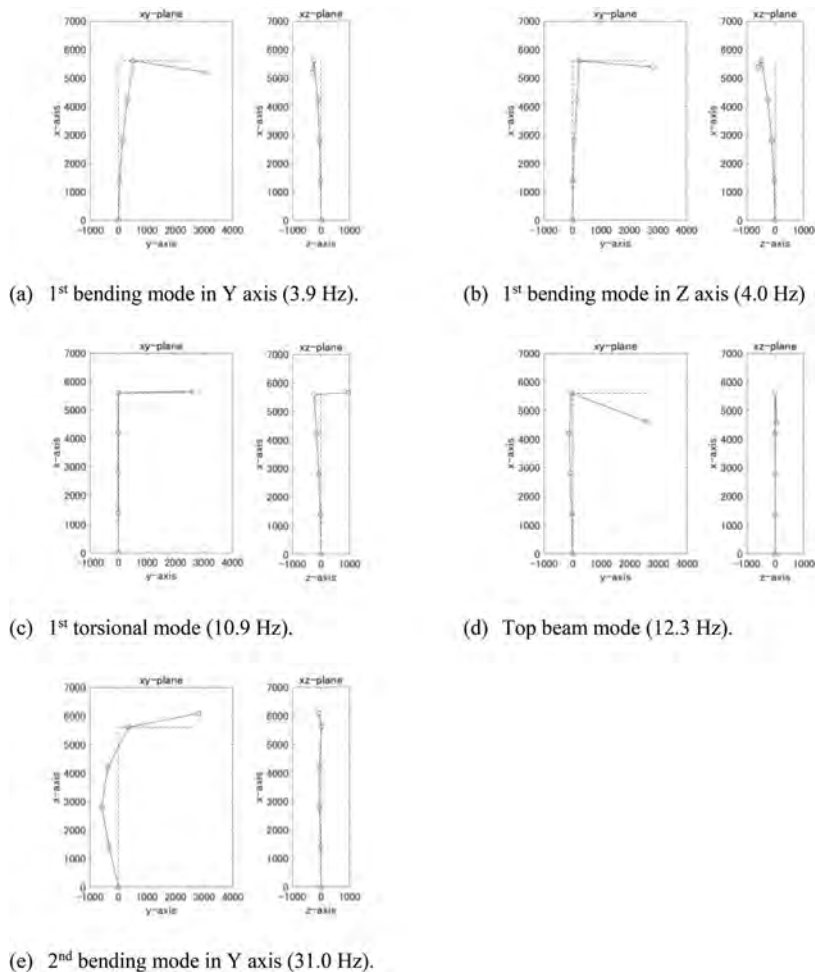

Figure 3. Identified natural frequencies and mode shapes of the pole.

Table 1 shows the identified frequencies in INT and Damaged scenarios. The change in natural frequency due to one anchor bolt loosening was 0.4 Hz which was an 11% reduction from the INT state and was the largest ratio of other modes. It implies that the 1st bending mode of the pole structure can be most easily affected by the changes in boundary conditions at the basement.

3 VIDEO PROCESSING FOR EXTRACTING MODAL PARAMETERS

3.1 Phase-based motion magnification

Wu et al. (2012) demonstrated how imperceptible movements in videos can be revealed using Eulerian video magnification. The Eulerian video magnification is an algorithm for the amplification of small motions in videos. Since videos are made of a series of images and thus have two domains - the spatial domain and time domain - the basic principle behind this algorithm is to take a video and decompose it in the spatial domain by filtering into amplitude and phase signals, followed by time-frequency bandpass filtering. The filtered signal is amplified and reconstructed back into a video where the apparent motion of objects in a video is larger than in the real-time video, occurring at a temporal frequency selected by the user. As a result, small motions in video footage that were difficult to see can be magnified to become obvious to the viewer.

This study uses phase-based video motion processing (Wadhwa et al. 2013) which updates the Eulerian video magnification to be significantly less sensitive to noise. The key approach in the phase-based method is to use complex-valued steerable pyramids at the spatial decomposition process. If f stands for the image intensity at position and time, one can express the observed intensities with respect to a displacement function $f(x + \delta(t))$ in which $\delta(t)$ indicates a displacement function. Since the goal of motion magnification is to synthesize the signal for some amplification factor α , the intensities are modified to $f(x + (1 + \alpha)\delta(t))$. Using the Fourier series decomposition, the displaced image profile can be written in Eq. (1) as a sum of complex sinusoids.

$$f(x + \delta(t)) = \sum_{\omega=-\infty}^{\infty} A_{\omega} e^{i\omega(x+\delta(t))} \quad (1)$$

where ω represents a single frequency at each band. From Eq. (1), to express the motion of the targets, the phase differences between the base frame and a frame at a certain time are calculated.

A complex sinusoid of the band for frequency ω is defined as Eq. (2).

$$S_{\omega}(x, t) = A_{\omega} e^{i\omega(x+\delta(t))} \quad (2)$$

Since S_{ω} in the phase part contains image motion information, changes in motion can be manipulated by changing in phases. To isolate the motion at temporal frequencies, the phase $\omega(x + \delta(t))$ is applied to a DC balanced filter. The result is written in Eq. (3).

$$B_{\omega}(x, t) = \omega\delta(t) \quad (3)$$

The phase B_{ω} is, then, multiplied by the sub-band phase S_{ω} and the complex sinusoid of temporal frequencies ω whose motion is magnified can be written as Eq. (4).

$$\hat{S}_{\omega}(x, t) := S_{\omega}(x, t) e^{i\alpha B_{\omega}} = A_{\omega} e^{i\omega(x+(1+\alpha)\delta(t))} \quad (4)$$

Table 1. Identified frequencies at INT and Damaged scenarios.

	INT	Damaged
1 st bending mode of the pole in y-axis	3.9 Hz	3.5 Hz

Sinusoid $\hat{S}_\omega(x, t)$ is the complex sinusoid that has motions $1+\alpha$ times the input. By reconstructing decomposed images, the magnified video of temporal frequencies ω is built.

3.2 Video setting

This study uses a mirrorless camera that is commercially available. The camera was positioned 9 m away to fit in the angle of the view. Considering the Nyquist frequency, the framerate and resolution were set to 120 fps, and 1920×1080 , respectively. Although the recording time for each dataset is 10 seconds, frames from 301 to 600 were used for the analysis. INT and Damage scenarios were recorded twice and three times, respectively.

Figure 4. Full-scale pole structure and the locations of the tri-axial accelerometer.

(a) Magnified video (an enlarged view in Figure 4).

(b) Original video.

Figure 5. Comparison of frames at the top of the main pole in the magnified video with those in the original video.

3.3 Results in applying phase-based motion magnification

The result of applying the phase-based motion magnification is shown in Figure 4, where the lower and upper bandpass was set to 3Hz and 3.5Hz so as to include the target frequency of the 1st bending mode in the Y axis of the pole (see Table 1). The amplification factor α was set to 100 in this study. Figure 4 represents the frame images when the main pole is most amplified in the front-back Y direction. The vertical red dashed lines draw from the center position of the pole at the basement. For clear visualization, Figure 5a shows an enlarged view of the enclosure around the top of the main pole in Figure 4. For comparison, Figure 5b shows the original video frame at the same location in Figure 5a. It is clear that the processed video visualizes the amplification of vibrations of the pole.

3.4 Magnified wave extraction by use of KLT tracker

Modal characteristics of the target pole are identified from the processed video. This study focused on two regions around the tip of the beam and the top of the main pole (see red marks in Figure 6) where the amplitude of the 1st bending mode in the Y direction is relatively large. Both regions coincide with the accelerometer positions. The ID numbers of the accelerometers are called sensors 60, and 61, respectively. Then, the featured points inside the regions are detected and tracked. We use minimum eigenvalues of the gradient matrix as featured points (Shi 1994). For example, extracted featured points at the tip of the beam under INT condition are shown in Figure 7, where eight featured points were extracted. It can be seen that the featured points are well extracted from the edge of the beam. The KLT Tracker which is one of the Optical Flow methods is used for tracking the featured points. In this study, the average of the sub-pixel values of the point cloud in each region in each frame image is calculated and considered as the displacement waveform at the location where the sensor was featured.

Figure 6. Regions of extracting featured points. The number indicates the ID number of the accelerometers.

Figure 7. An example of detecting featured points at the region of the tip of the beam shown as white cross symbols.

The extracted displacement wave of the INT condition is shown in Figure 8. Figures 8a and 8b indicate horizontal and vertical directions, respectively. According to Figure 8a, the horizontal displacement near sensor 61 (top of the pole) was larger than that near sensor 60, while the vertical displacement showed the opposite trend. From the result, it can be said that the vibration waveforms can be extracted from the video in which 1st bending mode in the Y direction is magnified using the method for detecting and tracking featured points at each frame.

The displacement waveform in INT and Damaged conditions are compared as shown in Figure 9. Blue and red lines indicate the extracted results from the 1st recording in the INT condition and from the 1st recording in the Damaged condition, respectively. It is clear that the wave frequency in the Damaged condition is decreased because the period of the Damaged condition is longer than that of the INT condition.

(a) Extracted horizontal displacement waveform.

(b) Extracted vertical displacement waveform.

Figure 8. Extracting displacement waveform from magnified video in INT condition.

Figure 9. Comparison of displacement waveform from INT scenario with that from Damaged scenario.

Table 2. Identified frequencies at INT and Damaged scenarios.

	1 st recording	2 nd recording	3 rd recording	Identified by accelerometers
INT	4.0 Hz	4.0 Hz		3.9 Hz
Damaged	3.6 Hz	3.6 Hz	3.6 Hz	3.5 Hz

Furthermore, this study conducts Fast Fourier Transform to obtain the peak in the frequency domain of the waveform as the estimated natural frequency of the 1st bending mode in the Y direction. Horizontal displacement at the region on sensor 61 and vertical displacement at that on sensor 60 is used. Table 2 shows the estimated natural frequencies from the video footage of the INT scenario and the Damaged scenario. The natural frequencies estimated from the processed video, both in the INT and Damaged condition, were estimated to be 0.1Hz higher than those from the accelerometers. One reason might be the resolution of the identified frequency from the short time history. Although the accuracy of identifying frequency still needs improvement, it can be seen that the identified frequencies in the Damaged scenario were decreased. Therefore, there is a possibility of detecting structural anomalies in the pole structure by estimating natural frequencies from the magnified video although the amount of sampling should be added for clarification of the estimated variables.

4 CONCLUSIONS

This study conducts a damage-induced experiment on a full-scale pole structure to extract the frequency from the video footage and discusses the feasibility of anomaly detection. To clarify

the accuracy of estimated modal information obtained from videos, modal parameters identified from accelerometers installed on the pole are assumed as ground truth.

Phase-based motion magnification method is used to extract the vibration information from the video footage. This study focused on the 1st bending mode in the direction parallel to the top beam. Featured points using minimum eigenvalues of gradient matrix were detected from the processed video near a region of the tip of the beam and that of the top of the pole where their amplitudes were relatively large, and tracked using the KLT Tracker. Observations showed that displacement waveforms mostly consistent with the 1st bending mode were obtainable. In order to clarify the natural frequency, tracked displacement waveforms were transformed to the frequency domain using the fast Fourier transform, and the dominant frequencies were picked up. Both in the INT and Damaged conditions, 0.1Hz higher frequencies than those from the accelerometers were observed. One reason might be the resolution of the identified frequency from the short time history. Although the accuracy of identifying frequency still needs improvement, the decreasing tendency of the frequency due to the loosened bolt was observed. It encourages us to identify frequencies from the magnified video for detecting structural anomalies in the pole structure.

ABSTRACT: As the significant number of European bridge stock comprises more than 100 years old masonry arch bridges, restrictions to the operation of these bridges or their closure due to increased traffic load can result in network disruptions with subsequent economic losses. Apparently, most of these bridges are carrying loads above those envisaged by their original designs. This paper presents the development of a framework for the digital twinning of masonry arch bridges to enhance their management and provide informed decisions for their repair and maintenance schemes. As a case study, a full-scale masonry arch bridge with a 3.0m span is considered here. The framework starts with the development of a 3D geometry using an innovative photogrammetry approach, which accurately captured the overall geometry and local irregularities of the masonry bridge. Afterwards, dynamic characteristics i.e., natural frequency and modal shape of the masonry arch bridge can be obtained from ambient vibration tests by instrumenting the bridge with accelerometers. A Bayesian approach is then implemented to identify structural modal properties under different time windows as a comparison for further assessments. Data from the developed 3D geometry (via photogrammetry) and modal properties are combined to develop a high-fidelity numerical model for structural analysis. This numerical model can be continuously calibrated using monitoring data from the testing of the masonry arch bridges under service loadings. The framework presented in this study has the potential to conduct an autonomous condition-based assessment of ageing masonry arch bridges, characterised by advanced real-time monitoring, and data-informed decisions to understand damage accumulation.

1 INTRODUCTION

Although the introduction of new and modern construction materials such as steel, reinforced and prestressed concrete has reduced the further development of masonry arch bridge construction, there are still thousands remaining stone and brick masonry arch bridges around Europe, most of which were built between the second half of the 19th century and the first decades of the 20th century. For instance, only in the UK, there are about 40,000 masonry arch bridges in daily use on highways, railways and canals, representing an estimated 40–50% of the total bridge stock (Page 1993). Most of these bridges are still in service despite the current traffic loads are much higher than those assumed in the original design, which was carried out on the base of empirical criteria or simple design rules (Brencich & Morbiducci 2007). Moreover, masonry arch bridges are deteriorating over time after being subjected to a prolonged exposure to traffic loads, large vibrations, foundation settlements, environmental conditions and extreme natural events.

The management and assessment of ageing masonry structures constitute a major challenge across the public infrastructure. Network Rail (UK) acknowledged that the assessment methods currently used by the industry are antiquated and/or over-simplistic (Network Rail 2011). For example, for the assessment of masonry arch bridges, the Military Engineering Experimental Establishment (MEXE) method is still in use; which dates back to the 1940s, has a very limited predictive capability, and offers little scope for future enhancement (Sarhosis et al. 2016).

Over the last three decades, significant efforts have been devoted to the development of numerical models to represent the complex geometry and non-linearity behaviour of masonry bridges subjected to external loads and extreme events e.g. floodings, subsidence and earthquakes. Such models range from considering masonry as a continuum (macro-models) to the more detailed ones that consider masonry as an assemblage of units separated by mortar joints (meso-models). The precise quantification of the masonry structure is further complicated by the higher degree of spatial variability of the masonry material properties compared to other construction materials, such as steel or concrete. Variations of material properties can be incorporated into the finite element analysis (FEA) combined with Monte-Carlo simulation (Muhit et al. 2022, Sarhosis et al. 2020).

Furthermore, a vital aspect when modelling masonry structures based on the meso-scale modelling approach is the accuracy in which the geometry of the masonry structure is transferred in the numerical model. So far, the geometry of masonry bridges is captured with traditional techniques (e.g. visual inspection and manual surveying methods) which are labour intensive and error prone. In the last ten years, advances in laser scanning and photogrammetry have started to drastically change the building industry since such techniques are able to capture rapidly and remotely digital records of objects and features in a point cloud format. In particular, there are cost-effective works in transitioning from point clouds obtained from images and/or terrestrial laser scanning to structural analysis models (Loverdos & Sarhosis 2022, 2023a, 2023b).

On the other hand, considerable research efforts have also been devoted to replacing traditional maintenance plans based on periodic visual inspections with more efficient structural health monitoring (SHM) plans. In general, SHM relates the implementation of long-term monitoring systems and damage identification algorithms to conduct condition-based maintenance. Damage identification is organised on a scale of increasing complexity, including (i) Detection, (ii) Localization, (iii) Classification, (iv) Extension, and (v) Prognosis. In this context, damage identification algorithms are generally classified as unsupervised or supervised techniques (Giglioni et al. 2021). The implementation of unsupervised techniques is relatively simple, since damage inference is conducted by simply processing monitoring data. Nevertheless, their ability to achieve damage identification levels beyond detection (Level I) is considerably limited. Conversely, supervised learning techniques exploit both monitoring data and engineering knowledge through structural simulation models. While the implementation of such techniques is challenging due to the epistemic uncertainties typically involved in any structural model, their ability to relate the structural performance to the intrinsic health condition makes it possible to detect, localise, quantify and predict the evolution of damage. It is thus essential to count on reliable structural models to effectively develop condition-based maintenance plans.

Therefore, it is evident that the traditional way of assessing masonry arch bridges becomes obsolete with the rapid changes in traffic loading and natural material degradation; hence, management practices will have to evolve to reduce the impact of novel threats. This paper presents the development of a framework for the digital twinning of masonry arch bridges to enhance their management and provide informed decisions for their repair and maintenance schemes.

2 MASONRY ARCH BRIDGE DIGITAL TWIN FRAMEWORK

The principal motivation of the proposed framework is to develop and establish a methodology for autonomous condition-based assessment of ageing masonry arch bridges, characterised by advanced photogrammetry and/or laser-scanning, real-time monitoring, probabilistic damage identification and data-informed decisions for repair and maintenance schemes. The first step of the workflow is to develop an initial geometric digital twin of masonry

arch bridges from digital images followed by the development of high-fidelity numerical models capable of reproducing the main damage mechanisms and accounting for the inherent variability of the material properties. Then, automated Operational Modal Analysis (OMA) using ambient vibration data can be accomplished in order to develop a computational digital twin model through surrogate modelling. Continuous model calibration using Bayesian model selection and parameter inference methods are necessary to localise and quantify the damage of the masonry arch bridge. As a case study, a full-scale masonry arch bridge constructed in the George Earle testing laboratory of the University of Leeds is considered here. The bridge has been constructed as part of the EPSRC project, Exploiting the resilience of masonry arch bridge infrastructure: a 3D multi-level modelling framework (EP/T001348/1).

2.1 *Advanced photogrammetry/ laser-scanning*

The workflow of documentation, inspection, and assessment of existing structures can be improved by the use of modern technologies such as laser-scanning and photogrammetry. Terrestrial laser-scanning (TLS) uses specialised equipment which able to emit multiple laser-beams to measure the distance of random points in space and acquire their XYZ coordinates, and possibly colour. The recorded points form a point cloud (Point Cloud Data, PCD), that provides an accurate representation of an object or space. Multiple records can be combined to extend the coverage to regions not visible from a single capture point. Photogrammetry, on the other hand, refers to the process followed to obtain realistic information about an object or area from image data (i.e. distance, colour, etc.). It can be used to produce similar results to TLS by following a different approach. A sequence of images is used to generate a PCD of the captured object and can be achieved by identifying the location of a common point between multiple images through triangulation. Due to the nature of photogrammetry, it is more approachable, than laser-scanning, since it does not require specialised equipment.

Regarding structural assessment, the PCD can also be used to generate numerical models for structural analysis (Kassotakis & Sarhosis 2021). Other applications of photogrammetry/laser-scanning include the generation of orthorectified imagery of structures. Ortho-images may be used for reliable measurements on a single plane (i.e. XY, XZ, YZ). Combined with recent advances in computer vision can offer a further understanding of the asset. Applications of image processing allow the automatic feature detection of masonry elements. Especially when combined with artificial intelligence to provide more reliable results (Loverdos & Sarhosis 2022). That even makes the generation of discrete models of masonry structures viable (Loverdos et al. 2021), albeit limited to 2D-plane. The integration of detected features, to the PCD or reality mesh directly, is also possible (Kalfarisi et al. 2020) which assists with the aspect of visualisation and can be a powerful tool for automation of the visual inspection of existing masonry structures. Lastly, a combination of the methods and technologies mentioned above is the precursor of future developments regarding the generation of digital-twin models, of existing masonry structures from visual-data. Those techniques can be utilised to generate semi-automatically a complete digital replica of a structure, visualise changes to the structural form, assess the current state, and evaluate the future behaviour of the structure.

The case study considered here is a 3.0 m span masonry arch bridge constructed in the laboratory and using sophisticated photogrammetry techniques a 3D model of the structure was generated. Initially, 1218 pictures of the structure were captured, with a minimum of 50% overlap. Sample images used to generate the PCD are shown in Figure 1. These images were recorded using a smartphone with a 64-megapixel camera and a maximum resolution of 9248 x 6944 (POCO F2 Pro). The images were captured from the surrounding of the structure, at different heights and distances (Figure 2). Photogrammetry software such as the Context-Capture from Bentley was used to generate the dense point-cloud and reality-mesh. Four control points were assigned manually, to improve the alignment and scale the structure to the real dimensions. The control points were assigned to multiple images, at the 4 main corners of the structure near the bottom (upper side of the concrete floor). The control points were necessary to connect the multiple alignments produced. Finally, the reality mesh was coloured, textured, and smoothed (Figure 3).

Figure 3. Textured reality-mesh of the dense point-cloud.

2.2 Stochastic computational model and numerical analysis

The imported 3-D geometry can be used to develop a high-fidelity stochastic numerical model of the masonry arch bridge. This numerical model can be a finite element model (FEM) or discrete element model (DEM) depending on the requirements. Stochastic spatial numerical modelling, which considers the variability of material properties within a given structural system, often better represents the real scenario; nevertheless, it involves different levels of complexity in terms of model development, probabilistic information of crucial material

parameters, computational cost, etc. For a simplistic case a deterministic model can be considered, where various material properties are each assumed to have a single de-fined value (mean value) throughout the structure. However, since inconsistency in the quality of workmanship, curing processes, and masonry materials may result in spatial variability even in the same structure, it is vital to consider the spatial and temporal variability of material strengths to estimate the capacity of the masonry arch bridge. In this way, the mesoscale modelling approach can be combined with the Monte-Carlo simulation (MCS) technique. The rationale for this choice is that not only does mesoscale allows separate descriptions of masonry units and mortar joints, but also it permits the consideration of the unit-to-unit variability in the spatial stochastic analyses. In this case, it is necessary to quantify and restrict the number of random variables to only those parameters on which the masonry arch bridge response under service loading is sensitive. Random variables or uncertainty parameters can be categorised as statistically independent, spatially variable, and/or spatially dependent.

2.3 *Operational modal analysis and digital twin*

The computational model developed in the previous stage (initial numerical model) may involve considerable sources of uncertainty that should be minimised before constructing the digital twin. Hence certain parameters of the numerical model should be calibrated using structural health monitoring data. One way could be utilising the modal properties determined by an initial ambient vibration test (AVT). Vibration-based structural health monitoring technique originated in the 1990s and is now being used extensively. Its fundamental principle is to assess the state of a structure by detecting changes in its dynamic properties, such as natural frequencies, mode shapes, and modal damping ratios, before and after damage occurs. More specifically, the natural frequency (or the natural period of vibration) of a structure is regarded to be only associated with the mass and stiffness of the structure. For a large-scale structure, i.e., a bridge, the damage-induced loss in the mass of the structure is negligible. However, these damages, including the local buckling and cracks, can result in stiffness reduction, which can further lead to changes in the natural frequencies of the structure (Huynh et al. 2005).

The process of AVT consists of two main steps. The first is the detection of the vibration response of the structure. In principle, structural vibration should be excited by external loads and captured by, i.e. accelerometers. In the laboratory condition, the vibration of model structures could be excited by impact-load or other forced vibration excitation techniques. For the real large-scale structure, the usage of forced vibration excitation techniques (e.g. shakers) as excitation is usually impractical. In these cases, measuring structural response triggered by environmental excitations or ground microtremors (i.e. traffic loads, wind, etc.) could be an option. The number of sensors and the location of each sensor should be designed based on the geometry, dynamic response characteristics, and boundary conditions of the structure. So far, several methodologies have been proposed for optimising the placement of sensors (Gao et al. 2005). After the dynamic response is captured, extraction of the dynamic properties from the measurements and identification of damage indicators is the second step. It is worth noting that pre-processing of the raw data may be required to attenuate the influence of environmental noise on the detected signal, such as baseline correlation and low-pass filtering.

The masonry arch bridge considered in this paper as a case study was instrumented with four tri-axial accelerometers on top of the two spandrel walls of the full-scale masonry arch bridge model as shown in Figure 4. Three of the accelerometers were mounted on the south-face of the spandrel wall above the quarter span, crown and three-quarters of the arch barrel, and one on the middle of the north wall, allowing the torsional mode of the bridge to be determined. It's worth noting that the setup of these accelerometers is not definitive and can be arranged in different patterns, if needed. AVTs were conducted before and during each phase of loading applications to capture frequency variations of the masonry arch bridge which facilitated the identification of the damage to the bridge resulting from load applications. For each vibration test, impact loads were applied manually using a rubber hammer as the excitation. Ten impacts were carried out with an interval of 5 seconds between each impact.

Therefore, each measurement took around 1 minute. In addition, the sampling frequency was set to be equal to 200 Hz in order to accurately capture the dynamic response of the bridge.

Figure 4. Accelerometer instrumentation for ambient vibration test on the masonry arch bridge (note: backfill is not shown here for simplicity).

The modal features of the structure can be identified through operational modal analysis (OMA), and the uncertainties in the numerical modelling shall be reduced through model updating, minimising the differences between the experimental and the numerical modal signatures. On this basis, potential damage scenarios and failure patterns of the masonry arch bridge can be simulated from this stochastic computational model followed by sensitivity analysis for parametrisation. The simulated damage mechanisms then be used to train a set of computationally efficient surrogate models, which will act as black-box functions mapping the considered damage-sensitive parameters and the modal features of the structure (Garcia-Macias & Ubertini, 2022). In particular, the surrogate modelling approach can combine adaptive sparse polynomial chaos expansion (PCE) and Kriging meta-modelling to provide local/global modelling capabilities with maximum flexibility. These surrogate models will act as Digital Twins of the structure under investigation, being possible to conduct quasi-real-time damage identification. To do so, automated OMA techniques can be developed to continuously extract the modal features of the bridge from periodically recorded ambient vibrations.

2.4 Bayesian model update and damage identification

Damage identification is organised in a scale of increasing complexity, including Level I - Detection, Level II - Localization, Level III - Classification, Level IV - Extension, and Level V - Prognosis. The time series of modal signatures can be processed through statistical pattern recognition and in case an anomaly is detected (Level I), the damage identification algorithm should be activated. This algorithm can involve a Bayesian model selection approach, through Transitional Markov Chains (TMC) to identify which damage mechanism has been activated. A major limitation of traditional Bayesian model updating regards the difficulties related to the presence of ill-conditioning in the inverse model calibration. Although the definition of prior probability distribution functions to certain parameters may limit this aspect, ill-conditioning can be hardly eliminated, and the appearance of misidentifications may arise. This may compromise the efficiency of the subsequent detailed inspection or rehabilitation intervention. To alleviate this issue, an innovative approach, post-event photogrammetry (captured from laboratory tests after the damage occurred) can be used to constrain the optimisation problem, thus minimising the ill-conditioning in the calibration. To achieve so, simple local metrics based on image processing are under development to constrain (0 – unconstrained, 1- fully constrained) certain model parameters that do not clearly experience damage, while imposing no constraints on model parameters that may have experienced

damage. Once the Bayesian model selection completes, the probability distributions of the model parameters will be used to localise and quantify the damage. The general workflow of the digital twin development based on photogrammetry, MCS and SHM techniques are sketched in Figure 5.

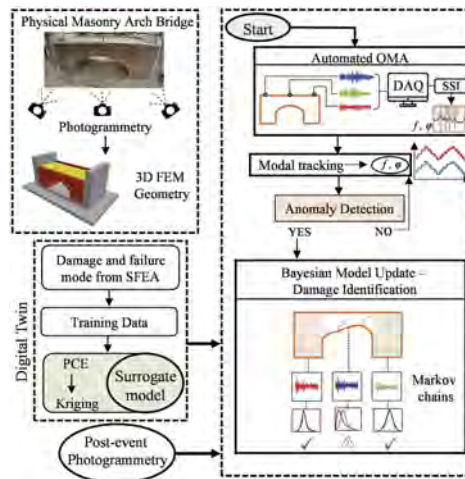

Figure 5. Workflow of masonry arch bridge digital twin development.

3 CONCLUSIONS

This paper presents an overview and workflow of the framework for digital twinning of masonry arch bridges which will automate the SHM of masonry arch bridges from a physical bridge to the prediction of damage by digital twin. This concept is well-positioned to promote world-class state-of-the-art research and a significant academic and scientific impact is envisaged through the utilisation of innovative algorithms, high-quality monitoring techniques and novel numerical methods.

This proposed framework involves the systematic development of the 3D geometry of the masonry arch bridge from digital images, i.e. using photogrammetry. Unit block and mortar joint recognition can be achieved by using an image processing algorithm based on an improvement of the marked controlled watershed algorithm. The result will be an automatically segmented point cloud with each individual masonry unit isolated and in a format suitable to be inputted into structural analysis models, if necessary. The geometrical accuracy of the algorithm can be assessed based on its ability to map geometric irregularities by verification against measurements from total stations.

The processed 3D computational modelling geometry can then be used to develop a high-fidelity stochastic numerical modelling of masonry arch bridges. A suitable FEM or DEM can be considered where spatial variability of material strengths are considered and the modelling approach is combined with the Monte-Carlo simulation technique to evaluate the probabilistic response of the bridge.

To improve the computational model and minimise the sources of uncertainty, the developed model should be calibrated using the modal properties determined by an ambient vibration test. The modal features of the structure could be identified through operational modal analysis, and the uncertainties in the FEM/DEM can be reduced through model updating, minimising the differences between the experimental and the numerical modal signatures. Then a digital twin can be developed from surrogate modelling which combines adaptive sparse polynomial chaos expansion and Kriging meta-modelling to provide local/global

modelling capabilities. These digital twins can be further calibrated or enhanced through Bayesian model updates when any anomaly is detected from the automated operational modal analysis.

This concept is still in its infancy and several components of it need further studies to enhance clarity and obtain reliable information. The framework proposed and the work reported in this paper is part of a broader project, which is in progress. The developed framework would inform dynamic characteristics such as parametric resonance, eigenfrequencies, dynamic amplification factor, and periodic motions attributed to the interaction between vehicle and masonry arch bridge. The fundamental idea is to establish a relationship and form a ‘bridge’ between existing knowledge/practice and advanced automation techniques.

ABSTRACT: Recent studies have demonstrated that important bridge dynamic properties can be extracted from crowdsourced smartphone data collected during vehicle trips. The key benefit of crowdsourced smartphone vehicle trip (SVT) data is the potential ease in producing large volumes of useful data at very low costs compared to modern SHM networks. Crowdsourcing inherently involves trade-offs in data quality for data scale; however, the extent to which data quality varies with respect to trip metadata, such as vehicle speed or smartphone model, etc., are not well understood. This paper evaluates the sensitivities of bridge dynamic property estimates with respect to individual trips or groups of trips, i.e., subsets, based on about 700 SVT datasets collected on a real bridge. Overall, this paper demonstrates an application of classification models in identifying “low quality” datasets, i.e., those that corresponded to less accurate mode shape estimates. This tool shows potential to quickly flag low-quality datasets during preprocessing which could help optimize the accuracy of the SHM information produced.

1 INTRODUCTION

Structural Health Monitoring (SHM) and Structural Modal Identification (SID) aim to assess the condition and performance of structures through the measurement and analysis of their dynamic behavior. In practice, SHM and SID are subject to challenges that can inhibit regular implementation. The setup and maintenance of SHM systems can require significant financial resources, investments in hardware, software development, and human resources. Traditional monitoring methods are based on a distributed sensor network that is installed directly on the structure (Brownjohn et al., 1992; Smyth et al., 2003; Lynch and Loh, 2006). Over the past two decades, indirect modal identification methods for bridges have been developed to determine bridge modal properties by analyzing measurements from sensors that are not installed on the structure, instead, the sensors may be within a moving vehicle (Yang et al., 2004; Lin and Yang, 2005). These methods aim to mitigate issues related to data acquisition, data management, system cost, and system maintenance.

Indirect methods have the advantage of being non-intrusive, low-cost, simple, and comparatively easy to implement; but as these tools are relatively new, their accuracy and reliability have primarily been demonstrated in controlled experimental tests or using synthetic data that not necessarily represent real-world conditions (Yang and Chang, 2009; McGetrick et al., 2015; Yang et al., 2020; Gonzalez et al., 2012; Eshkevari et al., 2019, 2020, 2022; Gkoumas et al., 2023; Malekjafarian et al., 2022). Simultaneously, the efficiencies of a mobile sensor network and the ability to incorporate cheap, ubiquitous sensors such as smartphones are appealing. Smartphones have gained unprecedented penetration rates and have been broadly utilized across research fields such as epidemiology Massaro et al. 2019, mapping Li et al. 2017, human mobility Miranda et al. 2021, Schlapfer et al. 2021, driver behavior Vlahogianni and Barmponakis 2017, road surface analysis Mednis et al. 2011, and others. While smartphones contain less accurate sensors overall, studies have established how they can successfully be applied in SHM and some limitations trips Feng et al., 2015, Sitton et al., 2020. Recent studies of indirect methods using smartphone sensors in real-world applications in real-world settings that consider operational traffic loading and typical bridge trips McGetrick et al., 2017, Matarazzo et al., 2018. Specifically, it has been shown that accurate bridge modal frequency estimates can be extracted from data crowdsourced from smartphone-vehicle trips (SVT) (Matarazzo et al., 2022).

Crowdsourcing smartphone measurements inherently involves trade-offs in data quality for data scale. Crowdsourced SVT data fall into one of three classes based on the analysts' ability to oversee and influence data collection: controlled, partially-controlled, and uncontrolled (Matarazzo et al., 2022). The extent to which SVT data quality varies with respect to trip metadata, such as vehicle speed or smartphone model, etc., are not well understood. In some cases, the crowdsourced SVT metadata might indicate that the quality of an individual dataset is poor, and its inclusion would negatively affect SHM quantities of interest. In other words, the aggregate estimates considering all collected data may not be the most accurate. These considerations become especially important when data volumes become orders of magnitude larger, i.e., tens of thousands of datasets. For instance, crowdsensing platforms with monthly data streams on the order of thousands would greatly benefit from pre-processing tools that can discard datasets that may be noisy or less likely to positively impact SHM features of interest. This study investigates the evaluation of the quality of individual datasets with respect to the population (all data) and their classification, which can help develop tools used to produce accurate estimation results.

2 CROWDSOURCED DATA COLLECTED ON A REAL BRIDGE

The smartphone-vehicle trip (SVT) data used in this study were collected by smartphones within moving vehicles as they traveled over a 272-m long, steel arch bridge in northern Italy as part of the *Good Vibrations* project (Lab, 2023). The data was collected as part of a collaboration with Anas Sp.A. The data are best described by the partially-controlled data class as the analysts provided guidelines to those collected data, but did not enforce them or oversee data collection. In total 677 SVT datasets were collected using smartphones in the organization's maintenance trucks.

The accelerometer and GPS sensors within the smartphone were utilized to record physical response measurements during each trip. The data logged for each trip included the trip start time, GPS (latitude, longitude) sampled at a rate of 1 Hz, as well as phone orientation and triaxial accelerometer measurements (X, Y, and Z-directions) sampled at 100 Hz. In addition, a standard fixed sensor network was installed on the bridge to document structural modal properties. Existing methods can be implemented to extract bridge dynamic properties from the aggregated SVT data (Matarazzo et al., 2022; Cronin et al., 2022). This paper focuses on the estimation of the absolute value of the mode shape (AMS) of the first vertical vibration mode. Cronin et al., 2022 describes the modal properties of this bridge and presents the method used to compute the AMS in detail.

3 MEASURING DATASET QUALITY

The quality of a dataset is a relative property. Metrics used to assess quality are constructed with respect to specific quantities of interest. In this study, the estimated structural modal properties are of interest; specifically, the absolute value of the mode shape (AMS) of the first vertical vibration mode. The methodology used to extract the AMS based on the SVT data is described in Cronin et al., 2022. Overall, the methodology provides one aggregated AMS estimate, $|\phi_{total}|$, considering all 677 datasets.

Figure 1. A) Probability Density Function (PDF) and b) Cumulative Distribution Function (CDF) of the quality score metric (QS).

The goal is to evaluate an individual dataset's contribution to the overall AMS. It is important to note the methodology for estimating AMS requires a group of datasets; therefore, it is not possible to obtain an AMS estimate using only one dataset. A Monte Carlo Sampling technique is used to group an individual dataset i , with $N - 1$ other datasets at random (group size is N). The Monte Carlo sampling technique is repeated R times for each dataset, for all 677 datasets. To quantify the quality of an individual dataset i , the mode shapes are compared using the MAC value. MAC values are computed between all R AMS and the aggregated AMS, $|\phi_{total}|$, and the Quality Score (QS) for dataset i is defined as the average of these MAC values.

$$QS_i = \frac{1}{R} \sum_{j=1}^R MAC(|\phi_{i,j}|, |\phi_{total}|)$$

Like the MAC value, the QS metric ranges between 0 and 1, where 1 indicates the highest consistency with the AMS considering all 677 datasets. Note QS is affected by the group size N and the total number of iterations R . Overall, if the group size N is too large, the quality scores will not vary much between individual datasets because the computed AMS estimates will be very similar to the aggregate AMS. In this study, $N = 25$, which is approximately 4% the size of the total number of samples, and $R = 200$.

The probability density function (PDF) and cumulative distribution function (CDF) for the QS values are shown in Figures 1a and 1b. The PDF shows a distribution with one primary peak, and small peaks on either side. The large peak has a mode near $QS = 0.66$, the small peak on the left has a mode near $QS = 0.61$, and the small peak on the right has a mode near $QS = 0.75$. Overall, these plots suggest that it may be a subset of datasets that correspond to lower QS values. This study will consider a classification problem in which two classes of datasets are defined based on a QS threshold: (i) good quality data and (ii) poor quality data. At first glance, it appears a QS threshold near $QS = 0.65$ or above may result in a useful data split.

4 DATASET FEATURES

Each SVT dataset contains over a dozen measurement channels such as acceleration in three directions, vehicle speed, GPS, GPS accuracy, etc. The goal is to use these channels to discover or identify features that will ultimately have some predictive power with respect to the QS

metric, which, in the context of this problem, would suggest a strong influence on dataset quality. There are nearly endless possibilities for features as they can be based on raw channel data, transformed data, combinations/interactions of the data, and more. Simultaneously, dimensionality reduction techniques such as principal component analysis (PCA), autoencoders, T-distributed Stochastic Neighbor Embedding (t-SNE) Van der Maaten and Hinton 2008, or uniform manifold approximation (UMAP) McInnes et al. 2018 are useful when selecting features. Nonetheless, relatively basic features were chosen at first to help maintain model interpretability and to consider recent findings in the indirect bridge monitoring and vehicle-bridge-road interaction literature, e.g., higher vehicle speeds can result in datasets with low signal-to-noise ratios (SNR) (McGetrick et al., 2015; Eshkevari and Pakzad, 2019; Yang et al., 2020).

Figure 2. Correlation matrix of selected data features, “RQS” corresponds to the QS metric.

To start, eight features were considered in this study: 1-2) mean and variance of the vehicle speed, and the 3-8) mean and variance of the acceleration in all three directions. Figure 2 shows a matrix of the Pearson cross-correlation coefficients of all nine features and the QS. Overall, there are some notable cross-correlations among the features, e.g., variances of different accelerations. Most of these features have a low correlation with QS. The variance of the acceleration in the x-direction and z-direction features had the highest correlation with QS, although they were still relatively low. This indicates that individually, these specific features may not be strong predictors if considering isolated linear models. Although, it is not possible to fully evaluate each feature’s predictive potential for QS without further analysis, which may include some preliminary model fitting.

5 CLASSIFICATION PROBLEM SETUP AND ANALYSES

Each dataset was assigned a label as either “high-quality” (HQ) or “low-quality” (LQ). This classification is determined based on the CDF of the QS metric. The data are split at the 75th

Figure 3. Pairs plot of the scaled features and dispersion of classes. Blue dots correspond to low-quality (LQ) labels and orange dots correspond to high-quality (HQ) labels.

percentile, which corresponds to a RQ threshold of 0.67 and results in 508 “poor” datasets and 169 “good” datasets. Figure 3 shows scatter plots of the eight features considered and specifies which datasets were labeled as HQ or LQ. These sorts of scatter plots can be useful for several reasons. They may help uncover potential multicollinearity problems. They can also help the analyst get a picture of whether the classes are completely mixed or if there are some clear separations. Overall, the features do not appear to have strong linear relationships with each other and there were no cases that yielded a “clean” separation between the two classes (HQ and LQ).

Once the features are selected and the datasets are labeled, classification models can be considered. An array of machine learning (ML) models were considered such as Logistic Regression, Support Vector Machines, Decision Trees, Naive Bayes, and others. Notice that the class sizes are imbalanced: there are 508 low-quality datasets and 169 high-quality datasets. Some of the ML models considered achieved a relatively high accuracy (about 75%) with the trivial solution of simply classifying all datasets as LQ. Of course, that is not a desirable model and there are formal methods for treating the class balance problem; however, for the context of this study, suitable models were found using basic ML methods.

6 RESULTS AND DISCUSSION

Three ML models were found to provide a reliable performance and were considered further: (1) support vector machines (SVM) with rbf kernels, (2) Logistic regression (LR), and (3) eXtreme gradient boosting (XGB). All models used the default hyperparameters specified in

Figure 4. The output of ML models, ROC curves for a) training datasets, b) testing datasets.

the scikit-learn Python library. These models were selected based on the receiver operating characteristic (ROC) curve area under the curve (AUC). To better evaluate these models, the data were split into training and testing portions (70% training, 30% testing).

Figures 4a and 4b show the ROC for the three models based on training data and testing data. Overall, the testing ROC AUC values were 0.60 and above which indicates a satisfactory prediction performance. The XGB model appears to have the best performance out of the models considered; however, it is important to note the potential for a high false positive rate. In the context of this problem, false positives would suggest the removal of HQ datasets, which is undesirable. It may be beneficial to have a reduced true positive rate in order to maintain very few false positives. This trade-off can be accounted for in the cost function of an ML model or via the operating point in the ROC.

The models determined are a good start in establishing a basic capability for predicting whether the inclusion of certain datasets will negatively affect a quantity of interest, i.e., the absolute value of the mode shape. This preliminary study was limited in scope and considered basic features that were directly related to the measured channels in an effort to maintain basic model interpretability. Furthermore, this study did not consider advanced feature selection methods. That is, it is possible to find more accurate classification methods (perhaps those with lower false positive rates) using the same source data.

7 CONCLUSIONS

When considering a large number of noisy datasets, there could be tradeoffs in quantity and quality. This study analyzed 677 smartphone datasets collected during vehicle trips, i.e., smartphone-vehicle trips (SVT), over a bridge in Italy. Depending on the SHM analysis and the quantities of interest, the omission of some datasets can result in more accurate estimates of dynamic properties. That is, some of the collected datasets negatively contribute to the aggregate result. This paper focused on determining which SVT datasets should be selected when estimating the absolute value of the mode shape (AMS) for the first vertical mode.

Eight features within the SVT data were considered, which were based on basic statistics of the vehicle speed and triaxial acceleration measurements. A quality score (QS) metric was defined to quantify the contributions an individual dataset has on the AMS estimate. A QS threshold was implemented to assign each dataset with a “low quality” label or a “high quality” label. A suite of machine learning (ML) models were applied to the classification problem. The models (SVM, XGB, and LR) with the best overall performance (as measured by ROC AUC) were kept for further analysis. When using a 70-30 train-test split, all three models produced AUC values above 0.60 for the testing data, which is satisfactory.

This study established a basic capability for predicting whether the inclusion of certain datasets will negatively affect a quantity of interest. Nonetheless, it is important to note

limitations. High false positive rates could have potentially negative consequences: by removing higher quality datasets from the analysis, the expected advantages of this type of data filtering system could be negated. The exploration of ML models that penalize false positives in the cost function could resolve this issue. Simultaneously, this study considered relatively basic features; more advanced feature engineering, feature selection, and dimensionality reduction through the use of autoencoders or uniform manifold approximation (UMAP), could yield models with superior performances.

One potential outcome from research on the quality of SVT data is the identification of trip metadata or features that are indicative of a positive contribution to the data set as a whole. These types of results can help develop tools to quickly flag low-quality datasets during pre-processing, a consideration which becomes especially important when data volumes become orders of magnitude larger, i.e., tens of thousands of datasets. For instance, crowdsensing platforms with monthly data streams on the order of millions would greatly benefit from pre-processing methods that can discard datasets that may be excessively noisy or otherwise negatively impact the determination of SHM features of interest.

ABSTRACT: This study proposes a remote scour monitoring system especially focusing on ambient vibration monitoring as an alternative method for the conventional impact test. The remote scour monitoring system consists of an edge computing system, wireless communication and cloud computing. The ambient vibration signals are processed and the target frequency is identified in the edge computing system. The identified frequencies are sent to a cloud computing system via mobile telecommunications. In the cloud computing, possibility of scour is estimated and warnings are sent out. A stochastic warning index is proposed for alarming the scour event because of relatively poor signal to noise of the ambient vibration signals comparing to that from the impact test.

1 INTRODUCTION

Many Japanese railway companies adopt an impact test on the railway bridge pier as a promising scour detection method focusing on changes in frequencies. However, the impact test is a labor-intensive and time-consuming method and is inapplicable for real-time monitoring during heavy rains. Real-time scour monitoring using bridge vibrations thus has been considered an alternative method to the conventional impact test (Kim et al. 2017). Since changes in the stability of the pier foundation link to changes in natural frequencies for the rocking motion of the pier, identification of modal frequency is the first step for vibration-based scour detection.

This study aims to propose a remote scour monitoring system which comprises an edge computing system, a remote data-delivering function, and a cloud system for scour alarming. To estimate the natural frequency of the target bridge, accelerometers were installed on the top of the bridge pier and the bridge girders for the impact test, and two sensors on the pier top were left for the ambient vibration-based scour monitoring. A fast Bayesian FFT (Au 2011) is adopted for the modal identification from microtremor measurement, which provides higher identification accuracy and statistical information about the identification.

The estimated posterior distribution of the target frequency is used for real-time scour detection. Two approaches are investigated. One is the method utilizing an index from the ratio of newly identified frequency to that of a healthy state. The possibility of the scour is estimated by comparing the index with a scour assessment scale specified in the Japanese guideline (Ministry of Land, Infrastructure, Transport and Tourism, Railway Bureau 2007). The other is the method utilizing probability distributions of the identified frequency during the normal river water period (hereafter “normal period”) and swollen river water period (hereafter “swollen period”).

2 REMOTE MONITORING SYSTEM

The remote monitoring system comprises triaxial accelerometers, an edge computing system, data delivering module, and a stochastic scour assessment system. Using this system, there is no need to dispatch engineers to the bridge during flood events, while changes in the target frequency of the observation piers are remotely monitored for scour detection. Instead of a conventional impact test that detects changes in frequency from the free vibration, the remote monitoring system examines the ambient vibration. The monitored ambient vibration signals are processed and the target frequency is identified in the edge computing system, and the identified frequencies are sent to a cloud computing system via a mobile phone network (see Figure 1). In cloud computing, the possibility of scour is estimated, and send out warnings as needed. In another implementation, it is also possible to identify the target frequency on a cloud server without installing an edge computer. Furthermore, by adding a water level sensor to the system, it is possible to analyze the relationship between water level and identified frequency.

3 SCOUR MONITORING

The monitoring bridge is a steel plate girder railway bridge with a span length of 22.5 m, a pier height of 9 m, and a width of 3 m, designed for a single railway track. The photo of the target pier is shown in Figure 2. 13 triaxial sensors were installed on the top of the pier and connecting girders during the impact test, while all sensors except two sensors installed upstream and downstream of the pier top were removed after the impact test. Figure 3 shows the sensor deploying map. Two sensors left on the pier top (sensors ①-① and ①-③) are used for long-term ambient vibration monitoring. The sampling frequency of the measurement is 200Hz.

Modal parameters of the monitoring pier such as frequency, damping ratio, and mode vector were first identified from the vibration data during the impact test. The dominant frequency for the rocking mode was identified as 9.2 Hz. The scour assessment needs vibration data not only from the normal period but also from the swollen period. Figure 4 shows examples of ambient vibration observed during the normal period whose amplitude was less than 0.1 gal. During the swollen period, it was around 1 gal caused by rising water and increasing speed of river flow. The fast Bayesian FFT is used to identify the posterior probability of modal parameters from ambient vibrations.

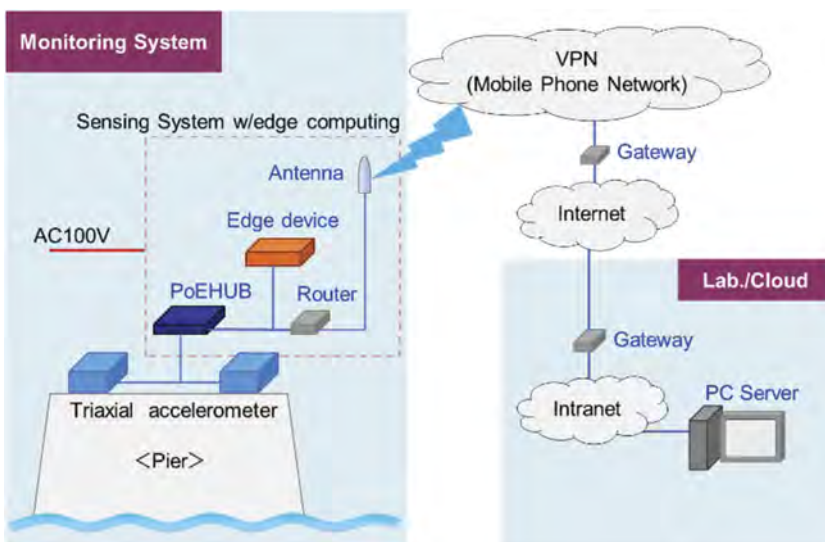

Figure 1. Remote scour monitoring system.

This study examines the ambient vibrations monitored on 30th September 2018 and 1st October 2018 as data during the swollen period. Figure 5a) shows the change in water level per five minutes from noon on September 30 to noon on October 1. The “water level” represents the distance between the water surface and the lower flange of the bridge girder. The “swollen condition” is defined as the period the water level is lower than 6m and the other period is defined as the “normal condition”. Figure 5b) shows the identified target frequency by means of the fast Bayesian FFT in which the horizontal axis shows the observation time.

Table 1. Soundness index of scour.

Soundness Index	Category	Assessment
$\kappa \leq 0.70$	A1	Scour
$0.70 < \kappa \leq 0.85$	A2	Scour progressing
$0.85 < \kappa \leq 1.00$	B	Low possibility
$1.00 < \kappa$	S	Healthy

4 REAL-TIME SCOUR ASSESSMENT

The PDF of the Levy flight distribution of the frequency during the normal period is estimated, and the parameters of the PDF of the Levy flight distribution are identified by the maximum likelihood estimation (MLE). The characteristic function of the Levy-flight distribution is given by Equation 1.

$$\Psi(t, \alpha, \beta, \gamma, d) = E(e^{-itZ}) \quad (1)$$

where the characteristic exponent α determines the rate of decay, *i.e.*, if it becomes smaller the tails get fatter. While the parameter β is an indication of the skewness of the distribution, with $\beta = 0$ corresponding to the symmetric case. The parameters γ and d simply translate and scale the distribution but have no effect on its shape. The location parameter d equals the median of the PDF. Z is the random variable and t denotes the parameter for the characteristic function (Adler et al. 1996). The parameters used in the Levy flight distribution are summarized in Table 2.

The PDF of the Levy flight distribution is represented as $S_N(\alpha_N, \beta_N, \gamma_N, d_N, Z)$ which is the inverse transformation of the characteristic function shown in Equation 1. The parameters of PDF of the Levy flight distribution under normal conditions (S_N) were estimated by means of the MLE. Identified parameters were $\alpha_N = 1.59$, $\beta_N = 0.32$, $\gamma_N = 0.18$ and $d_N = 9.11$.

The CDF of S_N is shown in the blue line of Figure 6a) while the red line shows the CDF of the observed frequency in the normal period. For comparison, the CDF following a normal distribution is shown in Figure 6b). From Figure 6a), it is obvious that the CDF curve of the Levy flight distribution matches well, especially at tails, with that of the observed CDF. On the other hand, Figure 6b) demonstrates that the tails in the normal distribution do not match well with the observed one and as a result lead to a poorer accuracy in scour assessment.

Since the number of data samples of the observed frequency during the swollen period is small, it was quite difficult to grasp the whole picture of the PDF. Therefore, measured ambient

vibration was overlapped in order to increase the number of data samples for system identification, and 50% of the data block was overlapped. Then the PDF of the observed frequency from the overlapped data samples, $S_F(\alpha_F, \beta_F, \gamma_F, d_F, Z)$, was estimated in the same manner to the normal period. Identified parameters were $\alpha_F = 1.62$, $\beta_F = 0.94$, $\gamma_F = 0.14$ and $d_F = 8.99$.

The CDF of S_F is shown in the blue line of Figure 7a). For comparison, the CDF assumed to follow normal distribution is shown in Figure 7b). Similar to the normal period, it is obvious that the CDF curve of the Levy flight distribution matches well with that of the observed CDF while the tails in the normal distribution do not match well with the observed one. Assuming the PDF of the estimated reference frequency of the pier during the normal period is given by $S_N(\alpha_N, \beta_N, \gamma_N, d_N, X)$, the stochastic warning index (SWI), Ψ_c is estimated as follows.

$$\Psi_c = \Psi(\alpha_N, \beta_N, \gamma_N, d_N, Z_m) \quad (2)$$

where, $\Psi(\alpha_N, \beta_N, \gamma_N, d_N, Z_m)$ is the CDF of S_N and Z_m denotes the mean natural frequency during the swollen period. The SWI estimated using Equation 2 is called *Method-A* in this study.

Here, a concept of marginal indicator of stochastic warning index (MISWI), Ψ_s , is proposed to assess scour occurrence. If SWI during the swollen period reaches the MISWI, it indicates a possible occurrence of scour. The MISWI can be defined considering relationships with the soundness index in Table 1. The soundness indices 0.70, 0.85, and 1.00 correspond to frequencies of 6.4Hz, 7.7Hz, and 9.1Hz respectively if the frequency in healthy condition is 9.1Hz.

The relationship between the soundness index κ and the SWI, Ψ_c is summarized in Table 3. When the soundness index κ is 0.70, the corresponding frequency $Z_m = 6.4$ Hz and the corresponding SWI is $\Psi_c = 0.0016$. Indeed, category A1 shows extremely low probability as SWI = 0.0016, and the stochastic approach can link to risk analysis.

In order to obtain the higher probability of the Type I error (occurrence of scour is determined even under health condition) and lower probability of the Type II error (scour is occurred while health condition is determined), the MISWI is set to be $\Psi_s = 0.05$ as an example, which is larger than the threshold value ($\Psi_c = 0.0053$). It is noted that how to decide MISWI depends on the risk sensitivity of bridge authorities.

Assuming that the PDF for the target frequency during the swollen period can be represented by S_F , the SWI during the swollen period is estimated utilizing Equation 3 which is called *Method-B* in this study.

$$\Psi_c = \int_{-\infty}^{\infty} S_F \int_{-\infty}^X S_N dZ dX \quad (3)$$

Although the scour assessment taking into account of the uncertainty of the frequency during the swollen period was discussed, one needs to wait until the water level return to the normal period to identify the PDF characteristic of the target frequency using Equations 2 and 3 during the swollen period. Thus, considering the time series on the identified frequency of the target pier during the swollen period, three different methods for calculating the real-time stochastic warning index (RWI) are proposed.

Assuming that the empirical PDF parameters of α_F , and γ_F are given beforehand from the past observations, and the frequency, X_t , during the current swollen period is observed, the likelihood function during the swollen period is given as Equation 4.

$$L_F(X) = S_F(\alpha_F, \beta_F, \gamma_F, X_t, X) \quad (4)$$

where X_t is the identified frequency from a data sample measured at a time span, e.g. identified frequency from every 1-minute data sample.

Replace $S_F(\alpha_F, \beta_F, \gamma_F, X_t, X)$ in Equation 3 to the likelihood function $L_F(X)$ in Equation 4, the RWI is given as Equation 5 that is called *Method-C*.

$$\Psi_c(t) = \int_{-\infty}^{\infty} L_F(X) \int_{-\infty}^X S_N dZ dX \quad (5)$$

In real-time scour detection, it is crucially important to reduce computation time. Therefore, instead of applying Equation 5, as a simplified method the time series of frequency, Z_t , during the swollen period is considered in estimating RWI using Equation 6 which is called *Method-D*.

$$\Psi_c(t) = \Psi(\alpha_N, \beta_N, \gamma_N, d_N, Z_t) \quad (6)$$

Considering each frequency of swollen river water period as a normal distribution by using the identified frequency and standard deviation obtained from the fast Bayesian FFT, RWI can be given as Equation 7 that is called *Method-E*.

$$\Psi_c(t) = \int_{-\infty}^{\infty} N(X_t, \sigma_t) \int_{-\infty}^X S_N dZ dX \quad (7)$$

Figure 8. Stochastic warning index according to different methods.

where, X_t and σ_t denote the mean and standard deviation of the identified frequency during the swollen river water period, which is obtained by means of the fast Bayesian FFT.

Ambient vibration data from 22:00 to 23:00 on 30th September 30 in 2018 is again considered an example the ambient vibration data. Assume every identified frequency at a time as real-time data X_t and estimate the RWI at each time, time series of the RWI during the swollen river water period is shown in Figure 8, where the vertical axis indicates the RWI and the horizontal axis indicates the monitoring time. The horizontal red dotted line denotes the assumed MISWI, $\Psi_S = 0.05 = 5\%$. It can be seen that a warning is not announced during the swollen river water period.

Figure 8 shows that SWI is in the range of $0.0053 < \Psi_c \leq 0.46$ which corresponds with category B, which means that there is a low possibility of scour during the target period. It can also be seen that *Method-D*, which estimates the RWI using the CDF of the normal period and

time series of frequency during the swollen period, resulted in a decision on the safe side among three methods, *Method-C* to *Method-E*. In other words, *Method-C*, which considers the probability distribution of frequencies both from the normal period and the swollen period, resulted in the most economic decision on the scour occurrence.

5 CONCLUSIONS

This study proposes a remote scour monitoring system using ambient vibration monitoring of the bridge pier during swollen river water period. The natural frequency of the bridge pier was identified with high accuracy from the ambient vibration during the swollen river water period.

Reliability-based scour assessment, parameters of the PDF of the Levy flight distribution are identified by means of the maximum likelihood method using the frequency of the pier during normal and swollen river water periods, and the stochastic warning index is proposed and data collected from real swollen river water period is used as a case study. A real-time reliability-based scour assessment is also investigated.

This study demonstrated the effectiveness of the proposed remote scour monitoring system. It is possible to assess probabilistic scour occurrence by using the ambient vibration data during swollen river water period. Moreover, the feasibility of the real-time stochastic scour assessment was observed.

The ratio of stress amplitudes between two directions around welded part of trough rib in orthotropic decks with fatigue cracks

Faculty of Science and Engineering, Iwate University, Morioka, Iwate, Japan

ABSTRACT: Usually, an inspection for fatigue cracks in steel structures is often executed with visual inspection, penetrant testing and magnetic particle testing as necessary. However, the visual inspection depends on inspectors' knowledge and skills, so overlook of cracks can occur. Non-destructive inspection such as penetrant testing and magnetic particle inspection cannot detect fatigue cracks inside steel plates. Therefore, the authors proposed cracks detection method focusing on the ratio of stress amplitudes between two directions near the weld as an auxiliary mean of an inspection of steel structures. In this study, we verified whether cracks can be detected quantitatively by comparing and examining the results of vibration fatigue test and FEM analysis for the welding lines of trough rib in orthotropic decks. As a result, fluctuations in the ratio of stress amplitudes are confirmed due to the occurrence and progress of cracks. This method isn't dependent on inspectors' knowledge and skills, may be able to detect damage inside the structure, so it can be an auxiliary mean of the existing inspection method.

1 INTRODUCTION

Orthotropic steel decks are widely used because they are lighter than concrete decks and the rapid execution of orthotropic steel decks is possible in recent years. On the other hand, fatigue cracks in steel orthotropic decks due to repetitive loading have become a serious problem in the maintenance of bridges. Many fatigue cracks occur in places near welding lines and they progress. Among them, cracks that progress in the direction penetrating the deck plate may cause the road surface to collapse if the cracks progress to the deck plate. It must be careful because it may cause damage to use. Usually, an inspection of fatigue damage is often executed with visual inspection, penetrant testing and magnetic particle testing as necessary. However, visual inspection is dependent on the inspector's knowledge and skills. Magnetic particle testing and penetrant testing are also unable to detect cracks if they are not on or near the surface. These inspections cannot deal with cracks and defects inside the structures. To solve these problems, this study investigates a method that can detect cracks even by inexperienced inspectors as an auxiliary tool to visual inspection and nondestructive testing.

In a previous study conducted by Horiai at Iwate University, they carried out vibration fatigue test using specimens that simulate the welding lines of trough rib in orthotropic steel decks (Horiai et al. 2017.). It shows that the presence or absence of cracks can be judged by checking the stress ratio (Y/X) in the longitudinal direction (X -axis) and the right-angle direction (Y -axis). When considering the presence or absence of cracks, it is difficult to judge by stress in one direction only. Because it must be judged including the load (external force) applied to the candidate structure at that time. Therefore, in the study conducted by Horiai et al., the stress in each axial direction is nondimensionalized by taking the ratio of the stress, which makes it possible to judge the presence

or absence of cracks more easily. On the other hand, fatigue problems are usually organized using stress amplitude rather than actual stress value.

Therefore, in this study, based on the data from previous study, we examined whether it is possible to detect cracks quantitatively by confirming the ratio of stress amplitudes in two directions around fatigue cracks (hereinafter, this is called “stress amplitude ratio”). In addition, we studied the effectiveness of this method in confirming the stress amplitude ratio centered on the fatigue crack, by comparing the vibration fatigue test data with the results of the FEM analysis.

2 VIBRATION FATIGUE TEST ON TROUGH RIB

This chapter presents an overview of the vibration fatigue tests on the welded part of trough rib in orthotropic decks, which was a previous study conducted at Iwate University.

2.1 Test overview

Figure 1 and Figure 2 show an overview of the vibration fatigue tester used in the previous study and a photo of the test situation (Yamada et al., 2008.). In this study, the specimen was set up so that the ribs were facing upward, referring to the test conducted by Yamada (Yamada & Samol. 2008.). In the previous study, a coil spring was installed at the tip of the specimen, and the specimen was pushed down by this coil spring. The fatigue test was carried out with the stress ratio applied to the specimen being pulsated ($R > 0$).

2.2 Test specimens

Figure 3 shows the specimen used in this study. The material of the specimens is SM400A, and a rib corresponding to a plate thickness of 6 mm of trough rib is welded at an angle of 78° to a base material of 12 mm thickness, 300 mm width and 700 mm length simulating orthotropic steel deck plate. Usually, the standard is that the penetration amount in the welding lines of U-rib is 75 % or more of the plate thickness. In this study, as shown in Figure 4, by making from end parts of the rib about 75 mm into a range where the amount of penetration was large, by making the rib center about 50 mm into a range where the amount of penetration was small. We attempted to generate cracks starting point in the center of the width of the specimen. A hole with a diameter of 24 mm is for installation in a vibration fatigue testing machine, and a hole with a diameter of 14 mm is for installing an eccentric motor.

Figure 1. Overview of vibration fatigue test.

Figure 2. Vibration fatigue test of simulated the welding lines of trough ribs.

2.3 Attached gauge situation

Figure 5 shows the state of the strain gauge attached to the specimen. To measure the stress including the effect of stress concentration, the gauge was attached to a position 5 mm away from the weld toe in the longitudinal direction (X-axis) and 50 mm away from

Figure 3. Test specimens.

the right-angle direction (Y-axis), referring to bridge measurements (Notional institute for land and infrastructure management ministry of land, 2008.) and wheel load running tests (Yoshinami et al. 2012). G1' gauge is 70 mm away from G4 in the longitudinal direction (X-axis), G2' gauge is further 75 mm away from G1' in the right-angle direction (Y-axis), and G3' gauge is away from G4 in the right-angle direction (Y-axis). We used the results of strain measured with the G1', G2', and G3' gauges, the nominal stress range was determined from the proportional relationship (Kinoshita and Arakawa 2012; Kinoshita and Arakawa 2013; Sakano and Arai 2004). G1 to G4 triaxial gauges were FRA-1-11, and G1' to G3' uniaxial gauges were FLA-1-11.

2.4 Experimental conditions

Table 1 shows the nominal stress of each of specimens at the start of the test and the number of cycles at the end of the test. The test end condition is that when the stress in the right-angle direction (Y-axis) is larger than the stress in the longitudinal direction (X-axis) or the fatigue cracks occurring from the weld toe reached this position and the enameled wire which was attached to the plane side without a rib until the cracks generated from the vicinity of the weld progressed in the thickness direction and penetrated broke.

3 TEST RESULT

3.1 How to calculate stress amplitude and stress amplitude ratio

In this consideration, strains measured by triaxial strain gauges are used to calculate the stress amplitude. The first axis of the triaxial gauge is the longitudinal direction (X-axis) and the second axis is the right-angle direction (Y-axis). From the strains in each of these two directions, the stress amplitude in the longitudinal direction (X-axis) and the right-angle direction (Y-axis) were calculated, respectively, using following equation (1).

$$\Delta\sigma = \frac{(\varepsilon_{\max} - \varepsilon_{\min}) \times E}{2} \quad (1)$$

Where $\Delta\sigma$ = Stress amplitude (MPa); ε_{\max} = Maximum Strain (μ),
 ε_{\min} = Minimum Strain (μ); E = Young's modulus ($2.1 \times 10^5 \text{ N/mm}^2$).

The stress amplitude ratio was calculated by referring to the method used by Horiai et al. In this study, since the principal stress were oriented is the longitudinal direction (X-axis), the stress amplitude ratio was calculated using the following equation (2).

Figure 4. Cross section of the specimen groove.

Figure 5. Attached gauge position (Rib side).

Table 1. Nominal stress range and Number of cycles.

Specimen	Nominal stress range (MPa)	Number of cycles
No.1	99.7	1,941,900
No.2	99.8	2,001,900

$$\text{Stress amplitude ratio} = \Delta\sigma_Y / \Delta\sigma_X \quad (2)$$

Where $\Delta\sigma_X$: Stress amplitude (MPa) in longitudinal direction (X-axis);
 $\Delta\sigma_Y$: Stress amplitude (MPa) in the right-angle direction (Y-axis).

3.2 Fluctuation of stress amplitude ratio around cracks

Figure 6 shows the variation of the stress amplitude ratio of each gauge for specimens No. 1 and No. 2 in the vibration fatigue test. The stress amplitude ratio of all specimens tended to increase as the cracks progressed. For each specimen, the fluctuation of the stress amplitude ratio at the G4 gauge was the largest. This is because G4 is closest to the crack and was greatly affected by crack growth.

Because the trough rib is a closed cross section, it is difficult to take measurements on the inside of the rib, such as at the G4 gauge position, which is close to where the deck plate penetration crack would be expected to occur. Stress amplitude ratio variations similar to those of the inner ribs were observed in the outer ribs such as G1 to G3.

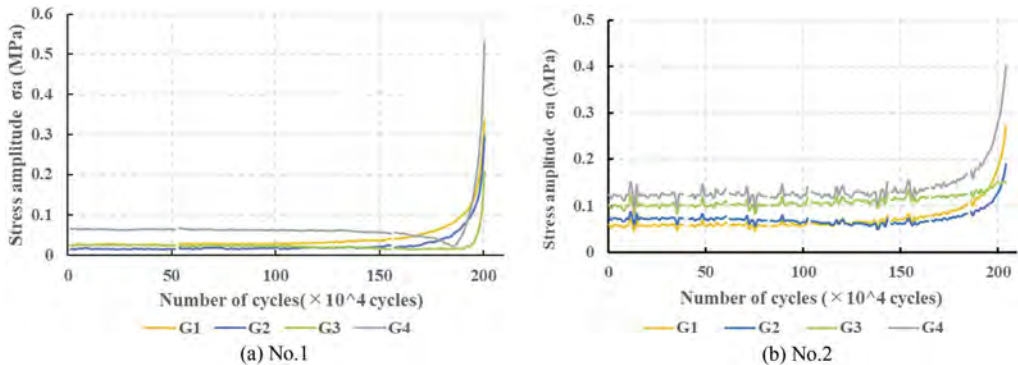

Figure 6. Fluctuation of stress amplitude ratio.

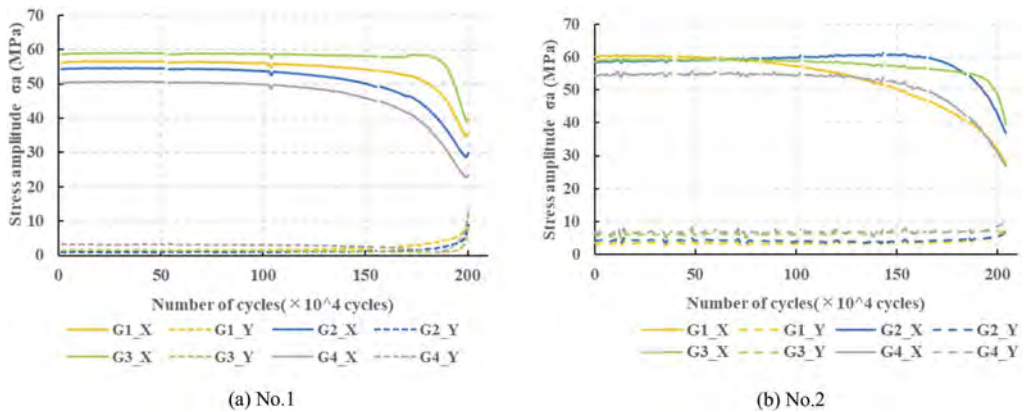

Figure 7. Fluctuation of stress amplitude.

3.3 Fluctuation of stress amplitude around cracks

Figure 7 shows the fluctuation of stress amplitude in the longitudinal direction(X-axis) and right-angle direction(Y-axis) at each gauge position for specimens No.1 and No.2. Figure 7 shows that the stress amplitude in the x-axis direction decreases significantly until the end of the test. On the other hand, the stress amplitude in the y-axis direction increased slightly toward the end of the test, but this was not a significant change compared to the stress amplitude in the x-axis direction. The reason for this fluctuation may be as follows. If fatigue cracks occur near the position where the strain gauge is attached, the amount of stress transfer in that area decreased. Therefore, the stress amplitude in the longitudinal direction(X-axis) at the attachment position decreases. When the cracks occur, the direction of the principal stress is to avoid the cracks. Therefore, the stress amplitude on Y-axis tended to increase with the cracks progress.

4 FEM ANALYSIS

4.1 FEM analysis overview

Based on the result of the vibration fatigue test, the analysis model was examined. The analysis was performed using three-dimensional FEM general-purpose analysis software (Sofistik). The material properties of the analysis model were set to be the same as those of the test specimen, with Young's modulus of steel $E = 2.1 \times 10^5 \text{ N/mm}^2$ and Poisson's ratio $\nu = 0.3$.

4.2 Analysis model

The analysis model is a model of a part of the fatigue test specimen as shown in Figure 8, and was rigidly bounded with constrained XYZ displacement and rotation on the side fixed to the vibration fatigue testing machine. Based on the test results, the crack was assumed to be a deck plate penetration crack that propagated from the weld root of the trough rib. The point of crack occurrence is assumed to be at the center of the specimen. A total of 10 models with crack lengths ranging from 0 mm to 36 mm were analyzed. The crack pattern and study area are shown in Figure 9. In this figure, cracks are indicated by red lines and welds by gray filled areas. The area outside the trough ribs, where strain gages can be attached on the bridge, is considered to be the study area in this study. The area is bounded by the black line. Since the crack depth was not measured during the vibration fatigue test, the crack depth was assumed to be about (crack depth/crack length = 1/2~1/3). We checked the stress status around the cracks in each model. The mesh size of the area around the weld to be verified is 1 mm.

Figure 8. FE model overview.

Figure 9. Crack length pattern and study area.

4.3 Analysis result

Fluctuation of the stress amplitude and stress amplitude ratio at G2 and G4 position is shown in Figure 10. Similar to the test results, the stress amplitude in the X-axis direction decreased significantly with crack initiation and propagation at each gauge positions; the stress amplitude in the Y-axis direction showed a slight decrease but no clear fluctuation. Therefore, with crack propagation, a trend toward an increase in the stress amplitude ratio was confirmed. The increase in the stress amplitude ratio is larger at the G4 gage position closer to the crack and smaller at the G2 gage position farther from the crack.

Contour diagram of stress amplitude ratio for each crack length is shown in Figure 11. The study area is shown in Figure 9. In the case of no crack, stress amplitude ratio of less than 0.3 were confirmed for all elements in the study area. For crack length (b) 4 mm, 0.30–0.35 in stress amplitude ratio was confirmed at 2 mm from the weld toe, indicating that the crack occurrence was affected by the crack. (hereinafter, the area of stress amplitude ratio above 0.30 is called “influence area”).

Figure 10. Fluctuation of stress amplitude ratio (FEM analysis).

In the case of crack length (c) 8 mm, the influence area was confirmed to be 4 mm from the weld toe, and in the case of crack length (d) 12 mm, the influence area was confirmed to be 9 mm from the weld toe. Thereafter, it was confirmed that the influence area of the stress amplitude ratio expanded as the crack propagated. It is considered possible to judge the presence or absence of cracks by attaching strain gauges within the influence area where the fluctuation of the stress amplitude ratio is confirmed. In the vibration fatigue test, a strain gauge was attached at a distance of 5 mm from the weld end for measurement. This method is considered to be effective for cracks longer than 12 mm, when a strain gauge is attached 5 mm from the weld toe to detect cracks.

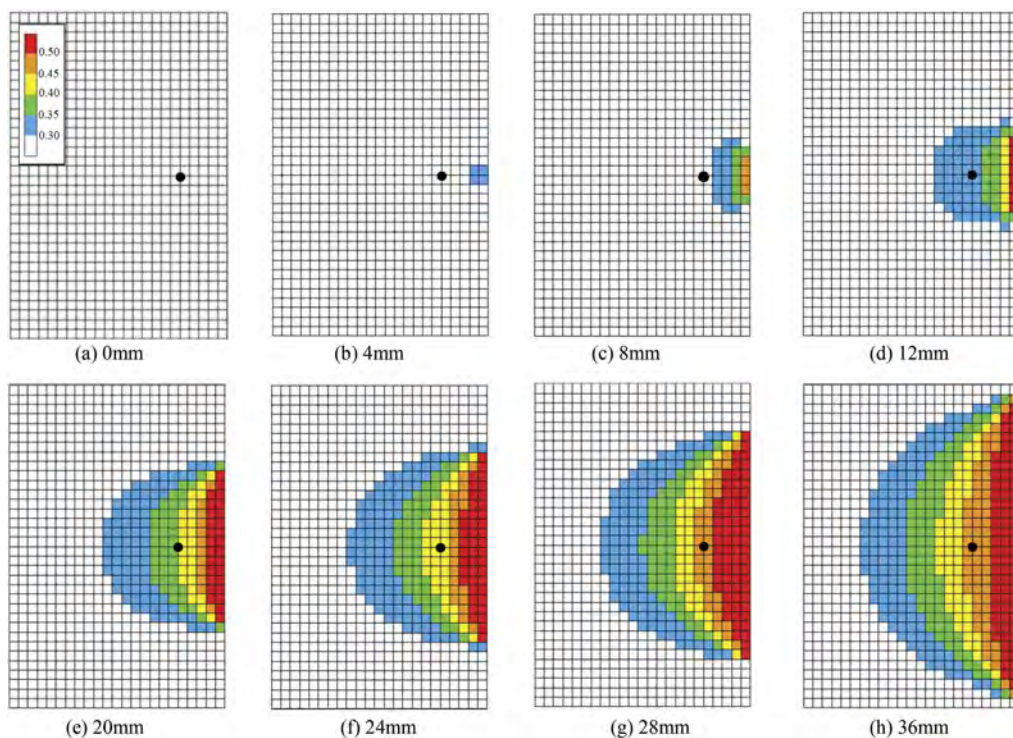

Figure.11. Contour diagram of stress amplitude ratio.

5 CONCLUSION

In this study, in the fatigue damage of steel structures, we focused on cracks in welded part of trough rib in orthotropic decks. We examined whether the presence or absence of cracks could be determined by confirming the stress amplitude ratio around the cracks. The findings of this paper are shown below.

- (1) The stress amplitude ratio increases with crack propagation because the decrease in the stress amplitude in the longitudinal direction(X-axis) is larger than the fluctuation of the stress amplitude in right-angle direction(Y-axis).
- (2) Regarding the deck plate penetration crack, it is clarified that the cracks can be judged by examining the ratio of stress amplitudes between two directions near the welded part outside the rib.
- (3) In the FEM analysis, it is confirmed that the area where the stress amplitude ratio increased with crack propagation was expanded.

For the purpose of detecting deck plate penetration cracks for welded part of trough rib in orthotropic decks, strain gauges are attached at a distance of 5 mm from the weld toe in the direction perpendicular to the bridge axis. From fatigue test and analysis results, it is considered possible to detect a crack by confirming the fluctuation of the stress amplitude ratio.

Ambient-vibration-based operational modal analysis and cable tension estimation in the long-term SHM of a cable-stayed bridge

W.J. Jiang & C.-W. Kim
Kyoto University, Kyoto, Japan

K. Ono
Eight-Japan Engineering Consultants, Kobe, Japan

ABSTRACT: This paper presented a study of operational modal analysis and cable tension estimation using ambient vibration in long-term bridge SHM. Bayesian operational modal analysis under ambient vibration was conducted in a cable-stayed bridge by the means of a Bayesian FFT and the coupling effect of cable-deck vibration is discussed. A Bayesian cable tension estimation method is proposed with the identification uncertainty in the estimates of cable tension. Further, the effect of EOVs in long-term SHM of cable tension was investigated with an integration of identification uncertainty using a probabilistic predictive model. The result indicated the effect of EOVs in the longest cable is much more dominant compared to the shortest cable at bridge deck end. Finally, a Gaussian mixture model (GMM) based anomaly detection method in the long-term SHM of stay cable was proposed and investigated with the likelihood as a damage sensitive feature (DSF) and the damage effect according to a simulated analysis. The result showed that this method can provide a meaningful indication of damage under a certain premise.

1 INTRODUCTION

The cable-stayed bridge has been widely constructed around the world. As a crucial component in this structure, the stay cable is always faced with long-term deterioration caused by corrosion, fatigue, etc. For the management and maintenance of cable-stayed bridges, it is of great meaning to conduct real-time long-term structural health monitoring (SHM) of the stayed cables, among which the dynamic characteristics and cable tension are acknowledged as two informative features reflecting the condition of cables and bridge.

The ambient-vibration-based long-term SHM, which does not require artificial excitation, offers a promising way for realizing remote and economical monitoring of bridges. There have been many types of research such as frequency domain decomposition (FDD), stochastic subspace identification (SSI), a series of Bayesian operational modal analysis (OMA) methods (e.g., Fast Bayesian FFT), etc., which make the ambient-vibration-based modal analysis efficient and flexible. Further, cable tension, as a more intuitional physical feature, has also been investigated in the relation to the dynamics of cables (Shimada 1994, Zui et al. 1996, Yamagiwa et al. 1999).

By examining the estimated cable tension in long-term bridge SHM, it is believed that potential damage effects in cables can be traced timely. However, there are still many issues remaining in the ambient-vibration-based long-term bridge SHM. One is the low signal-to-noise ratio (SNR) with weak excitation which makes the identification uncertainty (IU) prominent. Another one is the effect of environmental and operational variations (EOVs), which raises the variability of long-term records in SHM. Therefore, to make a deep perception of these issues, this study investigates ambient-vibration-based cable tension estimation and the

identification uncertainty and EOVs-induced variability in the long-term monitoring of cable tensions with Bayesian approaches.

2 METHODOLOGY

2.1 Fast Bayesian FFT

As one of the ambient-vibration-based operational modal analysis methods, a fast Bayesian FFT approach (Au et al. 2013, Au 2017) is introduced here. By associating Bayesian inference with the FFTs of vibration response, Bayesian FFT gives a basic form as follows.

$$p(\boldsymbol{\theta}|\hat{\mathcal{F}}_k) = p(\hat{\mathcal{F}}_k)^{-1}p(\hat{\mathcal{F}}_k|\boldsymbol{\theta})p(\boldsymbol{\theta}) \quad (1)$$

where $\boldsymbol{\theta}$ denotes the system parameters of the structure to be identified, and $\hat{\mathcal{F}}_k$ are the estimated FFTs data at different frequencies f_k .

Assuming that the power spectral density (PSD) is complex Gaussian distribution and independent at different frequencies, the posterior distribution in Equation 1 has a linear relationship with the likelihood function as follows.

$$p(\boldsymbol{\theta}|\hat{\mathcal{F}}_k) \propto p(\hat{\mathcal{F}}_k|\boldsymbol{\theta}) = \frac{\pi^{-nN_f}}{\prod_k |E_k(\boldsymbol{\theta})|} \exp\left[-\sum_k \hat{\mathcal{F}}_k^* E_k(\boldsymbol{\theta})^{-1} \hat{\mathcal{F}}_k\right] = e^{-L(\boldsymbol{\theta})} \quad (2)$$

The theoretical PSD matrix of data at the k^{th} FFT for given $\boldsymbol{\theta}$ is shown in Equation 3.

$$E_k(\boldsymbol{\theta}) = E\left(\hat{\mathcal{F}}_k \hat{\mathcal{F}}_k^* | \boldsymbol{\theta}\right) + E[\varepsilon_k \varepsilon_k^* | \boldsymbol{\theta}] = \sum_{i=1}^m \sum_{j=1}^m h_{ik} h_{jk}^* S_{ijk} \boldsymbol{\phi}_i \boldsymbol{\phi}_j^T + S_e \mathbf{I}_n \quad (3)$$

The negative log-likelihood function (NLLF) of Equation 2 can be written as Equation 4. The most probable value (MPV) of $\boldsymbol{\theta}$ can be estimated as, $\hat{\boldsymbol{\theta}} = \arg \min_{\boldsymbol{\theta}} L(\boldsymbol{\theta})$.

$$L(\boldsymbol{\theta}) = nN_f \ln \pi + \sum_k \ln |E_k(\boldsymbol{\theta})| + \sum_k \hat{\mathcal{F}}_k^* E_k(\boldsymbol{\theta})^{-1} \hat{\mathcal{F}}_k \quad (4)$$

where, the system parameter $\boldsymbol{\theta}$ comprises modal frequencies $f_{i=1}^r$ and modal damping ratios $\zeta_{i=1}^r$ denoted in transfer functions h_{ik}^r corresponding to each mode, partial mode shapes $\boldsymbol{\phi}_{i=1}^r$, PSD matrix of modal forces $S = [S_{ij}]_{r \times r}$, and the PSD matrix of prediction errors $S_e \mathbf{I}_n$. In addition, r represents the number of dominant modes in a specified frequency band where the estimation is conducted. n is the number of sensors to collect the ambient vibration response. N_f is the number of FFT points in the specified frequency band.

2.2 Bayesian cable tension estimation

The relation between modal frequency of cable and cable tension can be derived from the free vibration differential equation of cable as follows.

$$m \frac{\partial^2 v(x, t)}{\partial t^2} + EI \frac{\partial^4 v(x, t)}{\partial x^4} - T \frac{\partial^2 v(x, t)}{\partial x^2} - h(t) \frac{\partial^2 v(x, t)}{\partial x^2} = 0 \quad (5)$$

where $v(x, t)$ denotes the vertical vibration deflection, x is the longitudinal coordinate of the cable and t denotes time. The symbol m is the mass of the cable per unit length, EI denotes the flexural rigidity of the cable and T is the cable tension force. $h(t)$ denotes the dynamic tension.

According to relative research (Shimada 1994, Zui et al. 1996, Yamagiwa et al. 1999), the influence of ambient vibration-induced dynamic cable tension $h(t)$ and the cable sag is generally small and ignorable for simplicity. Assuming that the boundary condition is simply supported, the solution of Equation 5 can be presented as follows.

$$\left(\frac{f_i}{i}\right)^2 = \frac{\pi^2 i^2}{4ml^4} EI + \frac{1}{4ml^2} T \quad (6)$$

where i is mode order and f_i denotes the i^{th} modal frequency of the cable; l is the length of cable.

With identified modal frequencies of the cable, the estimation of cable tension from Equations 6 can be treated as a regression problem. A basic form of the Bayesian linear regression (BLR) model can be written as follows.

$$y = X\beta + \varepsilon, \quad \varepsilon \sim N(0, \sigma^2) \quad (7)$$

where y is an $n \times 1$ vector of response variable; X is an $n \times d$ matrix of predictor variables; β is a $d \times 1$ vector of coefficients; ε denotes the *iid* error term which obeys a normal distribution with zero mean and variance σ^2 for each observation; n is the number of observations, and d is the number of predictor variables. The Bayesian inference can then be used to obtain the posterior distribution of (β, σ^2) as follows.

$$p(\beta, \sigma^2 | y, X) = p(y|X)^{-1} \cdot p(y|X, \beta, \sigma^2) \cdot p(\beta, \sigma^2) \quad (8)$$

Further, the marginal posterior of β can be given as,

$$p(\beta | y, X) = \int p(\beta, \sigma^2 | y, X) d\sigma^2 \quad (9)$$

When the Jeffreys non-informative prior is given as Equation 10,

$$p(\beta, \sigma^2) \propto \frac{1}{\sigma^2} \quad (10)$$

the marginal posterior of β is analytically tractable and follows a d dimensional *t-location-scale* distribution shown in Equation 11.

$$p(\beta | y, X) \sim t_d \left(\hat{\beta}, \frac{(y - X\hat{\beta})'(y - X\hat{\beta})}{n - d} (X'X)^{-1}, n - d \right) \quad (11)$$

where the three parts in the right hand are the location parameter, scale parameter, degree of freedom, in sequence. $(\cdot)'$ represents a transposition of (\cdot) . The notations (y, X, β, n, d) are the same as Equation 7, while $\hat{\beta}$ is the least-squares estimate of β with a form as follows.

$$\hat{\beta} = (X'X)^{-1} X'y \quad (12)$$

Without loss of generality, substituting Equation 6 into Equation 7, the Bayesian cable tension estimation framework can be established as shown in Equation 13.

$$y = \left\{ \left(\frac{f_i}{i} \right)^2 \right\}_{n \times 1}, \quad X = \left[\frac{\pi^2 i^2}{4ml^4} \quad \frac{1}{4ml^2} \right]_{n \times 2}, \quad \beta = \left\{ \begin{matrix} EI \\ T \end{matrix} \right\}_{2 \times 1} \quad (13)$$

The posterior distribution of β contributes to a simultaneous estimation of cable tension and flexural rigidity, along with the estimation uncertainty.

2.3 Gaussian mixture model and conditional likelihood

It is rational to model the temperature effect as a way of data normalization which aims to improve the damage sensitivity while reducing the interference of EOVs (Jiang et al. 2022). Intuitively, regression may be a simple way to model the relationship between temperature and cable tension. However, there are other complex and unknown environmental factors (latent variables) in a real system of EOVs also, which can make it difficult to represent the correlation between temperature and cable tension in a regressive manner. Alternatively, modeling the joint distribution of temperature and cable tension offers a probabilistic way to consider the temperature effect and uncertainty. The conditional likelihood of cable tension estimate over temperature plays a role like data normalization of the temperature effect. In practice, the joint distribution of temperature and cable tension may be complicated due to the effect of latent variables. The Gaussian mixture model (GMM), as a flexible way to model almost arbitrary distribution, is introduced in this study to model the temperature effect in cable tension estimates in long-term bridge SHM.

A basic form of a multivariate GMM can be given as,

$$p(x) = \sum_{k=1}^K \pi_k N(x|\mu_k, \Sigma_k) \quad (14)$$

which is a linear superposition of K Gaussian components with mixing coefficients denoted as π_k , and the sum of π_k is equal to 1. $p(z_k = 1) = \pi_k$ denotes the mixing proportion of the k^{th} Gaussian component.

It has been proved the Expectation-Maximization (EM) algorithm can be used to estimate the parameters of GMM $\theta = \{\pi_k, (\mu_k, \Sigma_k)\}_{k=1}^K$ with a closed form of iteration. The major steps of using EM for parameter estimation can be summarized below (Bishop 2006).

Step 1. Initialization of the parameters $\theta = \{\pi_k, (\mu_k, \Sigma_k)\}_{k=1}^K$ and calculate the log-likelihood of data.

Step 2. **E step.** Calculate the responsibilities (posterior probabilities of component memberships) with the parameters from the previous step as follows.

$$\gamma(z_{nk}) = p(z_k = 1|x_n) = \frac{\pi_k N(x_n|\mu_k, \Sigma_k)}{\sum_{j=1}^K \pi_j N(x_n|\mu_j, \Sigma_j)} \quad (15)$$

Step 3. **M step.** Update the parameters with the calculated responsibilities as follows.

$$\mu_k^{\text{new}} = \frac{1}{N_k} \sum_{n=1}^N \gamma(z_{nk}) x_n \quad (16a)$$

$$\Sigma_k^{\text{new}} = \frac{1}{N_k} \sum_{n=1}^N \gamma(z_{nk}) (x_n - \mu_k^{\text{new}})(x_n - \mu_k^{\text{new}})^T \quad (16b)$$

$$\pi_k^{\text{new}} = \frac{N_k}{N} \quad (16c)$$

$$N_k = \sum_{n=1}^N \gamma(z_{nk}) \quad (17)$$

Equation 17 can be interpreted as the effective number of observations assigned to the k^{th} Gaussian component.

Step 4. Evaluate the log-likelihood with the updated parameters as,

$$\ln p(X|\mu, \Sigma, \pi) = \sum_{n=1}^N \ln \left\{ \sum_{k=1}^K \pi_k N(x_n|\mu_k, \Sigma_k) \right\} \quad (18)$$

and check the convergence of either the parameters or the log-likelihood. If not converged, return to Step 2.

With the excellent properties of Gaussian distribution (the marginal and conditional distributions are still Gaussians), it can be proved that the conditional distribution of the multivariate GMM is still a GMM. Here, we take T as a notation of the cable tension, and H as a notation of temperature. Then, we can get the conditional likelihood as Equation 19, which is still a GMM and leads to an analytical form of conditional likelihood.

$$p(T|H) = \frac{p(T, H)}{p(H)} = \sum_{k=1}^K \frac{\pi_k N(H|\mu_k^H, \Sigma_k^H)}{\sum_{j=1}^K \pi_j N(H|\mu_j^H, \Sigma_j^H)} N(T|\mu_k^{T|H}, \Sigma_k^{T|H}) \quad (19)$$

Table 1. OMA of three typical cables by fast Bayesian FFT.

Cable	Item	Order				
		1	2	3	4	5
C1	f_i (σ)(Hz)	1.07(0.0010)	2.11(0.0012)	3.18(0.0009)	4.24(0.0020)	5.31(0.0013)
C5	f_i (Hz)	2.07(0.0013)	4.14(0.0014)	6.26(0.0031)	8.45(0.0058)	10.63(0.0035)
C8	f_i (Hz)	1.64(0.0026)	3.32(0.0088)	4.96(0.0040)	6.65(0.0057)	8.14(0.0033)

3 LONG-TERM SHM OF A CABLE-STAYED BRIDGE

3.1 Background

The monitored bridge is a single-tower cable-stayed bridge shown in Figure 1. The major span length of the bridge is about 124 m and the height of the pylon is about 48 m. A short-term ambient vibration test was carried out in November 2020. The corresponding sensor setup and structural layout are shown in Figure 2. Ambient-vibration signals from cables at the anchor, cables at the bridge deck, bridge deck, and the pylon were collected during the short-term test. Further, the long-term SHM of two cables, the longest one denoted as C1 and the shortest one denoted as C5 in Figure 2 at the bridge deck, was conducted from December 2020 to January 2022. During the long-term SHM, the ambient vibrations were recorded remotely.

3.2 OMA and cable tension estimation

To get the dynamic characteristics of the bridge and cables, the fast Bayesian FFT was first applied for operational modal analysis of the bridge and cables. In this paper, three typical cables (C1, C5, and C8 cables as marked in Figure 2) are selected to simplify the discussion even though all the cables were measured during the short-term bridge SHM.

Figure 3. OMA of the whole bridge (first three mean bending modal properties).

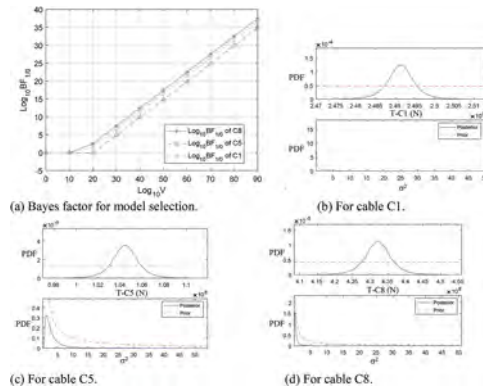

Figure 4. (a) Bayes factor along with increasing uncertainty in prior distribution of cable tension; (b)(c) (d) Prior and posterior estimates of cable tension T and error variance σ^2 .

Figure 3 showed the OMA results of the whole bridge. The first three modal frequencies are quite low as the cable-stayed bridge is a very flexible structure. Meanwhile, it should be noted that for the cables at the bridge deck end, the cable vibration is affected by the bridge vibration seriously, which calls for more attention to the OMA of the cables at the bridge deck end. Table 1 presented the OMA results of three typical cables. It shows that the identification uncertainty in the OMA results of the cables is not significant.

The proposed Bayesian cable tension estimation is applied to identify cable tensions from ambient vibrations. A model selection between Equation 6 for the simply supported beam theory and Equation 7 for the string theory was carried out by the means of Bayes factor $B_{1/0}$ which is the ratio of two model evidence with two hypotheses H_0 and H_1 . Therein, H_0 denotes the null hypothesis meaning that identified modal frequencies support Equation 6 more, i.e., the effect of the flexural rigidity on cable tension identification cannot be ignored, while H_1 denotes the alternative hypothesis meaning that the data support Equation 7 more, i.e., the effect of flexural rigidity can be ignored. The Bayes factor along with increasing uncertainty in the prior distribution is presented in Figure 4(a), where V stands for a hyper-parameter of Gaussian-Inverse-Gamma conjugate prior which controls the uncertainty in the prior of parameters (EI , T). It indicates that with less prior information about cable tension, the identified modal frequencies support the string theory more, i.e., the effect of flexural rigidity can be ignored in the subsequent procedure of the Bayesian cable tension estimation. The estimated cable tension using the Bayesian linear regression is shown in Figures 4(b-d). It is noted that the identification uncertainty in the three cables was different; i.e., the lowest identification uncertainty was observed at the longest cable at the bridge deck (C1 cable).

3.3 Long-term SHM with GMM and conditional likelihood

Long-term ambient vibration monitoring was also conducted for the longest and the shortest cables at the bridge deck, i.e., C1 and C5 cables. The long-term sequence of Bayesian cable tension estimates is shown in Figure 5. Observing the sequence of cable tension estimates, it is noted that the identification uncertainty and the effect of EOVs in two cables occupied different extents. Further, by using the predictive probabilistic model introduced in the study (Zhang & Au 2016), the predictive distribution for an unknown future time point is given in Figure 6 with a depiction of ensemble variability. From Figure 6, it is clear that the effect of EOVs is dominant in the longest cable at the bridge deck, while for the shortest cable, the identification uncertainty contributes more to the ensemble variability. This observation may offer some guidance for the research of seasonal effects in long-term SHM of cable tensions.

The effect of IU and EOVs in the long-term monitoring of cable tensions previously discussed may decrease the sensitivity to damage occurrence. As a way to consider the temperature effect

(one of the major EOVs), a multivariate GMM is used to model the joint distribution of the temperature and cable tensions monitored for almost one year. As shown in Figure 7, the fitted GMM and trace of conditional means indicated complex but different correlations between cable tension and temperature in cables, with the interference of other latent environmental variables.

In this study, the conditional likelihood of cable tension over temperature is introduced as a damage-sensitive feature (DSF) which eliminated the temperature effect in the cable tension. To get a comparison with the damage state, a finite element model (FEM) is established using ANSYS and updated by the particle swarm optimization (PSO) algorithm, as shown in Figure 8. The relative changes of cable tension caused by the damage in the effective area of target cables are checked using the updated FEM, of which results are summarized in Table 2. Then, based on the fitted GMM, the conditional negative log-likelihood function (NLLF) is investigated for anomaly detection in long-term bridge SHM while removing the temperature effect in cable tension. As shown in Figure 9, the result indicates the conditional NLLF based on the fitted multivariate GMM performed well as a DSF which removed the temperature effect and is sensitive to the damage extent of 10% and even 5% of cable section area.

4 CONCLUSIONS

This study investigates the ambient-vibration-based OMA and cable tension estimation in a cable-stayed bridge with Bayesian approaches. The identification uncertainty and effect of EOVs in cable tensions are discussed with a long-term SHM campaign in two typical cables C1 and C5. Finally, a GMM and conditional NLLF-based approach is proposed to eliminate the temperature effect in cable tension and operate as a DSF in anomaly detection in long-term bridge SHM.

Figure 9. Conditional NLLF of cable tension over the temperature in long-term SHM.

The feasibility of fast Bayesian FFT for OMA and Bayesian cable tension estimation using environmental vibrations was verified to reveal the identification uncertainty. It should be noted that the cable vibration at the bridge deck end is seriously affected by the bridge vibration under ambient excitations, which calls for more attention compared to those cables at the bridge anchor end in the identification process.

Observations from identification uncertainty and the effect of EOVs in cable tensions demonstrated that the effect of EOVs is more prominent in the longest cable than the shortest one, which indicated the longer cables in the cable-stayed bridge may be more sensitive to the EOVs and it may be worthwhile to conduct data normalization in these cables.

The correlation between cable tension and temperature is proved to be complicated and different in two cables C1 and C5, with the interference of other latent environmental variables. The GMM and conditional NLLF-based approach is therefore used to remove the temperature effect like a data normalization process. Further, the use of conditional NLLF as a DSF is proved to be an effective monitoring index for anomaly detection in long-term SHM of cables.

Uncertainty quantification of modal properties using half year monitoring data of a plate girder bridge

Y. Goi & C.-W. Kim

Department of Civil & Earth Resources Engineering, Kyoto University, Kyoto, Japan

ABSTRACT: In short to medium span bridges, traffic induced vibration enables vibration monitoring of bridges without interrupting the traffic. Changes in modal properties possibly indicates stiffness loss caused by damages on the bridges. In actual bridges, however, the noisy condition caused by the traffic loadings interrupts modal estimation. Also, the seasonal fluctuation of temperature alters modal properties of bridges. To deal with the uncertainty involved in noisy condition, authors previously proposed Bayesian inference method to quantify uncertainty of modal properties. In the proposed method, the uncertainty involved in modal properties are quantified as posterior distribution using unsupervised machine learning. This study investigates the efficacy of the proposed method under the temperature fluctuation. A half-year monitoring data on a plate girder bridge is adopted for the investigation. On the plate girder bridge, 10 uniaxial accelerometers equipped on the lower flange continuously measure acceleration. Firstly, to clarify that the proposed method detects changes in modal properties caused by temperature change, the proposed method is applied to the datasets separately measured from different seasons. Secondly, to verify the feasibility of the proposed uncertainty quantification for the varying temperature, the samples monitored from different seasons are mixed with each other. The posterior distribution of the modal properties are compared to their temperature fluctuation.

1 INTRODUCTION

Vibration based structural health monitoring provides a research field for nondestructive evaluation based on physical measurements and computer analyses to complement existing visual inspection methods. Changes in modal properties possibly indicates stiffness loss caused by damages on the structures. Especially for short to medium span bridges, the traffic excites the bridges continuously, and thus vibration monitoring is available without interrupting the traffic. In actual bridges, however, the noisy condition caused by the traffic loadings is one of the difficulties involved in the operational modal identification. That is because the noisy condition induces spurious estimators of modal properties. To cope with the problem, the authors have proposed an efficient time-domain modal identification method for bridges by uncertainty quantification using unsupervised machine learning (Goi and Kim 2021). This study applies the proposed uncertainty quantification to half year monitoring data of a plate girder bridge (Goi and Kim, 2018) and verifies the proposed method.

Aiming at practical use, the authors have intended to avoid complicate model as possible. So far, the proposed method is based on steady dynamical model and no temperature fluctuation is taken in account. This study investigates scope of the previously proposed model in advance of developing further expansion of the model for machine learning. In the proposed method, the vector autoregressive (VAR) model is adopted as the stochastic model representing the bridge vibration. Bayesian inference method is applied to obtain the posterior distribution of the regressive coefficients of the VAR model. Following the well-known modal

analysis theory, the regressive coefficients are transformed to the estimators of modal properties. The uncertainty of the modal properties are quantified through the transformation.

Although the proposed method enables to evaluate uncertainty involved in steady VAR process, it have been not validated for non-steady process with varying temperature. Therefore, this study investigates the efficacy of the proposed method under the temperature fluctuation. Firstly, the proposed method is applied to the datasets separately measured from different seasons, namely on September and on February, and the posterior distributions of the modal frequencies are compared with each other. Secondly, the samples monitored from the two seasons are mixed with each other. The posterior distribution from mixed sample are observed to verify the feasibility of the proposed uncertainty quantification for the varying temperature.

2 METHODOLOGY

2.1 Bayesian inference

Here, the previously proposed Bayesian inference method is described. For further discussion, see also (Goi and Kim 2021). We assume that a synchronized discrete time series of the acceleration measured at m measurement locations on a bridge, and assume that the time series includes n data points. A zero-mean time series is produced by subtracting the mean value from the measured acceleration. Letting $\mathbf{y}_k \in \mathbb{R}^{m \times 1}$ ($k = 1 \dots n$) denote a column vector at the k -th time step of the time series with components corresponding to the measurement locations, and letting $\boldsymbol{\phi}_k = [\mathbf{y}_{k-1}; \dots; \mathbf{y}_{k-p}]$, then the following VAR model with sufficient model order p is known to approximate the time series obtained from a linear structural system excited by white noise (He and De Roeck 1997).

$$\mathbf{y}_k = \mathbf{W}\boldsymbol{\phi}_k + \mathbf{e}_k \quad (1)$$

Here, $\mathbf{W} \in \mathbb{R}^{m \times m}$ denotes the AR coefficient matrix and $\mathbf{e}_k \in \mathbb{R}^{m \times 1}$ denotes a zero-mean Gaussian white noise vector. Letting $\boldsymbol{\Sigma}$ denote the covariance matrix of \mathbf{e}_k , \mathbf{y}_k follows the following Gaussian distribution.

$$p(\mathbf{y}_k | \boldsymbol{\phi}_k, \mathbf{W}, \boldsymbol{\Sigma}) = \mathcal{N}(\mathbf{y}_k | \mathbf{W}\boldsymbol{\phi}_k, \boldsymbol{\Sigma}) \quad (2)$$

where $\mathcal{N}(\cdot | \mathbf{W}\boldsymbol{\phi}_k, \boldsymbol{\Sigma})$ denotes the PDF following the multivariate Gaussian distribution with expectation $\mathbf{W}\boldsymbol{\phi}_k$ and covariance matrix $\boldsymbol{\Sigma}$. This study presumes that the time series are measured l times. Let \mathbf{y}_k^i ($i = 1 \dots l$) denote the measured acceleration at k -th time step in i -th time series and n_i denote its data length. Let $\mathbf{Y}_i = [\mathbf{y}_{p+1}^i, \dots, \mathbf{y}_{n_i}^i]$ and $\boldsymbol{\Phi}_i = [\boldsymbol{\phi}_{p+1}^i, \dots, \boldsymbol{\phi}_{n_i}^i]$. Because the noise term \mathbf{e}_k is white noise, the following PDF is obtained.

$$p(\mathbf{Y}_i | \boldsymbol{\Phi}_i, \mathbf{W}, \boldsymbol{\Sigma}) = \prod_{k=p+1}^{n_i} \mathcal{N}(\mathbf{y}_k^i | \mathbf{W}\boldsymbol{\phi}_k^i, \boldsymbol{\Sigma}) \quad (3)$$

The PDF in Equation 3 is the likelihood function for parameters \mathbf{W} and $\boldsymbol{\Sigma}$. The Bayesian theorem provides the following relationship.

$$p(\mathbf{W}, \boldsymbol{\Sigma} | \mathbf{Y}_1, \dots, \mathbf{Y}_l) \propto \prod_{i=1}^l p(\mathbf{Y}_i | \boldsymbol{\Phi}_i, \mathbf{W}, \boldsymbol{\Sigma}) p(\mathbf{W}, \boldsymbol{\Sigma}) \quad (4)$$

For simplicity, this study adopts uniform prior distribution, i.e. $p(\mathbf{W}, \boldsymbol{\Sigma}) \propto \text{Const.}$, to represent non-informative prior. Accordingly, Equation 4 produces following distribution.

$$p(\mathbf{W}, \boldsymbol{\Sigma} | \mathbf{Y}_1, \dots, \mathbf{Y}_l) = \mathcal{M}\mathcal{N}(\mathbf{W} | \mathbf{M}, \boldsymbol{\Sigma}, \mathbf{L}^{-1}) \mathcal{I}\mathcal{W}(\boldsymbol{\Sigma} | \boldsymbol{\Psi}, \nu) \quad (5)$$

where

$$\mathbf{L} = \sum_{i=1}^l \Phi_i \Phi_i^T \quad (6)$$

$$\mathbf{M} = (\sum_{i=1}^l \mathbf{Y}_i \Phi_i^T) \mathbf{L}^{-1} \quad (7)$$

$$\nu = -(mp + m + 1) + \sum_{i=1}^l (n_i - p) \quad (8)$$

$$\Psi = \sum_{i=1}^l \mathbf{Y}_i \mathbf{Y}_i^T - \mathbf{M} \mathbf{L} \mathbf{M}^T \quad (9)$$

In that equation, $\mathcal{MN}(\mathbf{W}|\mathbf{M}, \Sigma, \mathbf{L}^{-1})$ and $\mathcal{IW}(\Sigma|\Psi, \nu)$ respectively stand for the following matrix-normal and inverse-Wishart distributions (Dzunic et. al. 2017) as

$$\mathcal{MN}(\mathbf{W}|\mathbf{M}, \Sigma, \mathbf{L}^{-1}) = (2\pi)^{-\frac{mp \times m}{2}} |\mathbf{L}^{-1}|^{-\frac{m}{2}} |\Sigma|^{-\frac{mp}{2}} \times \exp\left\{-\frac{1}{2} \text{tr}\left[\mathbf{L}(\mathbf{W} - \mathbf{M})^T \Sigma^{-1} (\mathbf{W} - \mathbf{M})\right]\right\} \quad (10)$$

$$\mathcal{IW}(\Sigma|\Psi, \nu) = 2^{-\nu m/2} \Gamma_m\left(\frac{\nu}{2}\right) |\Psi|^{\frac{\nu}{2}} |\Sigma|^{-\frac{(\nu+m+1)}{2}} \times \exp\left\{-\frac{1}{2} \text{tr}[\Psi \Sigma^{-1}]\right\} \quad (11)$$

where $\Gamma_m(\cdot)$ is the multivariate gamma function.

To find optimal model order p , this study adopts following Bayesian information criterion (BIC) (Schwarz 1978).

$$BIC = N \left(m \ln 2\pi + \ln |\hat{\Sigma}| + m \right) + M \ln N \quad (12)$$

where $\hat{\Sigma}$ represents most likelihood estimator of Σ , M denotes the number of parameter, and N denotes total data length.

2.2 Uncertainty quantification

The uncertainty of the each identified mode is derived from Equation 5 as follows. First, this study assumes Σ is fixed to the most likelihood estimator for simplicity, instead of the inverse-Wishart distribution. Therefore, the posterior distribution of \mathbf{W} is given as follows instead of Equation 10.

$$p(\mathbf{W}|\mathbf{Y}_1, \dots, \mathbf{Y}_l) = \mathcal{MN}(\mathbf{W}|\mathbf{M}, \hat{\Sigma}, \mathbf{L}^{-1}) \quad (13)$$

It is known that the VAR model in Equation 1 is reproduced to the following state space model (Heylen et. al. 1997).

$$\phi_{k+1} = \mathbf{A} \phi_k + \begin{bmatrix} \mathbf{I}_m \\ \mathbf{O} \end{bmatrix} e_k \quad (14)$$

$$\mathbf{y}_k = [\mathbf{I}_m \quad \mathbf{O}] \phi_{k+1} \quad (15)$$

where \mathbf{I}_m denotes the eigenmatrix of size m , \mathbf{O} denotes the zero matrix with the appropriate size, and $\mathbf{A} \in \mathbb{R}^{mp \times mp}$ represents the following matrix.

$$\mathbf{A} = \begin{bmatrix} \mathbf{W} \\ \mathbf{I}_{m(p-1)} \quad \mathbf{O} \end{bmatrix} \quad (16)$$

The eigenvalue decomposition of the matrix \mathbf{A} is given as follows.

$$\mathbf{A} = \mathbf{P} \Lambda \mathbf{P}^{-1} \quad (17)$$

where $\mathbf{\Lambda}$ denotes diagonal matrix composed of the eigenvalues of matrix \mathbf{A} , and \mathbf{P} denotes a matrix composed of the corresponding eigenvectors. It is well known that the eigenvalues represent the poles of the transfer function of the dynamic model given in Equations 14–15. That is, letting ω_i and ζ_i respectively represent the i -th eigen-angular frequency and damping ratio, and λ_i denote the i -th eigenvalue of the matrix \mathbf{A} , the following relation is given.

$$\lambda_i = \exp \left[\left(-\zeta_i \omega_i + j \sqrt{1 - \zeta_i^2} \omega_i \right) \Delta t \right] \quad (18)$$

where Δt represents the sampling interval and j represents the imaginary unit. Accordingly, the i -th eigen frequency f_i is given as

$$f_i = \frac{1}{2\pi\Delta t} |\ln \lambda_i| \quad (19)$$

This study adopts standard deviation (std) of the eigen frequencies to quantify the uncertainty of modal estimation. The std is defined as

$$\text{std}(f_i) = \sqrt{E[(f_i - E[f_i])^2]} = \frac{1}{2\pi\Delta t} \sqrt{E[(|\ln \lambda_i| - E[|\ln \lambda_i|])^2]} \quad (20)$$

where $E[\cdot]$ denotes the expectation of a random variable. Because the matrix \mathbf{W} in Equation 13 is composed of random variables, the random distribution of \mathbf{W} is transformed into the random distribution of λ_i .

For efficacy, this study produces approximated closed form solution of $\text{std}(f_i)$ as follows. First, according to Equations 13 and 16, the expectation of matrix \mathbf{A} is given as

$$\bar{\mathbf{A}} = \begin{bmatrix} \mathbf{M} \\ \mathbf{I}_{m(p-1)} & \mathbf{O} \end{bmatrix}. \quad (21)$$

Let the eigenvalue decomposition of $\bar{\mathbf{A}}$ represent with the following equation.

$$\bar{\mathbf{A}} = \bar{\mathbf{P}} \bar{\mathbf{\Lambda}} \bar{\mathbf{P}}^{-1} \quad (22)$$

And let the deviation of matrices \mathbf{A} and $\bar{\mathbf{A}}$ respectively represent as $\tilde{\mathbf{A}} = \mathbf{A} - \bar{\mathbf{A}}$ and $\tilde{\mathbf{\Lambda}} = \mathbf{\Lambda} - \bar{\mathbf{\Lambda}}$. Ignoring the squared deviations, the eigenvalues are approximated as follows.

$$\text{diag}(\tilde{\mathbf{\Lambda}}) = \text{diag}(\bar{\mathbf{P}}^{-1} \tilde{\mathbf{A}} \bar{\mathbf{P}}) \quad (23)$$

where $\text{diag}(\tilde{\mathbf{\Lambda}})$ represents a vector composed from the diagonal elements of matrix $\tilde{\mathbf{\Lambda}}$. Equations 16 and 21 ensures that matrix $\tilde{\mathbf{A}}$ is given as

$$\tilde{\mathbf{A}} = \begin{bmatrix} \mathbf{W} - \mathbf{M} \\ \mathbf{O} \end{bmatrix}. \quad (24)$$

Letting $\tilde{\mathbf{W}} = \mathbf{W} - \mathbf{M}$ and $\mathbf{V} = \left(\left\{ \bar{\mathbf{P}}^{-1} \right\}_{[:,1:m]} \right)^T$, where $\{\cdot\}_{[:,1:m]}$ denotes a submatrix consisting of the first m columns, Equation 23 is transformed as

$$\text{diag}(\tilde{\mathbf{\Lambda}}) = \text{diag}(\mathbf{V}^T \tilde{\mathbf{W}} \bar{\mathbf{P}}). \quad (25)$$

Therefore, the i -th diagonal member $\tilde{\lambda}_i$ is given as $\tilde{\lambda}_i = \mathbf{v}_i^T \tilde{\mathbf{W}} \mathbf{p}_i$ where \mathbf{v}_i and \mathbf{p}_i are respectively represent the i -th column of matrices \mathbf{V} and \mathbf{P} . It is known that mode shapes are estimated as real value of \mathbf{v}_i . Using Taylor expansion, $\ln \lambda_i$ in Equation 20 is approximated as

$$\ln \lambda_i \cong \ln \bar{\lambda}_i + \frac{1}{\bar{\lambda}_i} \tilde{\lambda}_i. \quad (26)$$

Therefore, the std is approximated as

$$\begin{aligned} \text{std}(f_i) &= \frac{1}{2\pi\Delta t} \sqrt{\text{E} \left[\left(|\ln \lambda_i| - \text{E}[|\ln \lambda_i|] \right)^2 \right]} \cong \frac{1}{2\pi\Delta t} \sqrt{\text{E} \left[\left(|\ln \lambda_i| - |\ln \bar{\lambda}_i| \right)^2 \right]} \\ &\leq \frac{1}{2\pi\Delta t |\bar{\lambda}_i|} \sqrt{\text{E} \left[\left(|\tilde{\lambda}_i| \right)^2 \right]} = \frac{1}{2\pi\Delta t |\bar{\lambda}_i|} \sqrt{\mathbf{p}_i^T \mathbf{L}^{-1} \mathbf{p}_i^* \mathbf{v}_i^T \hat{\Sigma} \mathbf{v}_i^*} \end{aligned} \quad (27)$$

3 FIELD MEASUREMENT

The field experiment was conducted on a single span composite steel plate girder bridge shown in Figure 1. The span length is around 40m. On the bridge deck, accelerometers and strain gauges were installed as shown in Figure 1b. Each of the accelerometers and the strain gauges monitors dynamic response of the bridge at sampling rate 200 Hz. Each of the accelerations are measured in vertical direction, the strain gauges settled on the middle of the span measured longitudinal strain on the bottom of the lower flange. The traffic-induced vibration is monitored from September 2016 to March 2017. Further detail of the field experiment is discussed in (Goi and Kim 2018).

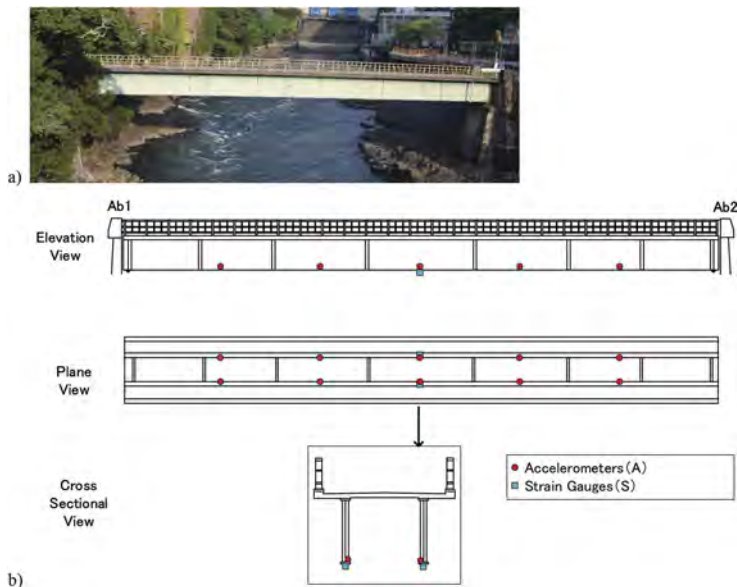

Figure 1. The target bridge: a) photograph; b) sensor deployment.

To crop the time series for Bayesian inference, this study utilizes strain gauges equipped on the lower flange at the middle of the span. For instance, Figure 2 shows 5 minutes time series measured by the strain gauges and the accelerometer. Therein, the time series of the strain are smoothed with low-pass filter of 1 Hz and averaged together for clarity. The peaks appear in the time series of the strain, which is marked as circles in Figure 2a as the vehicles pass on the

bridge. Those peaks and their widths are detected by means of peak picking analysis. Accordingly, the moment at the entrance and exit of the vehicle can be roughly estimated from the peak width. This study experimentally obtains time series data by following rules:

- The vehicle-induced vibrations between the vehicle entrance and 5 seconds after the vehicle exit are extracted from long term monitoring data.
- If the extracted areas coincide with each other, those time series are discarded.
- The extracted time series are normalized by dividing root mean square of the all data contained in the time series.

The vertical lines depicted in Figure 3 represent extraction window in the time series for instance. Figure 2b describes that the vehicle-induced vibrations are correctively extracted from the raw time series data.

Figure 2. Time series before the pre-processing: a) Averaged strain; b) Acceleration.

4 RESULTS

This study provide datasets which derive from the summer and winter. This study adopts time series measured on 2nd-3rd September as the datasets from summer; time series measured on 1st-2nd February as the datasets from winter. The datasets contain 24-hour time series in each day. For fair comparison, the time duration for Bayesian inference is fixed as two days. As mentioned in the introduction, the proposed method is applied to the datasets separately measured from the different seasons. Also, the samples from the two seasons are mixed with each other. Accordingly, this study examine the three cases provided in Table 1. Case 1 and 2 are datasets respectively measured in the summer and winter, and Case 3 is the mixed dataset.

Table 1. Test cases for the hypothesis testing.

Case	Duration	Description
Case1	2nd Sep. and 3rd Sep.	Measured in summer
Case2	1st Feb. and 2nd Feb.	Measured in winter
Case3	2nd Sep. and 1st Feb.	Mixed dataset

Table 2. Expectation and std of the estimated modal frequencies (Hz).

Mode	Expectation (Hz)			Standard Deviation (Hz)			Mode shape
	Case1	Case2	Case3	Case1	Case2	Case3	
Mode1	3.1417	3.1160	3.0977	0.0018	0.0020	0.0020	1st Bending
Mode2	3.7007	3.7383	3.7237	0.0013	0.0011	0.0011	1st Torsional
Mode3	4.9857	4.9414	4.9574	0.0011	0.0010	0.0011	1st Torsional
Mode4	8.4821	8.4318	8.4435	0.0015	0.0014	0.0018	Not clear
Mode5	9.3394	9.4725	9.3848	0.0013	0.0013	0.0023	2nd Bending
Mode6	11.0347	11.1178	11.0756	0.0012	0.0010	0.0012	2nd Torsional
Mode7	15.4165	15.5730	15.4735	0.0016	0.0014	0.0021	Not clear
Mode8	17.8136	17.9514	17.8581	0.0015	0.0015	0.0015	3rd Torsional

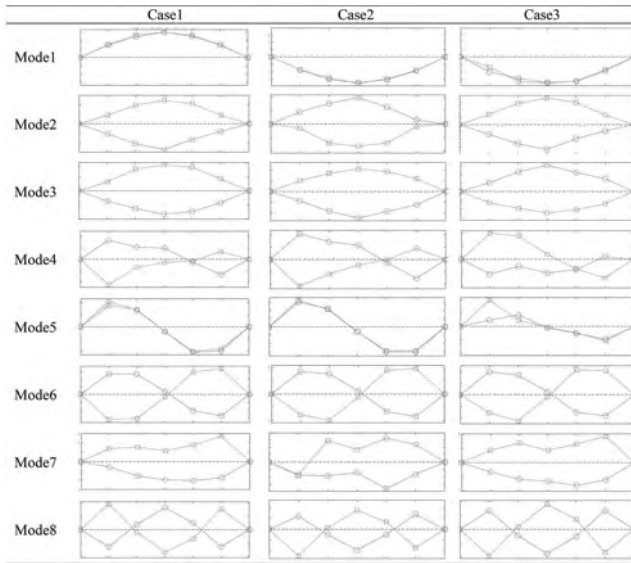

Figure 3. Estimated mode shapes.q.

Figure 4. Probability density functions of posterior distribution.

The proposed method is applied for each of the dataset and the posterior distribution of the modal frequencies is produced. Table 2 summarize the expectation and std of the modal frequencies. Figure 3 shows estimated mode shapes corresponding to each of the estimated frequencies. These modal properties are automatically extracted by sorting the std of modal frequencies in ascending order (Goi and Kim 2021). The results in Table 2 are also summarized in probability density functions shown in Figure 4.

It is observed that the posterior distribution of the modal frequencies slightly altered between the two season. Except Model1, the posterior distribution obtained from Case3, the mixed dataset, locate between the Case1 and Case2. That result indicate that the most probable value of the modal frequencies except Model1 estimated from the mixed dataset is located between the two seasons. However, it seems the posterior distribution of Case3 underestimate the uncertainty caused by temperature changes, i.e. its deviation are much less than frequency changes between Case1 and Case2. That is possibly because the VAR process merely assumes steady dynamic system and changes in modal properties caused by temperature is not taken into account. Further investigation

5 CONCLUSION

This study validate uncertainty quantification using Bayesian inference steady vector autoregressive (VAR) model. Posterior distribution of the modal frequencies is approximately formulated from the posterior distribution of regressive coefficients. A half-year monitoring data on a plate girder bridge is adopted for the investigation. The proposed method is applied to the datasets separately measured from summer and winter. Also, the samples monitored from different seasons are mixed with each other for comparison.

The quantified uncertainty enables prompt modal identification from long term monitoring data. Most of the expectations estimated from mixed dataset locate between the ones estimated from the two seasons. However, the posterior distribution tends to underestimate uncertainty caused by seasonal fluctuation. Their deviation were much less than the changes in frequency between the two seasons. That is possibly because the VAR model does not take the seasonal fluctuation into account. The results indicate room for improvement in the proposed method. Aiming at practical health monitoring, the proposed method is to be expanded to multi-class unsupervised machine learning or hierarchical Bayesian models.

ABSTRACT: In this research, a method for estimating reaction forces using the vibration characteristics of steel plates is examined. In general, it is known that the natural frequencies of steel plates decrease as compressive forces on them increase. Applying compressive forces to the steel plates experimentally, the vibration characteristics of the steel plates are obtained, and the changes in natural frequencies of the steel plates as the load increases are understood. The change in natural frequencies when compressive forces act on steel plates is theoretically and analytically determined, and the reaction forces acting on the steel plates are inversely estimated by comparing the change of natural frequencies determined theoretically and analytically with those determined experimentally.

1 INTRODUCTION

It is important to understand the dead load distribution of each bearing to ensure the safety of the bridge design in bridge construction and maintenance. However, it is currently not possible to determine the dead load distribution. After bridges put into service, localized corrosion which is likely to occur in the bearings due to the fact that bearings tend to be installed in narrow spaces and other factors such as age-related deterioration, natural disasters such as earthquakes and heavy rainfall, and movement of the superstructure and substructure due to active loads such as vehicle traffic and wind loads may cause uneven dead load distribution. In general, a slight non-uniformity of dead load on bridges does not immediately cause functional failure, such as crushing of the bearings due to exceeding the design load. If the dead load distribution can be determined, it is desirable to equalize the dead load distribution by reinforcing the structure when unexpected non-uniformities occur. Currently, inspection methods for bearings rely on subjective judgment, such as close-up inspection. A rubber bearing with a built-in sensor that acts as a load cell to measure the load has been developed, but this method can only be applied to newly constructed bridges or when the bearing is replaced. Therefore, it is an urgent issue to develop a nondestructive inspection method to measure the dead load contribution.

This study aims to develop a methodology for estimating the reaction forces acting on structural members using the vibration characteristics of steel. Researches show that the vibration characteristics are used for estimating column force acting on spherical tank, and cable tension. As a fundamental study, steel plate specimens are prepared and subjected to a compressive force to determine those vibration characteristics. The vibration characteristics obtained by experiments are compared with those obtained by analysis and theory, and the compressive force acting on the steel plate is estimated from the vibration characteristics.

2 NATURAL VIBRATION OF A FLAT PLATE

2.1 Theory of bending vibration of a plate

The H-steel specimen, which is loaded from the top and bottom, is assumed to be a double-end fixed beam subjected to compressive forces. The vibration equation for deflection v of a beam with compressive load can be expressed as follows,

$$\rho A \frac{\partial^2 v}{\partial x^2} + EI \frac{\partial^4 v}{\partial x^4} + P \frac{\partial^2 v}{\partial x^2} = 0 \quad (1)$$

where ρ is the density of the plate, E is Young's modulus, I is the moment of inertia, A is the area of the cross-section, x is the coordinates of the bridge axial direction, and P is the compressive load.

Assume the special solution is $v = X(x)e^{int}$, where n is the angular frequency, Equation (1) becomes an ordinary differential equation.

$$EI \frac{d^4 X}{dx^4} + P \frac{d^2 X}{dx^2} - \rho A n^2 X = 0 \quad (2)$$

Put $X(x) = X_0 e^{\lambda x}$ as a solution for the equation, then let λ as shown below.

$$\lambda = \begin{cases} \pm i\lambda_1 \\ \pm \lambda_2 \end{cases}, \left(\lambda_1 = \sqrt{\frac{\sqrt{P^2 + 4\rho A E I n^2} + P}{2EI}}, \lambda_2 = \sqrt{\frac{\sqrt{P^2 + 4\rho A E I n^2} - P}{2EI}} \right) \quad (3)$$

Therefore, the solution of Equation (2) is

$$X(x) = A \sin \lambda_1 x + B \cos \lambda_1 x + C \sinh \lambda_2 x + D \cosh \lambda_2 x \quad (4)$$

Since the displacement and deflection angle at the fixed end is 0,

$$\begin{cases} X(0) = 0, & \left. \frac{dX}{dx} \right|_{x=0} = 0 \\ X(l) = 0, & \left. \frac{dX}{dx} \right|_{x=l} = 0 \end{cases} \quad (5)$$

where l is the bridge span.

Substituting the boundary condition (5) into Equation (4), the following equation is obtained.

$$2\lambda_1 \lambda_2 + (\lambda_2^2 - \lambda_1^2) \sin \lambda_1 l \sinh \lambda_2 l - 2\lambda_1 \lambda_2 \cos \lambda_1 l \cosh \lambda_2 l = 0 \quad (6)$$

Then Equation (6) is

$$2\sqrt{\frac{\rho A}{EI}} n (1 - \cos \lambda_1 l \cosh \lambda_2 l) - \frac{P}{EI} \sin \lambda_1 l \sinh \lambda_2 l = 0 \quad (7)$$

When $P = 0$, put $\lambda = \lambda_0$, $n = n_0$, then Equation (7) is as follows.

$$1 - \cos \lambda_0 l \cosh \lambda_0 l = 0 \quad (8)$$

By solving Equation (8), λ_0 , n_0 is obtained as follows.

$$\lambda_0 = \sqrt[4]{\frac{\rho A n_0^2}{EI}}, \quad n_0 = \frac{1}{l^2} \sqrt{\frac{EI}{\rho A}} (\lambda_0 l)^2 \quad (9)$$

Define α as follows where P_{cr} is the buckling load of the fixed beam at the both end.

$$\alpha \equiv \frac{1}{2} \frac{1}{\lambda_0^2} \frac{P}{EI} = 2 \left(\frac{\pi}{\lambda_0 l} \right)^2 \frac{P}{P_{cr}} \left(\because P_{cr} = \frac{4\pi^2 EI}{l^2} \right) \quad (10)$$

Then Equation (7) can be rewritten as follows.

$$\begin{aligned} \frac{n}{n_0}(1 - \cos\lambda_1 l \cosh\lambda_2 l) - a \sin\lambda_1 l \sinh\lambda_2 l &= 0 \\ \rightarrow n &= \frac{a \sin\lambda_1 l \sinh\lambda_2 l}{1 - \cos\lambda_1 l \cosh\lambda_2 l} n_0 \end{aligned} \quad (11)$$

where λ_1, λ_2 are as follows.

$$\lambda_1 = \lambda_0 \sqrt{\sqrt{\frac{n^2}{n_0^2} + \alpha^2} + \alpha}, \quad \lambda_2 = \lambda_0 \sqrt{\sqrt{\frac{n^2}{n_0^2} + \alpha^2} - \alpha} \quad (12)$$

By solving Equation (11) using Equation (12) and the dimensions of the H-steel specimen of Figure 4, the following graph can be obtained.

Figure 1. Theoretical load-frequency relation.

2.2 Analytical approach to H-steel specimen

Finite element analysis is performed using the analysis software ABAQUS. The dimensions of the specimen are shown in Figure 4, and fillets are omitted for simplicity. The analysis is performed using solid elements, which are first-order reduced integral elements with eight contacts. Unit volume mass is $7850 \text{ (kg/m}^3\text{)}$, Poisson's ratio is 0.3, and Young's modulus is 206 (GPa) . The mesh of the specimen is a 5 mm regular hexahedron shown in Figure 2. However, only in the direction of the web thickness, a mesh of 0.1 mm is used for the analysis shown in Figure 3. The bottom flange is completely fixed, while the top flange is free to displace only in the loading direction, restraining the displacement of the sides of the top flange in two directions perpendicular to the load. Surface forces were applied to the upper flange to determine the natural frequencies of the specimen.

Figure 2. Specimen overview.

Figure 3. Enlarged mesh view of the web.

3 COMPRESSION TEST OF A PLATE

3.1 Specimen dimensions and test method

3.1.1 Specimen dimensions

Specimen dimensions and the location of accelerometers and uniaxial strain gauges are shown below. The accelerometers are placed about 10 mm above the uniaxial strain gauges so that they do not overlap. Uniaxial strain gauges are installed on both front and back sides. The names are set as shown in the Figure 4. The specimen is made of SS400. Uniaxial strain gauges are used to ensure that eccentric loading does not occur.

3.1.2 Test method

Compression forces are applied vertically by hydraulic system universal testing machine. The load is increased by 10 kN up to 240 kN. Under each loading condition, acceleration data are collected while striking the specimen 50 times by a hammer. The strike point is at the center of the specimen, about 20 mm to the left of the uniaxial strain gauge so as not to strike the uniaxial strain gauge and the striking plane is the opposite plane on which the accelerometers are placed. The accelerometers used are NP2110 (Ono Sokki Co.,Ltd.), NP-2110 (Ono Sokki Co., Ltd.), and PV-87 (Rion Co.,Ltd.) from left to right in the figure above. The sampling frequency is 50 kHz.

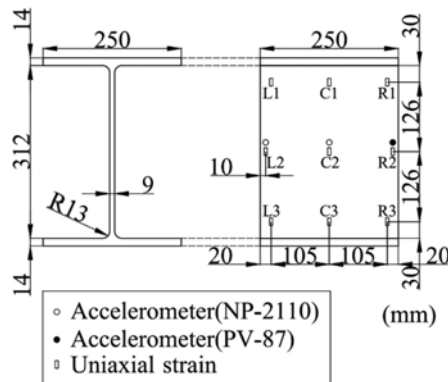

Figure 4. Dimensions of a H-steel specimen.

3.2 Target mode frequency

Frequency analysis is performed using the accelerometer of PV-87 because it is more accurate at lower frequency. Figure 3 shows the graph obtained by the Welch's power spectral density estimation method (Pwelch) when 100kN is applied on the plate. The window length is 2^{15} , a Hamming window is used for each segment, and the overlap ratio is 50%.

Next, the superimposed results of the Pwelch for each loading condition are shown in Figure 4. As an example, the results for 50 kN, 100 kN, 150 kN, and 200 kN loading conditions are superimposed.

Referring to Figure 5, Figure 6 is enlarged to focus on the area around 450 Hz where the power is maximum. Theoretical calculations show that the frequency is 400-500 Hz in the 0-250 kN loading range. Therefore, the peak near 450 Hz is presumed to be the target vibration mode, and the mode shape of the target mode is expressed as shown in Figure 7.

Figure 5. Example of Pwelch.

Figure 6. Superimposed Pwelch result.

Figure 7. Target vibration mode.

3.3 Comparison of frequency transition by theory, analysis and experiment

Peaks near 450 Hz are picked up for each loading condition and compared with the frequency transition identified in Chapter 2. Figure 8 shows an overlay of Pwelch for all loading conditions. As can be seen in Figure 8, the peak around 450 Hz is prominent under each loading conditions, and analytical and numerical results show that the target mode remains near 450 Hz. Therefore, the target mode is considered to be consistent between the experimental results and the analytical and numerical results. The natural frequencies of the target mode under each loading condition are obtained by peak picking from the graph. Figure 9 shows that the frequencies of the target mode obtained by the experiment tends to increase from 0 to 100 kN loading and to decrease from 100 to 240 kN loading. The peaks for the 0 and 10 kN loadings are not obtained because the peaks are crushed or does not appear.

One possible cause of the increased frequency in the small load region is a lack of support condition settings. Compressive load is applied using a compression plate of $\phi 180mm$. Two $380 \times 380 \times 25mm$ plates are placed on top of the specimen to prevent the stress from concentrating only directly under the compression plate. However, stress transmission is insufficient, so rotation is possible at the upper end of the specimen and support conditions of fixed at the bottom end and simply supported at the upper end are established in the range of small loads. As the load increases, the support condition approaches asymptotically to fixed at both ends, and the frequency decreases after 100 kN loading.

Analysis is performed every 30 kN by ABAQUS. The relative errors between the theoretical and analytical values are less than 2.0% at all loading. The natural frequency transitions lower than the theoretical value. It is because the mesh is coarse. Bending deformation is dominant in thin plates. Therefore, it is thought that the analytical values can be brought closer to the theoretical values by refining the mesh or using shell elements.

After 100 kN loading, when the natural frequency starts to decrease, the relative errors between the theoretical and experimental values are less than 1.3%. Therefore, after 100 kN loading, the compressive force acting on the specimen can be estimated from the experimental vibration characteristics.

Figure 8. Superimposed figure of Pwelch for all loading condition.

4 CONCLUSION

In this paper, the compression bending test is conducted on SS400 steel plate specimen to confirm the relationship between compressive force and the natural frequency. The results are compared with theoretical and analytical values to confirm the validity of the results.

Figure 9. Comparison of theoretical, analytical and experimental frequency.

The relative errors between the theoretical and analytical values are less than 2.0%, therefore the validity of the analysis is confirmed.

The frequencies of the target mode obtained by the experiment tends to increase from 0 to 100 kN loading and to decrease from 100 to 240 kN loading, and after 100 kN loading, when the natural frequency starts to decrease, the relative errors between the theoretical and experimental values are less than 1.3%, therefore the compressive force acting on the specimen can be estimated from the experimental vibration characteristics.

ABSTRACT: This study aims to investigate change in vibration characteristics of full-scale poled structure made of steel by vibration test. Due to the cyclic loading, the poled structures are susceptible to failure resulting from the damages such as cracks or loosened bolts. As the fundamental study for the development of SHM technique, cyclic vibration test using exciter was conducted on the structure and relationship conditions and identified vibration characteristics were discussed. Additionally, data with loosening anchor bolts were also collected to simulate the damage on the base. The experimental result shows that natural frequency decreases with increasing the degree of damage. Besides, it was found that two vibration modes with close natural frequencies were identified as one when the structure was intact, but were separated into two modes when the support conditions changed.

1 INTRODUCTION

In Japan, proportion of the bridges which are 50 years old is 34%. Inspection, monitoring and maintenance has become increasingly important take early actions against defects and deterioration. For more effective structural management, SHM have been focused for many years. The target structure was a sign support structure, which is cantilevered with a single pole. Sign support structures mount signages and Variable Message Sign (VMS) to guide motorist to their destination or show them various information. These structures are constantly exposed to wind loading, and for those structures mounted on bridges, to bridge vibrations induced by passing vehicles (Kacin et al. (2010)). As they have long span length and relatively small cross-sectional area and mass, these sign structures are flexible, resulting in low natural frequencies and damping; they are prone to having large-amplitude vibration and fatigue cracking under wind loading or vibration of bridges. Due to the cyclic loading, the structures are susceptible to failure resulting from the damages such as cracks or loosened bolts (Li et al. (2005)). SHM techniques have large possibility in monitoring such structure to prevent failure. In this study, we were focusing the damage at the base. As the fundamental study of the damage detection technique using sensor, change in vibration characteristics with two types of damages at the base were investigated; one was conducted with loosening anchor bolts, and another was with cracks through cyclic loading test.

2 EXPERIMENTAL APPROACH

A post structure that the cantilevered support structure is supported by a single vertical pole, was fabricated specifically for the laboratory testing. Figure 1 gives its general view. The post

specimen was attached to the concrete foundation using four anchor bolts. At the middle of the post, an exciter was equipped to excite vibration mode of the structure. Information on the specimen are presented in Figure 1 and Figure 2. Vibration characteristics were estimated with two types of damages: loosening anchor bolts and cracks. The vibration was recorded through total 6 triaxial accelerometers with a sampling frequency of 200 Hz and vibration characteristics were estimated.

Figure 1. General view of target structure.

Figure 2. Base plate detail.

Figure 3. Anchor bolts loosening scenarios.

For the loosening anchor bolt case, total 7 cases for loosening anchor bolts and one intact case were examined (see Figure 3). S0 is an intact case. From S1 to S3, one bolt was loosened with 1/8, 1/4, and 1 turns, i.e., 45°, 90°, and 360°, respectively. Two or three bolts are turned once in S4 to S6. Sensors were installed as shown in Figure 4.

For the crack case, the structure were under cyclic loading to generate fatigue crack. Since a fatigue crack occurred in the weld of the mast arm after 600,000 cycles, the arm was removed for safety (Figure 5). Hence, for the crack case, we are focusing on the structural behavior after removing the arm. No other crack was observed just after

Figure 4. Test setup for bolt loosening case.

removing the mast arm. As show in Figure 6 and Figure 4, total 5 triaxial accelerometers and an exciter (URAS VIBRATOR KEE3-6C) were installed. The exciter, which can excite the vibration in various frequency by vibrating in the arm (Y) direction, was mounted 1.5 m from the base for cyclic loading test. Besides, to capture the stress response, two uniaxial strain gauges were mounted as shown in Figure 7 and 8. Cyclic loading test using an exciter was conducted. Crack lengths were examined by magnetic particle testing after every 10,000 loadings. Once a structure developed an crack connecting to a next crack, loading test was finished.

Figure 5. Schematic of target structure after removing the arm.

Figure 6. Test setup for crack case.

Figure 7. Strain gauge setup.

Figure 8. Close-up of strain gauge.

In order to identify the vibration characteristics, the structure was excited by pushing with hands in two directions: y-axis direction, the arm direction, and z-axis direction, perpendicular to the arm. The structure was pushed once every 1 minute for 11 minutes; it was excited 10 times in one test. For the crack case, the number of samples varied for each loading stage. Therefore the mean values of frequencies obtained for each cycle was taken as representative of the frequency for that cycle.

As an modal analysis method, stochastic subspace identification (SSI) (Van Overschee and De Moor (1996) & De Cock et al. (2003)), a time-domain system identification method which estimates state space model from output-only measurement, was used to identify structure's natural frequencies and mode shapes.

3 RESULTS AND DISCUSSION

3.1 Anchor bolt loosening case

Here, the vibration modes of first two smallest frequencies, 1st bending mode and 1st torsional mode, were focused. Mode shapes (Figure 9-10) and natural frequencies were identified. The rate of change in frequencies with respect to the frequency for S0, the intact state, were calculated as represented in Figure 12 and Figure 13. It should be noted that for the 1st bending mode, three directions of vibration were observed (Figure 11). The C-direction mode was separated into two directions A and B as loosening the anchor bolts. It could be thought that the structure originally has two adjacent modes, A-direction mode and B-direction mode, which can be seen as one mode, C-direction mode, in the intact condition because these two modes are too close.

Figure 11. Swing directions of the 1st bending mode in bolt loosening test.

Figure 12. Rate of change in frequencies for the 1st bending mode with respect to S0 frequency.

Figure 13. Rate of change in frequencies for the 1st torsional mode with respect to S0 frequency.

3.2 Crack case

For the crack case, after 723,000 cycles, cracks were found for the first time. The crack propagated with cyclic loading. All cracks initiated at a weld toe adjacent to the pole shaft, then propagated circumferentially from either side of the initiation point (see example in Figure 14). The record of crack propagation are described in Figure 15. The rate of section loss were calculated as given in Table 1. Here, the section loss is calculated as ratio of total length of crack to the original circumference. It can be seen that the crack growth is active in one direction (A-direction in Figure 11), and is gentle in another direction (B-direction in Figure 11).

From the output acceleration data, natural frequencies and mode shapes of this structure were identified with SSI method. The first four vibration modes were focused. Let the name of vibration mode be Mode 1, Mode 2, and so on, from the lowest natural frequency.

Typical mode shapes for each mode are listed in Figures 16a-16d. The value of the frequencies are for after 600,000 cycles of loading, the intact state. In these four modes, 1st and 2nd

bending mode in two directions were observed: direction A and B in Figure 11. Mode 1 and Mode 2 are the 1st bending mode with A and B-direction of swing, respectively. Mode 3 and Mode 4 are the 2nd bending mode with A and B-direction of swing, respectively.

Figure 14. Example of crack.

Figure 15. Crack length and location at each cycle.

Table 1. Section loss due to crack.

Cycles	Total crack length (mm)	Rate of section loss (%)
723,000	34	7.741
780,000	48	10.93
790,000	54	12.30
800,000	70	15.94
808,000	137	31.24

For each mode, natural frequencies were estimated and the rate of change in frequencies with respect to the frequency at 600,000 cycles, the intact state, were calculated. As can be seen in Figure 17a and 17c, it appeared that natural frequency of the vibration modes in which their swings are in direction-A tends to decrease as increasing cycles. For Mode 2 and Mode 4 however, relatively insensitive trend was observed compared to direction-A vibration modes' frequency changes. As in Figure 15, the crack propagation was not uniform in circumference. Hence, only the vibration mode in the direction where crack is propagating was sensitive to the increasing in crack length. According to these results, the selection of target vibration mode of focus is important in crack detection using the frequency change.

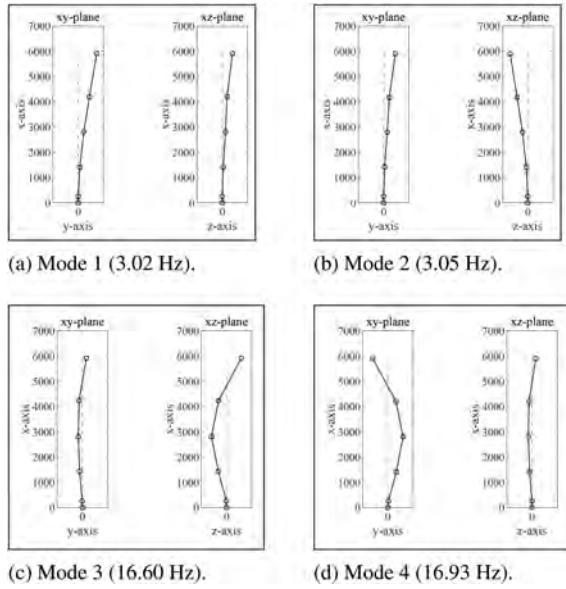

Figure 16. Typical mode shape for each mode.

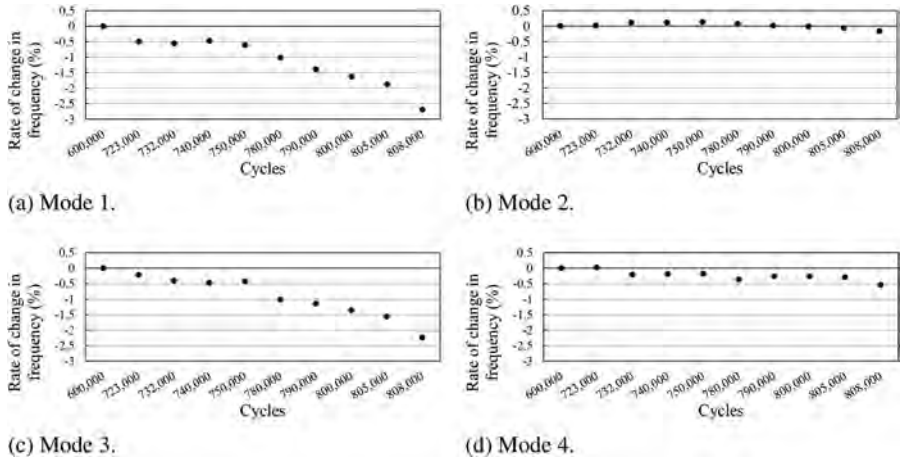

Figure 17. Rate of change in frequencies with respect to the 600,000 cycles' frequency.

Figure 18. Structure model for intact and with damage at the base.

The structure can be modeled as depicted in Figure 18. Model (a) is describing the intact case. For model (b), it can be said that the spring constant, which indicates how much the rotation at the base is restricted, is decreased as loosening anchor bolts. Suppose this model,

model (a) can be regarded as model (b) of which spring constant is increased, and the spring constant decreases as the crack grows. Therefore, it can be inferred that propagation of crack leads to decrease in natural frequency.

4 CONCLUSIONS

This article discusses the change in vibration characteristics with damage at the base. Two types of damage were simulated: loosening anchor bolts artificially and producing fatigue under cyclic loading test. Natural frequencies and corresponding mode shapes were estimated in each damage stages.

For both two types of damages, loosening anchor bolts and increasing crack length leads to decrease in natural frequencies. It was interpreted as the stiffness at the base was decreased due to these damages. Besides, as the natural frequencies changed, two modes with close natural frequencies were identified as one when intact state, but were separated into two modes when the support conditions changed. In the crack case, it was observed that the sensitivity of frequency changes to the crack propagation depends on crack locations and target vibration modes. Hence, if anomaly detection is attempted through changes in vibration characteristics, the selection of vibration mode is considered to be important. Moreover, this experiment was conducted indoors, with no traffic and no whether change. In order to apply in the real world, further investigation with external factors such as traffic loading or temperature changes should be conducted.

Review of advances in life-cycle seismic risk and resilience of bridges and bridge networks

L. Capacci & F. Biondini

Politecnico di Milano, Milan, Italy

D.M. Frangopol

Lehigh University, Bethlehem, PA, USA

ABSTRACT: Risk assessment and mitigation programs have been carried out over the last decades in the attempt to reduce transportation infrastructure downtime and post-disaster recovery costs after seismic events. Mathematical frameworks have also been proposed to provide a basis for development of predictive models for functionality and resilience of structures and infrastructure networks, particularly regarding bridges and transportation systems. In risk and resilience frameworks, the effects of aging and environmental aggressiveness should be explicitly considered, affecting the structural performance and functionality of civil infrastructure systems. This review paper discusses principles, methodologies, open issues, and current developments in the field of life-cycle seismic risk and resilience of aging bridges and bridge networks.

1 INTRODUCTION

The quality of life of modern communities relies on the ability of infrastructure networks to cope with hazards, absorbing their impact and restoring as soon as possible the pre-event conditions (Bruneau et al. 2003). Designing lifelines and infrastructure components to meet modern safety standards and planning proper management policies are key tasks to satisfy the primary needs of communities not only under operational conditions, but also in a state of emergency (Frangopol 2011). For this reason, transportation networks play a key role guaranteeing connectivity in the aftermath of extreme events, such as earthquakes, to ensure deployment of emergency aids and to promptly repair the built environment. Bridges are crucial elements designed to bypass obstacles otherwise not easily detoured (Capacci et al. 2022a).

The economic impact of aging and deterioration processes on existing structures and infrastructure systems is exceptionally high, particularly for bridges and transportation networks (ASCE 2021). Vulnerability assessment is traditionally carried out by neglecting any deterioration mechanism that may adversely affect the performance of structural systems, implicitly assuming that structures are optimally maintained during their lifetime. The detrimental effects of aggressive chemical attacks and other physical damage mechanisms can exacerbate losses over time in structural performance under both service loadings and extreme events, such as earthquakes (Biondini and Frangopol 2016). Despite the advances in civil and structural engineering, there has not been enough progress in developing methodologies and best practices for life-cycle design, assessment, maintenance, and management of bridges under seismic and other independent and interdependent hazards (Akiyama and Frangopol 2018, Biondini and Frangopol 2018, 2019).

This review paper focuses on concepts, methods, issues, and accomplishments in the field of life-cycle seismic risk and resilience of structures and infrastructure systems, with specific focus on bridges and bridge networks. Special attention is paid to: principles and dimensions of infrastructure risk assessment; established methodologies and open issues regarding regional seismic

hazard and fragility of spatially-distributed bridges; definitions and frameworks of infrastructure resilience; network functionality and bridge recovery for seismic resilience assessment; life-cycle probabilistic concepts affecting lifelines seismic resilience of under environmental stressors.

2 LIFE-CYCLE RESILIENCE-BASED SEISMIC RISK OF AGING BRIDGE NETWORKS

2.1 *Seismic hazard of spatially-distributed vulnerable assets*

Classical approaches to Probabilistic Seismic Hazard Analysis (PSHA) rely on the assumption that earthquakes are mutually independent following a stationary Poisson process fully described by their mean annual rate of occurrence (Cornell 1968). In the context of PSHA, seismic Intensity Measures (IMs) are synthetic parameters the ground motion at a reference site severity at the location of the investigated structure (Riddell 2007). Selecting the most appropriate metric is a fundamental task to define reliable estimates of structural demand (Luco and Cornell 2007). Attenuation laws or Ground Motion Prediction Equations are predictive models calibrated by multivariate regression analysis based on historical datasets adopted to statistically estimate IM likelihood based on seismogenic source features and causative rupture scenarios (Douglas 2003).

The spatial correlation of ground motion is critical for seismic hazard assessment of infrastructure networks with spatially distributed vulnerable elements. Statistical models of seismic hazard allow simulating seismic intensities maps at the relevant sites of vulnerable components (Stergiou and Kiremidjian 2010). Lognormal random fields are typically adopted to statistically model seismic IMs in the investigated region, with dispersion associated to within-event and between event variability (Crowley and Bommer 2006, Jayaram and Baker 2010). Regarding seismic sequences in the aftermath of major events, aftershocks tend to occur in time with decaying frequency and average magnitude lower than the mainshock (Iervolino et al. 2018). Refined frameworks can be applied to quantify consequences and uncertainties in seismic vulnerability and risk assessment (Dong and Frangopol 2015).

2.2 *Seismic fragility of vulnerable bridges*

The failure probability of vulnerable bridges is addressed based on the concept of fragility curves, which is the conditional probability of occurrence of a prescribed failure event given the seismic hazard IM (Shinozuka et al. 2000). Methodologies for seismic fragility assessment involve research efforts in the field of seismic engineering and structural reliability (Billah and Alam 2015). Analytical fragility curves establish the seismic response based on structural analyses and they are typically obtained by non-linear time-history analyses. Alternatives to analytical frameworks are provided by empirical fragility curves, correlating IMs with damage datasets obtained via in-field reconnaissance reports from past earthquakes (Basoz and Kiremidjian 1998). Depending on the available data related to earthquake-induced damage, statistical procedures have been developed to calibrate the related fragility curves (Porter et al. 2007, Baker 2015, Lallemand et al. 2015).

Uncertainties involved in seismic fragility assessment are mostly related to aleatory models in the investigated structure and to record-to-record variability of input ground motion. Model uncertainties on mechanical properties can be incorporated in seismic response analysis methods with simulation-based techniques (Franchin et al. 2018). Adopting a sufficiently large dataset of representative seismic signals is a key issue that should be carried out with appropriate procedures (Katsanos et al. 2010). Recently, the number of recorded accelerograms has increased considerably owing to strong events in countries with well-instrumented record networks, boosting the development of automated procedures of natural ground motion selection and scaling for seismic response analysis (Baker and Lee 2018). Physics-based numerical simulations of earthquake ground motion can complement the recorded data providing signals based on local source and site configurations (Paolucci et al. 2021).

Seismic reliability assessment of infrastructure networks can be carried out based on analytical methods relying on numerical simulation techniques (Kilantis and Sextos 2019). Assessing

the vulnerability of large-scale networks is challenging due to computational costs as well as incomplete information on bridge vulnerability and their statistical dependency (Der Kiureghian and Song 2008). Refined simulation frameworks can foster computational efforts and estimate accuracy (Capacci and Biondini 2022, 2023).

3 PROBABILISTIC LIFE-CYCLE INFRASTRUCTURE RESILIENCE

3.1 *Qualitative definitions and quantitative metrics of infrastructure resilience*

Resilience can be regarded as the ability of structures and infrastructure systems to: resist an extreme event, limiting operational outages and irreversible damage; absorb its impact, mitigating losses induced by disruptions and downtime; recover as rapidly as possible adequate operability conditions (Bruneau et al. 2003). Resilience indicators typically rely on the definition of a functionality metric Q comprehensively describing the system performance from the time of event occurrence t_0 up to a prescribed horizon time t_h . To compare the effect of different hazard scenarios and recovery strategies, resilience R is often quantified as the integral mean of the functionality profile over the interval from occurrence time to horizon time, respectively t_0 and t_h (Bruneau and Reinhorn 2007, Bocchini and Frangopol 2012a, Capacci et al. 2020):

$$R = \frac{1}{t_h - t_0} \cdot \int_{t_0}^{t_h} Q(t) dt \quad (1)$$

In the field of seismic risk mitigation, several frameworks have been developed to provide a basis to measure the functionality and resilience at various scales, including communities and societies (Chang and Shinozuka 2004, Rose 2004, Cimellaro et al. 2016) as well as lifeline components and systems such as transportation networks (Bocchini and Frangopol 2012a,b, Decò and Frangopol 2013, Dong and Frangopol 2015, Capacci et al. 2020). Significant reviews oriented to the definition of resilience indicators of critical infrastructure systems are available, mostly regarding different dimensions (Cantelmi et al. 2022), taxonomy (Poulin and Kane 2022), computational tools (Shadabfar et al. 2022). Among all hazards and critical infrastructure, particular efforts have been devoted to seismic risk assessment (Freddi et al. 2022, Yin et al. 2022) of transportation systems (Faturechi and Miller-Hooks 2015, Sun et al. 2020), with specific focus on bridge networks (Gidaris et al. 2017, Banerjee et al. 2019, Capacci and Biondini 2020).

3.2 *Functionality and recovery of infrastructure road networks*

Connectivity of transportation networks is critical in disaster response of hazard-prone communities, in which infrastructure managers are called to guarantee the users' safety by imposing regulatory restrictions to traffic (Mackie and Stojadinovic 2006). Sociological aspects exacerbate complexities in the seismic assessment of transportation lifelines since the state of emergency influence drivers' habits, such as adapting routes and travel modes and destinations depending on the traffic conditions (Erath et al. 2009), impairing economically valuable activities such as working or shopping (Cho et al. 2001), and exacerbating irrational behaviors under emergency when traffic information is limited (Feng et al. 2020). Besides direct costs of infrastructure repair, temporary limitations to traffic capacity due to traffic limitations over bridges damaged by seismic events induces significant indirect losses associated to ongoing maintenance activities (Liu and Frangopol 2006) and damage occurrence due to multiple hazards (Yang and Frangopol 2020a).

Functionality metrics of transportation networks can be classified into topological, relying on graph theory to rank vulnerable components by indicators of roads connectivity and nodes accessibility (Cimellaro et al. 2021), and flow-based metrics, comprehensive functionality measures of assigned traffic flows and travel times (Bocchini and Frangopol 2011a). Flow-based metrics require the solution of mathematical optimization problems, such as simplified

shortest path analysis or more complex congestion-based frameworks, which account for the actual traffic capacity (Bocchini and Frangopol 2011b).

The formulation of recovery models is an essential component in resilience assessment. Several analytical models have been proposed to capture the recovery pattern from seismic damage based on engineering judgment and statistical analysis from empirical data (Padgett and DesRoches 2007, Bocchini and Frangopol 2012b, Decò et al. 2013, Biondini et al. 2015, Karamlou and Bocchini 2016, Sharma et al. 2018, Misra et al. 2020, Mitoulis et al. 2021).

3.3 *Life-cycle seismic resilience under uncertainties*

Depending on the environmental conditions to which structures are exposed, chemical attacks and physical damage may dramatically reduce the mechanical properties of key structural members (Enright and Frangopol 2001, Biondini et al. 2004, Ellingwood 2005, Malerba 2014). Traditional design methodologies need to be revised to account for the evolution over time of structural performance over the service life and classical time-invariant indicators should be revisited (Frangopol and Das 1999, Yang et al. 2004, Saydam and Frangopol 2011, Zhu and Frangopol 2012, Biondini and Frangopol 2016, 2019, Ghosn et al. 2016a). Life-cycle structural and infrastructure performance assessment aims at investigating time-variant indicators, such as reliability (Akiyama et al. 2010, Bocchini and Frangopol 2011c, Ghosn et al. 2016b, Frangopol and Kim 2022), robustness (Ghosn et al. 2010, Biondini and Frangopol 2014, Lu et al. 2022), redundancy (Okasha and Frangopol 2010, Biondini and Frangopol 2017, Capacci et al. 2022b), risk (Saydam and Frangopol 2013, Yang and Frangopol 2020b, Messori et al. 2021), and sustainability (Dong et al. 2013, Bocchini et al. 2014).

The time-variant seismic performance of structures and infrastructure systems should be evaluated in probabilistic terms, accounting for uncertainties propagating over their lifetime and regarding seismic demand and capacity of structural systems (Decò and Frangopol 2011, Akiyama and Frangopol 2014, Dong and Frangopol 2017) and critical infrastructure networks (Akiyama et al. 2020, Argyroudis et al. 2019, 2020, Capacci et al. 2020). Deterioration processes exacerbate the impact of model uncertainties in time-variant seismic reliability (Akiyama et al. 2011, Ghosh et al. 2015, Yanweerasak et al. 2018), cost estimate (Kumar et al. 2009, Shekhar et al. 2018), and seismic performance assessment (Biondini et al. 2014, Titi and Biondini 2014). Research efforts are also focused on the calibration of time-variant fragility curves (Ghosh and Padgett 2010, Zhong et al. 2012, Rao et al. 2017, Silva et al. 2019, Su et al. 2019).

Infrastructure resilience should not be intended as a static property of the system since deterioration mechanisms exacerbate the impact of interdependent events on vulnerable lifeline components and systems (Capacci and Biondini 2020, Yang and Frangopol 2020a, Ishibashi et al. 2021). Therefore, life-cycle resilience frameworks under seismic and other interacting hazards should account for the effects of aging and deterioration processes (Biondini et al. 2015, Capacci and Biondini 2020, Capacci et al. 2020) and maintenance and repair interventions under uncertainty (Frangopol et al. 2017). Emphasis is currently devoted to addressing the impact of time-variant environmental stressors under non-stationary climate conditions to vulnerability and resilience assessment of structures and infrastructure systems (Dong and Frangopol 2016, Yang and Frangopol 2019, 2020b, Liu et al. 2020, Capacci and Biondini 2021).

4 CONCLUSIONS

Public authorities, owners, and political systems are called to ensure suitable resilience levels of critical infrastructure systems for optimal life-cycle management of aging structures and transportation networks, especially in earthquake-prone regions. This paper discussed recent advances and efforts made to establish probabilistic frameworks for life-cycle seismic risk and resilience assessment of aging structures and infrastructure systems, with emphasis on bridges and bridge networks. The presented review focused on concepts, methodologies and tools to be incorporated into practical policies to inform the decision-making process for ex-ante

preventive retrofit interventions and ex-post effective recovery actions of key lifeline components under seismic and other hazards.

Agile analysis of life-cycle damage cost of concrete frame structures under earthquake

J.M. Bairán & M. García

Universitat Politècnica de Catalunya (UPC - BarcelonaTech)

Department of Civil and Environmental Engineering, Barcelona, Spain

ABSTRACT: Seismic events can produce damage and collapse of constructions, impacting the expected life-cycle cost and out-of-service time. Past seismic events showed that socioeconomic consequences at community scale are dramatic, even with non-collapsed structures, resulting in low resilience. To improve this, understanding the probable condition along service life of current structures and new designs is crucial for prioritizing the needs for structural upgrade, and support decision making. This process must consider the effects of different damage scenarios, from light to collapse. Nevertheless, this process is costly and time consuming, making difficult its application at a large scale or in non-special designs. In this paper, a methodology for agile LCC produce by earthquake damage is applied to a case-study consisting of multi-storey moment-resisting concrete frame. Its low computational cost makes it adequate for supporting resilience decision making related to a suite of structures or the assessment of new designs.

1 INTRODUCTION

Seismic events can produce damage and collapse of constructions. As the expected resistance demands under large earthquakes are typically much larger than the ones under normal situations, design practice focuses on collapse prevention in order to guarantee life safety of the users at a reasonable initial cost. Therefore, severe damage is considered admissible. This is consistent with the consideration of earthquakes as accidental events. Nevertheless, the damage produced in the infrastructures of a given location causes a serious consequence to the community, in the socioeconomic point of view, due to the repair and demolition costs, and inoperative time or reduced functionality of the damaged structures during recovery time, Capacci et al (2022).

Events like the earthquake in Haiti 2009, showed the catastrophic consequences of extensive collapse in a community, which can extend during more than a decade under lack of preparedness. On the other hand, locations with generalized applications of seismic design regulations succeeded in preventing extensive collapse, such as Christchurch 2009, Pampanin (2012). However, the large extension of damaged structures required demolition and repair of most of the financial district, resulting in reduced functionality during several years, lack resilience, with dramatic socioeconomic consequences.

To improve this situation, understanding the probable condition along service life of current structures and new designs is crucial for identifying needs for structural upgrade and support decision making. This process should consider the effects different damage scenarios, from light to collapse. In addition, cost and probability of occurrence are then assessed in order to support informed decisions. However, this is usually costly and time consuming, which limits its applicability at a large scale for ordinary designs. Nevertheless, to achieve

realistic benefits in the community scale, agile and cost-effective methods that can be applied in broad scale are needed.

In this paper, a seismic damage assessment method which can be applied at an agile computation time is used to quantify the probability of exceedance of economic cost during the service life of a concrete frame structure. Through a rational basis, the method estimates the evolution of the damage intensity and distribution of structures along the push-over curve. It avoids iterative process to find the performance points at different seismic intensities for each increment of displacement. The seismic intensities are further associated to the annual probability of occurrence through a hazard model. The damage distribution and fragility curves are estimated in less computing time than required using detailed multiple time-history simulations, while providing an estimation of the probability of exceedance of the damage state. For each damage scenario, the repair cost is assessed considering suitable repair activities for simulated local damage intensity, characterized by means of plastic deformation, and a construction costs database. The methodology is applied to a case-study consisting of multi-story moment-resisting concrete frame. Because of the rational approach and low computation cost, the approach is adequate for supporting resilience decision taking related to a suite of structures or the assessment of new designs.

2 DAMAGE ESTIMATION METHOD

In order to estimate the repair cost of the structure under seismic events, the damage distribution should be assessed. A general approach to estimate structural damage produced by earthquakes in a structure requires the non-linear dynamic analysis of the structure under a given seismic event. To consider the uncertainties of future seismic events, it is necessary to analyse a number of seismic records that are representative of the location seismicity. On the other hand, the uncertainties on the structural performance, resulting from material variability, geometry imperfections, among others, can be assessed by considering these parameters as random variables. Nevertheless, it is generally accepted that the variability of the earthquake demand exceeds that of the structural characteristics, Yamin (2015), so a plausible estimation can be made considering only the earthquake variability.

The previously described approaches provide a good estimation of the damage; however, they require significant computation effort and time. Therefore, an agile methodology will estimate the damage by means of a static non-linear push-over analysis curve of the structure. Based on the characteristics of the push-over curve, damage thresholds are defined which are associated to specific repair operations. In this paper, the four damage thresholds described in Equations (1)–(4), as proposed by Lagomarsino et al (2003), will be used.

$$Sd_1 = 0.7D_y \quad (1)$$

$$Sd_2 = D_y \quad (2)$$

$$Sd_3 = D_y + 0.25(D_u - D_y) \quad (3)$$

$$Sd_4 = D_u \quad (4)$$

Where Sd_1 , Sd_2 , Sd_3 , and Sd_4 represent the spectral displacement at 0.5 probability of initiation of the damage limit states light (*LS1*), moderate (*LS2*), severe (*LS3*), and complete (*LS4*), respectively. D_y and D_u are the spectral displacement at yielding and ultimate conditions, in an energy equivalent bilinear representation of the push-over curve.

The previous thresholds can be used as an agile estimation of the fragility curve of each limit state. By accepting that the probability of not-exceeding a certain damage limit state, when the spectral displacement takes a value S_d , follows a log-normal distribution, the fragility curve of the limit state can be computed as in Equation (5). Where Sd_i is the displacement threshold, and β_i is the coefficient of variation of the natural logarithm of the spectral

displacement, which are taken as $\beta_1=0.28$, $\beta_2=0.29$, $\beta_3=0.34$, and $\beta_4=0.45$ for buildings, see Moreno and Bairán (2012, 2015).

$$P(DS \geq DS_i) = \Phi \left[\frac{1}{\beta_i} \cdot \ln \left(\frac{S_d}{S_{d_i}} \right) \right] \quad (5)$$

As mentioned above, the uncertainties structural characteristics can be considered small compared to that of the earthquake demand. In this case, the annual probability of not exceeding a specific spectral displacement S_d can be associated the probability of not exceeding the seismic intensity that produces that displacement in the structure. A seismic hazard function of the form of Equation (6) is used to relate the peak ground acceleration (PGA) intensity with the return period. The annual probability of not exceedance is computed in terms of the return period considering it as a Poisson process. To relate the spectral displacement (S_d) is determined as the performance point in the push-over curve given response spectrum with a PGA value (a).

$$a = a_{ref} \left(\frac{T_{ref}}{T} \right)^{\frac{1}{k}} \quad (6)$$

3 LIFE CYCLE COST

Each displacement in the performance point is associated to a probability of not-exceedance and a probability of developing a specific damage state, computed as described in the previous section. The expected life cycle repair cost of earthquake damage is computed by means of Equation (7). Here, P_{DS_i} is the probability of exhibiting a damage state j in one year, assuming that each seismic event probability is independent. RC is the reference repair cost of the damage state, associated to a repair technique in each damaged region. The distribution of damaged regions is taken according to the distribution and damage states in each plastic hinge. $PV(t)$ is the present value factor for a cost expended in time t . Finally, s is the discount rate that accounts for inflation and opportunity cost.

$$E(RC_j) = \sum_{t_i}^{t_{life}} \sum_j PV(t_i) P_{DS_i} RC_j \quad (7)$$

$$PV(t) = (1 + s)^{-t} \quad (8)$$

4 EXAMPLE

Consider the reinforced-concrete frame structure shown in Figure 1, representative of a square plan building, with identical frames in the two directions. The dead and live loads acting on each frame are 15 kN/m and 6 kN/m, respectively. The structure is built with concrete class C30/37 and steel reinforcement class 400C, according to Eurocode 2. The structure is considered located in a soil class C, with a reference PGA of 0.502 g for a return period 475 years. The seismic hazard is described by Equation (6), taking $k=3.71$.

Figure 2 show the push-over of the structure, where the displacements of each damage limit state thresholds have been highlighted. The resulting fragility curve, computed using Equation (5), is shown in Figure 3. Each curve represents the probability of not exceeding the corresponding limit state when the spectral displacement takes the value S_d . Therefore, the vertical distance between curves indicates the probability of exhibiting the damage in the limit state corresponding to the curve below.

The repair cost associated to each damage state the damage distribution under each displacement distribution are shown in Figure 4. Both the distribution, quantity and damage state in each hinge are analysed. A specific repair technique is applied to each concrete region depending the damage state that exhibits. Namely, crack injection is applied to light damage,

Figure 1. Reinforced concrete frame.

Figure 2. Push-over curve showing the displacement thresholds for the four limit states considered.

Figure 3. Fragility curves for each damage limit state.

concrete cover restitution is applied to moderate damage. Major repairs with reinforcement replacement restoring of concrete layer is associated to severe damage. Finally, in the case of complete damage, complete demolition and substitution is considered. The costs of the damage region have been estimated using a construction the construction database, CYPE (2022). The resulting unit costs per damaged region and limit state are summarized in Table 1.

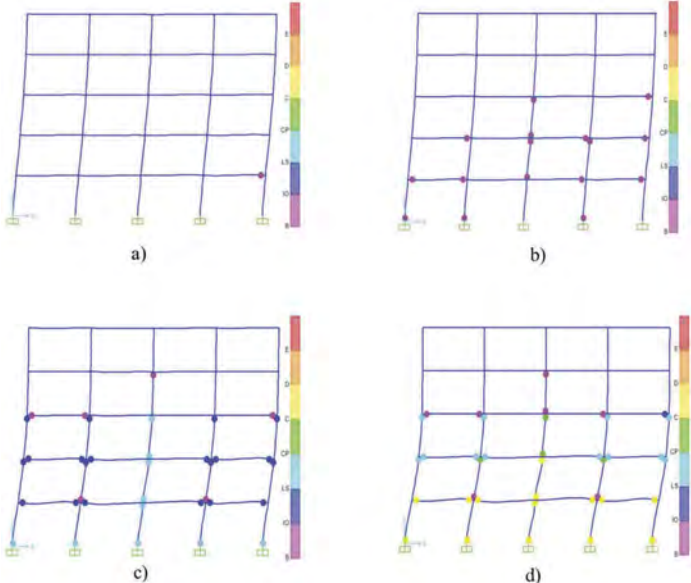

Figure 4. Damage distribution in each plastic hinge in the limit states a) light, b) moderate, c) severe, d) complete.

Table 1. Repair costs per damaged region.

Element type	Id.	Unit	Repair cost in each limit state			
			LS1	LS2	LS3	LS4
Column	C2	€/m	430.66	423.91	374.73	3,237.60
Column	C1	€/m	212.41	254.35	282.95	2,781.50
Beam	V1	€/m	302.05	275.54	297.80	611.70
Slab	L1	€/m ²	64.95	186.15	143.90	639.56

The repair cost in the threshold displacement of the damage state is computed based on the unit repair costs and the damage distribution. Furthermore, a repair cost function in terms of the spectral displacement is constructed, see Figure 5a, by multiplying the repair cost for each damage limit state by the probability of exhibiting each particular damage state, determined from the fragility function. This cost is accumulated during a reference service life period, taken as 50 years, by means of Equation (7). The annual probability of exceeding each spectral displacement is shown in Figure 5b. To obtain this distribution, the ground acceleration that produces a performance point in the displacement d was determined. Secondly, the probability of each seismic scenario is computed by means of the hazard function of the location. It can be inferred that displacements associated to complete and high damage, show very small probability of occurrence; while other damage intensities have larger contributions.

Figure 5. Variation of the expected repair cost with the spectral displacement (a) and annual probability of exceedance of the spectral displacement (b).

By combining the two curves of Figure 5, the probability distribution of exceeding a repair cost during the life of the structure is computed, as described in Figure 6, for the complete building. This cost accounts for the contribution of all possible damage states, from light to complete. As evidenced, there is a probability of 0.5 of exceeding a repair cost 4.1 M€ during the life of the structure, while there is a probability of 0.1 of exceeding a repair cost of 5.5 M€.

Figure 6. Probability of exceeding a repair cost (M€) during the reference service life of 50 years.

5 CONCLUSIONS

A simplified methodology for the agile or fast assessing of repair costs associated to seismic damage along the service life of a structure was presented, based on rational simplifications. The method was applied to reinforced concrete frames.

The approach requires significant less computation time than explicit non-linear time history analyses for the estimation of damage scenarios. In addition, it avoids iteration processes for finding performance points in the push-over, allowing for a fast estimation of the different seismic intensities along all points of the push-over curve. This makes the method suitable for estimation of the damage scenarios at increasing seismic intensities return periods in individual or system of buildings.

A case study consisting of a typical reinforced concrete ductile frame structure, design as per modern design standards, was investigated. The analysis showed that the costs related to light and moderate damage have a significant contribution to the expected repair cost to seismic damage along the service life. This can be attributed to the higher probability of occurrence of moderate earthquakes that are capable of triggering such damage distribution, without creating a risk of collapse. Considering independent events and one event per year, the probability distribution of expected repair damage along the service life showed a 0.5 probability of exceedance 4.1 M€, and a 0.1 probability of exceedance a repair cost of 5.5 M€.

The procedure can be used for fast analysis of the impacts of individual design alternatives and potential socioeconomical consequences of a system of infrastructures. Future extensions of the method will be dedicated to the assessment of time to recover functionality and of reliability indexes of isolated and a combination of structures in a location. Furthermore, as the method relies on the push-over estimation, it is sensitive to the structure irregularities and force distribution pattern. Current research is being carried out to assess the influence of the load patten in the predicted response.

It should be pointed out that the current application, the uncertainties of the structural parameters were considered negligible compared to that of the earthquake action, this hypothesis is supported on previous research that were more focused on extensive damage and collapse. Additional research will also investigate the influence of structural uncertainties on the light and moderate damage. Similarly, the impact of non-structural damage and components in the cost, functionality loss and time to recover may be also incorporated in the assessment approach by means of adequate engineering parameters that represent the non-structural damage events that can further be considered in the cost analysis.

M. Akiyama

Waseda University, Tokyo, Japan

S. Koshimura

Tohoku University, Sendai, Japan

ABSTRACT: A methodology for determining the optimal countermeasure for bridges subjected to ground motion and tsunami is proposed. Seismic and tsunami fragility curves of a bridge pier and bearing are developed considering the effects of seismic damage prior to tsunami action. The structural vulnerabilities against horizontal and vertical forces are investigated separately in this paper. Seismic and tsunami hazard curves are obtained assuming the occurrence of an earthquake. Uncertainties associated with fault movement, hazard intensity and structural vulnerability are considered based on Monte Carlo simulation. The expected recovery time of bridges (i.e. risk) is estimated based on the failure probabilities of bridge piers and bearings, and used to determine the optimal countermeasure for bridges. As an illustrative example, the proposed methodology is applied to bridges which would be affected by the anticipated Nankai Trough earthquake.

1 INTRODUCTION

In the 2011 Great East Japan earthquake, many bridge superstructures, despite being retrofitted to protect the superstructure from excessive displacement due to seismic actions, were washed away by hydrodynamic forces. The failure mode of a bridge subjected to both ground motion and tsunami is determined by the vulnerability of structural components, such as pier and bearing, and the hazard intensities. Moreover, the recovery time required for bridge reconstruction after an earthquake depends on the failure mode. For example, in case the bridge superstructure is washed away due to tsunami, the reconstruction work would take a very long time. It is considered that the pre-disaster preparation for achieving rapid reconstruction of bridge is needed in coastal regions potentially threatened by giant tsunami, whereas conventional seismic retrofitting is appropriate for the bridges located in inland regions. The appropriate countermeasures for bridges should be taken before an earthquake considering the recovery time.

Risk is expressed in the consequence and probability of the events (CIB 2001) and can be used as a performance indicator to determine the optimal countermeasures for undesired events. Ishibashi et al. (2021) proposed a methodology for determining the retrofitting prioritization of road structures under multiple hazards based on the risk. Decò & Frangopol (2011) presented a framework for assessing the time-dependent total risk of bridges considering the life-cycle performance. Risk-based approach is important to manage the bridges in earthquake-prone areas.

In addition to seismic retrofitting, the technologies for the rapid construction of temporary bridges are needed considering the possibility that bridge superstructures near the coastline would be washed away due to tsunami. Mineyama et al. (2020) proposed the bridge girder with double end plate connection using high strength bolts to reduce the on-site bridge construction time. Ishibashi et al. (2022) presented the precast reinforced concrete blocks for the bridge superstructure which can be assembled in a short time without using heavy machinery. These technologies on temporary bridges are useful in the severe situation after tsunami events and can contribute to enhancing the disaster resilience. It is important to develop a methodology for determining whether seismic retrofitting of piers or preparation of temporary bridges is more appropriate for bridges expected to be damaged by future earthquakes.

This paper presents a methodology for determining optimal countermeasures for bridges under seismic and tsunami hazards based on the risk of post-disaster recovery time. Seismic and tsunami fragility curves of a bridge pier and bearing and hazard curves are estimated by performing Monte Carlo simulation (MCS)-based analyses. Structural vulnerabilities of the pier against horizontal seismic force and the bearing against horizontal and vertical tsunami forces are estimated in the fragility assessment. Risk is defined as the recovery time of damaged bridges. The optimal countermeasure for bridges is determined by comparing the risk reduction due to seismic retrofitting of the pier and due to pre-disaster preparation of temporary bridge girders which can be used after washout of superstructures during the tsunami event. In an illustrative example, the proposed methodology is applied to the bridges located in a city affected by the anticipated Nankai Trough earthquake. The optimal countermeasures for individual bridges are discussed based on the risk.

2 PROCEDURE FOR DETERMINING OPTIMAL COUNTERMEASURE FOR BRIDGES UNDER SEISMIC AND TSUNAMI HAZARDS

2.1 Hazard assessment

Figure 1 shows the procedure for determining the optimal countermeasure for bridges under seismic and tsunami hazards. In this paper, probabilistic seismic and tsunami hazard analyses are performed based on the MCS given the occurrence of an earthquake. The average stress drops of the seismic and tsunami fault models, which are the critical parameters used to

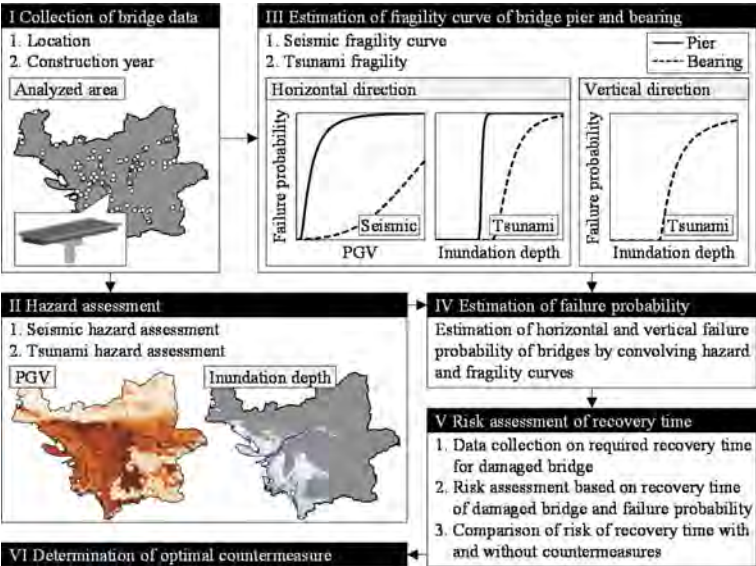

Figure 1. Procedure for determining optimal countermeasure for bridges under seismic and tsunami hazards.

calculate the dislocation and moment magnitude of an analyzed earthquake (HERP 2017), are considered random variable in the MCS. To estimate the seismic hazard curve at the location of analyzed bridges, the maximum velocity on the engineering bedrock is obtained using the attenuation relationship provided by Si & Midorikawa (1999) as follows:

$$\log V_b = 0.58M_w + 0.0031D_f - \log X_{eq} - 0.002X_{eq} - 1.19 + \varepsilon \quad (1)$$

where V_b is the maximum velocity on the engineering bedrock, M_w is the moment magnitude, D_f is the fault depth, X_{eq} is the equivalent hypocentral distance provided by Ohno et al. (1993), and ε is the associated model uncertainty.

Peak ground velocity (PGV) is then estimated by multiplying the maximum velocity on the engineering bedrock by the amplification factor calculated using the formula developed by Fujimoto & Midorikawa (2006).

Inundation depth is used as a tsunami intensity measure. The initial tsunami water level due to fault movement is computed using formulas developed by Okada (1985) considering the uncertainty associated with average stress drop. MCS-based horizontal 2D tsunami propagation simulations based on nonlinear longwave theory (Goto et al. 1997) are performed using the initial water level as the initial condition to estimate the inundation depth at the location of individual bridges. The cumulative distribution functions associated with the relationship between PGV and inundation depth are approximated by lognormal distributions based on the results of MCS.

2.2 Fragility curve

Seismic and tsunami fragility curves of a bridge pier and bearing are developed considering the horizontal and vertical failure directions. Sequential nonlinear seismic response analysis and tsunami pushover analysis are performed to consider the effects of seismic damage on the reduction in tsunami capacity. Horizontal force due to ground motion and tsunami and vertical tsunami force are used to estimate the horizontal and vertical structural vulnerabilities, respectively.

When estimating the fragility curves of a pier, the damage state for horizontal seismic force is determined based on the maximum displacement, shear force and residual displacement of the pier. For a bearing, both horizontal and vertical forces are considered in the vulnerability assessment. The damage states are determined according to the recovery time required after an earthquake and divided into three levels: none (= DS_1), moderate (= DS_2) and complete (= DS_3).

Many seismic waves observed during past earthquakes in Japan are used in the MCS-based nonlinear seismic response analyses. Horizontal and vertical tsunami forces are computed using empirical formulas provided by the Subcommittee on Analysis of Damaged Bridge due to the Great East Japan Earthquake (2015). The uncertainties associated with material properties, structural vulnerabilities and empirical formulas are considered in the MCS. Fragility curves are estimated by fitting the following equation based on a log-normal cumulative distribution function:

$$P_{fi}(DS_i|\gamma) = \int_0^\gamma \frac{1}{\sqrt{2\pi}\sigma_i(x-l_i)} \exp\left[-\frac{\{\ln(x-l_i) - \mu_i\}^2}{2\sigma_i^2}\right] dx \quad (2)$$

where DS_i is damage state, $P_{fi}(DS_i|\gamma)$ is conditional failure probability that damage state becomes greater than or equal to DS_i given the hazard intensity = γ , and μ_i , σ_i and l_i are parameters. The natural logarithm of $X-l_i$ is normally distributed with mean μ_i and variance σ_i^2 . Although l is commonly zero when estimating fragility curves, it is considered to improve the fitting of the estimated curves to the results of MCS.

2.3 Risk assessment

Horizontal and vertical failure probabilities are estimated using the fragility curves for horizontal and vertical failure directions, respectively, and hazard curves obtained at the locations of bridges. The recovery time of bridges is determined based on the data obtained in past disasters. The risk as the expected post-disaster recovery time of bridges is defined by the following equation:

$$T_r = \sum_{i=1}^3 P_{fp,h}(DS_i) \cdot T_{p,h}(DS_i) + \sum_{i=1}^3 P_{fb,h}(DS_i) \cdot T_{b,h}(DS_i) + \sum_{i=1}^3 P_{fb,v}(DS_i) \cdot T_{b,v}(DS_i) \quad (3)$$

where T_r is risk of post-disaster recovery time of a bridge, $P_{fp,h}(DS_i)$ and $T_{p,h}(DS_i)$ are failure probability and recovery time of piers given DS_i in the horizontal direction, respectively, $P_{fb,h}(DS_i)$ and $T_{b,h}(DS_i)$ are failure probability and recovery time of bearings given DS_i in the horizontal direction, respectively, and $P_{fb,v}(DS_i)$ and $T_{b,v}(DS_i)$ are failure probability and recovery time of bearings given DS_i in the vertical direction, respectively. In this study, since the failure events of pier and bearing are assumed to be independent, the expected recovery time due to the damage to bridge pier or bearing is assessed separately in Equation (3). The effects of countermeasures for damages to piers and bearings are assessed separately based on the risk reduction due to the countermeasure.

3 ILLUSTRATIVE EXAMPLE

3.1 Analyzed area

A megathrust earthquake along the Nankai Trough (i.e. the Nankai Trough earthquake) is predicted to occur in the near future and cause strong ground motion and tsunami in the Pacific coastal region of Japan (HERP 2013). The countermeasures for bridges in Wakayama City, which is located in the coastal region expected to be affected by the Nankai Trough earthquake, are discussed in the illustrative example. The data on location and construction year of bridges provided by MLIT (2022) are used in this study.

3.2 Hazard assessment

In the seismic hazard assessment, average stress drop is modeled as a truncated lognormal distribution with a mean of 2.1 MPa and a standard deviation of 1.1 MPa based on the data provided by the Cabinet Office, Government of Japan (2012). When estimating tsunami hazard curves, a truncated lognormal distribution with a mean of 1.9 MPa and a standard deviation of 1.9 MPa is used to generate average stress drops in the MCS (Murotani et al., 2013). In addition, two seismic and eleven tsunami fault models provided by the Cabinet Office, Government of Japan (2012) are used, respectively, considering the uncertainty associated with the locations of large-slip areas. Figure 2 shows the contours associated with mean PGV and inundation depth in Wakayama City.

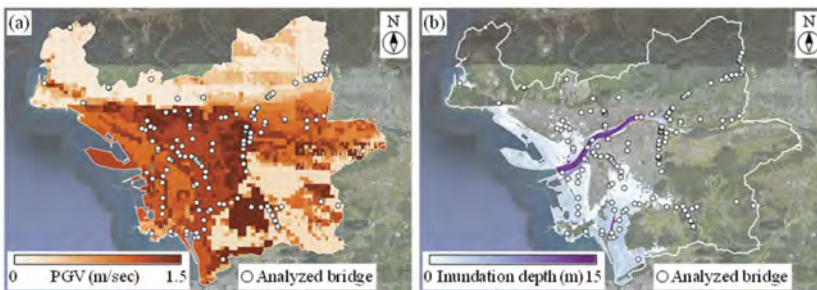

Figure 2. Contours associated with (a) mean PGV and (b) inundation depth in Wakayama City.

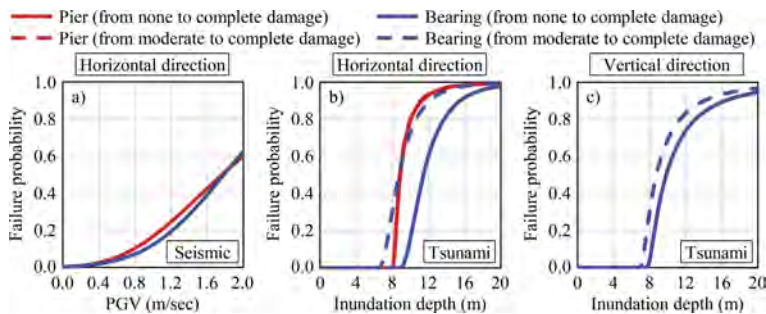

Figure 3. Fragility curves: (a) seismic fragility curves of 1996 pier, (b) tsunami fragility curves of bearing (horizontal direction) and (c) tsunami fragility curves of bearing (vertical direction).

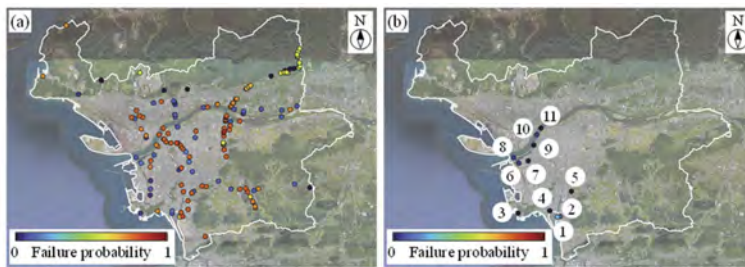

Figure 4. (a) horizontal failure probability of piers and (b) vertical failure probability of bearings.

Table 1. Recovery times of piers and bearings with moderate and complete damages.

Direction	Bridge component	Damage state	
		Moderate	Complete
Horizontal	Pier	30 days	90 days
	Bearing	3 days	5 days
Vertical		3days	120 days (without preparation of temporary bridge)
			30 days (with preparation of temporary bridge)

Figure 5. Estimated risk as the expected recovery time.

3.3 Fragility curves

Four types of piers designed in accordance with the Japanese seismic specifications published in 1964, 1980, 1990 and 1996 are modeled based on Karim & Yamazaki (2003) and applied to the

analyzed bridges considering the differences in seismic performance by the construction year. Herein, each pier is referred as 1964, 1980, 1990 and 1996 piers, respectively. 1996 pier has seismic performance equivalent to the current Japanese seismic design code. The pier height is assumed to be 6 m. Hence, vertical tsunami forces act on the bearings when the inundation depth is greater than 6 m. The bearing is designed based on Abe et al. (2004) and Hashimoto et al. (2005). The seismic and tsunami fragility curves of 1996 pier and the bearing are shown in Figure 3.

3.4 Determination of optimal countermeasure based on risk

Figure 4 shows the horizontal failure probability of piers and vertical failure probability of bearings of analyzed bridges. Eleven bridges can be completely damaged due to vertical tsunami force caused by the anticipated Nankai Trough earthquake as shown in Figure 4 (b). In this paper, seismic retrofitting of piers and pre-disaster preparation of temporary bridge girders for vertical damage to bearings are considered countermeasures. The recovery times of piers and bearings listed in Table 1 are set based on Shoji et al. (1997) and the report provided by the Subcommittee on the Survey on Emergency Temporary Bridges for Emergency Construction During Disaster (2020). The fragility curves of 1996 pier are applied when estimating the risk assuming seismic retrofitting of piers. Pre-disaster preparation of temporary bridge girders is considered to achieve rapid reconstruction of bridges as listed in Table 1. In the risk assessment using Equation (3), the failure probability of piers $P_{fp,h}$ and recovery time of bearings damaged vertically $T_{b,v}$ can be reduced by seismic retrofitting and pre-disaster preparation of temporary bridge girders, respectively.

The estimated risk as the expected recovery time is shown in Figure 5. Bridge 5 has sufficient seismic capacity even without retrofitting of the pier since bridge 5 was designed according to the seismic specification published in 1996. Seismic retrofitting of bridge piers can reduce the failure probability and associated risk calculated using Equation (3). However, the optimal countermeasure for bridge 1 is the pre-disaster preparation of temporary bridge girders because bridge 1 has high vertical failure probability due to tsunami as shown in Figure 4(b). This result demonstrates that optimal countermeasures for reducing the risk depends on the structural vulnerabilities of bridge components and hazard intensities.

4 CONCLUSIONS

A risk-based methodology for determining the optimal countermeasure for bridges under both seismic and tsunami hazards is proposed. Fragility curves of a pier and bearing are developed considering the damage in the horizontal and vertical directions since post-disaster recovery time of bridges depends on the failure mode. Hazard curves are also obtained based on MCS considering the uncertainty associated with fault movement. In the illustrative example, the risk of recovery time of bridges affected by the Nankai Trough earthquake is estimated. The optimal countermeasures for bridges should be determined based on the risk to achieve rapid reconstruction.

In this study, the risk as the expected recovery time is assessed without considering the correlation between the failures of piers and bearings. In addition, the differences in recovery time of bridges should be considered since the time associated with the recovery activities depends on various factors, such as bridge type, length and location. Further research is needed to improve the proposed framework to determine more appropriate countermeasures for bridges subjected to ground motion and tsunami.

Seismic damage control of bridges with deteriorated seismic isolation bearings by rupture of anchor bolts

H. Matsuzaki

National Defense Academy of Japan, Yokosuka, Japan

ABSTRACT: When accessibility to repair damage to bridge columns is a problem, as in the case of multi-span continuous bridges over rivers, it is necessary to avoid the ultimate failure of the bridge columns as well as the seismic isolation bearings. In this study, improving the reparability of seismically isolated multi-span continuous girder bridges by the rupture of the anchor bolts of the deteriorated isolation bearings was investigated by incremental dynamic analysis and fragility analysis. As a result, it was shown that the ultimate failure of rubber layers of the seismic isolation bearings and the columns can be sufficiently avoided under extreme ground motions by the rupture of the anchor bolts, even if the ageing deterioration of bearings is considered.

1 INTRODUCTION

Seismic isolation bearings are widely used to improve the seismic performance of bridges. However, rupture of laminated rubber bearings and large cracks in lead rubber bearings occurred at several bridges during the 2011 Tohoku earthquake and the 2016 Kumamoto earthquake (Akiyama et al., 2020; Takahashi & Hoshikuma, 2013). It is necessary to avoid the rupture of seismic isolation bearings to maintain the functionality of seismically isolated bridges after seismic events. Matsuzaki (2022) showed that the seismic safety of isolated bridges can be significantly improved by setting an adequate capacity hierarchy between the seismic isolation bearings and the bridge column, as it can prevent the rupture of the seismic isolation bearings under extreme ground motions even if the ageing deterioration of the bearings is considered.

When accessibility to repair damage to bridge columns is a problem, as in the case of multi-span continuous bridges over rivers, it is necessary to avoid the ultimate failure of the bridge columns as well as the seismic isolation bearings. For such bridges, it is expected that seismic damage control of bridges by the rupture of the anchor bolts of the bearings under extreme ground motions can be used to interrupt load transmission to columns, thereby preventing rupture of the rubber layers of the bearings and a large nonlinear response displacement development at the column, which needs a long repair time and significant costs. It is also noted that the rupture of anchor bolts can be used because multi-span continuous girder bridges can also prevent unseating of the deck after the rupture of the anchor bolts. Another factor that enhances restoration is that the rupture of the anchor bolts provides space corresponding to the height of the bearings so that the superstructure can be easily jacked up during restoration.

In this study, improving the reparability of seismically isolated multi-span continuous girder bridges by the rupture of the anchor bolts of the deteriorated isolation bearings will be investigated by incremental dynamic analysis (IDA) proposed by Vamvatsikos & Cornell (2002) and fragility analysis.

Table 1. Configurations of the target seismically isolated bridges.

Bridge	Bridge column		Seismic isolation bearing (lead rubber bearing)			
	Size (m)	Height (m)	Mass (ton)	Effective size (mm)	Total thickness of rubber layer (mm)	Anchor bolts
15- ϕ 48	3.4 \times 2.7	15	451	520 \times 520	68	4 \times ϕ 48
15- ϕ 32	3.4 \times 2.7	15	451	520 \times 520	68	4 \times ϕ 32
15- ϕ 30	3.4 \times 2.7	15	451	520 \times 520	68	4 \times ϕ 30
8- ϕ 46	2.7 \times 2.0	8	194	520 \times 520	68	4 \times ϕ 46
8- ϕ 30	2.7 \times 2.0	8	194	520 \times 520	68	4 \times ϕ 30
8- ϕ 28	2.7 \times 2.0	8	194	520 \times 520	68	4 \times ϕ 28

2 TARGET BRIDGES AND ANALYTICAL CONDITIONS

2.1 Target bridges

The target bridges are seismically isolated multi-span continuous steel girder highway bridges on the stiff soil in Kumamoto City, as shown in Table 1. Lead rubber bearings were adopted as seismic isolation bearings and the mass of superstructure was 600 ton. As the effects of the column height on the seismic behavior of isolated bridges is significant (Matsuzaki, 2022), columns with two different column heights were considered. Bridges 15- ϕ 48 and 8- ϕ 46 were designed according to the Design Specifications for Highway Bridges (Japan Road Association, 2017) and the Bearing Handbook for Highway Bridges (Japan Road Association, 2018). To investigate the effects of rupture of the anchor bolts under extreme ground motions, bridges with rupture of the anchor bolts are also considered by reducing the diameter of the anchor bolts.

2.2 Analytical modelling of seismically isolated bridges

Lead rubber bearings were idealized based on a tri-linear model considering strain hardening of rubber, as shown in Figure 1. In Figure 1, the ratio of K_{B1} to K_{B2} was set as 6.5:1 based on the Japan Road Association (2018) and the ratio of K_{B3} to K_{B2} was set based on Naito et al. (2017). The skeleton and hysteresis of reinforced concrete columns were idealized based on bi-linear model and Takeda degrading stiffness model by Takeda et al. (1970), respectively. Dynamic response analysis was conducted in the longitudinal direction by idealizing a reinforced concrete column with bearings as a two-degree-of-freedom model. Rayleigh damping was assumed, in which the damping ratios of the column and the isolation bearing were 2% and 0%, respectively.

2.3 Long-term ageing deterioration estimation of seismic isolation bearings

To investigate the effects of the ageing deterioration, time after construction $t=30$ years was considered. Long-term ageing deterioration characteristics of lead rubber bearings

5) Public Works Research Institute, 2013

were modelled based on accelerated thermal oxidation tests by Itoh et al. (2006) and Itoh & Gu (2009). It was assumed that lead core is kept sound during the service period of the target bridges. The average yearly temperature to evaluate the ageing process of the bearings was set as 17.2 °C based on observation data by the Japan Meteorological Agency from 1991 to 2020.

It has been reported that the decrease ratio of rupture strain and the increase ratio of shear stiffness are nearly the same based on the loading tests of isolation bearings used for actual bridges by Hayashi et al. (2014) and Shinohara & Hoshikuma (2015). Thus, it was assumed that the decrease ratio of rupture strain is same as the increase ratio of shear stiffness in this study.

2.4 Input ground motions

A total of 25 horizontal components of observed ground motions with a peak ground velocity (*PGV*) of 0.50 m/s or higher recorded at stiff soil in Japan were selected and used in this study, as shown in Table 2. In the incremental dynamic analysis and fragility analysis, ground motions that were adjusted to the required *PGV* by varying amplitude properties were used.

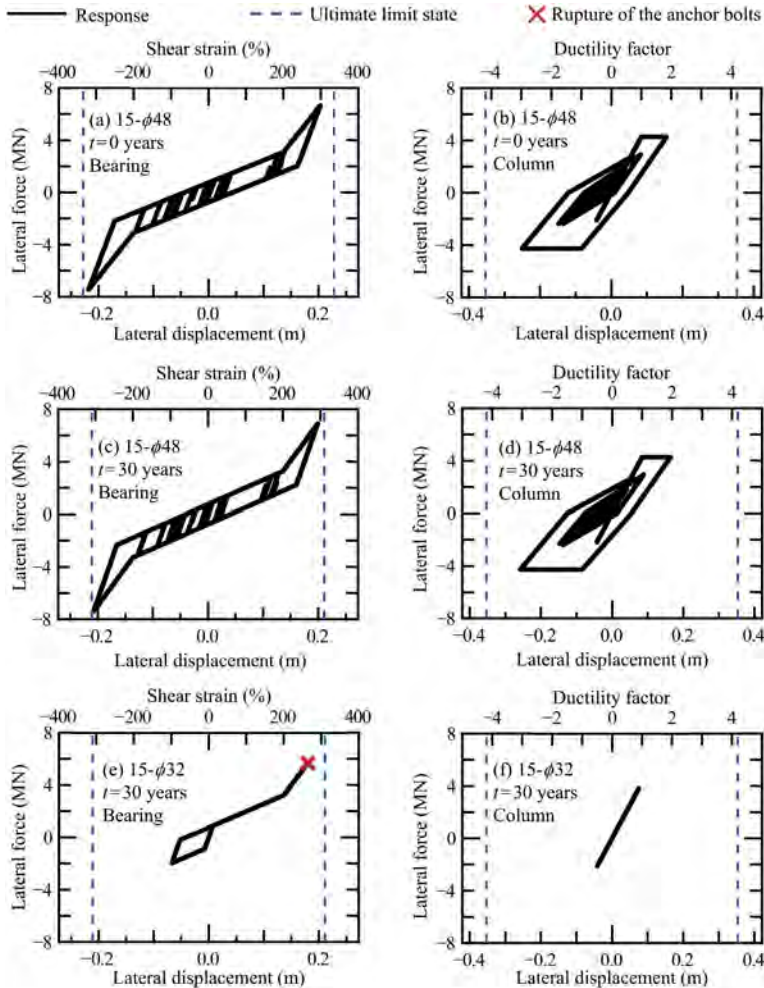

Figure 2. Lateral force–lateral displacement relationship of the isolation bearings and the 15 m high columns subjected to NS component of KiK-net Kikuchi record adjusted to *PGV* of 0.9 m/s.

2.5 Ultimate limit states of seismically isolated bridges

In the incremental dynamic analysis and fragility analysis, shear strength of the anchor bolts, rupture strain of the rubber layer of the bearings and the ultimate displacement of the column δ_{ls3} (Public Works Research Institute, 2013) were considered as the ultimate limit states. As the load transfer between the bearing and the column after the rupture of the rubber layer or the anchor bolts of the bearing is sufficiently small, the post-behaviour after reaching these ultimate limit states does not need to be considered.

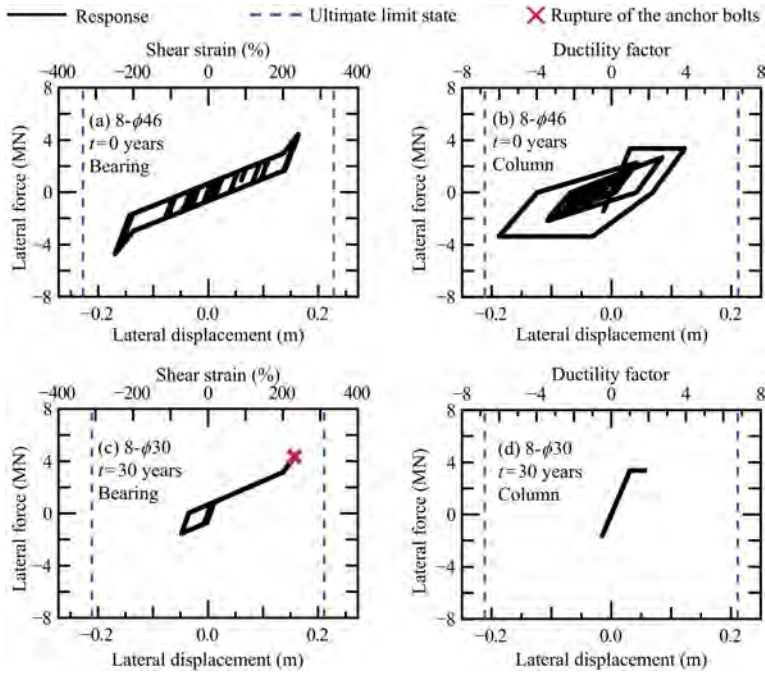

Figure 3. Lateral force–lateral displacement relationship of the isolation bearings and the 8 m high columns subjected to NS component of KiK-net Kikuchi record adjusted to PGV of 0.9 m/s.

2.6 Uncertain factors

Uncertain factors in evaluating the material and mechanical properties of seismically isolated bridges were considered, as shown in Table 3. Statistics on shear stiffness of bearings, shear stiffness ratio K_{B3}/K_{B2} , shear strength of anchor bolts, the ultimate displacement of the column $\delta_{l,3}$, and others were obtained from the Japan Road Association (2018), Naito et al. (2017), Public Works Research Institute (2022), Public Works Research Institute (2013) and Adachi (2002), respectively. In the incremental dynamic analysis and fragility analysis, Monte Carlo simulations were conducted with 25,000 trials for each peak ground velocity, and the discrete conditional probabilities of failure were approximated by a lognormal cumulative distribution function.

3 EFFECTS OF THE RUPTURE OF THE ANCHOR BOLTS ON THE BEHAVIOUR OF BRIDGES WITH DETERIORATED SEISMIC ISOLATION BEARINGS

3.1 Lateral force–lateral displacement relationships of the bearings and the columns

Figures 2 and 3 display the lateral force–lateral displacement relationships of the isolation bearings and the columns subjected to NS component of KiK-net Kikuchi record adjusted to PGV of 0.9 m/s using the mean values shown in Table 3. PGV of the design ground motion level corresponds to 0.67 m/s considering the regional modification factor, thus PGV of 0.9 m/s is higher than that of the design ground motion. Even immediately after the bridge is in service, the peak shear strain of the seismic isolation bearing is close to the rupture strain in case the column height is 15 m, as shown in Figure 2(a). However, it is confirmed that the progress of ageing deterioration reduces the rupture strain, resulting in a further reduction in the safety margin of the isolation bearing, as shown in Figure 2(c). Even at the same 30 years after construction, the response of the column is within the range of elastic response because the peak

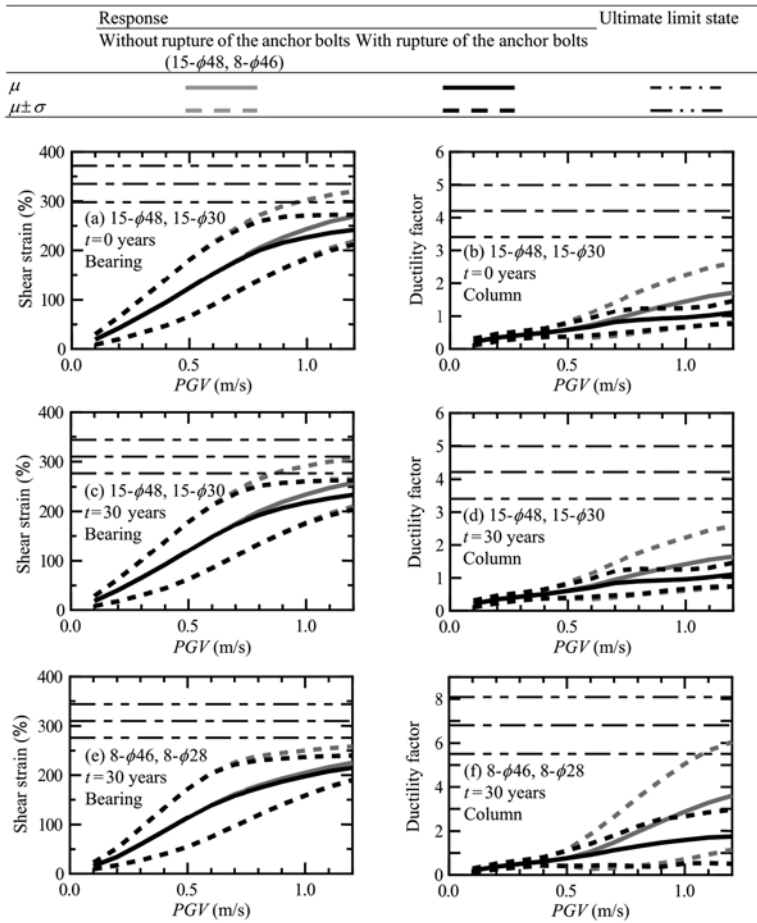

Figure 4. IDA curves with and without the rupture of the anchor bolts.

response shear strain of the seismic isolation bearing is reduced by the rupture of the anchor bolts, and the peak transmitted load from the isolation bearing to the column is also reduced, as shown in Figures 2(e) and (f).

In the case of 8 m high column as shown in Figure 3(a), while the safety margin of the seismic isolation bearing is large, the column exhibits seismic response displacement close to the ultimate displacement. The large response displacement of the column considering ageing deterioration for 30 years after construction can also be reduced to relatively small displacement by the rupture of the anchor bolts, as shown in Figure 3(d).

3.2 IDA curves

Figure 4 displays the mean and plus/minus the standard deviation of the response of the isolation bearings and columns. The responses of the seismic isolation bearing of Bridge 15- ϕ 48 shown in Figure 4(a) and the column of Bridge 8- ϕ 46 shown in Figure 4(f) indicate that the response exceed the ultimate limit states, respectively. Thus, if the anchor bolts are not ruptured under extreme ground motions, bridges with higher column heights are more likely to cause the rupture of the rubber layer of seismic isolation bearings, while bridges with lower column heights are more likely to cause the columns to reach their ultimate displacement, consistent with the results of Matsuzaki (2022). Furthermore, the possibility of rupture of the rubber layer increases as the isolation bearing is deteriorated, as shown in Figure 4(c).

Figure 5. Fragility curves of the target seismically isolated bridges.

It has been shown that damage control by the rupture of the anchor bolts not only suppresses the peak response shear strain of seismic isolation bearings, but also reduces the seismic response of columns, especially under extreme ground motion that exceeds the design ground motion. In the case column height is low, the seismic response of the columns tends to be large, and the effect of reducing the response of the seismic isolation bearing is relatively small, but the effect of reducing the nonlinear response of the columns with large variations is significant.

3.3 Fragility curves

Figure 5 displays the fragility curves of the target seismically isolated bridges. As is clear from the IDA curves shown in Figure 4, even if the seismic isolation bearings are not deteriorated, they are likely to rupture at the rubber layers of the isolation bearings when the column height is 15 m, and the response of the columns is likely to reach the ultimate displacement when the column height is 8 m. Furthermore, it can be confirmed that the possibility of damage is more likely to increase as the seismic isolation bearings deteriorate over time. On the other hand, as shown in Figures 5(c) and (f), it is shown that the ultimate failure of rubber layers of the seismic isolation bearings and the columns can be sufficiently avoided under extreme ground motions by the rupture of the anchor bolts, even if the ageing deterioration of bearings is considered.

4 CONCLUSIONS

In this study, improving the reparability of seismically isolated multi-span continuous girder bridges by the rupture of the anchor bolts of the deteriorated isolation bearings was investigated by incremental dynamic analysis and fragility analysis. The following conclusions can be drawn:

- 1) The damage control by the rupture of the anchor bolts not only suppresses the peak response shear strain of seismic isolation bearings, but also reduces the seismic response of columns, especially under extreme ground motion that exceeds the design ground motion. In the case column height is low, the effect of reducing the nonlinear response displacement of the columns is significant.

- 2) Fragility curves show that the ultimate failure of rubber layers of the seismic isolation bearings and the columns can be sufficiently avoided under extreme ground motions by the rupture of the anchor bolts, even if the ageing deterioration of bearings is considered.

Probabilistic resilience assessment of aging bridge networks based on damage disaggregation and stationary proposal importance sampling

L. Capacci & F. Biondini
Politecnico di Milano, Milan, Italy

A.S. Kiremidjian
Stanford University, Stanford, CA, USA

ABSTRACT: This paper presents a mathematical framework to investigate the relative importance of seismic damage scenarios to the probability of failing to meet target performance measures for spatially-distributed aging bridge networks. The proposed framework relies on a statistical approach adapted from disaggregation procedures typical of probabilistic seismic hazard analysis. The estimate accuracy is enhanced using a novel simulation-based methodology proposed in previous works based on Importance Sampling with Stationary Proposal distributions (SP-IS). The basic random variables involved in risk assessment are efficiently sampled from a near-optimal simulation density based on the minimization of the Kullback–Leibler cross-entropy. A simple road network is investigated to highlight the benefits to computational effort of the proposed SP-IS numerical method and to explore the potentialities of the concept of damage disaggregation in communicating to infrastructure managers and policy makers the large-scale consequences of natural hazards and aid the optimal management and prioritization of essential maintenance interventions.

1 INTRODUCTION

Life-cycle seismic risk assessment is critical for the optimal management of lifelines and for the emergency response of communities affected by natural hazards, such as earthquakes. In transportation systems and road networks, the damage induced by sudden extreme events and the consequences on the post-event performance of infrastructure systems with spatially distributed vulnerable elements can be evaluated with site-specific analysis (Stergiou and Kiremidjian 2010). In this context, the concept of resilience has been gaining increasing importance of performance-based assessment of infrastructure system, particularly for bridges and transportation networks exposed to natural and man-made hazards (Capacci et al. 2022a). Resilient infrastructure systems are able not only to resist the impact of extreme events, but also to absorb their consequences and promptly recover the pre-event functionality (Bruneau et al. 2003). Bridges are particularly vulnerable assets due to the interaction of seismic hazards with environmental aggressiveness inducing mechanical deterioration (Biondini et al. 2015, Rao et al. 2017).

Most probabilistic methodologies for seismic loss assessment that have been formulated based on the PEER's framework have the advantage of aggregating into a single comprehensive measure of seismic risk all the sources of uncertainty associated to regional hazards, element fragility and system exposure. The concept of disaggregation aims at evaluating the relative contributions of specific detrimental events representative of the risk components. For example, disaggregation is a well-established procedure to address the relative contribution of different sources and shaking characteristics of the

expected ground motion at a site (Bazzurro and Cornell 1999). In the context of seismic loss assessment, this concept can also be adopted to investigate the impact of different damage scenarios and structural components to risk metrics in terms of economic direct costs (Aslani 2004) as well as performance-based measures (Capacci et al. 2021).

The paper proposes a mathematical framework and a numerical procedure to assess the exceedance rate of target values of a life-cycle resilience-based risk measure and to disaggregate such metric into the time-variant relative contributions of relevant damage scenarios. The following sections summarize the constitutive components of seismic risk analysis of infrastructure systems, proposing a comprehensive analytical framework encompassing probabilistic seismic hazard of spatially distributed assets, life-cycle seismic fragility of aging structures and resilience-based exposure of infrastructure systems. The annual failure rate of occurrence of prescribed failure events is numerically quantified by means of Importance Sampling with a Stationary Proposal distribution (SP-IS) optimally selected from a chosen family of parametric distributions based on the minimization of the Kullback–Leibler Cross–Entropy (KL-CE). A simple network with three aging bridges is investigated to highlight the ability of damage disaggregation to identify the relevance of vulnerable network components, its evolution in time due to the interdependencies between seismic and environmental hazards, and the significance of the identification of dominant damage scenarios to inform retrofit prioritization strategies.

2 RESILIENCE-BASED SEISMIC RISK AND DAMAGE DISAGGREGATION

2.1 Seismic risk metrics based on failure recurrence rate

Probabilistic Seismic Hazard Analysis (PSHA) aims at describing the occurrence rate of severe seismic events under uncertainties. At the infrastructure level, seismic hazard is assessed at multiple sites accounting for the spatial distribution of vulnerable assets. Earthquake recurrence is described based on historical data and the characteristics of active faults and area sources, which can be conveniently collected in a vector with n_h seismic hazard parameters \mathbf{H}_h informative of possible rupture scenarios in the region. The multivariate lognormal random variable \mathbf{I} collectively describes the seismic scenario based on the intensity measure i_b of the ground shaking at the site of the n_b vulnerable infrastructure elements, such as bridges in a road network. Ground motion prediction models define the probabilistic relationship of intensity measures \mathbf{I} conditional on the hazard parameters \mathbf{H}_h . According to the total probability theorem (Ang and Tang 2007), the Probability Density Function (PDF) of seismic scenario \mathbf{I} is defined as:

$$f_{\mathbf{I}}(\mathbf{i}) = \int_{\mathbb{R}^{n_h}} f_{\mathbf{I}|\mathbf{\eta}_h}(\mathbf{i}|\mathbf{\eta}_h) \cdot f_{\mathbf{H}_h}(\mathbf{\eta}_h) \cdot d\mathbf{\eta}_h \quad (1)$$

where vectors \mathbf{i} and $\mathbf{\eta}_h$ represent outcomes of the intensity and hazard variates, respectively.

The recurrence of seismic events from the k -th seismogenic source in a prescribed region is commonly represented by Poisson processes with annual rate of earthquake occurrence ν_k . Based on the total probability theorem, the annual rate of occurrence of a failure event E can be described by its occurrence probability conditional on the seismic intensity scenario \mathbf{i} :

$$\nu_E = \int_{\mathbb{R}^{n_b}} P[E|\mathbf{i}] \cdot |d\lambda(\mathbf{i})| \quad (2)$$

where $|d\lambda(\mathbf{i})|$ is the differential annual rate of exceedance of a given seismic intensity scenario \mathbf{i} :

$$|d\lambda(\mathbf{i})| = \left(\sum_{k=1}^{n_f} \nu_k \right) \cdot f_{\mathbf{I}}(\mathbf{i}) \cdot d\mathbf{i} \quad (3)$$

and n_f is the total number of faults and area sources in the region.

2.2 Time-variant fragility curves and network damage rate

Given the seismic hazard scenario, the second step in seismic risk assessment of bridge networks deals with the probability that network components suffer damage in the aftermath of severe ground motions. Also, the life-cycle seismic capacity of vulnerable bridges can be affected in time by damage processes related to long-term environmental aging and short-term shock events.

Time-variant fragility curves represent the exceedance probability of a prescribed damage state s_b conditional to seismic intensity i_b at the b -th site of deteriorating bridges:

$$P_{s_b}^E(i_b, t) = P[S_b(t) \geq s_b | i_b] \quad (4)$$

where $S_b(t)$ is the discrete univariate stochastic process representing the time-variant bridge damage state. Fragility curves can also be analytically described by the Cumulative Distribution Function (CDF) of the bridge seismic capacity. Fragility curves can be fitted based on empirical data and physics-based models via suitable statistical procedures (Lallemant et al. 2015).

Damage state combinations among the set of bridges composing the infrastructure network can be represented by collecting into vector \mathbf{s} the damage states s_b of the b -th bridge. Given the seismic intensity scenario \mathbf{i} , the occurrence probability of a damage state combination \mathbf{s} corresponds to the conditional probability of the intersection of events representing the occurrence of a damage state to each bridge:

$$P[\mathbf{S}(t) = \mathbf{s} | \mathbf{i}] = P\left[\bigcap_{b=1}^{n_b} [S_b(t) = s_b | i_b]\right] \quad (5)$$

where $\mathbf{S}(t)$ is the discrete multivariate stochastic process representing in vectorial form the time-variant bridge damage combination. The damage combination probabilities depend on several factors affecting the bridge seismic capacities, such as their mutual correlation (Capacci and Biondini 2018).

2.3 Resilience and failure rate

When bridges suffer damage in the aftermath of a seismic event occurring at time t_0 , the operation of road networks can be severely impaired due to traffic restrictions imposed by infrastructure owners to ensure the users' safety in the emergency management. The network performance can be quantified based on a comprehensive measure of network functionality $Q = Q(\mathbf{d}) \in [0, 1]$ depending on the combination \mathbf{d} of traffic limitations d_b imposed along the n_b bridges in the network. For example, the functionality can be defined as the ratio between the Total Travel Time TTT of all road users in unrestricted conditions (i.e., $\mathbf{d} = \mathbf{0}$) and the TTT given the bridge damage combination:

$$Q(\mathbf{d}) = \frac{TTT(\mathbf{0})}{TTT(\mathbf{d})} \quad (6)$$

Then, the progressive repair activities carried out to recover the load-bearing capacity of damaged bridges allow releasing in time the traffic restrictions and, in turn, restore the network functionality. Given the initial damage combination \mathbf{s} and the repair interventions on each bridge in the network, resilience can be quantified based on the integral mean of the functionality profile $Q(t)$ from the time of seismic event occurrence t_0 up to a fixed horizon time t_h :

$$R(\mathbf{s}) = \frac{1}{\Delta t_h} \int_{t_0}^{t_h} Q(\mathbf{s}, t) dt \quad (7)$$

In the context of seismic risk analysis, this resilience measure can be adopted as an overall metric of exposure. Therefore, the failure probability to meet a prescribed resilience target

r given the seismic scenario \mathbf{i} can be defined based on the total probability theorem accounting for all possible damage combinations n_s over the bridge network:

$$F_{R(t)|\mathbf{i}}(r|\mathbf{i}) = \sum_s F_{R|\mathbf{s}}(r|\mathbf{s}) \cdot P[\mathbf{S}(t) = \mathbf{s}|\mathbf{i}] \quad (8)$$

where F_R is the CDF of the resilience measure, $F_{R|\mathbf{s}}$ is the same CDF conditional on the occurrence of a given damage combination \mathbf{s} . Finally, the annual failure rate in meeting a prescribed resilience target r is expressed as in Equation 2 considering as failure event $E = \{R \leq r\}$:

$$\nu_{R \leq r}(r, t) = \int_{\mathfrak{R}_+^b} F_{R(t)|\mathbf{i}}(r(t)|\mathbf{i}) \cdot |d\lambda(\mathbf{i})| \quad (9)$$

2.4 Damage disaggregation and predominant events

Damage disaggregation allows detecting which damage states suffered by the bridges in the network are more likely to cause unsatisfactory resilience levels based on their probability of occurrence. In analytical terms, the conditional occurrence probability of a generic event E_1 given the occurrence of event E_2 can be determined based on the Bayes' theorem (Ang and Tang 2007):

$$P[E_1|E_2] = \frac{P[E_2|E_1] \cdot \nu_{E_1}}{\nu_{E_2}} \quad (10)$$

In the present paper, events E_1 and E_2 are respectively associated to the occurrence of a seismic event that leads to an insufficient level of network resilience and the occurrence of a prescribed set of damage combinations. Therefore, the probability that resilience is lower than a threshold target r due to the occurrence of the bridge damage combination \mathbf{s} is defined as follows:

$$P_{s|r}(\mathbf{s}, r; t) = P[\mathbf{S}(t) = \mathbf{s}|r] = \frac{F_{R|\mathbf{s}}(r|\mathbf{s}) \cdot \nu_s(t)}{\nu_{R \leq r}(r, t)} \quad (11)$$

Given a target performance level in terms of network resilience, the predominant damage combination identifies which bridge or set of bridges in the network would provide the most relevant contribution to the seismic risk metric. This information can foster the prioritization of ex-ante retrofit activities as well as ex-post repair strategies, which would respectively benefit the seismic capacity of single bridges and the emergency response of the infrastructure system. Accounting for aging processes, the relevance of each damage combination would also evolve in time providing further insight on the optimal ex-ante preventive maintenance actions aimed at counteracting the detrimental effect of environmental deterioration.

3 EFFICIENT SIMULATION TECHNIQUE

3.1 Stationary Proposal Importance Sampling (SP-IS)

In life-cycle structural reliability and seismic risk assessment, uncertainties in bridge structural capacity vary in time due to stochastic deterioration processes. Simulation-based techniques numerically estimate the probability of event occurrence based on the multidimensional integral:

$$P_f(t) = \int_{\mathbf{x}} I(\mathbf{x}) \cdot f_{\mathbf{X}(t)}(\mathbf{x}) d\mathbf{x} \quad (12)$$

where $f_{\mathbf{X}(t)}$ is the time-variant joint PDF of the set of basic random variables $\mathbf{X}(t)$ and the indicator function $I(\mathbf{X}) = I\{g(\mathbf{X}) \leq 0\}$ is a Heaviside step function equal to 1 in the failure domain bounded by the limit state function $g(\mathbf{X})$ and 0 in the safe domain.

In life-cycle risk assessment of aging systems, traditional simulation strategies may be numerically inefficient in accurately estimating failure probabilities related to multiple reliability problems. Advanced simulation techniques rely on alternative formulations of the failure

probability integral to reduce the variance of the reliability estimator. In Importance Sampling (IS), the integral is reformulated in terms of the proposal simulation density $\psi(\mathbf{x})$:

$$P_f(t) = \int_{\mathbf{x}} I(\mathbf{x}) \cdot f_{\mathbf{X}(t)}(\mathbf{x}|t) \cdot \frac{\psi(\mathbf{x})}{\psi(\mathbf{x})} d\mathbf{x} \quad (13)$$

Such formulation relies on the definition of the IS weighting coefficients W as the ratio between the actual time-variant PDF $f_{\mathbf{X}(t)}$ and the sampling stationary PDF ψ (Capacci and Biondini 2021)

$$W(\mathbf{x}, t) = \frac{f_{\mathbf{X}(t)}(\mathbf{x})}{\psi(\mathbf{x})} \quad (14)$$

The IS failure probability estimator with sample size N is the mean of the indicator function I_i for the i -th simulated set of random variables \mathbf{x}_i weighted at time t by the coefficients $w_i(t) = W(\mathbf{x}_i|t)$:

$$p_{IS}(t) = \frac{1}{N} \sum_{i=1}^N I_i \cdot w_i(t) \quad (15)$$

In traditional Monte Carlo simulation methods, samples are generated from a distribution progressively evolving over the system lifetime, requiring one simulation per observation time t for a prescribed deterioration model. On the other hand, SP-IS requires a single simulation to estimate probabilities at different times t and aging model by suitably weighting each failed sample.

3.2 Cross-Entropy-based optimal Stationary Proposal sampling density (CE-SP-IS)

The choice of the sampling density ψ is a key issue to ensure accuracy and efficiency of the SP-IS framework. Minimizing the IS estimate variance effectively improves the simulation performance. The aim of the cross-entropy-based methodology is to formulate a near-optimal simulation density from a chosen family of parametric distributions that minimizes the Kullback–Leibler (KL) cross-entropy (CE), which is a measure of discrepancy between a prescribed distribution and the absolute best sampling density (Rubinstein 1981). The KL-CE between the best possible density p^* and a prescribed proposal PDF ψ with parameters \mathbf{v} is expressed as:

$$D_{KL} = \int_{\mathbf{x}} p^*(\mathbf{x}) \cdot \ln p^*(\mathbf{x}) d\mathbf{x} - \int_{\mathbf{x}} p^*(\mathbf{x}) \cdot \ln \psi(\mathbf{x}, \mathbf{v}) d\mathbf{x} \quad (16)$$

The formulation of the best density p^* accounting for the n_c reliability problems for all investigated combinations of time instants t , limit states s and parametric scenarios p is defined as follows (Capacci and Biondini 2023):

$$p^*(\mathbf{x}) = \frac{1}{n_c} \left[\sum_{c=1}^{n_c} \frac{I(\mathbf{x}|s) \cdot f_{\mathbf{X}(t)}(\mathbf{x}|t, p)}{P_f(t, s, p)} \right] \quad (17)$$

where the combinations $c = \{t, p, s\}$ encompass the n_c possible combinations. The basic random variables distribution $f_{\mathbf{X}}$ can change over time t given the parametric scenario p , whilst the limit states s affect the definition of the indicator function I . The density p^* is formally unknown, since it requires the knowledge of the target failure probabilities P_f of the n_c reliability problems.

The proposal parameters minimizing the cross-entropy are obtained by formulating an optimization problem that maximizes the second term in D_{KL} . Closed-form updating rules to iteratively solve the optimization problem are available for exponential distributions (Rubinstein and Kroese 2004). Proposal distributions characterized by Gaussian Mixtures (GMs) can be adopted to efficiently map the most significant regions in the failure domain based on K joint-normal variates with relative probability π_k , mean vectors $\boldsymbol{\mu}_k$, and covariance matrices $\boldsymbol{\Sigma}_k$ (Kurtz and Song 2013). The CE optimization problem is also equivalent to a Maximum Likelihood Estimate of the mixture parameters and expectation-maximization algorithms can

further refine the estimates of the statistical parameters $\{\pi, \mu, \Sigma\}_k$ of each Gaussian density (Geyer et al. 2019). When random variables are characterized by non-normal distributions, they can be simulated in the standard normal space \mathbf{u} , where also weighting coefficients w_i can be retrieved, whilst indicator functions I_i are sampled based on a suitable transformation into their actual space \mathbf{x}_i (Capacci and Biondini 2023).

4 APPLICATION

4.1 Seismic hazard scenario, lifetime bridge fragility and road network topology

The investigated infrastructure system is sketched in Figure 1. The road network is composed by three main cities interconnected by highways with a vulnerable bridge. Major seismic events are equally likely to occur with annual earthquake occurrence rate $\nu_m=0.05$ over the square seismogenic area sources with normal prevalent faulting mechanism. Moment magnitudes M_w are governed by a truncated Gutenberg-Richter distribution:

$$F_{M_w}(m) = \frac{1 - 10^{-b(m-m_{\min})}}{1 - 10^{-b(m_{\max}-m_{\min})}} \quad (20)$$

Uncertainties in the ground motion intensity at the bridge sites are incorporated by the ground motion prediction model derived from the Italian strong motion database in Bindi et al. (2011) with Peak Ground Acceleration as seismic intensity measure.

The life-cycle seismic capacity $\bar{I}_b(t)$ of the three spatially-distributed vulnerable aging bridges in the network is described by statistically independent lognormal fragility curves. The standard deviation of the logarithm of the seismic capacity is $\zeta=0.60$ for all bridges. The median seismic capacity $\bar{i}_{b,m}$ deteriorates in time due to environmental aging with the following degradation law:

$$\bar{i}_{b,m}(t) = \bar{i}_{b,m0} - k_b \cdot t^2 \quad (21)$$

Daily users' traffic flows f_{OD} from Origin O to Destination D are modeled as statistically independent symmetric triangular distributions over the range $f_{OD}^{mode} \pm 1500$ cars/hour. Traffic demands are also perfectly correlated within the same OD pair (e.g., f_{12} and f_{21}). Travel times t_{OD} are then assigned by shortest path analysis based on the network topology. Secondary roads of length $l_{detour}=30$ km also guarantee the connectivity between city pairs when the related bridge along the main highway is closed. Uniform random variables between 230 and 330 characterize the probabilistic model for the recovery times $T_{r,b}$ for each bridge. Traffic flow modes f_{OD}^{mode} , speed limits ν_{\max} and roadway lengths l_{OD} are all collected in Figure 1.

Additional information regarding seismic hazard, time-variant fragility model and network resilience assessment can be found in Capacci et al. (2020), Capacci and Biondini (2021).

4.2 Resilience-based life-cycle seismic risk mitigation by bridge retrofit

Figure 2a shows the time-variant mean annual rate of non-meeting $n_s=2$ resilience targets $r=60\%$ and 70% considering the retrofit of a single bridge at 30 years of lifetime. Figure 2b shows the time-variant risk measure considering the retrofit at 30 years of two bridges. For the sake of simplicity, each retrofit intervention is assumed to reset to pristine conditions both median seismic fragility model and deterioration rate. Risk is assessed at $n_r=26$ time instants from pristine conditions to 50 years (every 2 years) with $n_p=7$ deterioration scenarios: (1) no retrofit actions, (2-4) retrofit of a single bridge and (5-7) retrofit of bridge pairs. The risk estimates are obtained by calibrating with the CE-SP-IS methodology a near-optimal Gaussian mixture model composed by $n_k=3$ densities to solve $n_c=n_s \cdot n_r \cdot n_p=364$ reliability problems with a single simulation of sample size $N=10^6$.

The results discussed are consistent with the considerations on damage disaggregation discussed in the next Section. Although the retrofit of only bridge B1 is inducing the lowest risk

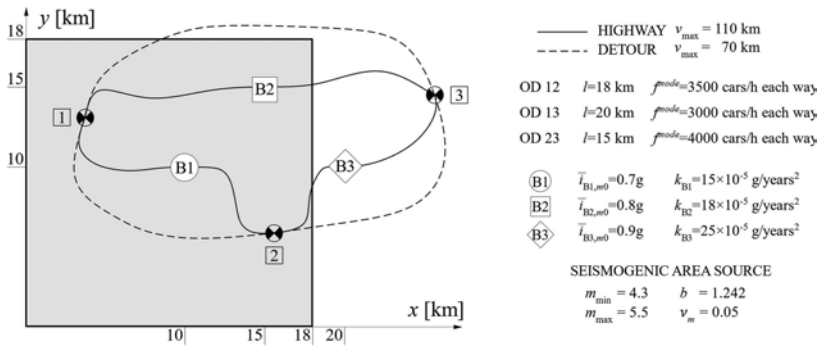

Figure 1. Seismic hazard scenario and road network topology of spatially-distributed aging bridge network.

at 30 years with resilience target 70%, the same intervention on only bridge B3 is more beneficial long-term due to its larger network exposure and faster capacity decay rate. For resilience target $r=60\%$, it is critical to prioritize the retrofit of the most relevant bridge B3.

Figure 2. Time-variant annual failure rate of target resilience $r=60\%$ and 70% with retrofit at $t=30$ years of (a) one bridge and (b) bridge pairs.

4.3 Damage disaggregation for resilience-based life-cycle seismic risk mitigation by retrofit

The sensitivity of the road network to the damage suffered by one or more of its vulnerable elements depends on the proportion of the risk metrics ascribed to the occurrence of such damage. The features in terms of hazard, fragility, deterioration, and exposure of each bridge are defined in such a way that it is not intuitive to capture which bridge damage scenario would be more relevant to the seismic risk measure. Since the median seismic intensity in the ground motion prediction model is inversely proportional to the source-to-site distance, the most prone bridge to seismic hazard is B1. This is due to the fact that the site of B1 is close to the geometrical centroid of the area source and it is more likely that the earthquake epicenter is close compared to bridges B2 (located at a peripheral zone of the seismicogenic area) and B3 (located outside the area source). Concerning the initial seismic fragility based on the medians $\bar{I}_{b,m0}$ collected in Figure 1, B1 and B3 are respectively characterized by the least and most capacity in pristine conditions. On the other hand, B1 and B3 respectively experience the least and most severe deterioration of seismic capacity given the decay rates k_b . Finally, the impact of bridge closure to the resilience metrics depends on network topology and traffic demand. Thus, bridge B3 is the most vulnerable since its closure induces the largest detour affecting on average the largest traffic flow.

Figure 3 represents the time-variant probability that a specific bridge is damaged when the resilience target is not met considering $r=60\%$ and 70% . This graph allows addressing which bridge failure is more likely to induce unsatisfactory system performance given all uncertainties in seismic hazard, time-variant fragility and network exposure. For more restrictive target

of seismic resilience (Figure 3a), the most critical bridge is B3 (i.e., the most exposed bridge in the network). For less restrictive target of seismic resilience (Figure 3b), the most relevant bridge is initially B1 (i.e., the most hazard-prone and fragile in pristine conditions). Nonetheless, the fast degradation rate of the most exposed bridge B3 progressively increases its relevance in time, overcoming the conditional probability associated to B1 after about 45 years. It is worth noting that the conditional probabilities in Figure 3 represent collectively exhaustive events since the resilience target may not be met only if at least one bridge is damaged (i.e., $\min_b\{s_b\}=1$), but they are not mutually exclusive since more than one bridge may be damaged by the earthquake.

Figure 3. Disaggregation of bridge damage occurrence for target resilience (a) 60% and (b) 70%.

Figure 4 shows the disaggregation with respect to the number of bridges damaged in the network for the same resilience targets. It is evident that $s_n=2$ damaged bridges is the most likely amount of collapsed elements inducing failure in meeting a resilience target of 60% (Figure 4b). For target $r=70\%$, the collapse of only one bridge (i.e., $s_n=1$) is the most relevant event. The probability of widespread damage (i.e., large s_n) increases in time due to deterioration. Since these probabilities are conditional to mutually exclusive and collectively exhaustive events, their sum at a given time t is unitary based on the total probability theorem.

Figure 4. Disaggregation of network damage occurrence for target resilience (a) 60% and (b) 70%.

5 CONCLUSIONS

The prioritization of essential interventions on vulnerable infrastructure components is critical in life-cycle management of lifeline systems, such as road networks with spatially-distributed aging bridges. The analytical framework proposed in the paper aims at quantifying the relative importance of relevant damage scenarios based on probability disaggregation of resilience-based seismic risk metrics. Investigating a simple road network with three bridges characterized by different features regarding seismic hazard, time-variant fragility and system exposure allowed demonstrating the capability of the proposed methodology in prioritizing retrofit strategies. The lifetime seismic risk estimates have been assessed with the aid of a novel advanced technique inspired by Importance Sampling that selects the optimal density

for the numerical simulation of seismic damage and network resilience. Further research should be devoted to investigating potentialities and issues of upscaling analytical and numerical approaches to life-cycle structural reliability of critical structures with complex deterioration patterns (Capacci et al. 2022b).

Dynamic characteristic of geodesic domes with different location of mass

D. Bysiec, T. Maleska & A. Janda

Faculty of Civil Engineering and Architecture, Opole University of Technology, Opole, Poland

ABSTRACT: The paper presents the numerical analysis of geodesic domes in which different location of mass was taken into account. In addition, the dynamic excitation was used and the seismic record from US (El Centro from 1941) was applied in the numerical models. The geodesic domes subjected to the dynamic analysis were created based on two different methods of subdividing spherical triangles (the original octahedron face). These structures are often used for the strategic reference point in the city. Sometimes, these structures are used in typical buildings. The analysed structures were made of steel, which is recommended for the lightweight structures with large spans. It should be emphasized, that the designing of steel domes is currently a challenge for structural engineering, as well as architects, who take into account their aesthetic considerations. In current research the finite element method in conjunction with numerical program was used. A non-linear analysis of the behavior of steel domes as a result of a given seismic excitation was performed. This paper presents the results of displacements and accelerations in time domain. The results of this analysis show the impact of the method of shaping the topology of the structure grid under seismic excitation on the response of geodesic domes. The obtained results will be helpful for these structures located on the seismic areas during designing and service. These results can also be helpful during the life-cycle of structure, where various types of equipment (additional masses) for domes are used at different stages of the structure's exploitation, which can change the nature of the work of the dome structure.

1 INTRODUCTION

Geodesic domes are light structures with a unique structure and are often a reference point for the place where they are built. These structures are called lightweight structures, which are characterized by a low use of structural material (usually made of steel) in relation to the span. As a result, they arouse the admiration of even outsiders. Apart from the aesthetic aspect, these constructions are part of the idea of sustainable development, through the appropriate use of construction material (Figure 1). On the other hand, sustainable development plays an increasingly important role in everyday life of every human being. As a result, lightweight structures become even lighter, and their load-bearing sections are stretched to the limit (Pilarska 2020, Bysiec 2023).

Lightweight structures have been analyzed for years in various optimization aspects. Most often, various types of algorithms and optimization methods are used as part of the optimization, the purpose of which is to reduce their weight. For example, Saka (2007a) as well as Carbas & Saka (2012) used the harmony search algorithm to present the optimal solution to the structure geometry. Another algorithm, that is the coupled genetic algorithm was presented also by Saka (2007b). To obtain the optimal cross-section of elements of domes, the enhanced colliding bodies optimization (ECBO) method was used in the paper by Kaveh & Rezaei (2015) or the charged system search (CSS) method in the paper by Kaveh & Talatahari (2011). Other algorithms used to optimize the structure include, for example SHADE algorithm used by Kaveh et al. (2022), the Jaya algorithm used by Dede et al. (2020), the Rao's algorithms used by Dede et al. (2022). Taking into account geometric nonlinear behavior of the domes, Gholizadeh & Barati (2014) considered the optimization process. Optimization of domes was also presented by Ye & Lu (2018), as well as by Grzywinski et al. (2019). The presented papers include activities that may translate into reduced environmental impact through lower consumption of construction material (steel). As part of these analyses, the effect of static load on the construction of geodesic domes, roofs, towers, etc. was investigated.

However, the influence of the method of shaping the topology of geodesic dome structures on the consumption of the construction material (steel) has been rarely investigated. Such actions were taken in the papers of Pilarska (2018a,b, 2020), where the focus was on the grid topology of single-layer geodesic domes. Two methods of creating the mesh topology of the tested domes were used in these papers. Based on these studies, it was noticed that the use of a different mesh shaping method has a more positive effect on weight reduction (by about 17%) than the use of an optimization algorithm. As a rule, such algorithms were able to reduce the weight of the supporting structure only by about 2% (Dede et al. 2022) or about 2 - 9% (Kaveh et al. 2022).

Figure 1. Example of geodesic domes of: a) residential house in Milan (Italy), b) dome of the Warsaw shopping center (Poland).

This approach was also tested for dynamic effects on the mentioned structures. In the paper of Pilarska & Maleska (2021), these domes were subjected to seismic excitation, and it was considered that as a result of seismic loading, the geodesic domes behaved differently than during static tests. It turned out that dome structures made according to method 2 better suppress seismic excitation.

Figure 2. Methods of subdividing of geodesic dome from numerical research.

However, the question arises what will happen when the ideal structure of the geodesic dome is disturbed or additionally loaded asymmetrically. Additionally, what happens if such a structure is subjected to strong seismic excitation. It should be added that the use of additional mass in the structure may affect the life-cycle of structure, and in some cases even destroy the structure due to the addition of too much mass (structure equipment, additional devices). In this paper, the authors will try to answer this question by locating the mass in different places of the domes. In addition, these domes will be loaded by the strong El Centro record. The paper analyzes the displacements and accelerations for the tested domes, which are analysed during life-cycle of structure.

2 DESCRIPTION OF GEODESIC DOMES

2.1 General remarks

Geodesic domes were made based on earlier research by Pilarska (2012, 2018a, b, 2020), as well as Pilarska & Maleska (2021). Selected structures were built based on two methods of

creating their mesh topology. These methods differ in the method of connecting the points formed by dividing the edges of the initial octahedron, which is the basis for creating the geodesic domes analyzed in this article. The methods are presented in detail in the papers by Bysiec (2008, 2009a, b). Figure 2 presents graphically the differences between the two methods of creating geodesic dome structures used in this paper. The tested domes has 2888 struts (method 1) and 2904 struts (method 2).

Figure 3. Models of geodesic domes from DIANA FEA: a) I¹, b) II¹, c) III¹, d) I², e) II², f) III².

These domes were the basis for numerical research (model I¹ and model I²), in which the impact of the mass located in two different places, i.e. in the middle of the dome span (model II¹ and model II²) and located about 10 meters from the centre of the dome (model III¹ and model III²) was tested. The mass suspended in these places had a weight of two tons and was suspended in a node. The individual models are shown in Figure 3. The suspended mass was designed to simulate the suspension of various types of equipment that is mounted to the lightweight construction. In addition, the central mass suspension does not interfere with the ideal and symmetrical construction of the geodesic dome. However, this arrangement may be disturbed by a mass located in a different place than the centre of the dome's span, which was done in models III¹ and III².

2.2 Material properties

In this research the geodesic domes were domes made of steel struts (round pipes) of S235 standard steel. The properties of this steel grade are: (i) Poisson's ratio (ν) 0.3, (ii) Kirchhoff module (G) 80.76 GPa, (iii) Young's modulus (E) 210 GPa, (iv) thermal expansion coefficient (α) 1.2×10^{-5} , (v) volumetric weight (γ) 7850 kg/m³, and (vi) partial safety factor (γ_M) 1.0. The steel elements were modelled as a linearly elastic isotropic material (according to Eurocode 3 (2005), Pilarska & Maleska (2021)).

3 RESULTS OF NUMERICAL ANALYSIS

3.1 General remarks

In order to determine the impact of a seismic excitations on geodesic domes, the numerical program DIANA FEA was used for two methods of shaping the topology of the structure. This program is based on the finite element method. In this program, a non-linear analysis of the behavior of steel domes as a result of the given El Centro seismic excitation was performed. The behavior of the domes over time was analyzed using the Time History method. This method is commonly used to determine the response to seismic excitation of various engineering structures (Maleska & Beben 2023, 2022, Maleska et al. 2021, Maleska et al. 2019, Bonkowski et al. 2018). Thanks to the obtained results, typical values for seismic analysis, i.e. displacement and acceleration, were analyzed (Table 1). In total, 6 numerical models were analyzed, in which two different methods of shaping the structure topology were analysed. Thus, in model I¹ and I², no additional mass was suspended, in models II¹ and II², the mass (2 tons) was suspended in the middle of the dome span, and in models III¹ and III², the mass (2 tons) was displaced from the centre by about 10 m, as shown in Figure 3c, f.

Table 1. Results of numerical analysis from DIANA FEA.

	Model I (without mass)		Model II (with central mass)		Model III (with lateral mass)	
	Method 1	Method 2	Method 1	Method 2	Method 1	Method 2
Displacements [cm]						
Dx	8.84	6.58	12.48	6.94	11.95	7.33
Dy	6.05	9.04	10.84	8.64	10.59	8.47
Dz	4.27	7.60	6.13	6.12	6.42	8.0
Accelerations [m/s ²]						
Ax	19.12	3.81	25.72	5.09	31.58	5.40
Ay	14.65	3.99	35.59	4.05	31.88	4.35
Az	14.99	5.15	29.88	4.78	32.11	4.17

3.2 Displacements

Based on the numerical analysis, the highest displacement values were obtained for horizontal directions (Dx, Dy). The highest displacement (12.48 cm - Dx) was observed for the model III¹, i.e. for the dome shaped according to the method 1 used to create the mesh topology, in which the additional mass was suspended in the middle of the span of the structure. Analyzing the displacement values obtained for models III¹ and III², in which the additional mass was suspended at a distance of 10 m from the centre of the span of the structure, it can be seen that they were similar to the displacement values of the models with the centrally suspended mass II¹ and II². Only in vertical displacements (Dz – Figure 4) a slight increase of 5-31% was recorded, respectively in models III¹ (6.42 cm) and III² (8.0 cm) compared to the values from models II¹ (6.13 cm) and II² (6.12 cm).

Comparing the displacement values for the initial model for method 1 (model I¹ - without additional mass), it can be seen that the addition of additional mass in the dome structure increased the maximum displacements in all directions (Dx, Dy and Dz). In the case of the model where the mass was shifted by 10 m relative to the centre of the span, the displacement values were lower in the horizontal directions (by 2-4% compared to models with the mass located in the centre of the span). For the vertical direction, a slight increase in displacements (by approx. 5%) was noted for the III¹ model with the mass located 10 m from the span centre, compared to the II¹ model.

In the case of method 2 of creating the dome structure, it can be seen that the use of additional mass in the structure does not significantly affect the displacement results. In general, it can be stated that the displacement results were very similar. The maximum difference in the case of horizontal displacements (model III²) was 6% in relation to the model I², and in the case of vertical displacements the difference was 20% also in relation to the model I².

Figure 4. Maximal displacements in numerical models.

Figure 5. View of maximal displacements of model: a) I¹, b) I², c) I², d) II¹, e) II¹, f) III².

In addition, it should be added that the place of maximum displacement values was observed in the side sectors of the domes. This trend was visible for models I and II (Figure 5a-e). In contrast, in models III (III¹ and III²), the highest values were observed in the places where the additional mass was suspended (Figure 5f).

3.3 Accelerations

The highest acceleration (Figure 6) values were obtained for structures created according to method 1 of shaping their topology. The maximum value was recorded in model II¹, and its value was 35.59 m/s² (Figure 7e). This value was obtained in the horizontal direction when the additional mass was located in the middle of the dome's span. Thus, based on the acceleration results, a significant effect of the additional mass located in the dome structure can be seen in both horizontal and vertical directions.

Figure 6. Maximal accelerations in numerical models.

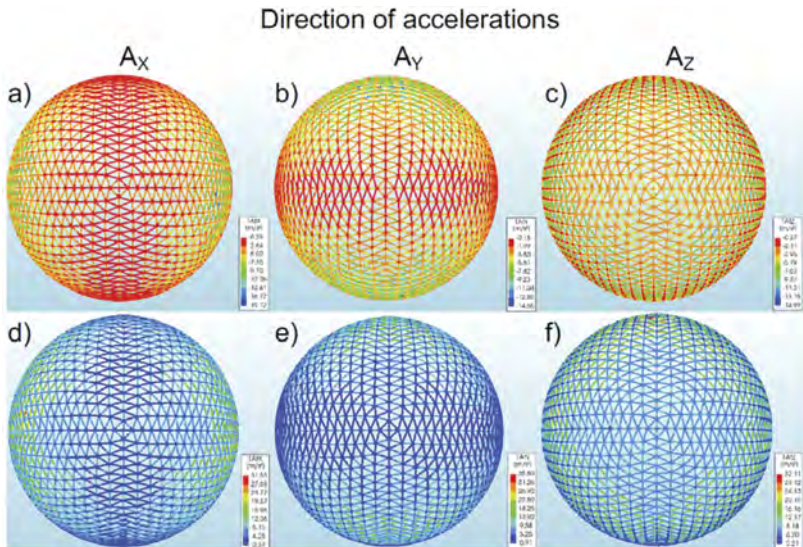

Figure 7. View of maximal accelerations of model: a) I¹, b) I¹, c) I¹, d) III¹, e) II¹, f) III¹.

It can also be seen that the use of an additional mass with a displacement (model III¹) in relation to the model where the mass was located in the middle of the span resulted in a slight reduction of accelerations in horizontal directions, i.e. by about 10%. On the other hand, in the vertical direction (model III¹) there was a slight increase (by 8%) compared to model II¹.

In the case of the second method of creating the structure of the domes, it can be seen that the use of additional mass in the construction of the domes does not significantly affect the obtained values. The acceleration values were much lower than for method 1 of creating a dome sphere. The maximum value for method 2 was 5.40 m/s² (model III²) and was lower in compare to method 1 by 85% (model II¹).

In turn, the maximum acceleration values were observed around 1/4 and 1/2 of the height of the dome (Figure 7). This tendency is noticeable in all the analyzed models, which is a different tendency than in the case of displacements, where the location of the maximum values was influenced by the asymmetrically suspended mass.

4 CONCLUSIONS

After the numerical analysis of the impact of seismic excitation on geodesic domes, it can be concluded that the obtained values are affected by the additional mass suspended in the dome structure. In all analyzed cases, there was an increase in the maximum values. In addition, it can be seen that geodesic domes made according to the second method of shaping the topology of the dome structure better suppress seismic excitations than domes made according to the first method. Moreover, it can be stated that:

- the location of the maximum displacements depends on the location of the additional mass, which is the opposite tendency as in the case of accelerations, in which the maximum values appeared in a specific area of the domes (regardless of the location of the additional mass),
- maximum displacements and accelerations occurred in the domes created according to the first method, in model II, where the additional mass was located in the middle of the span of the domes,
- the highest values were recorded in horizontal directions, both for displacements and accelerations,
- suspending additional mass (additional equipment or devices) in an existing structure may change its response to dynamic excitation and therefore may affect the life-cycle of structure.

As the conducted analysis showed, it is not possible to clearly determine the impact of the additional suspended mass in the dome structure. Therefore, further research is needed in this area to know the exact response of domes located in seismic areas and impact of life-cycle of geodesic dome structure. The conducted research will be helpful for designers dealing with dome structures and lightweight structures.

ABSTRACT: There is an ever-growing societal pressure for the development and implementation of earthquake risk mitigation solutions that not only minimize economic, environmental, and social losses due to seismic hazard during the building operational phase, but which also limit the environmental impact associated to the construction and other life cycle stages of the seismic protection product itself. Innovative active mass damper (AMD) devices are ideally placed to meet such societal demands, given their limited quantity of material use and low-maintenance needs, replaceability and recyclability of components. In addition, AMDs also present the added advantage of being particularly non-invasive, thus reducing architectural impact, and of being quickly installable, hence limiting disruption to the use of the building. This study, therefore, discusses life cycle economic, environmental, and social impact evaluations for a case-study building equipped with a novel AMD device, with a view to highlight the advantages, also in comparison with other seismic retrofitting techniques, of such a seismic protection solution under a life cycle perspective.

1 INTRODUCTION

Acknowledgement, amongst the structural engineering community, of the relevance of Life Cycle design considerations and approaches continues to increase, given current global concerns on:

- climate change;
- vulnerability of the built environment to natural hazards;
- scarcity of natural resources.

Given that the building sector is undoubtedly intertwined with all the above issues, in the recent years the combined targets of reducing carbon emissions, while improving the resistance to natural hazards and reducing the use of natural resources, have been set as a “strategic priority” by the European Union (EU) and consequentially by national governments. Significant funding has been allocated to the renovation of existing buildings, which is recognised as the key action to achieve the above combined targets. To foster such an integrated approach to buildings renovation, in 2019 the EU Parliament entrusted the Joint Research Centre (JRC) with the REEBUILD project, which had the scope of “producing knowledge, guidelines and policy recommendations for the implementation of integrated techniques for the seismic strengthening and energy efficiency improvement of existing buildings”. Among the project products, the reports on current national policies (Butenweg et al, 2022) provide a valuable image of the progress across the member countries towards these EU objectives.

The building engineering research community has thus now recognised that a “discipline-gap” exists in this field: current methods and practice tend to treat separately and with different levels of analysis and expected performances the various aspects (e.g. structural performance, energy efficiency, reusability) of the whole building, often preventing the achievement of retrofitting solutions that are the “best possible” given the above combined targets. This increased awareness has led to the recent conceptualisation, formalisation, testing and proposal of frameworks (e.g. Caruso et al., 2021, 2023; Clemett et al., 2022a; Passoni et al., 2021), that can include state-of-the-art assessment procedures and retrofit options from different disciplines (seismic/structural, energy, environmental, etc.), and provide measures of the combined targets fulfilment in terms of single or multiple parameters. The proposed assessment frameworks are essential elements of the effort towards the achievement of the combined targets; the scientific consensus on the use of such frameworks would allow the adoption, as a reference standard, of integrated life cycle approaches in the current practice of buildings renovation. In this context, two aspects are emerging as relevant and valuable for focus, even though, strictly speaking, external to the frameworks, i.e. the wide range of the retrofit options offer and their level of invasiveness.

The existing literature on seismic retrofit techniques is very extensive, and a state-of-art review is beyond the scope of this study. A typical taxonomy segmentation is given by the structural scheme: for reinforced concrete (RC) frames, steel frames and unreinforced masonry (URM) wall structures, several retrofitting techniques have been developed for both local and global interventions (e.g. Triantafyllou et al., 2022). The wide set of retrofit options available in practice to be used as input in an evaluation framework by a practitioner is however severely narrowed by two main “excluding factors”: the personal experience/familiarity of the design team with a given technique and the reluctance of the owner/tenant to consent interruption to the building’s use.

The impact of such “excluding factors” is deemed very high by the authors; their effect can range from an exiguous and sub-optimal initial set of retrofit options to the definitive renouncing to undertake a seismic retrofit. This hypothesis is well supported by the situation in Italy, where the strongest EU policies were in force, until current revision, through the “Superbonus 110%” scheme, instituted by the Italian law 77/2020 (Italian Parliament, 2020). The Superbonus created, in principle, an almost ideal context for the proliferation of seismic retrofit interventions; the tax discount was over 100%, covering the entire cost of retrofitting, and it was transferable to third parties, potentially reducing to zero the owner’s investment. Technical requirements were also limited thanks to the absence of minimal thresholds for the performance improvement indexes. Nevertheless, the most recent data (ENEA, 2019) on buildings renovation in Italy show that only 2% of the energy retrofitting interventions on multi-owner buildings has been integrated with seismic retrofit in the pre-Superbonus incentives context. Reliable statistics on the effects of the Superbonus scheme are instead still missing on the seismic side; a local survey conducted by the authors on practitioners working in high-hazard regions provides a rough estimate of 10%, almost entirely referring to local interventions from the outside (i.e., RC joints strengthening).

The scenario outlined above highlights the importance of focusing research efforts in the investigation of innovative and non-invasive seismic retrofitting techniques that, if properly disseminated in the current practice, would contribute to (i) reducing the retrofitting “excluding factors” in current practice, (ii) improving the effectiveness of EU policies on integrated renovation of buildings, and (iii) enhance the proposed integrated life-cycle assessment frameworks with a broader range of intervention options.

A recent and promising proposal in the family of innovative intervention techniques is the employment of Active Mass Dampers (AMDs), which, with respect to the more traditional Tuned Mass Dampers (TMDs), feature real-time active mass control, and are characterised by an engineered plug-and-play packaged arrangement that features a level of non-invasiveness that is superior to all other alternatives in the current panorama of structural retrofitting solutions.

This study, therefore, focuses on life cycle economic, environmental, and social impact evaluations of AMD devices, through their application to a case-study building discussed in another recent work (Caruso et al., 2023).

2 ACTIVE MASS DAMPERS

2.1 Description of AMD devices

The AMD systems considered in this work are developed by ISAAC Antisismica and rely on the concept of a single-degree-of-freedom sliding mass, to which a controlled force is applied. The reaction to the applied force generated by the sliding mass inertia is transmitted to the device supports and therefore it enters in the structure at the installation floor. The sliding mass can be also seen as a surrogate of a fixed point, not available in the structure, to which the reaction of the structure to the forcing action is applied.

The complete system is composed of four main elements: 1) the machine, which is the hardware package containing the mass, the actuator system, the local control logic and the sensors for the real time tracking of the machine's response parameters; 2) the power supply unit, for the energy storage and release to the machine during the working cycles; 3) the building's sensor network, which is an array of sensors distributed in the building for the real time transmission of the dynamic parameters required as input by the control algorithm; and 4) the central computer, where the control algorithm is stored and executed according to the input-output signals to the other components.

The first AMD device developed by ISAAC, named I-PRO 1 (Figure 1), featured an electro-hydraulic actuator, inertial mass of 2.4 tons, total mass of 4 tons, dimensions 1.25 x 4.2 m, and available mass stroke of ± 0.5 m (Rosti et al, 2022). The inertial mass motion could reach a maximum velocity of 5 m/s and an acceleration of 9 g, capable of generating on the installation floor a stabilizing force of up to 220 kN. The control algorithm was a velocity-based one, known as "sky-hook" in the literature. Its inputs are real-time velocities at the ground and at the machine installation floor (typically the top one); the target force calculated by the algorithm is the delta velocity times a gain parameter (G), expressed in kN·s/m or ton/s. The operational parameters are then calculated and transferred to the machine, which forces the mass to have the target reaction force at each time.

Figure 1. Left: I-PRO 1 machine during full scale test in EUCENTRE (from Rebecchi et al, 2021). Right: typical installation layout on the top floor of an RC frame existing building.

An important point about the "sky hook" algorithm implemented by ISAAC in AMD devices is the dynamic equivalence with a dashpot, confirmed by test-bench and full-scale tests (Rebecchi & Bussini, 2021). In brief, a comparative analysis between the full-scale test and nonlinear time-history analysis (NTHA) simulation on a numerical model, in which the machine was modelled as a linear dashpot connected to a top floor structural node and to an added external node subjected to the same acceleration time histories assigned to the base nodes, showed a near perfect coincidence in the force history. Based on this result, it was possible to explore the system capabilities in various application scenarios with a good confidence in simulation accuracy (Casto et al, 2022).

In 2022, ISAAC presented a second-generation AMD system, named Electro-Pro 20x (Figure 2). The design was greatly simplified by substituting the electro-hydraulic actuator with a 15-kW synchronous linear motor, thus eliminating the limitations related to the stroke of the hydraulic components. The system, in the basic single-machine configuration, has a reduced maximum force limit (i.e. 20.8 kN vs 220 kN of the I-PRO 1 prototype) and is intended for a multi-machine layout with an increased flexibility of the system to meet the required design performance and with a much simpler installation in any building. Rebecchi et al (2022) investigated the performance of an 8-machines system through numerical simulations of the

application to a 14-storey building in region with a low level of seismic hazard. In this work, this second-generation AMD system will be considered as first scenario, termed AMD-1.

Figure 2. Electro-Pro 20x machine and main technical data (adapted from Rebecchi et al, 2022). 1) permanent magnets, 2) basement for the anchor to sub-structure, 3) linear forcer, 4) mobile mass; 5) machine box including drivers, power system and other electrical components.

2.2 Environmental impact assessment of AMD devices

The Life Cycle Assessment (LCA) for the AMD Electro-Pro 20x requires some assumptions to address the analysis according to EN 15978 (CEN, 2011), which is the current reference standard for buildings LCA in the Europe. The reference to this standard is necessary since the AMD system is completely defined only after installation in the building and its use and end-of-life phases follow that of the building itself. AMD is therefore assimilated to a “technical building system”, somehow extending the definition 3.35 in EN 15978, which is currently limited to systems traditionally installed in buildings (heating, lighting, etc.).

The functional equivalent is a single Electro-Pro 20x in a building. System boundaries are analysed according to the “modularity principle” of EN 15978; in this first attempt the Product Stage (modules A1 to A3) is investigated. The Transportation Stage (A4) and the Construction/Installation Stage (A5) are not considered, due to variability of the former related to the installation location and, to the neglectable contribution of the latter since installation is realised by human work with no further impact. The stage B (Use) is also not considered, due to the peculiar characteristics of the system, i.e. the inherently negligible active time (up to minutes) if compared with the whole building service life. Stages C (end-of-life) and D (reuse-recovery-recycle) will be instead investigated in future research, given that a refined analysis is needed to properly assess the input flows, especially to stage D, due to the highly diversified nature of the system components.

The Life Cycle Inventory (LCI) for the Product Stage (A1 to A3), following what is typically referred to as “cradle-to-gate” LCA, was carried out based on the Bill of Materials (BOM) of the considered system. The BOM was divided in three main component categories: (i) raw and semi-finished components (e.g. steel plates, aluminium profiles etc.), analysed with the ICE database (Hammond & Jones, 2008); (ii) electrical power components (such as linear motor, power cables, batteries etc.), analysed with available Environments Declarations of Performance (EDPs) on similar components and LCA literature and (iii) electronic components, analysed with the available LCA literature.

The cradle-to-gate LCA resulted in 2.5 ton of equivalent carbon dioxide (eCO₂) for a single Electro-Pro 20x machine. This value is a first estimate, suitable for the scope of this study but to be refined in future research. The estimate of AMD carbon footprint is expected to be significantly reduced by considering the foreseen high percentage of components that will enter in phase D, producing a negative contribution to the LCA summation.

2.3 Economic and social impact evaluations of AMD devices

The current cost per AMD machine is in the 50-80 k€ range, depending on the number of machines to be installed and on the related economies of scale. Since the considered solution is still at an early stage of its commercial life, an “R&D quota” related to development costs is included. The cost also includes an “Engineering quota” related to the technical services provided by ISAAC before and after the supply and installation. The combined incidence of the

quotas is estimated to be around 10% and it can be neglected in a comparative analysis with other retrofitting options, whose costs are estimated from a market price-list summation.

For what concerns the social impact, which is typically associated to the reduction of earthquake-induced casualties/injuries, whilst the I-PRO 1 device features already a high potential for improvement with respect to the as-built configuration, its second generation counterpart is still in requirement of further technological developments before it may be capable of providing a similar benefit, as will be shown in the subsequent Section.

3 CASE-STUDY APPLICATION

3.1 Case-study building description

The case study building is a 6-storey residential building located in Sanremo, in the North-West of Italy (illustrated in Figure 3). The site is characterised by a medium level of seismic hazard, with a peak ground acceleration (PGA) on rock soil of 0.146 g for a return period of 475 years, corresponding to the code-defined life safety limit state (LSLS). The building, described in more detail in Caruso et al (2023), was built in the 70s with a RC structure composed of frames in the X (East-West) direction. The interstorey height of 3 m determines a total height of 18 m, the total floor surface is 2800 m² and the total mass is about 2350 tons.

Figure 3. Left: building configuration (a) South and (b) East elevations, (c) first and (d) typical floor plans. Right: site hazard curve for six Intensity Levels with return periods of 50 (DLLS), 101, 201, 475 (LSLS), 975 (CPLS) and 2475 years. Both figures adapted from (Caruso et al., 2023).

In the as-built configuration, a nonlinear distributed inelasticity model was developed with the software SeismoStruct (Seismosoft, 2022), with slabs modelled as rigid diaphragms, and stairs and infills simulated by equivalent loads on the beams.

3.2 As-built earthquake loss assessment

The earthquake loss assessment was performed through the FEMA P-58 procedure, as implemented in the PACT tool (FEMA, 2018). The engineering demand parameters (EDPs) needed for the loss assessment were calculated through a Multiple Stripe Analysis (MSA), with 20 horizontal pairs of ground motion recordings for the six intensity levels (ILs) shown in Figure 3. A total roof displacement of 0.15 m was assumed as the collapse criterion and a complete performance model was built in PACT, with detailed inventory of structural and non-structural damageable elements divided in 8 categories in both directions. All the fragility functions considered were drift-based, thus the interstorey drift ratio (IDR) was the driving EDP for the entire assessment process. The main as-built loss assessment results were: (i) economic Expected Annual Loss (EAL) equal to 9,600 €, i.e. 0,26% of the building replacement cost (ReC); (ii) environmental Expected Annual Emissions (EAE) equal to 4.2 ton eCO₂, i.e. 0.27% of the building replacement environmental impact (ReI); (iii) social Expected Annual Loss of Life (EALL) equal to 0.008 casualties per year.

3.3 Application of the AMD device on the case-study building

In the first retrofit scenario (AMD-1), the as-built structural model was updated with the introduction of AMD Electro-Pro 20x devices. These were modelled through a “dashpot equivalence”, using a linear dashpot in series with a bilinear link element that simulates the force saturation at 20 kN. In such first configuration, 16 machines were applied on the 5th floor of the building, namely, 8 in X direction and 8 in the Y direction, respectively. The main machine parameters are the moving mass of 1 ton and the Gain parameter, set at 150 kN·s/m. Compared with the total mass of the structure, and considering that each machine has as upper force limit of 20 kN, a synthetic index can be defined as the ratio between the structure weight and the max damping force that the AMDs can apply to the installation floor. This ratio, named AMD_{WR} , is equal to 0.7% in both directions, and it can be used to evaluate the AMDs effectiveness at different levels of base shear and for comparison between different scenarios and case studies. A second retrofit scenario (AMD-2) was explored as well, removing the force limit of AMD-1 and doubling the Gain parameter to 300 kN·s/m, with a view to investigate the damping forces generated by such a retrofit solution that is not constrained by current-state technology (it is noted that this level of retrofitting performance can be readily achieved by the first generation devices). Finally, an AMD-3 scenario was also investigated, further increasing the Gain parameter, which was set at 600 kN·s/m, with the objective to study if and how the building interacts with a higher level of damping forces, in terms of members capacity and vibrational regime.

The MSA results of the building in all retrofitted scenarios are summarized in Figures 4 and 5 in X and Y direction, respectively, for three significant ILs: i) at IL1 all AMD scenarios are comparable, and their effectiveness is driven by the Gain parameter increase; ii) at IL4 AMD-1 is prone to saturation in the stiffer X direction, maintaining its effectiveness in Y, while AMD-2 and AMD-3 are able to extensively keep the IDR profiles within 0.5% (code-specified DLLS); iii) at IL5, the AMD-3 scenario shows the negative effects of the interaction between the high damping forces and the building local capacity to transmit them, at the 5th floor in both directions.

Figure 4. MSA results; IDR profiles in X direction for most significant ILs. From left: IL1-50y (DLLS); IL4-475y (LSLS); IL5-975y (CPLS).

Figure 5. MSA results; IDR profiles in Y direction for most significant intensity levels (IL). From left: IL1-50y (DLLS); IL4-475y (LSLS); IL5-975y (CPLS).

For each scenario, the IDR values at 3rd, 4th and 5th floors in both directions were averaged to obtain a more synthetic index, termed IDR₃₄₅, that facilitates the evaluation of the global effect of the retrofit in the building's portion that is more prone to damage (Figure 6). These results clearly show the high potential of AMD devices, as their technological/performance capabilities evolves, to reduce the IDR response values, in this specific application up to 0.5% in absolute terms (as shown for IL5 in Figure 6, left) and keeping the relative reduction in the 30-40% range (as visible from IL1 (DCLS) up to IL5 (CPLS) in Figure 6, right). These results can be achieved by AMD systems with AMD_{WR} ratio in the 3-4% range.

Figure 6. IDR₃₄₅ variation after the retrofit scenarios; the baseline is the as-built scenario. Left: absolute variation; Right: relative variation.

3.4 Comparison with other retrofitting measures adopted

The EDPs obtained from the MSA analysis were introduced in PACT to carry out the performance-based loss assessment for all the AMD scenarios herein considered, and compared with the results of both the as-built and the base-isolation retrofitting solution considered in Caruso et al (2023). The preliminary results of the loss analysis are reported in Table 1, which, it is noted, does not show or highlight the extremely significant (low-)invasiveness advantage of the AMD solution with respect to the base-isolation. In other words, whilst the base-isolation retrofitting strategy does manage to achieve a higher degree of reduction of the socio-economic-environmental impact of earthquakes on this specific building, it also imposes a very significant level of disruption, given that the building will not only have to be vacated for a lengthy period, but will also then require important post-seismic retrofit restoration works of non-structural elements and contents. Such type of disruption, inexistent with the AMD solutions, would in most cases render the base-isolation retrofitting strategy effectively unapplicable.

Table 1. PACT loss results. As-built and base isolation from Caruso et al (2023).

Loss results	As-built reference	Base isolation retrofit	AMD-1 retrofit	AMD-2 retrofit	AMD-3 retrofit
EAL (£/yr)	9,557	1,097	6,640	3,314	4,178
EAL (% ReC)	0.26	0.03	0.18	0.09	0.11
EAE (kg eCO ₂ /yr)	4,240	506	3,178	1,799	2,090
EAE (% ReI)	0.27	0.03	0.20	0.12	0.13
EALL (casualties/yr)	0.0082	0.0009	0.0060	0.0019	0.0042

Another interesting observation from the results shown in Table 1 is the confirmation that there is an optimum upper limit to the level of damping forces that one might wish to introduce with AMD devices; when the level of “restrain” introduced at the top of a building becomes too high, it might start having a counterproductive effect (due to the large local forces that are introduced at the top floors, and the ensuing damage), as the comparison between the results obtained with the AMD-3 configuration with respect to the AMD-2 one clearly shows.

4 CONCLUSIONS

This study is a first attempt to investigate the effectiveness of a novel AMD retrofit system considering environmental, economic, and social performance parameters in a multi-scenario analysis that considers both current technology and potential evolutions. The system was tested in a case study building from existing literature. The environmental evaluation was performed via a simplified LCA, limited to the embodied equivalent carbon emission.

The set of results obtained thus far are very encouraging; they show that, with the evolution of the AMD technology (see AMD-2 scenario considered above) and the natural decrease in the production cost of these devices, a significant reduction of life-cycle impact from earthquakes can be obtained with an essentially negligible level of invasiveness. The latter, it is reemphasised, is instead extremely high for traditional retrofitting solutions, which often discourages seismic retrofitting, with an ensuing high cost for society and the planet.

ABSTRACT: Given the current climate emergency, it is already well-known that retrofitting interventions on existing buildings should be aimed not only at reducing their operational energy consumption, but also at improving their seismic performance. Indeed, the environmental impact of repair and retrofitting activities after strong earthquakes, or other hazardous events, cannot be overlooked, especially in regions with high seismic hazard. Several multi-criteria decision-making (MCDM) approaches are available in the literature for the identification of optimal retrofitting solutions for buildings. Such methods typically consider a range of economic, social, and technical aspects that are assumed to be of interest to decision-makers (e.g. duration of works, architectural impact, need for specialised workers, etc.), however, the importance of including environmental indicators among the relevant decisional variables has been only recently explored. The present study shows the application to a case-study building of two alternative MCDM approaches (i.e. those recently developed by Caruso et al., 2021, and Clemett et al., 2023) for identification of optimal retrofitting strategies, accounting for energy efficiency and related environmental impacts. The main differences between the approaches are highlighted and discussed, in terms of considered decision-making parameters and corresponding weights, rankings of retrofitting options and identification of optimal retrofitting strategies.

1 INTRODUCTION

The recently adopted Paris Agreement on Climate represents the international commitment to mitigate the impacts of climate change by keeping the rise in the global average temperature ideally below 1.5°C above pre-industrial levels. Such ambitious target is expected to be achieved by at least halving global carbon emissions by 2030 and by reaching climate neutrality by 2050.

As it is already well known, the building sector is one the main contributors to global greenhouse gas (GHG) emissions, raw material depletion and waste production. In addition, repair and retrofitting activities after strong seismic or other hazardous events, can affect the environmental impact of buildings' operational life. In Italy, a large portion of the building stock was built after the second world war and prior to the introduction of modern seismic design codes. Such buildings, mostly reinforced concrete (RC) moment-resisting frames with unreinforced masonry infills, are extremely vulnerable to seismic events, and, at the same time, they have poor energy performance. For these reasons, retrofitting interventions on existing buildings should be aimed at reducing their operational energy consumption as well as at improving their seismic performance.

During the last years, the scientific community has made significant efforts to quantify earthquake-induced environmental impacts, typically not included in standard life cycle assessment (LCA) procedures, demonstrating their relevance, especially in regions with a high level of seismic hazard

(e.g. Belleri and Marini, 2016). In tandem, researchers have also recently been focusing on the development of combined/integrated energy and structural retrofitting solutions, acknowledging the importance of improving both performances towards increased sustainability and the advantage of shared construction activities (e.g. Marini et al., 2017; Menna et al., 2021; ReLUI5 WP5, 2019-2021).

In this ongoing research and development context, several multi-criteria decision-making (MCDM) approaches have been proposed in recent literature for the identification of optimal seismic and/or energy retrofitting solutions for buildings. Such methods, which usually do not consider seismic and energy retrofitting in an integrated manner, mostly consider economic, social, and technical criteria that are typically of interest to decision-makers (e.g. duration of works, architectural impact, need for specialised workers, etc.). Only recently, environmental indicators have been included among the relevant decisional variables in some MCDM methods.

The present study illustrates the application of two different MCDM approaches (i.e. those recently developed by Caruso et al., 2021, and Clemett et al., 2023) to a case-study school building in Central Italy, highlighting and discussing their advantages and disadvantages.

2 MULTI-CRITERIA DECISION-MAKING APPROACHES

The multi-criteria decision-making approach proposed by Clemett et al. (2023) provides a framework for considering the performance of alternative retrofitting strategies across a broad range of decision variables and uses a weighted average method to select the optimal solution. The decision maker is first asked to identify a set of relevant parameters, on which the performance of each retrofitting alternative will be evaluated. Each variable is then assigned a weighting factor based on how important it is to the decision maker (i.e. a larger weight factor indicates that a variable is assumed to be more important to the decision maker than one with a smaller weight). Weights can be determined using rigorous methods, such as the analytical hierarchy procedure (AHP) (Saaty, 1980) or based on engineering judgement. The ideal and least ideal solutions based on each decision variable are then identified (i.e., the best and worst performing retrofitting option for each decision variable) and compared with each retrofitting option considered (by calculating the n-space Euclidean distance between the decision matrix values for a design alternative and the ideal and least ideal alternatives). Lastly, once the relative closeness of each alternative to the least ideal solution is calculated, the option with the highest relative closeness (i.e., the farthest from the least ideal) is identified as the preferred solution. The decision variables proposed in Clemett et al. (2023), and corresponding weights, are: C1 – installation cost of the retrofit intervention (0.15); C2 – expected annual costs, including expected seismic losses, maintenance cost of retrofit components, and annual energy costs (0.19); C3 – life cycle environmental impacts, including contributions of retrofitting intervention (both installation and end of life), expected seismic losses, maintenance, and energy consumption (0.18); C4 – annual probability of failure (0.14); C5 – duration of works (0.13); C6 – architectural impact (0.06); C7 – need for specialised labour/design knowledge (0.05); and C8 – required interventions at the foundations (0.1). The considered weight vector was determined using AHP and the professional judgment of the authors (Clemett et al., 2023).

The MCDM for the identification of optimal seismic/energy retrofitting strategies for buildings proposed instead by Caruso et al. (2021), and further extended in Caruso et al. (2023), is based on four relevant decision-making parameters, namely, post-retrofit economic and environmental life cycle impacts (including both earthquake-induced losses and energy consumption, similar to decision variable C3 proposed in Clemett et al., 2023), payback period of the retrofit investment and expected life losses due to seismic hazard. Life cycle costs and carbon emissions are evaluated throughout the post-retrofit building's life cycle by summing up the contributions of retrofitting intervention (both installation and end of life), earthquake-induced losses, and operational energy consumption, all normalised by the total floor area of the building and its expected post-retrofit life. The payback period (PB) of the retrofit investment quantifies the number of years needed to recover the initial investment through the savings due to the retrofitting option adopted (e.g. reduction of seismic expected losses achieved through a seismic strengthening intervention). Lastly, the expected annual life losses (EALL) can be estimated through a chosen casualty model (e.g. ATC, 2018). Based on the above four parameters, the optimal retrofitting option for a given building can

be visually determined through the use of radar plots by checking the one with the smallest ensuing area, i.e. the one that concurrently minimizes all the considered variables. It is noted that the PB is normalised by the expected post-retrofit life of the given building, whilst the other three parameters are normalised by the as-built corresponding values.

3 CASE-STUDY APPLICATION

3.1 Case-study building: As-built seismic and energy performance assessment

The case-study school building is located in Isola del Gran Sasso d'Italia, Abruzzo, Italy, featuring one-way RC moment resisting frames with unreinforced masonry (URM) infills. The school consists of two aboveground stories and a small partial basement at the east end. The first and second floors each have an area of approximately 630 m² and interstorey heights of 3.75 and 4.25 m, respectively. The structure was built between the 1960s and 1970s, thus representing an example of typical Italian construction prior to the introduction of modern seismic design codes. A more detailed description of the building, along with architectural plans and elevations, can be found in Prota et al. (2020).

A numerical model of the case-study building for the seismic performance assessment was developed using OpenSees (McKenna et al., 2010), as presented in Figure 1. The model consists of flexural elements (i.e., beams and columns), beam-column joints (BCJs), a staircase, and URM infills. More information about the modelling of structural and non-structural elements of the case-study building can be found in the studies of Carofilis et al. (2020, 2021). A preliminary seismic assessment, carried out through pushover analyses (as further described in Clemett et al., 2023), identified the moment capacity of the BCJs at which tensile cracking occurs and the shear capacity of the short columns adjacent to the URM infills as the most critical structural weaknesses of the building. Following the preliminary assessment, a detailed seismic loss assessment was performed using multiple-stripe analysis (MSA) through the PEER performance assessment and calculation tool (PACT) (ATC, 2018).

Figure 1. Three-dimensional representation of the numerical model developed in OpenSees (taken from Clemett et al., 2023).

The energy performance of the case-study building was assessed using the EDILCLIMA software (EDILCLIMA, 2021). Most of the modelling parameters were defined by local design codes based on the building's occupancy typology. Four different thermal zones representing the basement, ground floor, first floor, and the stairwell were included in the model. All thermal zones were assumed to be heated, with heating set-point temperature of 20°C. Ventilation of the building was assumed to be provided naturally (i.e., no mechanical ventilation plant). The thermal properties of the envelope elements were determined by defining the stratigraphy of each component's constituent materials, and the ensuing total thermal transmittances (U-values) are summarized in Clemett et al. (2023). Thermal bridges were included to correct the two-dimensional heat flow that occurs at the intersections of different building elements (i.e. external wall elements, external and internal wall elements, external walls and RC columns, external walls and roof/

interstorey floors/ground floor, and external walls and windows). The heating energy was assumed to be supplied by a traditional natural gas boiler system. Domestic hot water was assumed to be provided by the same heating system used for space heating.

3.2 Seismic/energy retrofitting options

Following the preliminary seismic assessment, which identified the structural deficiencies of the building, four different seismic retrofit measures (SRMs) were designed and analysed. A description of each SRM is provided in Figure 2. For all SRMs, URM infills were separated from the RC frames by the provision of a seismic gap to eliminate column–infill interaction and reduce the shear forces acting on the columns. The design procedure for each SRMs and any associated assumptions are reported in previous studies (Carofilis et al., 2020; Clemett et al., 2022).

Regarding the improvement of the energy performance of the building, three different combinations of energy retrofit measures (ERMs) were considered. A summary of the ERMs adopted for each energy retrofit intervention is presented in Figure 2. Each intervention aims, simultaneously, at reducing heat losses to the external environment and at increasing the energy efficiency of systems operating within the given building. The invasiveness of each intervention increases from E1 to E3 to meet the performance requirements described in the Italian Ministerial Decree (Il Ministro Dello Sviluppo Economico, 2015).

Finally, the four seismic interventions were coupled with each energy intervention, leading to twelve possible retrofit alternatives, as illustrated in Figure 2. Each coupled intervention is designated by S_iE_j , where S_i and E_j correspond, respectively, to the reference number of the considered seismic and energy retrofit schemes.

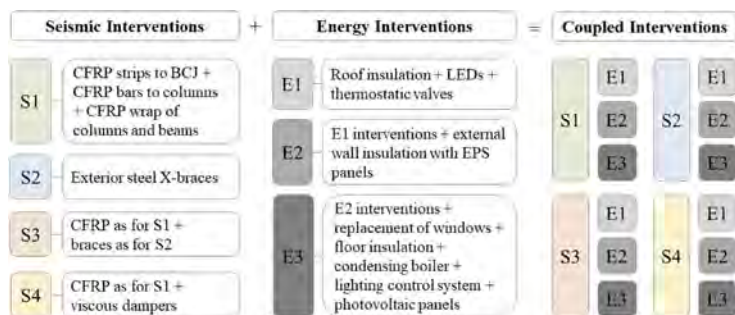

Figure 2. Summary of seismic (S_i), energy (E_i), and coupled interventions (S_iE_j).

3.3 Integrated assessment of the coupled retrofitting strategies

The seismic and energy performance of the twelve possible retrofit alternatives was herein assessed, with the following assumptions:

- SRMs were assumed not to be relevant for the energy assessment of the retrofitted building (for instance, S_1E_1 , S_2E_1 , S_3E_1 , S_4E_1 have the same energy performance);
- the influence of the ERMs on the structural response of the building was neglected, given that these types of measures mostly involve non-structural components (e.g. windows, lighting systems, etc.) not influencing the structural behaviour of the structure.

The impact of the SRMs on the seismic performance of the case-study structure was, at first, assessed through the employment of the N2 method and later through a comprehensive performance-based seismic assessment and loss analysis. The results of the preliminary assessment through pushover analysis have shown an increase of the base shear capacity of the structure at the life safety limit state for all SRMs, with the largest improvements given by S3 and S4, and an increase of the interstorey drifts due to the separation of the URM infills from the RC frames (still compliant with code-specified limits). The performance-based seismic assessment was then conducted through MSA, and, as a result, S4 showed the best improvement, with a noticeable reduction of peak floor accelerations (PFAs) and peak story drifts (PSDs) if compared to those of the as-built structure.

The energy performance of the building for each energy-retrofitted configuration was assessed using EDILCLIMA and the main results, consisting of the primary energy performance (PEC), equivalent CO₂ emissions, annual energy costs (AECs), and Italian energy class ratings, are summarized in Table 1. PEC represents the total energy consumption of the building and it is used to determine the corresponding energy class rating. Classes are represented by a 10-letter scale (A4-G) and are assigned based on the performance of the building compared to that of a reference building with the same geometry and occupational class but with code-defined energy efficiency minimum requirements. By comparing the results obtained for the as-built configuration with the ones from each energy retrofitting option, the improvements of the energy performance are noticeable, progressively increasing from E₁ to E₃, in line with the severity of the intervention.

Table 1. Energy performance assessment summary results for each energy retrofitting option.

Option	PEC (kWh/m ²)	Eq. CO ₂ (kgCO ₂ e)	AEC (€)	Energy Class
As-built	309	76,651	12,718	E
E ₁	221.76	52,476	8,765	D
E ₂	166.63	40,716	7,121	C
E ₃	64.92	14,982	3,109	A2

Finally, a detailed seismic loss assessment was performed through the PACT calculation tool (ATC, 2018) for each combination of seismic and energy retrofit interventions. The presence of ERMs was accounted for in the seismic loss assessment in terms of additional repair consequences to specific non-structural components and in an increased building value (as seen in Table 2). Both parameters increase with the severity of the intervention (from E₁ to E₃). The influence of ERMs on the loss assessment was also considered as described in Clemett et al. (2023).

Table 2. Replacement cost and environmental impacts (EIs) for the as-built and retrofitted structures.

Option	Replacement cost (€)	Replacement EI (kgCO ₂ e)
As-built	2,652,242	1,830,000
S _i E ₁	2,700,684	1,867,485
S _i E ₂	2,792,918	1,888,749
S _i E ₃	2,858,340	1,982,159

The main results of the seismic loss assessment are presented in Table 3 in terms of expected annual loss (EAL), expected annual environmental impacts (EAEI), annual probability of failure (APF), and expected annual loss of life (EALL), which will be then used to apply the MCDM methods described previously.

Table 3. Loss assessment summary results for each combined intervention.

Option	EAL (€/yr)	EAEI (kgCO ₂ e/yr)	APF (10 ⁻² yr ⁻¹)	EALL (p/yr)
As-built	34,151	23,344	1.002	0.2665
S ₁ E ₁	6,775	4,240	0.166	0.0832
S ₁ E ₂	7,320	4,634	0.187	0.0832
S ₁ E ₃	7,478	4,755	0.181	0.0832
S ₂ E ₁	15,897	10,099	0.455	0.1851

4 OPTIMAL INTEGRATED RETROFITTING STRATEGIES

4.1 Decision variables

Table 4 summarises the decision variable values used in the Clemett et al. (2023) methodology, as well as the resulting ranking (R). The option ranked as 1 (i.e. S₄E₃) is the optimal solution, while the option ranked as 12 is the worst one. In turn, Table 5 summarises the decision variable values used in the Caruso et al. (2021) methodology as the ranking of each alternative, while Figure 3 shows the radar plots for three coupled retrofitting intervention (i.e. S₁E₁, S₃E₃, S₄E₃), those representing the best and the worst solutions, and an intermediate one. The red dashed lines indicate the as-built configuration, for which the normalised parameters are equal to 1 (except for the PB, where the unit value refers to the expected post-retrofit life, which here is assumed as 20 years). Option S₄E₃ resulted to be the optimal solution, based on its ensuing area in radar plots.

Table 4. Decision variable values to be implemented in Clemett et al. methodology.

Option	C ₁ (€)	C ₂ (€/yr m ²)	C ₃ (kgCO ₂ e/ yr m ²)	C ₄ (10 ⁻² yr ⁻¹)	C ₅ (days)	C ₆ (-)	C ₇ (-)	C ₈ (-)	R
S ₄ E ₃	817,230	14.22	16.99	0.068	48	0.1617	0.1511	4.77	1
S ₄ E ₂	645,245	16.43	34.27	0.074	44	0.1617	0.1511	4.77	2
S ₄ E ₁	584,415	17.05	42.12	0.079	44	0.1617	0.1511	4.77	3
S ₃ E ₃	529,907	16.10	19.67	0.274	46	0.0934	0.0844	16.61	4
S ₃ E ₂	357,922	17.74	36.56	0.266	42	0.0934	0.0844	16.61	5
S ₂ E ₃	416,678	16.68	21.52	0.437	29	0.0555	0.0135	16.54	6
S ₃ E ₁	297,092	18.07	44.19	0.246	42	0.0934	0.0844	16.61	7
S ₂ E ₂	244,694	18.83	38.83	0.470	24	0.0555	0.0135	16.54	8
S ₂ E ₁	183,863	19.48	46.57	0.455	22	0.0555	0.0135	16.54	9
S ₁ E ₃	1,462,370	14.45	23.49	0.181	65	0.0227	0.0844	5.71	10
S ₁ E ₁	1,229,555	16.87	48.28	0.166	61	0.0227	0.0844	5.71	11
S ₁ E ₂	1,290,386	16.55	40.72	0.187	61	0.0227	0.0844	5.71	12

4.2 Comparison of results obtained with the two MCDM approaches

From both methods, the optimal solution is S₄E₃, which couples the global energy retrofitting intervention (roof, floors and walls insulation + LEDs + thermostatic valves + new windows + condensing boiler + lighting control system + photovoltaic panels) and the structural intervention with CFRP and viscous dampers. However, some differences can be found in the above-presented rankings.

Table 5. Decision variable values to be implemented in Caruso et al. methodology.

Option	Life cycle costs (€/yr m ²)	Life cycle emissions (kgCO ₂ e/yr m ²)	PB (years)	EALL (p/yr)	R
S ₄ E ₃	36.03	28.48	23	0.0346	1
S ₄ E ₂	31.95	42.86	20	0.0346	2
S ₃ E ₁	23.73	49.51	11	0.1321	3

Figure 3. Examples of radar plots: normalized post-retrofit costs (C), carbon emissions (CE), payback period (PB) and expected loss of life (EALL) of three retrofitting configurations (i.e. S_1E_1 , S_3E_3 , S_4E_3).

The ranking of alternatives obtained by applying the Clemett et al. (2023) methodology shows that, from the seismic viewpoint, S_4 performs always better than S_3 , S_3 better than S_2 , and S_2 better than S_1 . Regarding the energy performances, instead, E_3 is preferred over both E_1 and E_2 . The surpassing of S_2E_3 over S_3E_1 on the ranking list demonstrates the higher benefits of the energy performance improvement of E_3 over the improved structural performance of S_3E_1 . Among the eight decision variables, S_4E_3 was observed to be the best solution based on four of them, namely: expected annual costs (C2), life cycle environmental impacts (C3), annual probability of failure (C4) and required intervention at the foundations (C8).

When applying the Caruso et al. (2021) methodology, from the structural viewpoint, S_1 is always the worst option, but the other solutions led to different results. S_2 and S_3 perform well in terms of life cycle costs and payback periods, moderately in terms of life cycle emissions, and inadequately in terms of EALL when compared to other solutions. S_4 , instead, has yielded the lowest EALL values, and performed moderately on all the other variables. From the energy point of view, E_3 is not always the best solution, since it has very high costs (thus a high PB) and environmental impacts due to installation. Moreover, E_3 solutions foresee seismic economic losses that are more relevant than costs of energy consumption, whereas the opposite occurs in terms of environmental impacts. Among the four considered decision variables, S_4E_3 was observed to be the best solution based on two of them, i.e. life cycle carbon emissions and expected annual loss of life.

The application of both methods has highlighted some relevant differences, not only in the results, but also in the approach. Concerning costs, it is noted that in the methodology of Clemett et al. (2023) the costs of installation (C1) and other costs (C2) are not considered as a single decision-making variable (as the life-cycle costs in Caruso et al. (2021)), whereas C3 refers to the total life-cycle EI (similar to life-cycle carbon emissions in Caruso et al. (2021)). In addition, in Caruso et al. (2021) the post-retrofit life is assumed to be 20 years, whereas in Clemett et al. (2023) the code-based nominal building life is considered (i.e. 75 years). Lastly, in the methodology of Caruso et al. (2021) costs and environmental impacts due to maintenance of retrofitting components are not included.

Concerning the decision variables used, one last observation is related to the weights assigned to each variable and the ensuing results. In the Caruso et al. (2021) method, all four variables are assumed as equally important, thus a 25% weight is assigned to each of them. On the other hand, economic parameters in Clemett et al. (2023) (i.e. C1+C2) have a total weight of 34%, whereas life-cycle environmental impacts have a weight of 18% and the annual probability of collapse of 10%. The overall similarity between the results from the two methods may be related to the fact that the highest weights are assigned to similar (economic, environmental and social) parameters.

Lastly, in the Clemett et al. (2023) approach a relative comparison is made between the options, i.e. the optimal solution is identified based on the relative closeness to an ideal solution that is the best in the considered range. On the contrary, in the Caruso et al. (2021) approach, every retrofitting option is compared to the as-built configuration (through the normalisation of variables).

5 CONCLUSIONS

Several multi-criteria decision-making (MCDM) approaches have been recently proposed in the literature for the identification of optimal retrofitting strategies for existing buildings. The present study demonstrates the application to a case-study building of two alternative MCDM approaches (i.e. those recently developed by Caruso et al., 2021, 2023, and Clemett et al., 2023), which account

for economic, environmental, and social aspects that are assumed to be of interest to decision-makers (e.g. running costs and environmental impacts, duration of works, architectural impact, need for specialised workers, etc.). An existing school building, located in Central Italy, representative of typical Italian construction prior to the introduction of modern seismic design codes was analysed with twelve integrated retrofitting options, and the two MCDM approaches were used to identify the optimal retrofitting solution. The optimal solution given by the application of both methodologies was observed to be S_4E_3 , which couples the global energy retrofitting intervention (roof, floors and walls insulation + LEDs + thermostatic valves + new windows + condensing boiler + lighting control system + photovoltaic panels) and the structural intervention with CFRP and viscous dampers. Despite this global agreement, some differences between the approaches were found, mostly in terms of the type of decision variables considered, the definition of economic decision variables and expected post-retrofit building life, the weights assigned to each decision variable of interest, and the methodology with which the alternative retrofitting options are compared.

ACKNOWLEDGEMENTS

This research was funded by the Italian Civil Protection Department (Dipartimento della Protezione Civile), within the framework of the ReLUIS-DPC 2022–2024 research project, more specifically its WP5 activities (focused on the development and verification of integrated seismic and energy retrofitting solutions) and by the Portuguese Foundation for Science and Technology, through the project SERENE - 2022.08138.PTDC.

Multi-stakeholder service life design for rail level crossings

Y. Shang, R. Binnekamp & A.R.M. Wolfert

*Department Materials, Mechanics, Management Design, Faculty of Civil Engineering & Geosciences,
Delft University of Technology, Delft, The Netherlands*

ABSTRACT: Improvement in rail asset safety, comfortability and serviceability is gaining importance. This requires effective service life management by incorporating multi-stakeholder desires in the early design stage. Typical stakeholders are asset owners, train users and maintenance service providers. To allow for this change, the traditional single-sided engineering mechanics track design approach requires a shift towards an integrative design approach that best fits for common purpose while assuring continuous rail asset performance. Within the current paper, a multi-objective simulation-based optimization methodology that combines finite element modeling with preference function modeling is proposed to integrate multi-stakeholder preferences into the service life design. The applicability of the methodology is demonstrated in a design case for level crossings. It is shown that integrating specific stakeholders' preferences will substantially influence the optimal track design configuration, allowing the level crossing design to be managed focusing on best fit for common purpose rather than on mechanical behavior only.

1 INTRODUCTION

Transition zones in a railway network occur at changes in track form and or substructure properties. Examples can be found where a track transits from the open track (normally of the ballast type) to a slab track section to cross a roadway or waterway through supporting structures such as bridges and level crossings. The variation in track form causes a sudden change in track support stiffness, which gives rise to additional dynamic forces when vehicles pass by, associated with a change in elevation of the wheels. This, over a number of loading cycles, leads to the development of differential settlement between the (settlement-free) supporting structures and connecting track, which further increases loads and accelerates track degradation through successive deterioration of track geometry and components (Le Pen et al., 2014).

A typical design guiding principle for mitigating the transition problems is to reduce the dynamic amplification by smoothing stiffness variations along the track. This can be achieved by modifying railpad stiffness, varying sleeper sizes, and installing under sleeper pads at transitions (Indraratna et al., 2019). Amongst these measures, incorporating elastic elements (e.g., the railpads) with different properties can be considered an efficient means to vary track vertical stiffness and dampen vibrations and noise (Sol-Sánchez et al., 2015). Besides, sleepers act as supporting elements to distribute vehicle loads on the track. The design parameters such as spacing and size are also relevant to the local track dynamic behavior. For instance, a reduction in sleeper distances causes an increase in track (vertical) support stiffness, which however also implies more construction costs. As Ortega et al. (2021) reported, the separation of 1 m per spacing results in a 40% cost reduction per km compared to the standard sleeper spacing (0.6 m).

Parametric variations can effectively provide a design solution that allows for a homogeneous distribution of stiffness throughout the track, reducing the dynamic impact in the vehicle-track system and improving long-term track performance. This further reduces the associated maintenance efforts/costs, relevant to the management goals of maintenance service providers. Besides, as

system dynamics are interactive between the vehicles and track, the level of track dynamic amplification also influences the vehicle system responses, e.g., carbody accelerations, which relate closely to the driving comfort of passengers and hence the level of service.

The above impact of variations in track design reflects multi-stakeholder desires. It demonstrates that the railway track design requires an integrative approach incorporating both rail asset feasibility (technics) and stakeholder desirability (e.g., affordability, serviceability). However, the traditional ways of designing the transitions (or the railway track in general) mainly focused on meeting one single technical objective. The mitigation measures for the transitions are mainly developed based on mechanical responses such as wheel-rail contact forces without considering related social needs.

The current study proposes a novel way of integrating hard engineering and soft social aspects to model design problems for railway track structures. Since stakeholder objectives might be conflicting (where no single design solution exists that simultaneously satisfy all), integrating multi-perspectives to evaluate track design alternatives requires optimization techniques to balance stakeholders' preferences and actual rail structural performance. For this purpose, a preference-based optimization tool is combined with a finite element (FE)-based model to capture a wider variety of design aspects. The former translates vague societal needs into crisp engineering design variable values. The FE model characterizes the track dynamic behavior under moving vehicles and serves as a basis for parametric optimization.

2 METHODOLOGY

2.1 Overview - problem definition

The relationship between track input parameters and dynamic responses can be defined by

$$\mathbf{y} = g(\mathbf{x}) \quad (1)$$

where $\mathbf{x} = (x_1, x_2, \dots, x_n)$ is a vector containing a list of track parameters defined in n -dimensional space, e.g., railpad stiffness, sleeper spacing. $\mathbf{y} = (y_1, y_2, \dots, y_k)$ is the vector collecting k responses of interest. Eq. (1) is defined by a FE model, which is introduced in Section 2.2.

Three stakeholder groups are of high relevance in railway service life management, i.e., asset owners, train users, and maintenance service providers. Their interests can be reflected in investment cost, riding comfort, and long-term track performance, respectively (see Table 1).

Table 1. Objectives and performance measures.

Objectives	Performance measures	Unit
Minimize initial investment	C_{cap} - investment cost	€
Maximize riding comfort	A_{max} - max-to-min of carbody acceleration	m/s ²
Minimize expected long-term degradation	E_{max} - max. differential energy dissipation	N·m

Specifically, 1) the sleeper spacing and number of strengthened sleepers in a transition can influence the investment cost. 2) The riding comfort is quantified by *max-to-min difference of carbody accelerations* induced when a vehicle passes through a transition. The lower the carbody accelerations, the higher level of service is expected. 3) The long-term degradation mainly concerns the damage to the ballast layer, as it is the main driver causing track geometry degradation in the transitions. This can be directly related to the mechanical energy dissipated in the ballast layer. The *maximum differential energy dissipation* between adjacent sleepers is selected here as an indicator to assess the sensitivity of a track design to the expected damage (Sadri et al., 2019). The higher the energy dissipated into the ballast layer, the stronger the degradation can be expected. Therefore, reducing the amount of dissipated energy represents an important aim for damage reduction in overall track geometry condition and savings in maintenance efforts/costs.

The objective C_{cap} is evaluated through an explicit function, which is elaborated in Section 3. A_{max} and E_{max} are quantities generated from numerical simulations, where an FE-based model is developed (Section 2.2) to model the coupling dynamics between the vehicle and track.

2.2 Modeling of vehicle-track dynamics

A numerical model is developed to simulate vertical dynamic interaction between the railway track and moving vehicle, which is parametric for optimization purposes. As shown in Figure 1, the vehicle is represented by a multi-body system consisting of a carbody, a bogie, and a wheel, which are connected through suspension systems. The vehicle travels at a constant speed on a ballast-slab transition. The load from the vehicle is assumed to be symmetrically distributed, and consequently, half of the track is studied in this work.

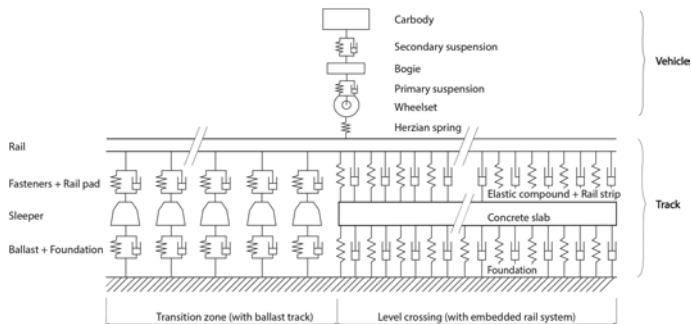

Figure 1. Schematics for a vehicle and a ballast-slab transition.

The track structure is formulated by FEM: the ballast track (left) is represented by a two-layer discretely supported model, and the slab track (right) is continuously supported according to system features of the embedded rail system (ERS). Various design options are available for slab track structures. We consider ERS in this work as it is an innovative track design solution and has been increasingly employed in discrete railway assets such as bridges and level crossings. For details of the ERS features, the reader is referred to Yang et al. (2021).

In the model, the rail and concrete slab are meshed with Euler-Bernoulli beam elements. The supporting components in the ballast track consist of railpads represented by Kelvin-Voight (KV) elements, sleepers as masses, and underlying ballast and foundation layer modelled collectively as the KV elements. Similar to the railpads in the ballast track, elastic compound and rail strip in ERS are placed underneath the rail to provide track elasticity and constrain the vertical rail deflection, which is also modelled by the KV elements, as proposed in Yang et al. (2021).

The vehicle-track interaction problem is solved by integrating the two subsystems into a global system, where the individual system matrices are coupled to formulate global ones, and the global equations of motion (EOM) can be expressed as

$$\mathbf{M}_g \ddot{\mathbf{U}}_g + \mathbf{C}_g \dot{\mathbf{U}}_g + \mathbf{K}_g \mathbf{U}_g = \mathbf{F}_g \quad (2)$$

where \mathbf{M}_g , \mathbf{C}_g and \mathbf{K}_g denote, respectively, the mass, damping, and stiffness matrices of the global system. \mathbf{U}_g , $\dot{\mathbf{U}}_g$ and $\ddot{\mathbf{U}}_g$ are the displacement, velocity, and acceleration vectors of the global system, respectively. \mathbf{F}_g is the global force vector.

The track model is developed in COMSOL, where the system matrices are formulated and exported to MATLAB. The vehicle system matrices are established in MATLAB, which are then coupled with the exported track matrices to formulate the global ones, as written in Eq. (2). The global EOM is solved in the time domain using the Newmark integration method, which is implemented in MATLAB. This co-simulation methodology of connecting COMSOL and MATLAB to solve vehicle-structure dynamics was first developed and validated with a beam case by Shang

et al. (2022) and extended to a railway structure by Shang et al. (2023). The reader is referred to these works for extensive descriptions of the coupling method.

2.3 Preference based design optimization

Multi-objective design optimization (MODO) applies to decisions that need to be taken in the presence of trade-offs between several objectives. This applies to all types of design scenarios, including the railway track design. Various methods have been devised to solve MODO problems, which can be categorized depending on how the designer articulates the preferences, i.e., a priori and a posteriori articulation of preferences. *A priori* articulation indicates that the relative importance of the objective functions is specified before running the optimization. In cases where no a priori information is available, it is adequate to map all potential solutions and allow the designer to make a decision afterward. Such methods are referred to as *a posteriori* methods.

A priori methods are reflected by parameters such as weights and aggregation scores (Zhilyaev et al., 2022; van Heukelum et al., 2022). The weighted min-max (or goal attainment) approach is a common solution technique in *a priori* methods. The basic idea is that the designer specifies a target value (i.e., the goal) for each objective, and the ‘min-max’ seeks to find a solution that minimizes the maximum deviation between the target values for the objectives and values of a candidate solution. When it is applied in the preference-based decision-making domain, all the solutions are mapped by preference scores on a 0-100 scale, and the value of 100 implies the goal. This solution mapping essentially translates the stakeholder preference into deviation from the goal in relative terms, and the minimization of the largest deviation can be formalized as

$$\underset{\mathbf{x}}{\text{minimize}} \quad U = \max_i \{w_i \times [100 - P_i(g_i(\mathbf{x}))]\} \quad (3)$$

where $g_i(\mathbf{x})$ represents the value of i^{th} ($i = 1, 2, 3$) objective (see Table 1) given a specific design configuration \mathbf{x} . $P_i(\cdot)$ is the preference function corresponding to i^{th} objective. It translates $g_i(\mathbf{x})$ to a preference measurement, where stakeholder preference information is encoded in the function and used to rank design solutions. w_i is the weight associated to i^{th} objective.

In each single run, the ‘min-max’ approach produces a single best solution, representing the best compromise among stakeholders. To provide more flexibility in the decision making process, a posteriori articulation is integrated as an alternative in the proposed methodology to solve the MODO problem. Techniques based on genetic algorithms (GA) seem suitable for solving MODO as they can simultaneously handle a set of potential solutions (or a population). This allows the designer to find several members of the Pareto set in a single run of the algorithm (Chang, 2014). The GA-based approaches have extensive applications in railway mechanics, such as the design of vehicle suspensions (Alkhatib et al., 2004), switches and crossings (Pålsson & Nielsen, 2012), and a ballast-slab transition (Aggestam & Nielsen, 2019).

One of the most popular GA-based approaches for MODO is the Nondominated Sorting Genetic Algorithm II (NSGA-II) developed by Deb et al. (2002). The process includes the creation of the initial population and design iterations. Initial individuals are randomly created, and function evaluations are performed for each individual, which is then sorted based on two attributes: non-domination rank and crowding distance. The non-domination rank of an individual is assigned by comparing its function value with the rest. The lower rank (higher fitness) is preferred between two solutions with different ranks. Further, the crowding distances apply when the solutions are in the same rank, and the solution in a less crowded area is preferred. The computation of the two entities guides the selection process at each iteration toward a uniformly spread-out Pareto front (Chang, 2014). Further details of the sorting process are referred to Deb et al. (2002).

2.4 The Kriging metamodel

Applying optimization algorithms in railway mechanics is in general a computationally demanding task. Simulating railway mechanics often requires advanced computational methods, e.g., FEM and discrete element method. The evaluation of these models can be time-consuming and

even more challenging when vehicle-track interaction is considered (as is the general case in transition-related works). To keep the computational cost affordable, metamodeling techniques are integrated into the current methodology, which can provide accurate approximations to the responses of the FE model (see Section 2.2) at reduced computational time.

Metamodeling (also known as surrogate modeling) is frequently used across engineering disciplines in combination with physical experiments or expensive simulation models. Due to the computational efficiency (than the original model), it often supports engineering tasks that require the design space exploration, such as design optimization, model calibration and reliability analysis.

The effectiveness of using metamodels is interconnected with the problem types and modeling conditions (e.g., dimensionality, (non)linearity, sample size). Kianifar & Campean (2020) systematically compared the performance of several metamodeling options in relation to the well-defined problem categories, where the Kriging model with Matérn 5/2 correlation function shows competing performance among the candidates in terms of accuracy and robustness. Therefore, we choose the Kriging model in this work to approximate Eq. (1), which can be expressed as

$$\hat{g}(\mathbf{x}) = \mathbf{f}^T(\mathbf{x}) \boldsymbol{\beta} + Z(\mathbf{x}) \quad (4)$$

where $\hat{g}(\mathbf{x})$ is the approximation of $g(\mathbf{x})$ predicted by the Kriging. $\mathbf{f}^T(\mathbf{x}) \boldsymbol{\beta}$ is the mean value of $\hat{g}(\mathbf{x})$, including q arbitrary functions $\{f_j; j = 1, \dots, q\}$ and the corresponding coefficients $\{\beta_j; j = 1, \dots, q\}$. It represents the global characteristics (the trend) of the model. $Z(\mathbf{x})$ captures the local deviations by a Gaussian process with expectation being zero and variance being σ^2 .

For a single objective, when training samples $\mathbf{x} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_m\}^T$ are determined, the corresponding output $\mathbf{y} = \{y_1, y_2, \dots, y_m\}^T$ can be obtained by querying the FE model at \mathbf{X} . This forms a training set $\Phi = \{(\mathbf{x}_i, y_i) | i = 1, \dots, m\}$, and the covariance of $Z(\mathbf{x})$ can be given by

$$\text{cov}[Z(\mathbf{x}_i), Z(\mathbf{x}_j)] = \sigma^2 R(\mathbf{x}_i, \mathbf{x}_j) \quad (5)$$

where $R(\mathbf{X}_i, \mathbf{X}_j)$ is the correlation function for any pair of $(\mathbf{X}_i, \mathbf{X}_j)$. The Matérn 5/2 correlation function is used given its accuracy and robustness as evaluated by Kianifar & Campean (2020).

3 ILLUSTRATIVE EXAMPLE: A RAIL LEVEL CROSSING

3.1 Optimization problem formulation

A level crossing design case is selected to demonstrate the application of the proposed methodology. A ballast-slab transition is often presented in a level crossing, where the ERS design (with concrete slabs installed to replace the ballast layer) is applied for crossing traffic. This poses an abrupt variation in track support stiffness since the connecting section is of the ballast type. The current optimization problem is therefore formulated to achieve a smooth stiffness transition between the connecting ballast track and ERS-based level crossing.

The design variables are listed in Table 2, which are collected in a design vector \mathbf{X} ($\mathbf{X} = [x_s, x_r, x_{r1}, x_{r2}, x_{r3}, x_l]$). The variable x_l is specific to ERS design, while the others are related to the ballast track. The rail strips in ERS are elastic components underneath the rails, similar to the railpads in the ballast track. Two types of rail strips with predefined stiffness properties have been developed for ERS. The current practice in the Netherlands utilizes type I strip, and the effect of applying (softer) type II strip on the mechanical behavior of level crossings is under investigation. It is also worth mentioning that the variables x_s and x_l are treated as discrete values to align the optimization setting with the FE discretization. The value implies the number of 0.05m-long finite elements. The lower bound of x_s means 0.5 m, and the upper bound is 0.7 m. This range is considered reasonable and can maintain structural integrity, according to Ortega et al. (2021). x_l has a lower bound of 0 and upper bound of 6 m, implying that a 6-m level crossing is considered in the example.

The track parameters in the FE model are defined according to a typical Dutch level crossing design. The vehicle parameters refer to VIRM trains, which are double-deck trains operated by Dutch Railways. For details of the parameter setting, the reader is referred to Shang et al. (2023).

Table 2. Definition of design variables.

Variables	Unit	Range of definition	Related objectives
Sleeper spacing (x_s)	-	$x_s \in \mathbb{Z} : x_s \in [10, 14]$	$A_{max}, C_{cap}, E_{max}$
Number of strengthened sleepers (x_n)	-	$x_n \in \mathbb{Z} : x_n \in [0, 15]$	$A_{max}, C_{cap}, E_{max}$
Railpad stiffness ($x_{r_i}, i = 1, 2, 3$)	MN/m	$x_{r_i} \in \mathbb{R} : x_{r_i} \in [50, 1000], i = 1 \dots 3$	A_{max}, E_{max}
Length of type II rail strip (x_l)	-	$x_l \in \mathbb{Z} : x_l \in [0, 120]$	A_{max}, E_{max}

Three objectives (see Table 1 and 2) are considered in the optimization. Two Kriging meta-models are established to approximate E_{max} and A_{max} , respectively. Initially, 2000 points of \mathbf{x} are generated based on Latin Hypercube sampling. The FE model is queried at these input locations to generate the quantities of E_{max} and A_{max} . The input-output formulates a dataset further split into training, validation, and test sets. The Kriging parameters are tuned based on the leave-one-out (LOO) cross-validation (CV) approach using the training and validation data. The model performance is evaluated on the test set using relative training error, which yields 2% and 1% for the metamodels of predicting E_{max} and A_{max} , respectively.

The objective C_{cap} is calculated depending on x_s and x_n . 1) x_s is varied within a 5-m section adjacent to the level crossing. Ortega et al. (2021) analyzed the effect of sleeper spacing (x_s) on construction cost savings. A brief resume of cost reduction in spacing alternatives was reported compared with the standard spacing (0.6 m). This work utilizes this cost relation, where the total cost of placing sleepers with the standard spacing is assumed as €3000, and the costs for other spacing alternatives are calculated based on the cost ratio provided by Ortega et al. (2021). 2) x_n concerns the number of strengthened sleepers in the transition. It is assumed that the cost ratio between the strengthened and normal type is 1.5 and the unit cost of using the normal sleeper in the transition region is €400.

3.2 Results and discussion

Single-objective optimization problems are firstly solved, and the results are presented in Table 3. The optimum produced from Alt. 1-3 represents the preferred track design solution for maintenance service providers, train users, and asset owners, respectively. The maximization problems in Alt. 4-6 are solved to gather extremes for each objective and facilitate the association of a preference function to each objective in the following multi-objective problem formulation.

Table 3. Design solutions and corresponding objective values from single-objective optimization. Optimal values are highlighted for each problem.

Design alternatives	Design solutions	Objective values		
	$\mathbf{x}=[x_s, x_n, x_{r1}, x_{r2}, x_{r3}, x_l]$	$E_{max}(N)$	$A_{max}(m/s^2)$	$C_{cap}(€)$
Alt. 1: E_{max} minimization	$\mathbf{x}=[13,6,139,179,50,30]$	0.1107	0.2300	9967.7
Alt. 2: A_{max} minimization	$\mathbf{x}=[10,3,74,50,50,0]$	0.1814	0.2148	10013
Alt. 3: C_{cap} minimization	$\mathbf{x}=[14,0,78,78,0]$	0.2836	0.2529	8562.2
Alt. 4: E_{max} maximization	$\mathbf{x}=[14,0,885,50,1000,41]$	1.3880	0.2332	8562.2
Alt. 5: A_{max} maximization	$\mathbf{x}=[14,4,50,593,792,84]$	0.6909	0.2570	9362.2
Alt. 6: C_{cap} maximization	$\mathbf{x}=[10,15,78,78,78,0]$	0.2160	0.2136	12413

The optimization of C_{cap} depends on variable x_s and x_n only (as highlighted in Design solutions to Alt. 3&6), and the remaining variables are fixed as default values. It can be observed that C_{cap} is conflicting with the other objectives: the design with larger sleeper spacing and ‘zero’ use of strengthened sleepers is preferable from a cost perspective; however, it does not help reduce expected damage in the ballast (E_{max}) and maintain the level of train service (A_{max}).

By comparing the solutions from Alt. 1-2 and Alt. 4-5, the first observation is that softer railpads ($x_{r_i}, i = 1, 2, 3$) are recommended to reduce the dynamic impact in the vehicle-track system. In Alt. 1, the optimum of x_{r3} is far less than those for x_{r1} and x_{r2} . x_{r3} refers to the stiffness of the

railpad adjacent to the crossing, and the optimum is linked to x_l . $x_l = 30$ means a 1.5m-long type II (softer) strip is recommended in connection with a soft railpad (x_{r3}) in the ballast track. This allows for a homogeneous distribution of track support stiffness. Hence, a lower effect of load transmitted to the ballast layer can be expected (i.e., reduced E_{max}). It also explains the optimal solution in Alt. 4, where a contradicting outcome is produced. Compared to Alt. 1, Alt. 2 suggests not using the softer strip in ERS in order to minimize A_{max} . The reason could be that E_{max} focuses on the dynamics in track underlayers while A_{max} relates to the upper vehicle dynamics.

The objective values in Table 3 show that by minimizing C_{cap} (Alt. 3), E_{max} and A_{max} will deviate from their minimum; however, E_{max} can be minimized without degrading A_{max} too much (Alt. 1). This can be explained by the interactive dynamics between the vehicle and track structure, i.e., the objectives E_{max} and A_{max} are correlated. It is also worth mentioning that the objectives considered depend on different design variables: C_{cap} is influenced by x_s and x_n only, while the others depend on the entire variable set. Therefore, the competing nature of these objectives can be observed but optimizing one does not necessarily lead to the opposite extremes of the others. Still, the MODO formulation is required as trade-offs are presented between the objectives.

In the MODO, a linear preference function is assigned for each objective. The max and min of each objective are used to construct a reasonable range for associating a preference function to an objective. For example, as shown in Figure 2 (a), for maintenance service provides, the preference for E_{max} of 0.1 equals 100, representing the desired level, and the preference for E_{max} of 1.4 equals 0, which is the worst scenario that should be avoided.

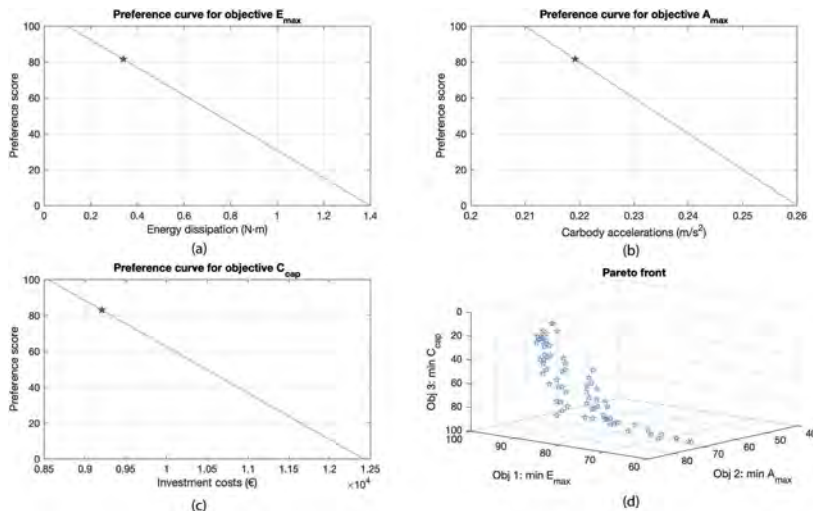

Figure 2. MODO outcomes: preference curve for objective (a) E_{max} , (b) A_{max} , and (c) C_{cap} including the optimum obtained from a priori min-max method; (d) Pareto front for three objectives from a posteriori GA-based approach.

The optimal objective values from the minmax method are also marked on the preference curves in Figure 2 (a)-(c), where equal weights are assigned. The objective scores are almost equal (~82), with $E_{max} = 0.3398$, $A_{max} = 0.21982$, and $C_{cap} = 9207$. Compared with the outcomes from single-objective problems (Table 3), it illustrates the rationale behind the goal attainment paradigm: the method seeks to find a balanced solution among the stakeholders. Besides, the solution is $\mathbf{X} = \{11, 0, 89, 50, 50, 53\}$, showing that the soft railpads and strips (x_{ri} , x_{ji} , $i = 1, 2, 3$) are recommended from both the single-objective and MODO problems at the junction between the level crossing and transition. However, compared with the single-objective problems, MODO formulation that integrates the stakeholders' preferences substantially influences the solution to sleeper parameters (x_s and x_n), since the variables have an actual influence on the objective C_{cap} and it is conflicting with the others.

The Pareto front generated from NSGA-II is presented in Figure 2 (d). It shows that none of the objective functions can be improved in value without degrading some of the other objective

values. The solutions mapped on the front are equally good, allowing the designer to make a decision afterward.

4 CONCLUSIONS

Effective service life management of railway assets requires multi-stakeholder desires to be incorporated into the early design stage. This necessitates an integrative design approach that incorporates both rail asset feasibility and stakeholder desirability. For this purpose, the current work presents a novel way of integrating hard engineering and soft social aspects to model design problems for railway track structures. Three representative stakeholder groups and respective interests are defined in terms of railway mechanics, affordability, and serviceability. The perspectives are translated to preference measures, which are further used to formulate design optimization problems. Three techniques, namely, FEM, metamodeling, and preference-based modeling, are integrated into the optimization framework, which seeks to find optimal design configurations that balance stakeholder preferences and actual track performance in a reasonable computational effort. A level crossing design case is provided, where the obtained design solutions demonstrate relevance to stakeholder preferences and long-term track performance. It shows that the proposed methodology allows the track design to be managed focusing on best fit for common purpose rather than on mechanical behavior only. The case study is for demonstration purposes, and the design methodology is applicable to other railway asset types.

ABSTRACT: Floating wind farms are a promising solution for offshore wind energy production in deep waters. However, the design optimisation process of these farms is difficult due to their complex and multidisciplinary nature. Furthermore, current optimisation methods: 1) ignore and/or provide no insight into the dynamic interplay between the preference-dominated management domain and the object-performance-dominated engineering domain; 2) are limited to evaluating potentially sub-optimal design alternatives; 3) contain fundamental aggregation modelling errors; 4) do not return a single optimal design point. This paper presents an optimisation framework that overcomes these shortcomings and enables truly integrative multi-objective design optimisation. It includes a surrogate model that interacts with the wind turbine simulation tool OpenFAST to enable preliminary design of the structure's mooring system. Applied to a demonstration project and validated against real projects in a maritime contractor environment, the workflow shows improvements in tender performance and added value over single-sided cost optimisations.

1 INTRODUCTION

A promising solution for wind energy production in deep waters is the development of Off-shore Floating Wind Farms (OFWF), as areas with deeper water tend to have higher wind energy densities, but do not allow the economic installation of bottom-founded structures (Spring 2020). The complexity introduced by e.g. high quality requirements, the novelty of the technology and the number of (external) stakeholders (see also Van Gunsteren (2011)), together with the multidisciplinary nature of these developments, create an environment in which modelling and optimising of the (iterative) design process is of great added value, but also challenging and complicated.

In addition, classical design optimisation methods have inherent problems because they are single-sided and ignore and/or provide no insight into the dynamic interplay between the preference-dominated management domain and the object-performance-dominated engineering domain (Van Heukelum et al. 2022). Furthermore, design optimisation is often limited to a posteriori evaluation of (manually) generated design alternatives, with no guarantee that the optimal design alternative is considered because the number of feasible design alternatives is too large to evaluate them all.

Moreover, to enable proper multi-objective design optimisation (MODO), all objectives must be translated into a common domain, for which the affordability domain is commonly chosen in the offshore industry. However, according to classical utility theory, decisions are made based on value or preference and not based on money, as money is not a (fixed) property of objects (Barzilai

2010). Moreover, classical MODO methods contain fundamental (aggregation) modelling errors because mathematical operations are applied without being defined (Barzilai 2006, 2022).

Finally, ignoring preferences is also a major shortcoming of the commonly used Pareto front (Lee et al. 2011, Kim et al. 2022). Searching for the most fit for common purpose design solution involves finding the most preferred solution, not a set of equally preferred solutions from which decision-makers still have to choose through negotiation.

To overcome all the aforementioned problems, this paper presents an optimisation method for the service-life design of OFWFs that integrates preference function modelling and engineering performance, allowing the unification of the managerial domain (subject desirability) with the engineering domain (object feasibility). To this end, an optimisation framework is created within the so-called Preferendus, a software tool that is part of the Odesys design methodology and uses the IMAP optimisation method (Van Heukelum et al. 2022). This paper demonstrates this framework through a demonstration project and gives insight into the applicability of the framework, which has been validated at the Dutch marine contractor Boskalis.

1.1 Data availability statement

The optimisation framework, including the input file of the demonstration projects with all the modelling information, can be found on the GitHub repository of the Preferendus: <https://github.com/TUDELFT-Odesys/Preferendus>.

2 THE OFWF SERVICE-LIFE DESIGN DEMONSTRATOR

The optimisation framework is modelled based on the Odesys mathematical statement introduced by Van Heukelum et al. (2022), see Figure 1. Two stakeholders are considered: 1) an energy service provider (the client) and 2) the marine contractor Boskalis. They are interested in the design of the mooring system and the installation schedule, which creates an optimisation problem where feasibility plays an important role in finding the optimal solution based on the desires of the stakeholders.

Four objectives are considered: project duration, installation costs, fleet utilisation and CO₂ emissions. For the client, a shorter project duration means that the OFWF will start generating revenues sooner. In addition, reducing CO₂ emissions benefits the client’s carbon footprint and the social acceptance of the project. For the contractor, the focus will be on reducing costs to make it more competitive. Secondly, its fleet management department will be interested in the opportunity to improve fleet utilisation through the project.

Figure 1. Conceptual threefold framework, where desirability-subject (preference functions, level 1) and the feasibility-object (design performance functions, level 3) are integrated subject-object (objective functions, level 2). Source: Van Heukelum et al. 2022.

3 LEVEL 3 – DESIGN PERFORMANCE FUNCTIONS

This section introduces the relevant design performance functions and design variables in two parts: installation scheduling and mooring system design. This mooring design is restricted to Drag Embedded Anchors (DEA), Suction Piles (SP) and Anchor Piles (AP).

3.1 Installation schedule

The installation schedule depends on two components: the number of available vessels (and their characteristics), and the time it takes these vessels to perform a task. The available vessels are

listed in Table 1. Whether a vessel can perform a task ($x_i = 1$) or not ($x_i = 0$) is expressed by boolean design variables (x_1 to x_{21}) for all tasks except hook-up. For the hook-up, only one vessel is used (see subsection 3.1.1), and the integer design variable x_{22} expresses which vessel. All vessels have different properties (e.g. deck space for anchors) that affect their performance, which can be found in the input file of the framework (see subsection 1.1).

In addition, each task is decomposed into building blocks that describe the time required to complete a sub-activity. During optimisation, the workable months are determined based on environmental data (see subsection 3.2.1) and the overall schedule is constructed from these building blocks, which can be found in the input file of the framework.

To correctly model the installation schedule, three design performance constraints are added to ensure that: 1) the number of installation vessels is ≥ 0 , since the definition of the design variables x_1 to x_{21} allows a total number of installation vessels equal to zero; 2) an equal number of vessels are present when both anchors and mooring lines (ML) are installed simultaneously; 3) a vessel does not perform overlapping tasks.

Table 1. Available vessels and the associated design variables.

Vessel	SP install	AP install	DEA install	Taut ML install	Catenary ML install	Stev-tensioning*	Hook-up
Winchester	x_1	x_5					
Atlas	x_2		x_7	x_{10}	x_{15}	x_{18}	$x_{22} = 0$
Edinburgh	x_3			x_{11}			$x_{22} = 1$
Symphony			x_8	x_{12}	x_{16}	x_{19}	$x_{22} = 2$
Legacy			x_9	x_{13}	x_{17}	x_{20}	$x_{22} = 3$
Scout	x_4	x_6		x_{14}		x_{21}	

* method to achieve higher proof-loads by vertical lifting instead of horizontal pulling (Vryhof 2017).

3.1.1 Assumptions

Some assumptions are made in the modelling: 1) if the design force on the DEA is greater than the bollard pull of the installation vessel, stev-tensioning will be required. If this is carried out using the Scout (a heavy lift vessel), an additional anchor handling tug will be required for the same period at a day rate of €50,000; 2) the hook-up is limited by the delivery time of new Floating Wind Turbines (FWTs), which is assumed to be one FWT every six days. As this rate is lower than the hook-up period, the number of hook-up vessels is set to one. In addition, the hook-up requires one large and one medium tug for towing and station keeping, which have a fixed day rate of €54,000 and €24,000 respectively; 3) for an AP, the ML is always installed at the same time as the anchor, as is the case for a DEA. For an SP, the ML can be installed simultaneously or separately. Stev-tensioning is always done separately.

3.2 Mooring system design

Most of the design variables for an OFWF mooring system are uncontrollable and result from factors like soil and environmental conditions and local marine policy. Of the controllable design variables, the following are considered in the optimisation:

- Anchor type, x_{23} : DEA, SP, or AP.
- Mooring type, x_{24} : Taut or catenary. Catenary moorings consist only of chain ($d=0.333\text{m}$; $M=685\text{ kg/m}^3$; $EA=3.27\text{E}9\text{N}$), taut moorings have a lower and an upper chain with polyester rope ($d=0.211\text{m}$; $M=23\text{ kg/m}^3$; $EA=3.89\text{E}9\text{N}$ (BEXCO n.d.)) in between.
- Shared anchors, x_{25} : an AP or SP can connect two or three MLs, reducing the total number of anchors to be installed.
- Anchor diameter/width, x_{26} : the diameter (for AP or SP) or width (for DEA) of the anchors.
- Anchor length, x_{27} : the length of the anchor.
- Anchor radius, x_{28} : the radius of the anchors with respect to the FWT.
- Unstretched length, x_{29} : the unstretched length of the ML.

To check that the mooring design is sufficient, a design performance constraint is added to the model, stating that the so-called utilisation factor u should be less than 1:

$$u = \frac{\text{design force on the anchor}}{\text{design resistance of the anchor}} = \frac{F_d}{R_d} = \frac{\gamma_f F_a}{\gamma_M R_a} < 1 \quad (1)$$

Where γ_f is a safety factor for the anchor load; γ_M is a safety factor for the anchor resistance; F_a is the anchor load; R_a is the anchor resistance. For determining this force F_a , the open-source wind turbine simulation tool OpenFAST (NREL n.d.[a]) is used, together with the IEA 15MW reference turbine (Gaertner et al. 2020) and its semi-submersible platform (Allen et al. 2020).

3.2.1 Environmental conditions

TurbSim (NREL n.d.[b]) is used to simulate the wind field for the OpenFAST simulations. This software generates fully stochastic wind fields that allow the effect of turbulence on the dynamics of an FWT to be considered. The reference wind speed for the simulation is determined by statistical analysis of hourly data obtained via Hershbach et al. (2018).

The (irregular) wave field is generated by HydroDyn (Jonkman et al. 2014), where the wave spectrum is determined using the JONSWAP spectral equation (Katopodes 2018). This is a function of both the significant wave height H_S and the peak wave period ω_m , which can be determined by statistical analysis of the hourly data obtained via Hershbach et al. (2018). Sea currents are also simulated in the HydroDyn module, using the power law (Jonkman et al. 2014). This is a function of the velocity of the sea current at the still water level U_0 and the water depth d . U_0 is obtained either from local databases (e.g. EMODnet (n.d.)) or from scientific papers.

Two Design Load Cases (DLC) are considered in the optimisation: DLC1.6 and the Survival Load Case (SLC) (DNV 2021c). During DLC1.6, the turbine operates at the rated wind speed in waves with a 1/50-year H_S . During the SLC, both the 1/100-year wind speed and the 1/100-year H_S occur and the turbine is idling. The environmental conditions are simulated co-aligned (i.e. with the same heading) for a heading of 0° , 30° , and 60° relative to the FWT, where 60° is the heading parallel to a mooring line. A yaw-misalignment of $\pm 8^\circ$ is also included in the simulations.

3.2.2 Integration of OpenFAST in the optimisation

Due to the long runtime of OpenFAST simulations, the integration into the optimisation framework is currently done via a surrogate model. This integration consists of five steps divided into two phases: the offline phase (steps 1 to 3), which is performed separately and prior to optimisation, and the online phase, which is an integral part of the framework.

Step 1 – offline phase: determine mooring configurations

The reference mooring design (Allen et al. 2020) is scaled to different water depths (120-150 metres) and taut configurations, based on a comparison between the behaviour of the new design and the reference design under different (static) loads (via Hall et al. (2021)). For this scaling, the design variables have been limited to the anchor radius (x_{28}) and the unstretched length of the mooring line (x_{29}), which consequently become indirect design variables.

Step 2 – offline phase: run OpenFAST

OpenFAST is being run with six 700-second simulations per design scenario, each being a combination of two design load cases (DLC1.6 & SLC), three propagation directions (0° , 30° , 60°), two mooring types (taut & catenary) and three yaw misalignments (-8° , 0° , 8°), resulting in 216 runs per water depth. The result of a simulation is a binary file containing, among other things, the time series of forces on all three anchors of the FWT.

Step 3 – offline phase: analyse the OpenFAST results

The results of the OpenFAST simulations are processed in a script, which for each design scenario: 1) eliminates the initialisation phase of the catenary mooring systems; 2) generates 60-minute time series for three FWTs by (quasi-randomly) combining the six 700-second runs; 3) calculates the net force on the shared anchors using the time series of three FWTs; 4) finds the forces F_a for one, two and three connected MLs per design scenario. All these forces are then multiplied by a safety factor (DLC1.6: $\gamma_f = 1.35$; SLC: $\gamma_f = 1.1$ (DNV 2021c)) to give the design forces F'_d . At the same time, a script is run to determine the angles of the taut MLs with respect to the mudline.

Step 4 – online phase: determine governing forces

The final design forces F_d are determined for both catenary and taut moorings, and for both shared and non-shared anchors, by taking the maximum of the design forces F'_d from the relevant design scenarios. Note: for shared anchors, F_d is the highest of either two or three connected MLs.

Step 5 – online phase: determine anchor dimensions

For all three types of anchors, the point where the chain attaches to the anchor (i.e. the padeye) is below the mudline. Because of friction with the soil, the chain will form a (so-called) inverse catenary shape below the mudline. Neubecker & Randolph (1995) describe a system of equations to determine the tension T_d and angle θ_a of the ML at the padeye, based on the design force F_d and angle θ_m at the mudline and the ML and soil characteristics. In addition, the position of the padeye is required, which for APs and SPs is set to 1/2 the anchor length below the mudline for clay and 2/3 the anchor length for sand. For DEAs, the optimum angle θ_a is determined by the manufacturer and set as a constant in the calculation for T_d . Here $\theta_{a,DEA} = 41^\circ$ for clay and $\theta_{a,DEA} = 31^\circ$ for sand (Vryhof 2018). The anchor resistance R_d and the utilisation factor u can then be calculated, applying the safety factors γ_M according to the DNV-OS-C101 design code (DNV 2021a):

- Drag embedded anchors: the design is limited to Vryhoff's Stevin MK3, Stevpris MK5 and Stevpris MK6 anchors. ABS (2013) describes design formulae that can be used to obtain the required mass $M_{required}$ of a DEA for a given force T_d . In addition, based on the information provided by Vryhof (2018), it is possible to determine the DEA that best matches the values for the anchor length (x_{27}) and width (x_{26}). Knowing the mass of this DEA (M_{DEA}), it is possible to calculate the utilisation factor:

$$u = \frac{F_d}{R_d} = \frac{M_{required}}{0.77 \cdot M_{DEA}} \leq 1 \quad (2)$$

- Suction anchors: for SPs, first the maximum suction-assisted penetration length must be determined (Houlsby & Byrne 2005a,b), in order to calculate the horizontal (H_{ult}) and vertical (V_{ult}) capacity of the anchor (Equation 42 to 49 of Arany & Bhattacharya (2018)). Finally, T_d must be decomposed into a horizontal (H_d) and vertical (V_d) component in order to calculate the utilisation factor (Randolph & Gourvenec 2017):

$$u = \frac{F_d}{R_d} = \frac{M_{required}}{0.77 \cdot M_{DEA}} \leq 1 \quad (3)$$

- Anchor piles: for APs, the horizontal and vertical failure mechanisms are considered separately. For the horizontal failure mechanism, the 'short' pile failure mechanism can be used as described by Randolph & Gourvenec (2017), since 1) the padeye is at a significant depth below the mudline and 2) the lengths of the APs are limited compared to e.g. deepwater moorings of oil & gas platforms. Plastic hinging is therefore unlikely and only soil failure needs to be considered. The vertical failure mechanism of an AP is mainly determined by the weight of the anchor and the soil-pile friction. Therefore, the same design formulae can be used as for an SP. The utilisation factor can be calculated as:

$$u = \frac{F_d}{R_d} = \frac{M_{required}}{0.77 \cdot M_{DEA}} \leq 1 \quad (4)$$

In addition to Equation 1, the mooring system has two other design performance constraints. The first is that a DEA cannot be used for taut and shared anchor systems as it is not designed for vertical and multidirectional loads. The second restricts the L/D and D/t ratios of the APs and SPs. See ABS (2013) for reference values.

3.2.3 Assumptions

In the current development phase of the optimisation framework, only a preliminary design is considered, as the improvement in optimisation results that a more detailed design will entail does not currently outweigh the additional complexity of developing the necessary design

calculations. For this preliminary design, some assumptions are made: 1) all MLs can be stretched indefinitely, and the minimum breaking load (MBL) is not currently considered; 2) the effect of cyclic loading on the anchors and associated fatigue is neglected, only the ultimate limit state is considered; 3) the soil is assumed to be uniform.

The current approach to determine the force F_d for shared anchors is likely to result in the over-dimensioning of anchors with three MLs, as the net force for two MLs is often greater than the net force for three MLs. Therefore the design force F_d of anchors with three MLs will be too high. This should be addressed in further development, although the current approach overcomes problems with the reliability of shared anchors in the event of ML failure (DNV 2021b).

4 LEVEL 2 – OBJECTIVE FUNCTIONS

The optimisation framework considers four objectives that form the link between the design performance (level 3) and the preference functions (level 1):

1. Project duration (PD): the project duration is determined by a proprietary Discrete Event Simulation (DES) combining the design variables with the task durations.
2. Installation cost (IC): installation costs are primarily based on the day rates of the vessels multiplied by the time they work on the project. In addition, a daily surcharge is added for anchor installation vessels, depending on the type of anchor (x_{23}).
3. Fleet utilisation (FU): fleet utilisation is represented by normalising the number of days a vessel is booked over the next 12 months (i.e. the vessel with the lowest number of days booked has a score of 0 and the vessel with the highest number of days has a score of 1).
4. CO₂ emission (CE): the CO₂ emission of a project depends on the fuel consumption of the vessels, related to the activity of the vessel (e.g. idling, sailing, towing), multiplied by a conversion rate (per tonne MGO, 3.206 tonne CO₂ is emitted).

5 LEVEL 1 - PREFERENCE FUNCTIONS

To quantify stakeholder desirability, preference functions are constructed that describe the relationship between an individual stakeholder's preference P and a particular objective O . In addition to these functions, the weights associated with the different preference functions have to be determined, both in close cooperation with the different stakeholders. Furthermore, they can change during the design process when stakeholders better understand the impact of their preference functions and associated weights on the process (Arkesteijn 2019). Both the demonstration project and the validation described in this paper, use preference functions and weights determined based on input from floating wind project experts within Boskalis.

6 DEMONSTRATION PROJECT

To demonstrate the application of the framework, a demonstration project has been set up where 45 FWTs are installed (see the data availability statement for the input file containing further project specifics). Three optimisations have been compared: Single-Objective Design Optimisation (SODO) of the installation costs, and MODO with the IMAP and min-max method (Van Heukelem et al. 2022). The final ranking and outcomes for the objectives are shown in Table 2. All designs favour (shared) SPs, MODO min-max with a taut mooring and others with a catenary mooring. The MODO IMAP achieves the best design configuration by balancing the four objectives to best reflect stakeholder preferences. Three other observations are made:

- 1) Due to the conflict between installation cost and fleet utilisation objectives, employing less expensive vessels will reduce the fleet utilisation factor. Rather than choosing one over the other, the min-max method finds a compromise that does not benefit the overall design configuration, revealing a significant drawback of this method.
- 2) The lowest cost is achieved by installing anchors and MLs separately, reducing the time one vessel has to wait for another to complete an installation task. However, this significantly

increases the duration of the project, as the hook-up will start a year later. It could be argued that this design configuration would never be considered because the project duration is unrealistically long. The fact that the actual design configuration would be similar to the configuration obtained by MODO IMAP confirms that this model is a welcome addition to design optimisation in the offshore industry.

- 3) The demonstration project shows the added value of integrated design optimisation. Traditionally, the anchor design is determined by the client and the contractor has to build their schedule around it (waterfall design process). However, this can lead to inefficient use of vessels and delayed project delivery. Here, the design is an integral part of the optimisation, allowing for an overall better design, even if this would deviate from a purely engineering perspective. This is particularly interesting for shared anchors, which are unfavourable from an engineering viewpoint but favourable from a schedule and cost perspective.

Table 2. Table with the results of the objectives and their ranking.

Optimisation	PD [days] <i>weight = 0.25</i>	IC [€1E6] <i>weight = 0.50</i>	FU [-] <i>weight = 0.20</i>	CE [kt] <i>weight = 0.05</i>	Final Ranking
MODO IMAP	619 (<i>P = 96.5</i>)	56.81 (<i>P = 98.5</i>)	0.83 (<i>P = 74.4</i>)	21.9 (<i>P = 94.6</i>)	1. (<i>P = 100</i>)
SODO Costs	985 (<i>P = 41.5</i>)	54.71 (<i>P = 99.2</i>)	0.83 (<i>P = 74.4</i>)	21.6 (<i>P = 94.8</i>)	2. (<i>P = 41</i>)
MODO min-max	619 (<i>P = 96.5</i>)	61.13 (<i>P = 96.8</i>)	0.98 (<i>P = 97.6</i>)	19.7 (<i>P = 96.1</i>)	3. (<i>P = 0</i>)

7 VALIDATION OF THE OPTIMISATION FRAMEWORK

The optimisation framework has been validated during a meeting with offshore floating wind experts within Boskalis and demonstrated that it can be of great value to a tender team. A tender team always has a bias and especially when the design process consists of evaluating design alternatives, this bias can lead to eliminating alternatives based on intuition, when in fact they are competitive. The optimisation framework removes this bias from the design process, which is in line with what Kahneman (2011) suggests when he distinguishes between thinking fast (decision-making based on intuition) and thinking slow (decision-making using e.g. mathematical decision support tools). Moreover, the framework delivers initial results within an hour (if the surrogate model contains sufficient data), compared to one or more days in the current situation. This is a significant improvement and offers opportunities beyond the development of OFWF.

8 STEPS FOR FURTHER DEVELOPMENT

Based on the assumptions made, the following steps have been identified for further development. To improve the integration of the surrogate model, two steps for further development are identified: 1) consideration of the MBL of the MLs; 2) inclusion of fatigue loading in the design of the anchors. The first will address a shortcoming of the current model and resolves a problem with the script that calculates the taut mooring designs, which currently results in excessive tensions in the polyester rope. The second will add an important element to the design of the anchors, as dynamic loads have a significant effect on the anchor resistance R_a . It would also be interesting to extend the surrogate model to include platforms other than the current semi-submersible platform.

In addition, the following development steps are identified based on the validation in the tender team: 1) take the delivery of the first FWT as $t = 0$ for the schedule; 2) improve the DES with a focus on the calculation of the number of anchors and MLs on board vessels and the start of ML installation if it is done separately from the anchor installation; 3) improve the calculation of installation costs by including procurement and fuel costs; 4) improve the calculation of CO₂ emissions by including emissions from anchor fabrication and onshore activities.

9 CONCLUSIONS

This paper presents an optimisation framework that enables the unification of the engineering domain (object feasibility) with the management domain (subject desirability) and a truly integrative MODO method that can accommodate conflicting objectives of multiple stakeholders whilst simultaneously considering different engineering object variables and design constraints. The applicability of the optimisation framework is shown for a demonstration project, demonstrating its added value over a compromise solution and single-sided cost optimisation, and the efficiency of integrative design. Finally, validation of the framework shows it brings significant improvement in tender performance, both in terms of removing bias from design and improving process speed. Steps for further development include improving the surrogate model and DES and extending the installation cost and CO₂ emission calculations.

A life-cycle assessment framework for pavement management considering uncertainties

A. Vargas-Farias, J. Santos & A. Hartmann
University of Twente, Enschede, The Netherlands

F. Van der Pijl
Rijkswaterstaat, Utrecht, The Netherlands

ABSTRACT: Life cycle assessment (LCA) is a methodology widely endorsed by the pavement community and increasingly adopted by transportation agencies worldwide to account for the environmental impacts of pavements throughout their entire life cycle. LCA studies in this context are prone to the effects of uncertainties due to (1) the long analysis periods that stretch across numerous maintenance and rehabilitation (M&R) cycles, (2) the need of different types and sources of data and additional models and (3) multiple methodological decisions to be made by the analyst. Nevertheless, LCA studies are often done deterministically and omit important phases and phenomena from the systems boundaries, thereby reducing the reliability and representativity of the results. To overcome this challenge and to foster the integration of LCA models with existing pavement management systems, this paper presents the development and application of a LCA framework that evaluates the environmental performance of pavement M&R treatments. Further, it incorporates the effects of pavement-vehicle interaction into the analysis and accounts for multiple types of uncertainties, namely those associated with the value of parameters, methodological choices and data quality. Probability distributions and value scenarios are used to characterize the uncertainties which are propagated into the results using Latin hypercube sampling and scenario analysis. A sensitivity analysis using tree-ensemble methods is adopted to unveil the most influential parameters on the variance of the outputs. The outcomes of this research work aim to advance the applicability of LCA in the context of pavement management, and to improve the understanding of the effects of uncertainties in the outcomes of the analysis.

1 INTRODUCTION

Road pavements are long-lived infrastructures that undergo periodic maintenance and rehabilitation (M&R) treatments over their lifetime. The application of such treatments ensures that pavement condition remains above desirable levels, but it also results in significant cumulative environmental impacts due to the vast consumption of natural resources and energy it entails. In light of the rising environmental awareness, assessing the environmental impacts of road pavements is an important step towards the achievement of sustainability goals.

Life cycle assessment (LCA) is an approach that evaluates the environmental impacts of road pavements over the course of their service life that has gained significant recognition in the field of pavement management (PM) and has become instrumental in the context of sustainability transition (Miliutenko *et al.*, 2014; Rangelov *et al.*, 2020; Santero *et al.*, 2011; Santos *et al.*, 2015). However, the validity of LCA in this setting is often called into question, as most pavement LCA studies tend to exclude important phases from the system boundaries of the analysis, particularly the use phase (Xu *et al.*, 2019), and ignore the effects of uncertainty on the results.

LCA offers the option to calculate the impacts of pavement materials production, construction, use, M&R, and end-of-life (EOL) (Santero *et al.*, 2011). Conventionally, the focus of the assessment has been placed in the production, construction and EOL phases (Xu *et al.*, 2019). However, as the environmental impacts of the use phase may represent a large share of total life cycle impacts (Harvey *et al.*, 2016; Santos *et al.*, 2022), recent LCA studies have begun to account for the effects of pavement-vehicle interaction (PVI), a use phase mechanism, in their assessments (Akbarian *et al.*, 2012; Gregory *et al.*, 2016; Noshadravan *et al.*, 2013; Santos *et al.*, 2022). PVI is the relationship between pavement characteristics and vehicle fuel efficiency, determined by pavement rolling resistance (RR). As RR increases, so do the fuel consumption and the emissions generated by the vehicles moving across the road (Bryce *et al.*, 2014; Van Dam *et al.*, 2015). Although in a comprehensive analysis it is essential to take into account every phase of the pavements' life cycle to ensure representativity and accuracy, the absence of the use phase is not the only omission often found in multiple pavement LCA studies.

Uncertainty is unavoidable in LCA studies, and despite the fact that it directly affects the reliability of the results, conventional LCA analyses often consider single input values. The need for the consideration of uncertainties in LCA has been recognized in the past (Huijbregts, 1998; Santero *et al.*, 2011), but limited attention has been given to developing and including uncertainty analysis approaches in LCA studies (Lo Piano and Benini, 2022), let alone in the pavement domain.

The first step of a un uncertainty analysis in LCA consists of identifying and selecting the main types and sources of uncertainty (Igos *et al.*, 2019). This includes distinguishing between parameter and scenario uncertainty. Parameter uncertainty is primarily caused by inaccuracies in input data used to model processes and flows caused by data quality and variability. LCA studies in the pavement domain place attention on several specific sources of parameter uncertainty related to the different pavement life cycle phases (Azarijafari *et al.*, 2018; Gregory *et al.*, 2016; Noshadravan *et al.*, 2013; Santos *et al.*, 2022), including PVI and the models used to predict the pavement condition over time (Gregory *et al.*, 2016; Noshadravan *et al.*, 2013; Santos *et al.*, 2022; Ziyadi *et al.*, 2017). Among other sources, scenario uncertainty arises from methodological and normative choices made during the goal and scope definition, such as LCA software and LCI database selection (Santos *et al.*, 2017), system boundary choices (Gregory *et al.*, 2016), allocation methods (Azarijafari *et al.*, 2018), etc.

After identifying sources and types of uncertainty, the next step is to characterize them. Characterization can be done qualitatively or quantitatively. In qualitative characterizations, it is common practice to estimate data quality levels and to construct alternative scenarios based on different methodological choices (Igos *et al.*, 2019). The pedigree matrix approach implemented in the ecoinvent database (Weidema *et al.*, 2013) has been employed in the pavement LCA field to account for the uncertainty due to data quality, rendering its further quantitative characterization possible (Azarijafari *et al.*, 2018; Gregory *et al.*, 2016; Noshadravan *et al.*, 2013). Quantitatively, uncertainties can be characterized by defining minimum and maximum parameter values and/or probability density functions (PDFs) (Igos *et al.*, 2019). Data variability can be represented with PDFs when the sample size is large (Yu *et al.*, 2018), or by minimum and maximum values for smaller sample sizes (Gregory *et al.*, 2016). When only single values are available, predetermined uncertainty values retrieved from the ecoinvent database can be used (Azarijafari *et al.*, 2018; Gregory *et al.*, 2016; Noshadravan *et al.*, 2013). In turn, scenarios can be represented by discrete choices with equal likelihood or with alternative value scenarios (e.g., minimum and maximum values) (Azarijafari *et al.*, 2018; Gregory *et al.*, 2016).

Once uncertainties have been characterized, they are propagated to the results. Two common methods used in pavement LCA literature are Monte Carlo sampling (MCS) and scenario analysis (Azarijafari *et al.*, 2018; Gregory *et al.*, 2016; Noshadravan *et al.*, 2013; Santos *et al.*, 2022; Yu *et al.*, 2018). MCS is a commonly used method to propagate parameter uncertainties (Igos *et al.*, 2019). However, it requires large sample sizes and can be computationally expensive. To reduce the computational time, Latin hypercube sampling (LHS) can be used. It is an efficient modification of MCS that divides the input distribution into equal intervals from which a sample point is selected randomly (Groen *et al.*, 2014; Igos *et al.*, 2019). It guarantees that all intervals are sampled equally, and that no area is over- or under-sampled. Therefore, it is particularly useful for contexts where the sample size must be kept as small as possible. Scenario analysis entails the single or

simultaneous variation of parameters, methodological choices and model formulations to analyze uncertainties in LCA (Igos *et al.*, 2019). Sampling and scenario analysis can be used together to combine parameter and scenario uncertainties (Azarijafari *et al.*, 2018; Gregory *et al.*, 2016).

Moreover, a comprehensive uncertainty analysis in LCA should include a sensitivity analysis to investigate how changes in parameters and methodological choices affect the results (Harvey *et al.*, 2016) and to identify which elements have the largest contributions to the overall uncertainty (Igos *et al.*, 2019). In the pavement field, one-at-a-time analyses (Godoi Bizarro *et al.*, 2020) and Spearman's rank correlation coefficients (Gregory *et al.*, 2016) have been used to identify the most influential parameters and scenarios. In other fields, the calculations of Sobol indices (Igos *et al.*, 2019; Jaxa-Rozen *et al.*, 2021a), a well-known global sensitivity analysis (GSA) technique, has been adopted to quantify the relationship and importance of each input in the variance of the LCA outputs. However, this method comes at a high computational cost. In turn, Extra Trees is a computational efficient method that can handle large number of parameters and produce reliable results at smaller sample sizes, while offering results comparable to those of Sobol indices (Jaxa-Rozen and Kwakkel, 2018). In LCA, Extra Trees has been used as a preliminary screening step to identify the most influential parameters on the uncertainty (Jaxa-Rozen *et al.*, 2021a), but to the authors' best knowledge it has never been applied in the pavement LCA field.

In view of the considerations and limitations mentioned above, this study aims to further expand the development and applicability of LCA in the context of sustainable pavement management by creating a framework tailored to road pavement M&R that accounts for the effects of PVI and includes a comprehensive uncertainty analysis methodology.

2 METHODS

2.1 LCA framework

The proposed LCA framework described in this paper focuses on the LCA of individual pavement M&R cycles that involve the application of asphalt overlays, although it can be expanded to include any other type of M&R treatments. LCA studies in the context of M&R often cover long analysis periods spanning multiple M&R cycles. In the current setting the analysis period is constrained to the time between the application of a treatment and the subsequent need for a new one. In addition to the analysis period, the definition of the functional unit considers the characteristics of the pavement system being treated, including its structure (surface, binder, and/or base layers and subgrade), geometrical and functional characteristics, materials and the traffic it is expected to carry (Harvey *et al.*, 2016).

Moreover, the LCA framework is consistent with Dutch reference documents, specifically the asphalt product category rules (NL-PCR) (Van der Kruk *et al.*, 2022) and the Determination Method (Nationale Milieudatabase, 2020). The system boundaries for the analysis encompass all relevant life cycle processes and flows, including the production (material extraction, acquisition, transportation, and processing into asphalt mixtures), construction (on-site paving activities and equipment use), use (processes that impact the environment during the service life, with an emphasis on PVI) and end-of-life (EOL) phases (i.e. removal, recycling and transportation of waste materials) as outlined by Santero *et al.*, (2011).

2.2 Uncertainty analysis

The uncertainty analysis starts with the identification of the different foreground-related uncertain parameters and methodological choices that potentially can influence the environmental impact calculations. Although accounting for uncertainty related to the background is to some extent feasible and would result in a more robust analysis, its actual realization would imply an extreme increase of the number of uncertain parameters and the level of complexity the analysis.

Data variability can be represented with PDFs derived from empirical data when available, or with the predefined values provided by theecoinvent method in the absence of empirical data

(Weidema *et al.*, 2013). These values are then aggregated with data quality uncertainty according to the criteria established by the ecoinvent method, with data quality being described using log-normal distributions. The procedure provided by Muller *et al.*, (2016) is adopted to facilitate the numerical integration with data quality uncertainty values when data variability is represented using distributions other than log-normal. Scenarios are developed based on different value options, such as different machinery production rates, recycled asphalt pavement (RAP) content in the composition of the mixture, and the type of bitumen added.

In the proposed LCA framework the propagation of uncertainties to the results involves the application of a combination of LHS and scenario analysis. LHS is employed to reduce computational time in the evaluation of parameter uncertainty. Scenario analysis, in turn, is used to evaluate the effect of changing scenarios. According to Jaxa-Rozen *et al.*, (2021), 12,000 simulations are sufficient for the LHS analysis when the sensitivity analysis method is adequate for a relatively small number of samples. As such, the Extra Trees method is adopted to identify the most influential parameters in the uncertainty of the outcomes for different scenarios following the configuration recommended by Jaxa-Rozen and Kwakkel, (2018). It is important to note that LHS should be performed for each scenario considered in the analysis, allowing for its subsequent sensitivity analysis. Figure 1 summarizes the uncertainty methodology proposed in the framework.

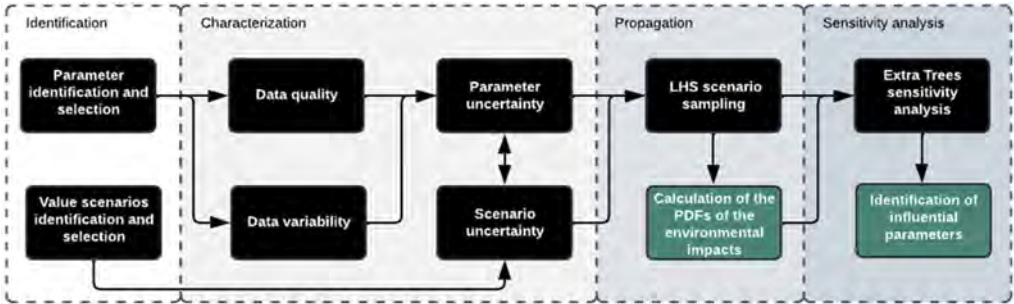

Figure 1. Uncertainty analysis methodology. Black boxes represent the application steps of the methodology, whereas the green ones depict the handling of the outcomes of the methodology.

3 CASE STUDY

The applicability of the proposed framework is illustrated by using the case study of a mill-and-fill M&R treatment for the main road pavement network in the Netherlands. The chosen treatment, selected from a collection of over 75 potential hot mix asphalt overlay options, involves the application of a 50mm-thick layer of Durable ZOAB (DZOAB), which is a porous asphalt mixture with enhanced durability commonly used in the Netherlands.

The functional unit for the analysis is defined as a straight and plan 1km-long carriageway road pavement segment section with 3 lanes, each 3.5km-wide. Traffic data, including average daily intensity values for passenger cars, heavy duty trucks (HDV), and HDV + trailers, were sourced from the INWEVA geographical information system and datasets (Rijswaterstaat, 2022) and are presented in Table 1. The traffic growth rate, set at 1.9%, was determined based on information from the National Statistics Office of the Netherlands (CBS, 2022). The analysis period, corresponding to the average lifespan of a DZOAB surface, is 14 years.

Table 1. Traffic intensity in number of vehicles: statistics.

Vehicle type	Mean	Std	Min	Max
Passenger car	26064	17513	2276	101325
HDV	1744	1035	219	7292
HDV + trailer	2061	1477	140	8872

The system boundaries were adapted from the NL-PCR to align them with the context of M&R (Figure 2), with the exception of leaching, which was excluded from the use phase due to the absence of primary data (Van der Kruk et al., 2022). A construction rate of 1000 ton/day was used in the analysis. Additionally, the environmental benefits of recycling RAP into new pavement materials outside the system boundaries were not considered as RAP enters the system free-of-burden in mixtures with RAP content. Input data for each life cycle phase, except PVI, were obtained from the NL-PCR and the Ecoinvent 3.3 database.

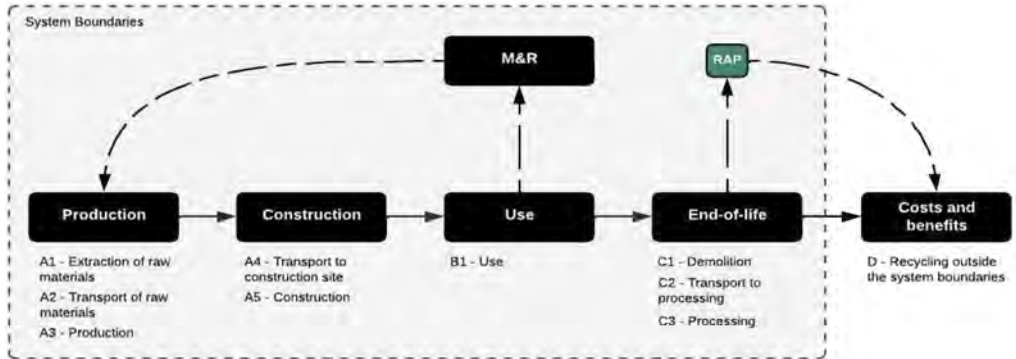

Figure 2. System boundaries of the case study.

The environmental impacts of PVI were calculated using the MIRIAM model (Hammarström *et al.*, 2012). Moreover, linear models were developed for predicting the evolution of roughness and macrotexture over time, respectively represented by the International Roughness Index (IRI) and Mean Profile Depth (MPD), using real IRI and MPD measurements of the Dutch main road network provided by the Dutch Ministry of Infrastructure ‘Rijkswaterstaat’ (RWS). The values of the parameters of the performance models using pavement age as predictor are presented in Table 2. The results are assumed to follow a normal distribution with a mean corresponding to the predicted IRI and MPD values and a standard deviation (std) equivalent to the mean absolute error (MAE) of the model. Vehicle speeds were determined based on Dutch speed limits (Rijksoverheid, 2022) and were assumed to follow a normal distribution with a mean corresponding to the speed limits and a coefficient of variation of 0.1. For facilitating the calculation and to match the size of the traffic intensity sample of the Dutch road pavement network, approximately 4000 MCS runs were completed to estimate the total additional fuel consumption due to RR over the analysis period. The results follow a normal distribution, and the values of the parameters are presented Table 3. The environmental impacts were then calculated and incorporated into the LCA model using the method described by Santos *et al.* (2022), which uses the fuel efficiency and environmental impacts of transportation services (excluding the upstream impacts attributed to infrastructure) to model PVI effects.

Table 2. IRI and MPD linear pavement performance models parameters and statistics.

Pavement performance model	Year 0	Annual increase	MAE
IRI (m/km)	0.9993	0.0296	0.0325
MPD (mm)	1.1063	0.0209	0.1207

Table 3. Total extra fuel consumption due to RR in the analysis period (l/km).

Vehicle type	Mean	Std
Passenger car	68967.84	46675.05
HDV	17729.00	10516.89
HDV + trailer	58536.78	41941.30

The uncertainty analysis was conducted using two scenarios for RAP content: (1) a mixture with 0% RAP and (2) a mixture with 30% RAP. The NL-PCR was used to determine the input values for mixture composition and energy expenditure for asphalt mixtures production, as well as diesel consumption for construction and removal processes, based on the amount of RAP in the mixture (Van der Kruk et al., 2022). All foreground input value parameters assigned to each scenario, including materials, transport, additional vehicle fuel consumption, and energy consumption for production, construction and EOL were considered in the analysis. Data quality uncertainty was calculated using the ecoinvent method (Weidema *et al.*, 2013), as well as the variability of the parameters, with the exception of PVI, whose variability values were computed in the earlier step.

Each scenario was sampled 12,000 times with LHS and environmental impacts of each sample were calculated using the OpenLCA software with a Python interface adapted from the one developed by Jaxa-Rozen et al. (2021b). To identify the most uncertain parameters, an ExtraTrees regression was applied using the scikit-learn Python library (Pedregosa *et al.*, 2012). Finally, given that the environmental impacts of the use phase are expected to be predominant and highly uncertain, two additional scenarios in which one excluded the effects of PVI in module B (use phase) were considered to provide more meaningful insights on the influence of the several parameters on the uncertainty of the outcomes.

4 RESULTS AND DISCUSSION

The environmental impact results for the scenarios including and excluding the use phase are illustrated with the global warming impact category and are presented in Figure 3(a) and (b), respectively. From the analysis of the Figures, it can be seen the use of RAP allows the reduction of the environmental impacts, although this result is almost imperceptible when the use phase is considered. This is due to the overwhelming contribution of the environmental impacts associated with PVI, which outweigh the influence of the remaining phases.

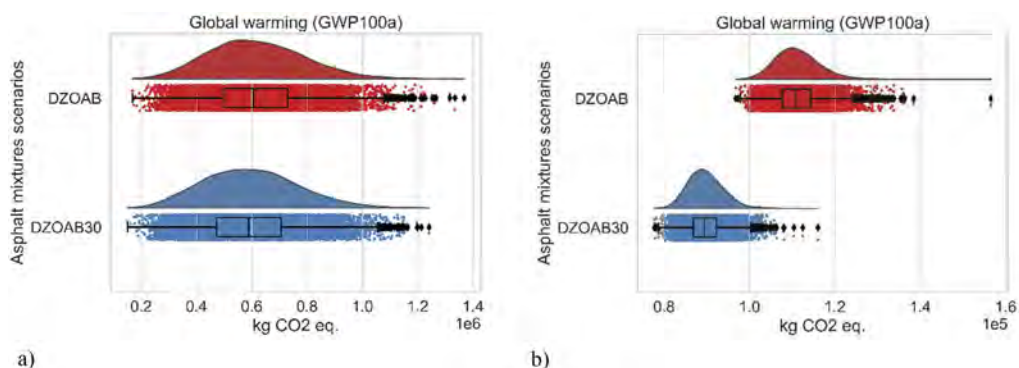

Figure 3. Environmental impact for scenarios (a) including PVI effects and (b) excluding PVI effects.

The results of the sensitivity analysis indicate that in scenarios that include the use phase, fuel consumption has the greatest influence on the uncertainty of the outcomes. This can be attributed to the large variability and predominant contribution of extra fuel consumption to the environmental impacts. In contrast, the contribution of other parameters in the scenarios thereof is relatively similar and mostly below the order of 1%. In scenarios that exclude the use phase, there is greater variation in the contributions of different parameters to uncertainty. Notably, transport has a significant effect on uncertainty, particularly the transportation of raw materials via transoceanic ships in module A1, and freight transport to and from the construction site in modules A4 and C2. This can likely be credited to the large uncertainty values assigned to transport exchanges by the ecoinvent method. When taking a closer look at individual life cycle phases, activities related to EOL in module C1, encompassing milling, sweeping and cleaning, and the consumption of natural gas for mixture heating in module A3, are

the major contributors to total uncertainty after transport. Finally, when examining the contribution of raw asphalt materials processes in module A1 to total uncertainty, bitumen and large size aggregates present the greatest contributions from this phase.

5 CONCLUSION AND FUTURE RESEARCH WORK

In this study, an LCA framework is proposed for evaluating the environmental impacts of M&R treatments under uncertainty. The key features of this framework include the consideration of PVI in the analysis, the incorporation of parameter and scenario uncertainties in the assessment, and the application of a tree-based ensemble method for sensitivity analysis to determine the most influential parameters in the uncertainty of the outcomes.

The environmental impact results of the case study indicate that when the use phase is considered, the reduction of impacts occurring in other phases becomes imperceptible, even when PVI impact values are relatively low. This substantiates the importance of including the use phase in the analysis, and ensuring that the pavement remain in good condition during the analysis period to reduce extra fuel consumption due to increased RR.

The sensitivity analysis conducted in this study revealed that in scenarios that include the use phase, the contribution of PVI to the uncertainty in the results is overwhelming. In order to gain a deeper understanding of the influence of the various parameters on the uncertainty, further sensitivity analyses were conducted using scenarios that exclude the use phase. The results showed that transportation processes have a significant impact on the uncertainty of the outcomes.

In conclusion, the outcomes of this research work helped to advance the applicability of LCA in the context of pavement M&R, and to improve the understanding of the effects of uncertainties on the outcomes. Further, it offers the possibility of identifying areas with the highest potential for environmental performance improvements by determining the extent to which impacts can be reduced.

Additional research work in this domain will be performed by incorporating other M&R measures beyond asphalt overlays. Additionally, the incorporation of advanced GSA techniques, such as variance-based and distribution-based methods (e.g. Sobol and PAWN), as well as the development of empirical uncertainty factors to account for process variability will be pursued.

To replace or not to replace: A model for future functional performance of bridges

S.C.A. Mooren, A. Hartmann & S. Asgarpour

University of Twente, Enschede, The Netherlands

ABSTRACT: In The Netherlands most bridges reach their end-of-life for functional reasons. Bridges need to be replaced because the adjacent network is widened or the traffic load has increased. Socio-technical developments lead to changes in the functional requirements of bridges and, thus, the decision to replace them. However, determining the functional end-of-life of bridges remains challenging, since it requires insights into future socio-technical trends and their impact on infrastructure networks. In this paper we present a model for the assessment of the future functional performance level of bridges under four future scenarios. The model covers three functional performance criteria: traffic flow, safety and environmental impact and uses a number of performance indicators: intensity/capacity ratio (traffic flow), automatic incident detection and lighting (safety), and noise (environment). It has been developed on the python-based platform MoViCI, which stands for and is used for modelling and visualizing critical infrastructure. The model estimates future traffic intensities of the national road network in the Randstad area in The Netherlands based on which the functional performance is computed per bridge, per indicator, per year. The model output shows that numerous bridges are expected to reach their functional end-of-life before the technical end-of-life. This can empower asset managers in their life cycle performance assessment and, as a result, in scheduling interventions and allocating budgets more effectively.

1 INTRODUCTION

Road transportation plays a central role in fulfilling mobility needs of goods and people. In academic literature a consensus exists that investment in road infrastructure yields economic growth and an increase in productivity, albeit limited by saturation (Arvin et al., 2015; Bougheas et al., 2000; Crescenzi et al., 2016; Fernald, 1999). The main mode of transport in The Netherlands is the car (Hilbers et al., 2020). Hence, road network infrastructure plays a significant role in the movement of people and economic growth. Meanwhile, major challenges lie ahead in the preservation of infrastructure. The usage of assets constructed at mass in the 1960s, has changed to an extent that was unforeseen at the time of designing it; traffic has increased 8-fold (Rijkswaterstaat, 2021). Statistical research shows that bridges and viaducts in The Netherlands, on average, have a lifespan of 80 years (Nooij, 2016). Rijkswaterstaat (RWS), the road agency managing the main road network in The Netherlands, faces a large number of assets reaching the end of their lifetime in the coming years (Klatter, 2019). As a result, expenditures for infrastructure renewal are expected to increase drastically (du Nouska, 2021; Bleijenberg, 2021).

A large challenge for road agencies is to get a clear picture of when assets reach their end-of-life. How assets reach their end-of-life varies (Mellal, 2020). Infrastructure obsolescence has often been studied from a structural perspective. Much less so has functional obsolescence been studied, or modelled. Nevertheless, at least in The Netherlands the majority of bridges have been replaced for functional reasons. Research conducted at the behest of RWS shows that demolition for 88.9% of 216 bridges took place because of functional obsolescence. (Nooij, 2016). Thus, for asset managers it is crucial to know how functional performance

develops over time. It is namely used to schedule maintenance activities, renovations, and renewals. Without these insights, asset managers are limited in their integral decision making.

Bridges require special attention as they are critical structures with a vital connectivity role in road infrastructure. Bridges are costly to construct and maintain, and are subject to unique loads that they must be able to withstand to ensure safety. Thus, the scope has been limited to bridges and viaducts. The following twofold research question has been formulated: *How does functional performance of bridges and viaducts as part of a network develop over time (1), and how can these insights contribute to infrastructure asset management decision making (2)?*

Bechtel et al. (2016) characterize functional obsolescence using congestion performance measures at bridges from probe-vehicle data. The study offers detailed insights into congestion performance. However, the methodology operates on past (or at best live) data. In contrast, this paper aims to aid asset managers with a model that provides insights into the possible future functional performance of bridges.

2 RESEARCH DESIGN

A design science research (DSR) approach has been adopted (van Aken et al., 2016) in order to answer the research question, where the model plays a central role. To develop the model, the process as displayed in the flowchart in Figure 3 has been followed. The ovals represent the starting point. The squares stand for activities that have been carried out. The parallelograms serve as a representations for input/output. The shapes with a curved bottom represent documents. Finally, the arrows show links between flowchart entities, where solid means uni-directional and dotted means bidirectional.

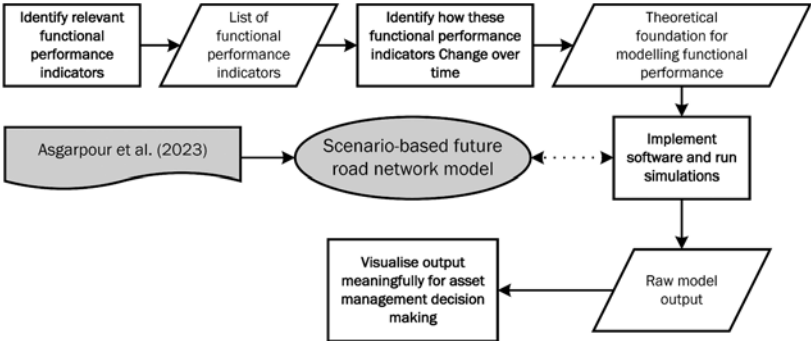

Figure 1. The research process.

The first step is to identify the functional performance indicators that are to be included in the model. First an extensive list of candidate indicators has been composed by reviewing studies previously conducted at RWS (Cuendias González, 2018; van Iddekinge, 2020; Xie, 2017) and scientific literature. All candidate indicators received a score [0-2] on three criteria: relevance, feasibility to model, and time dynamism. Relevance relates to the degree of functional nature of the indicator. In other words: does the indicator relate to functional requirements, and does an insufficient performance level induce interventions? Feasibility to model refers to whether the indicator can realistically be captured in a traffic model. The time dynamism score depends on whether the FPI’s value can reasonably be expected to change over time. Scores were initially assigned by the authors and discussed in interviews with employees at RWS, specialised in the end-of-life of bridges. Summing each candidate FPI over all three criteria gives us the total score: $s_i = p_i + t_i + m_i$. A shortlist has been created for every FPI where $s_i \geq 5$. Certain indicators from the shortlist could be combined, before reaching the final selection of FPI’s.

For the selected FPI’s a theoretical foundation has been built to allow for implementation in the model representing reality. Reviews of scientific literature, internal documents at RWS, and

legal documentation has been combined with interviews with experts at RWS (Table 1) for increased validity. Consequently, the modelling approach has been determined through investigation of the available datasets and the base model inherited from Asgarpour et al. (2023).

Table 1. Expert interviews.

Alias	Expertise	Date	Duration (min)
Expert 1	Assets end-of-life	8-3-22	60
Expert 2	Noise emission roads	30-3-22	60
Expert 3	Life cycle management	29-4-22	50
Expert 4	Traffic safety & road design	3-5-22	60
Expert 5	Safety indicator database	9-5-22	50
Expert 6	Noise emission roads	26-7-22	35

In previous research a traffic model has been developed “to propose an integrated, scenario-based, and transparent model for freight, passenger, emission, and energy demand estimation of the road network” (Asgarpour et al., 2023). The traffic model serves as the base model for this study. The base model contains road traffic prognoses from 2019 to 2050. The study area is confined to the Randstad in the West of The Netherlands, which accounts for the majority of the national economic activity and about half of the population. The main highways and national roads are represented in the network. The base model presents in annual time steps, among other indicators, the traffic flow throughout the network. 4 unique future scenarios have been simulated to account for uncertainty. The scenarios have been adopted from a Delphi study by Neef et al. (2020):

- **Green Revolution:** Green Revolution portrays the most environmentally friendly future possible, wherein emission and the use of fossil energy are drastically reduced. Energy transition investment and societal acceptance for a greener lifestyle are ample. Henceforth, remote working is ingrained.
- **Infraconomy:** The obvious wordplay and contraction on infrastructure and economy paints a world where the driving force is economic interest. Limited efforts will be made to tackle climate change. Meanwhile globalisation continues at a high pace in an upward trend. The economy is characterized by strong product-based developments, where a dependence of fossil fuel remains.
- **Missed-Boat:** The missed-boat scenarios is epitomized by challenges regarding governance, politics, society and the environment, which yields shortcomings with regard to a sustainable society. Fossil energy will remain a source of energy at large, whereas environmental friendly technologies will be adopted to a limited level.
- **Safety Revolution:** Safety Revolution depicts a world where well-being is the summum bonum, at the expense of economic growth. Work weeks are shorter, virtual meetings are on the rise, environmentally friendly means of transport experience an increase and population will grow disproportionately fast in rural areas. As a result of a more conscious lifestyle, slowbalization sets through. This expresses itself in more local consumption.

Following the modelling approach, the next step was software implementation, before finally running the simulations. After running the simulations, the final step was to visualise the model’s output to support the asset management decision process.

3 MODEL DEVELOPMENT

3.1 Indicator selection

An initial list of 89 candidate FPI’s has been composed based on previous literature reviews on the functional performance of bridges (Cuendias González, 2018; van Iddekinge, 2020; Xie, 2017). After assigning the scores and checking them with employees at RWS, 20 FPI’s

with an $s_i \geq 5$ remained. Certain FPI's have been combined, since they represent similar requirements. In the end, 3 FPI's remained:

- Traffic flow;
- Noise;
- Safety to users.

3.2 Modelling variables

The FPI's require a theoretical foundation, in order to implement them into the model. Traffic flow has thoroughly been studied since the popularisation of cars. Greenshields (1934) first described when the traffic flow approaches the maximum flow, density increases, and cars are forced to reduce speed. Subsequently, a considerable amount of research to formulate the speed-density relationship (de Dios Ortúzar and Willumsen, 2011; Ni, 2016), with variations in degree of fitness and parsimony. Akçelik and Rouphail (1993) showed that a reduction in speed gets increasingly sharper as the proportion between traffic volume and capacity approaches and exceeds 1.0 as a result of *overflow*. Ever since, the relationship between traffic volume and capacity is often referred to as volume/capacity ratio or intensity/capacity ratio (I/C ratio). In this paper, the latter definition will be used from now on. Geometry comes into the picture when the I/C ratio is too high and capacity enhancing measures are proposed.

RWS is legally obligated to comply with noise regulations. For 60,000 (fictitious) reference points along the highways in The Netherlands, an individual noise production ceiling has been stipulated. The stipulated noise production ceiling minus the computed noise level is called noise space. RWS annually reports the remaining noise space of all reference points to the ministry in a compliance report. All reference points with noise space less than 0.5 dB, or a negative value even, require clarification from RWS. At reference points where the (impeding) exceedance is not of temporary nature, RWS has a number of possible interventions at their disposal such as applying a new service level to the highway produces less noise. In case that is insufficient other measures such as noise barriers will be explored.

Safety is a precondition for a road network. Nevertheless, traffic safety has seldom been an immediate cause for replacement or renovation of bridges. Expert 4 indicated that generally safety starts playing a role once it has been ascertained that an asset has reached its end-of-life, and replacement and renovation is initiated. Nevertheless, other interventions such as the installation of lampposts may be required. Traffic safety can be described both quantitatively and qualitatively. To express traffic safety quantitatively, safety performance functions (SPFs), also known as accident prediction models, have been developed (American Association of State Highway and Transportation Officials, 2010; Intini et al., 2021; Lord and Mannering, 2010; Persaud et al., 2002). However, SPF's are more suitable for stretches of road, rather than on a bridge level. Instead, RWS has adopted a more proactive and pragmatic method to manage traffic safety: VIND (VeiligheidsINDicator; Safety indicator). In essence, VIND is a geographic database where road stretches' shortcomings are stored. Road stretches of 100 meter long are uniformly rated on a three point scale (green, orange, red) for 12 characteristics. Green means the situation meets the guidelines; there is no increased risk. Red depicts a highly undesirable situation. Orange means the situation is potentially unsafe, depending on compensating measures. It is up to the local road manager to make a judgement call on whether or not the risk is acceptable. The list of characteristics in VIND are as follows, where an asterisk (*) indicates a dynamic characteristic:

- Road surface roughness
- Shoulder right side
- Shoulder left side/middle
- Horizontal curve
- Traffic jam tail protection*
- Cant
- Transverse gradient
- Emergency lane presence

- Illumination*
- Driving speed
- Starting point guide rail right side
- Starting point guide rail left side/middle

The dynamic characteristics' values changes over time as a result of changes in the environment, contrary to the other characteristics where their values only change as a result of deterioration or interventions by the road agency. Thus, the 2 dynamic indicators have been incorporated into the model as FPI's for traffic safety, each according to their own evaluation process. Traffic jam tail protection receives the score 'Green' only if the I/C ratio is greater than 0.8 and automatic incident detection is present. Otherwise it is labelled 'Orange'. Lighting as an FPI receives the score 'Green' if lighting is present and/or when the traffic flow is smaller then 3000 pcu-e. Otherwise it is labelled 'Red'.

Multiple road segments with varying scores may be connected to a single bridge. To discover where interventions are required, the model has been programmed to find most critical value through minimum aggregation on the following list [Red, Orange, Green, N/A].

3.3 *Modelling approach*

To evaluate the future functional performance levels, the bridges should be connected to the road segments. RWS has all their bridges stored in a database. The database contains bridge properties such as ID, name, description, type, status, latitude, and longitude among others.

Several filters have been applied to the database to obtain the desired selection of bridges. First of all, all bridges outside the study area were filtered out. Secondly, all bridges out of service have been excluded. Finally, the remaining bridge records within the study area that were not part of the main road network were deleted. After the operations 1183 bridges remained.

The connection between the road segments and bridges depends on the topological reality. We distinguish 3 types of connections between the base model and the bridges from the database: bridges *in*, *over*, or *in and over* the road segment(s) from the base model. A bridge *over* the road segment(s) means that the national road is located under the bridge. On the upper side of the viaduct can be another road, bicycle path, foot path or railway that may be managed by another infrastructure agency such as a province, municipality or railway agency. A bridge *in* the road segment(s) means that the national road is on the upper deck. On the lower side may be a body of water, another road, a railway, or a valley. In the case of a bridge *in and over* the road segments, 2 national roads intersect at the location of the bridge. For all bridges two empty fields were created to store information on the connected to road segments, both on the upper deck and on the lower side. It can be deducted that in any case every record must contain a value for at least one of the fields. A large share of bridges could be linked semi-automatically to the road segments using QGIS' join attributes by nearest based on the (manually) entered number of nearest road segments. The database contained information on whether the bridge was in or over the national road. Thus, it was known whether to publish the road segments ID(s) to the upper deck or lower side columns. For bridges at the intersection of national roads a connection has been established by manually entering the road segments' IDs.

Out of the 1183 bridges 191 instance have road segments linked to both the upper deck and lower side; bridges at the intersection of national roads. In 197 cases road segments are only linked to the lower side; bridges over the national road. In the remaining 795 cases, the road segments are exclusively linked to the upper deck; bridges in a national road.

3.4 *Model output*

After software implementation took place and the simulations have been run, the model yields values for every bridge, per year, per indicator, per scenario. From this data 4-dimensional data cubes can be created (Gray et al., 1997). Asset managers can access any value or array of values through different queries such as roll-up, drill down, slice (and dice), and pivoting (Gray et al., 1997; Han et al., 2012; Neha, 2020).

For enhanced human interpretation, the model’s output can be displayed in multiple different visualisations (Sternadt and Tavares, 2010). Three types will be discussed, from macro to micro. Because the bridges contain spatial properties, the values can be displayed on a map. The platform MoViCI has the built-in functionality to present the results as displayed in Figure 2. Users can move the slider at the bottom to scroll through the years. Users can also hover over a bridge to see the exact values of each indicator of a bridge.

Alternatively, asset managers can select a series of bridges. These bridges can be sorted in ascending order on expected year of technical end-of-life. From the model output it can be derived for each scenario whether, and when, a critical value will be reached. In an example in Figure 3 bridges have been selected through a query on highway name A28. In this case it has been forecasted that 9 bridges reach a critical I/C ratio in at least one future scenarios before the bridge reaches its technical end-of-life. Analysis of all bridges in the model shows that 773 out of 1183 bridges (65%) will reach a critical I/C ratio of 0.8 in at least one scenario.

Figure 2. A screenshot of the model output where the selected scenario is infraconomy and the current year is 2030. The visualised indicator is the I/C ratio.

Figure 3. Bridges part of highway A28 from left to right in ascending order of expected technical end-of-life, with the first year they reach a critical I/C ratio value of 0.8 under the 4 scenarios.

On a micro level, asset managers may be interested in individual bridges, and how their indicator values progress over time. For this purpose, a python script has been created where users can enter a bridge number, and select indicator. In the example in Figure 4, the I/C ratio of bridge 173 can be inspected throughout the years for the 4 scenarios. In contrast with the previous figure, this visualisation gives more information on the duration of the critical value, as well as the magnitude.

Figure 4. An example plot displaying the progression of the I/C ratio throughout the years for bridge number 173. The change in functional performance between 2023 and 2024 is associated with planned investments to enhance capacity downstream that will be finished in 2024. This makes the highway segment of the viaduct more attractive, leading to higher traffic intensity. All the while the capacity of bridge 173 remains constant.

4 DISCUSSION

Asset managers seek to maximise value for the objects that they manage. Functional performance has been underexposed, as previous scholars have often focused on the technical intricacies of bridges. The model developed in this study adds a new dimension to assessing bridges' life cycle performance by considering the functional performance level of bridges over a longer period of time. Interventions can be scheduled differently as a result of the insights in the functional performance. Particularly when it is forecasted that the functional performance drops below the functional requirements before the technical end-of-life is reached.

The different scenarios offer insights into potential impact on the bridges. In the infraconomy scenario traffic intensities continue to grow throughout the network. This proves to be detrimental for bridges' service life. For all bridges where a critical I/C ratio (at 0.8) will be reached before 2050, infraconomy is always the scenario where this occurs first, if not exclusively, according to the model's output. Nevertheless, reaching an I/C ratio of 0.8 does not by definition necessitate replacement or renovation.

The model has a number of shortcomings that need to be taken into account for the interpretation of the output. The base model, where traffic intensity prognosis takes place, sets the intensity to 0 where there is a parallel road segment. Thus, the I/C ratio is also skewed, since the parallel road segment receives much more traffic than what can be reasonably expected in reality. Another shortcoming is that for the majority of bridges the road segments are only linked to the upper deck or lower side exclusively. On the opposite side of the bridge there might be a road that is managed by another agency. This model does not take into account when those segments' performance becomes insufficient, which jeopardizes the bridge's remaining life time.

5 CONCLUSIONS

The purpose of this research was to develop a model that aids asset managers in their decision making by providing more insight into how functional performance develops over time. The developed model shows that bridges' functional end-of-life is expected to be reached before their technical end-of-life in numerous cases. Through 3 different types of visualisations, the model informs asset managers about the future functional performance of bridges, based on 4 indicators: I/C ratio, traffic jam tail protection, lighting, and noise. As a result, asset managers are empowered in scheduling their interventions and allocating budgets more effectively. The current model compares 4 distinct possible future scenarios. However, from the model in its current form it cannot be derived how likely each scenario is to occur. For future research it is recommended to consider a range of scenarios, so that uncertainty can be quantified better. A Monte Carlo method could be used to sample from a probability distribution of input parameters. Additionally, alternative indicators could be considered and implemented.

The end-of-life of bridges: Integrating functional, technical and economic perspective

A. Hartmann

University of Twente, Enschede, The Netherlands

J.D. Bakker

Rijkswaterstaat, Utrecht, The Netherlands

ABSTRACT: Bridges are typically designed for 80-100 years. However, within this long period the performance requirements can change due to socio-economic and socio-technical developments. This can mean the bridge becomes functionally obsolete, since, for example, its dimensions do not allow certain vehicles to pass or it cannot offer the required traffic capacity. The residual life of a bridge is often a matter of whether the bridge and its components can still cope with changing performance requirements, whether there are technical solutions available to maintain the bridge, and whether it is economically attractive to keep the bridge in place. We propose an integrative approach for determining the residual life of bridges by bringing together the functional, technical and economic perspective on bridge performance.

1 INTRODUCTION

Bridges are essential infrastructure objects of transportation networks and as such their functioning at desired performance levels contribute to the economic prosperity and social welfare of nations. However, sustaining safe and reliable performance levels of bridges has become a challenging tasks for infrastructure agencies and the challenge will persist in the coming years. This is mainly because the majority of existing bridges in many countries was built in the period between 1950 and 1970. Since the typical design service life of bridges is between 80 and 100 years, many bridges are expected to reach the end of their lifetime within the next decades. To plan their renewal and replacement in a managerially and financially feasible manner, infrastructure agencies need to get a better grip on the residual life of their bridge stock. Often this is done from a technical perspective with the physical failure of structures defining the end of life (Chang and Garvin, 2008). Main emphasis is put on understanding the deterioration of bridges and detecting deficiencies such as concrete cracks, structural deflections, erosion, or fatigue that indicate physical failure (COST, 2014).

However, during the long lifetime of bridges the functional requirements can change due to social, technological and environmental developments that particularly lead to higher traffic intensities and loads than originally anticipated. Bridges can become functionally obsolete before the end of their designed life. This can mean, for example, bridge dimensions do not allow larger vehicles to pass or bridges cannot offer the required traffic capacity. Previous studies have shown that bridges are often renewed or replaced because of functional rather than technical deficiencies (Rijkswaterstaat, 2016). Of course, the interaction of functional and technical reasons finally determines the performance of bridges. For example, the increase in traffic loads has changed the functional requirement of many bridges. Although this changed requirement can be already seen as a reason for the obsolescence of bridges, the load bearing capacity or actual performance of bridges is often large enough to deal with increased

loads due to safety margins in the bridge design. However, increased traffic loads can lead to a faster deterioration of the bridge structure through which the performance level will drop. Maintenance and rehabilitation measures can counteract the deterioration process, but require the availability of technical solutions to cope with the structural deficiencies and sufficient resources to implement these solutions. Particularly the costs of keeping an aged and fast deteriorating bridge in place then become another decisive factor for setting the end-of-life of a bridge.

Whether it should be invested in a bridge or not, is a decision of the infrastructure agency. This also means, whether a bridge has reached its end-of-life is a decision to be made by the agency. The decision not only has to deal with the economic feasibility of bridge interventions, but also with the risk acceptance level of the agency. In the context of our example, the agency may conclude that the performance a bridge was designed for is not sufficient for the increased traffic load and decide that the bridge has reached the end of its life. The residual life of a bridge is then always a matter of whether an agency considers the current performance level of a bridge as sufficient to cope with changing requirements, sees possibilities to bring a bridge to an acceptable performance level, and considers sustaining an acceptable performance level as economically feasible. In this paper, we propose an integrative approach for determining the residual life of bridges by bringing together the functional, technical and economic perspective on bridge performance.

2 END-OF-LIFE OF BRIDGES

2.1 *Bridge performance*

Bridges are built to deliver mobility services to different communities (e.g., car drivers, transport companies, pedestrians) but also have undesired impacts such as noise or environmental pollution. The performance of a bridge then describes whether the bridge is able to provide the intended services and to prevent the unintended impacts over an extended time and at specified levels with the available resources. For example, a bridge of a certain load category can effectively provide mobility services for vehicles that fall within this load category as long as the bridge structure does not show serious deficiencies and, in case of deficiencies, resources are available to remove them. With this it becomes clear that the performance of a bridge hinges on its structural characteristics and material properties, here the load bearing capacity. It becomes also clear that bridge performance depends on a number of different functional characteristics of the entire bridge structure and its components, such as the load category the bridge belongs to. The performance level of a bridge then can change in two ways. First, the actual performance (e.g., load bearing capacity) can decline over time due to the degradation of structural characteristics and material properties until it approaches the minimum acceptable performance level. Second, the minimum acceptable performance level (e.g., load category) increases over time or at certain moments in time because of changing expectations and requirements. In both cases, the actual performance level can fall below the required performance level and in both cases an infrastructure agency can decide to implement intervention measures to increase the actual performance level. However, the agency can also decide that the bridge or its components have reached the end of their life.

2.2 *Functional end-of-life*

The functional end-of-life describes the point in time when a bridge no longer meets current or expected performance requirements, even though its technical deficiencies are marginal. The performance level of the bridge has not decreased because of a deteriorated structure. What has changed, is the required performance level the bridge needs to provide. These changed requirements typically stem from socio-technical and socio-economic developments and include technological changes (e.g., new types of vessels require higher bridges), regulatory changes (e.g., assessing structural safety of existing structures), economic changes (e.g., more heavy traffic due to local business park), and behavioral changes (e.g., less traffic due to more

homeworking) (Lemer, 1996). Although it is almost for sure that expectations and requirements will change, it is much more uncertain how fast they change and in which direction. The functional end-of-life implicates the replacement of the bridge, because it does not meet the minimal performance requirements accepted by the agency and it is not possible to technically adapt the bridge to the new requirements.

2.3 *Technical end-of-life*

The technical end-of-life often comes with two connotations. The first one corresponds with the design life of bridges and describes the period of time for which bridge performance should stay above a minimum acceptable level. Typically, bridge performance is decreasing over time as a result of technical deficiencies. The reasons for these deficiencies can be manifold and include deterioration and aging of bridge structure, environmental circumstances, material quality or execution of construction and maintenance works (COST, 2014). When serious technical deficiencies occur, the performance of a bridge and its components can reach a minimum acceptable level and, thus, their technical end-of-life. However, in most cases the bridge lifetime can be extended by applying maintenance and rehabilitation measures. The second connotation then refers to a situation in which a bridge or its components are unrepairable and the performance cannot be brought back above the minimum acceptable level. A reason might be outdated technology or the unavailability of spare parts. Since currently available technologies, techniques and materials can deal with most technical deficiencies, only a small number of bridges will be completely renewed or replaced due to technical reasons (Bakker, Roebers, & Knoops, 2016). The decision rather becomes an economical one.

2.4 *Economic end-of-life*

Considering that almost any bridge can be maintained or rehabilitated, costs finally dominates decisions. This not only includes the costs for individual interventions, but also the expected cumulated costs over the lifecycle of a bridge to keep it on a desired performance level. Since technical deficiencies can increase in number and frequency with older structures and components, the maintenance and rehabilitation costs will increase as well. At a certain point in time, it might no longer financially viable to keep the bridge or its components in place and replacing it becomes the economically more attractive alternative (Bakker, Roebers, & Knoops, 2016). The bridge has reached its economic end-of-life. However, deciding on whether replacement is economically more favorable compared to maintenance requires to set an expected replacement year until which the bridge needs to be maintained. This makes it challenging to estimate the residual life time of bridges. In the following an integrative approach is proposed that brings together technical, economical and functional perspective on performance and the end-of-life of bridges.

3 INTEGRATED APPROACH FOR DETERMING THE RESIDUAL LIFE OF BRIDGES

3.1 *Overview*

The approach consists of four main steps:

1. In a first step, the relevant performance aspects and indicators for the evaluation of bridges are identified and the assessment scale is established.
2. The second step is the evaluation of the bridge performance from a functional perspective which includes assessing the performance of the bridge in the light of current and future socio-economic and socio-technical developments and estimating the functional end-of-life.
3. In a third step the performance is assessed from a technical perspective and the technical possibilities to keep or attain an acceptable performance level until the end of the functional life are identified.

4. The fourth step is the assessment of whether it is economically viable to maintain the bridge until the end of its functional life or to replace it immediately.

3.2 Identifying performance aspects

Bridge performance is multidimensional and typically includes a number of aspects of the mobility service delivery. Typical performance aspects are shown in Table 1.

These performance aspects need further decomposition to become measurable. Here, different performance indicators need to be identified. A (not comprehensive) overview of potential indicators is given in Table 2.

Table 1. Bridge performance aspects.

Performance aspect	Definition
<i>Safety</i>	refers to the effect of bridges on the risk of user to get involved in an accident.
<i>Availability</i>	refers to the effect of bridges on the time duration in which they can be used when needed and as intended.
<i>Accessibility</i>	refers to the effect of bridges on the possibilities of users to cross over and under the bridges.
<i>Reliability</i>	refers to the effect of bridges on the time duration in which they can be used without any disruptions.
<i>Environment</i>	refers to the effect of bridges on their direct physical and natural surroundings.
<i>Resource efficiency</i>	refers to the effect of bridges on the absorption of material, energy, labor for constructing, maintaining and operating the bridges. It can be also regarded as the required life-cycle costs to have a functioning bridge in place.

Table 2. Bridge performance indicators.

Performance aspect	Potential indicators
<i>Safety</i>	Annual number of death people by traffic accidents on/ under the bridge Annual number of hospitalized people by traffic accidents on/ under the bridge Annual number of accidents with material damage on/under the bridge
<i>Availability</i>	Traffic flow on/under the bridge The average increase of time in minutes of detouring the traffic through an alternative route if the bridge is closed The average increase of time in minutes of using an alternative transportation if the bridge is closed
<i>Accessibility</i>	User delay costs derived from traffic congestion caused by the bridge Load class of the bridge Height under the bridge Width on/under the bridge
<i>Reliability</i>	Roughness index of the bridge surface Age of the bridge Failure probability of bridge components
<i>Environment</i>	CO2 emissions produced during the bridge lifecycle Noise emissions produced by the bridge Whether the bridge has been built with reusable or recyclable materials that could ease the bridge dismantling Whether the bridge construction materials contain polluting materials
<i>Resource efficiency</i>	Maintenance costs Operating costs Renewal costs

The selection of indicators should be driven by their representation of the performance aspect and the bridge context from the perspective of the infrastructure agency, their relevance for the agency, and the availability of data.

3.3 Functional assessment

The purpose of the functional assessment is to determine the current and future bridge performance as the result of changes in the bridge context and whether or when a bridge has reached its functional end-of-life and needs to be replaced. This requires in a first step to set up the measurement scale for performance indicators and defining the performance level that still meets the expectations and, thus, can be accepted. Infrastructure agencies often use qualitative scales to express bridge performance and acceptance level. For example, this might be a 4-point scale ranging from 1 (perfect performance) to 4 (poor performance). The quantification of the performance levels helps in assessing bridge performance but requires the availability of performance data. In Table 3 possible measurement scales for the two indicators user delay costs and bridge heights are shown.

Table 3. Performance indicator scale.

	Level 1 (Perfect)	Level 2 (Good)	Level 3 (Fair)	Level 4 (Poor)
<i>User delay cost (€/km)</i>	0 - 2.000	2.000 - 36.000	36.000 - 347.000	> 347.000
<i>Bridge height (m)</i>	$H \geq 4,45$	$4,05 \leq H < 4,45$	$3,85 \leq H < 4,05$	$H < 3,85$

The acceptable minimum performance level highly depends on the nature of the performance indicators, the context of the bridge, and the risk attitude of the agency. The minimum level can relate to specific regulations (e.g., for the load class), can be the result of policy constraints (e.g., maintenance costs), or can emerge from the user behavior (e.g., traffic flow). For example, it can be decided that the scoring of performance indicators at Level 4 is not acceptable and that Level 3 represents the minimum score to be achieved. After setting the minimum performance level, the current performance of a bridge is evaluated. The evaluation may reveal that one or more indicators score below the defined performance threshold. This would mean, the bridge has reached its functional end-of-life. However, this does not necessarily mean that the bridge needs to be immediately replaced. The bridge may still continue performing at this level if the agency is willing to temporarily accept the higher risks associated with it. This might be particularly the case if performance levels include larger safety margins (Chang and Garvin, 2008). There might be also possibilities for interventions to increase the performance level of the bridge. For example, a bridge that scores poor on user delay costs may have extra space on the bridge deck for adding an additional lane. In both cases, the bridge should be technically assessed to decide on its functional life.

The bridge could also score sufficiently on all relevant performance aspects. Then, the future performance development should be modelled to estimate the remaining functional life of the bridge. In other words, through simulating different future scenarios of the socio-economic bridge environment the moment in time can be identified when bridge performance falls below the acceptable performance level. Here, transport demand is the main factor linking socio-economic developments and bridge performance. For example, an increase in global trade will lead to higher transport demand which in turn can lower bridge performance in terms of availability and environment. Socio-economic developments that influence transport demand include economic development (e.g., world trade), transportation energy mix (e.g., fuel price), and mobility behavior (e.g., remote working) (Asgarpour et al., 2023). Other factors that can be expected to influence bridge performance as well are investments in innovations and environment protection commitment. Both factors affect energy demand and amount of emission. Besides socio-economic developments, climate change impacts also may increase the performance requirements of bridges. For example, regular heavy rainfalls may

set higher requirements in terms of availability and accessibility, because a bridge and adjacent roads are more often flooded.

An example of modelling the future infrastructure performance is the scenario-based strategic model proposed by Asgarpour et al. (2023). This model determines changes in the performance of road transport infrastructure under future scenarios. It estimates freight and passenger transport demand based on several socio-economic demand drivers, and capacity utilization, emission and energy consumption as performance indicators resulting from transport demand. By applying the model to the main road network in three Dutch provinces, it could be shown that if the road network stays at the current capacity level, it will experience noticeable capacity problems and delays until the year 2050 under an economic growth scenario. The model is further developed for the functional assessment of bridges for three performance indicators: traffic flow, noise, user safety (Mooren et al., 2023). There are two possible outcomes of this assessment: (i) the bridge is already at the end of its functional life or (ii) the expected remaining time before the bridge will reach its functional end-of-life.

3.4 *Technical assessment*

The purpose of the technical assessment is twofold: (i) it determines the current and future bridge performance as the result of a deteriorating bridge structure, and (ii) it identifies possible interventions to maintain or increase bridge performance to a desired level. While the functional assessment is interested in changes of performance requirements, the technical assessment concerns changes in the structural characteristics and material properties of a bridge through which performance requirements cannot be met. For example, reinforced concrete beams of a bridge can show degradation of structural stiffness and load bearing capacity leading to damages (Liu et al., 2018) and, thus, lower accessibility (e.g., load restriction) and resource efficiency (e.g., maintenance costs). Then, the technical end-of-life is reached when degradation processes reduce the performance level of a bridge to an extent that is no longer acceptable by the infrastructure agency. Here, the relationship with the functional end-of-life comes to the fore. The acceptable performance level reflects the expectations of stakeholders on bridge performance and the structural degradation reduces the capability of a bridge to meet these expectations. This means, one of the two outcomes of the functional assessment becomes the starting point for the technical assessment of a bridge.

In case the bridge is already at the end of its functional life, the technical assessment should determine whether an immediate replacement of the bridge is needed or to which extent and over which period of time reduced but still acceptable structural safety margins allow to fulfill the expected performance requirements. A bridge may experience more heavy traffic loads that extend the design loads of the bridge. The bridge has reached the end of its functional life, but due to safety margins in the bridge design the bridge is still able to accommodate the higher traffic load. For the agency this basically means a trade-off between reliability and accessibility. The agency lowers the requirements for reliability to allow higher accessibility requirements. Here, assessing the capability of the bridge to carry the higher traffic load asks for advanced probabilistic approaches that model significant deterioration mechanisms and load time dependency. However, these approaches involve intense working procedures, require larger amount of data and are usually costly. They seem only reasonable for bridges showing significant structural deterioration and for which a further reduction of safety margins can be expected (Viana da Rocha et al., 2016). An important part of the technical assessment then becomes the inspection of the bridge structure and the monitoring of the bridge behavior. Particularly the latter can help in providing information about the actual structural response of a bridge to increased loads and real structural changes, which allow for the prediction and identification of damages (de Raat et al., 2023). Based on the insights in the structural degradation of a bridge, the consequences for bridge performance, and the risk acceptance of the agency, the agency can decide on possible interventions to reduce or eliminated the deterioration over a certain period of time.

In case of a bridge with an expected remaining period of time before the bridge reaches its functional end-of-life, the technical assessment should show to which extent the structural characteristics and material properties of bridge are changing within the remaining functional life and whether these changes lead to the technical end-of-life. For example, the load class of a bridge might be sufficient for the current traffic loads but future scenarios in terms of truck platooning may reveal that within 10 to 15 years the loads will be above the bridge design level (Ling et al, 2022). The deterioration of the bridge within this period may lead to a drop in the performance level as well. The bridge may reach its technical end-of-life. However, maintenance and rehabilitation interventions can increase the performance level, so that the bridge can be kept in place until the end of the estimated end of the functional life.

3.5 *Economical assessment*

The purpose of the economical assessment is to estimate and compare the costs of different intervention options for dealing with bridge performance that are under a minimum acceptable level. This means, the economical assessment is done for the two cases described under technical assessment. For the first case, when a bridge has reached its functional end-of-life and for which the agency could identify measure to maintain the bridge at a higher performance level, the assessment should show for which period of time the maintenance costs outweigh the costs of a direct replacement of the bridge. At the end of this estimated period the bridge is at the economic end-of-life provided that the agency is willing to accept the functioning of the bridge at a performance level that is below the acceptable level but within safety margins. For the second case, when a bridge has a remaining functional life, the assessment should compare the life-cycle costs for two options: (i) maintaining the bridge and replacing it at the end of its functional life, and (ii) direct replacement of the bridge and subsequent maintenance. If the direct replacement is the economically more attractive option, the bridge is at its economic end-of-life.

4 CONCLUSION

When should a bridge be replaced or how long will a bridge perform at desired levels? Deciding on the residual life of a bridge is a challenging tasks for infrastructure agencies, since it cannot be reduced to technical deficiencies. The replacement of a bridge is a matter of functional, technical, and economical reasons. In this paper, we proposed an integrative approach for the assessment of bridge performance from a functional, technical and economical perspective and we showed how these three perspectives interact in determining the end-of-life of bridges. We believe that adopting such an integrative approach by infrastructure agencies can lead to more informed and underpinned decisions on the replacement of bridges and a more balanced planning of the replacement tasks many infrastructure agencies are confronted with.

How to estimate costs of replacement for an aging infrastructure, a Dutch case study

G.A. De Raat

Rijkswaterstaat, Utrecht, The Netherlands

ABSTRACT: In the Netherlands many objects in the national infrastructure are reaching or have reached the end of their designed lifespan. To ensure sufficient budget for replacement or renovation, an estimation of costs for the next 30 years is needed. This requires an estimate of the year of end-of-service life and an estimate of replacement costs. As Rijkswaterstaat is responsible for 64.000 structures, in addition to roads and waterways, an in depth investigation of each object is not feasible. Therefore, we use a combination of three methods. To estimate the costs of replacing or renovating an object we make use of the key figures that are derived from building new objects. However a replacement or renovation comes with different challenges. Furthermore there are some unknown cost variables. The paper also describes how the 2022 estimation process differs from the previous years.

1 INTRODUCTION

Rijkswaterstaat is the executive agency of the Ministry of Infrastructure and Water Management in The Netherlands. It manages and develops the main road network and waterway network plus the main water systems. Our objectives are to ensure that The Netherlands is protected against flooding, that there is sufficient green space and an adequate supply of clean water, and that people can travel quickly and safely from A to B.

To reach these objectives Rijkswaterstaat manages 64.000 structures, in addition to roads and waterways. These contain ca. 7000 km roads and 800 km dykes and dams, which contain 4000 larger fixed object like viaducts and the majority of bridges, and 500 objects with movable parts like sluices, movable bridges and storm surge barriers.

The majority of these objects will reach their designed lifespan in the current and upcoming decades and need to be replaced or renovated in the upcoming decades. In order to manage this wave of replacements and renovations a program was started to research ways of defining the end-of-service life and to determine the amount of funding (expenditure) needed to replace or renovate the infrastructure of Rijkswaterstaat. In this program we work together with engineering companies, other asset managers and knowledge institutes. Ultimately the goal of the program is to incorporate the developed methods into the day-to-day processes so that the program itself can be discontinued.

This paper describes how we have estimated the expenditure for these replacements or renovations over time in 2022 (Klatter 2022). This is the basis for government funding for these measures and is estimated per decade. Due to results of an audit on the previous way of estimating, in 2022 we changed our approach in a number of ways. Parallel to this change in approach there is an ongoing improvement in the estimation by collecting more and better data on our assets and the state they are in, by adding more types of assets, by more sharply defining the scope and by improving the costs models. This is a continuous effort for the whole of Rijkswaterstaat as e.g. the data and definitions are used for other purposes as well. The paper also discusses a number of the consequences of this way of working.

The paper describes the scope of the estimate (measures and assets), followed by the way the end-of-service life and the costs were determined. It then compares this estimate with the previous version and ends with conclusions and outlook.

2 SCOPE OF THE ESTIMATE

2.1 *Scope of measures*

Asset management activities at Rijkswaterstaat are funded out of three different sources. Firstly, investments in expansion of our infrastructure like adding new assets or new functionalities, secondly, maintenance during the lifespan of an asset and thirdly investments in renovation and replacement when an object has arrived at its end-of-service life due to economical (maintenance is getting more expensive) or technical (no longer able to function properly) reasons. These investments also include IT upgrades. The last source of funding is the subject of this paper.

In practice it is not always clear which source to use for a specific asset management activity. For example, the question can be asked when something is a large maintenance project or a renovation, or whether supporting heavier traffic is a new function that asks for an investment or merely a cause for faster deterioration and therefore a reason for replacement. This is an ongoing process, that over time will change the estimate of expenditure in more and more incremental ways.

2.2 *Scope of assets*

For the estimation in previous years the scope of the asset portfolio was partly determined by gathering asset overviews from our different regions. In 2022 the main corporate asset register was used. This led to a clearer and more orderly scope. However, not all objects are taken into account for the estimate:

As we are still refining the estimation process some types of assets are yet to be taken into account. These consists of large groups of smaller objects and about a dozen of larger ones. For example, Rijkswaterstaat owns one mechanical siphon, which has not been added yet. The first estimation is that these will add 4% to the total costs for replacement and renovation.

Secondly, some type of objects are managed just by maintenance measures, like river beds and dunes.

A third category of excluded objects are those that were under construction on March 1st 2022 and therefore already had funding. As soon as these objects are operational, the costs for renovation and replacement have to be added to the financial reserves for asset management, including maintenance. The same goes for objects that change owner. This category constitutes a small number of objects.

The final category consists of the objects with lacking data, like year of construction or measurements, or lacking a cost model. For those it was not possible to make a reliable estimate. This is still a significant quantity of small objects. It is expected that this leads to a small under-estimation of the needed funding, about 1%.

We therefore roughly estimate that the estimation covers 95% of the costs.

3 DETERMINING END-OF-SERVICE LIFE

As the scope states this paper describes the way we estimated the costs for replacement and renovation, which for this estimate are projected to take place at the end-of-service life. Due to construction planning in reality these can differ some.

The methods described below were used to determine the end-of-service life. Note that for the estimation process costs are accumulated per decade. The methods are applied in the

described order and each method excludes the objects that were subject of the previous method(s). A schematic overview of the methods in time is given in Figure 1. This shows that the further we move through time, the estimation relies more on statistical analysis. For the near future we are able to look at individual objects or smaller groups.

Figure 1. Schematic representation on how the assets are divided over the different methods over time.

3.1 Statistics

We start with a statistical analysis for all objects. Based on past experiences and design criteria a statistical lifetime for each type of structure has been determined. For example, for a sluice the statistical lifetime is 108 years. This lifetime is added to the year of construction, which results in the expected statistical end of life for each structure. The group and individual approach, see below, then overrule the statistical analysis. However, as shown in Figure 1, the major part of the objects have an estimated end-of-service life based on statistics.

3.2 Group approach

A group approach is used in the case that there are known problems for similar objects. These problems can arise from the same developments that are described under method 1: new insights and changings loads. Based on expert opinion a certain percentage of one type of assets was attributed to a decade. For example, 10 percent of a specific type of bridges is expected to fail between 2031 and 2040. It is at this point unknown to which exact structures this pertains. For the purpose of the cost estimate this method suffices. This method was limited to the current and the next decade. The approach per individual object can overrule the group approach. This has only occurred in a few occasions.

3.3 Per individual object

At the time of construction of an infrastructural object design calculations are made that take into account the degradation of the used material and the loads to withstand. One uses the available technical codes that describe the ways to execute these calculations and what safety factors to use. However, all of these can change over time. New insights in material degradation, calculation methods and safety factors arise, and loads can change in different ways than predicted at the inception of an object. For instance, bridges carry more and heavier traffic than their original design loads. All these factors can influence the end-of-service life. Therefore, we have recalculated the design of a number of bridges with help of finite element models. It is planned to do this for more bridges and other types of structures. However, these calculations can take up to two years to execute, including collecting data and sampling of material. In 2022 this was only done for a handful of objects.

As we try to make these calculations only for objects that are probably very near the end of their life, the resulting predictions of end-of-service life are mostly in the near future.

Besides calculations Rijkswaterstaat experts with a long service record estimated end-of-service life. Since we only give an estimation per decade, this is accurate enough for our purpose.

3.4 *Renovation regime for complex objects*

The determined end-of-service life of an object as described above is assumed for the object as a whole. The movable parts and operating systems in 500 more complex objects, like sluices and tunnels, that are to be replaced or upgraded during the service lifespan of the object are taken part of the estimation of the expenditure for renovation and renewal. To determine these moments of renovation we use standard intervals, e.g. 20 years for a small upgrade and for a big overhaul a standard interval of 50 years is used. The latter occurs theoretically only once, since the end-of-service life for most complex objects is about a 100 years. These renovations and replacement are shown in Figure 2.

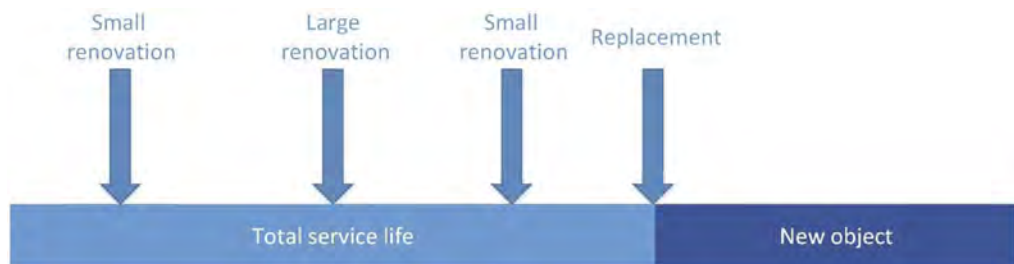

Figure 2. Schematic representation of the renovation and replacement regime of a complex object.

4 DETERMINING COSTS

Parallel to determining the end-of-service life, the costs for replacement and renovation were determined. We distinguish three categories that are described in the next paragraphs: The baseline: costs that we can substantiate with data, uncertainty in costs that we can only estimate, costs depending on future trends.

4.1 *Baseline*

For the baseline first the direct costs (man-hours for construction, material and equipment) are determined to which percentages are added for indirect costs like engineering and taxes. The latter are a percentage of the direct costs, varying per type of structure. The key figures for the direct and indirect costs are based on years of experience of commissioning new infrastructure. The uncertainty that this causes is addressed in the next paragraph. We then proceeded to parametrize these costs of the same type of objects over the surface area (e.g. m² surface of a small concrete bridge) or length (e.g. per running meter for sheet piles).

We set the price level of the direct costs at January 2022. Of course prices have increased significantly due to the war in Ukraine, for example for steel and it is uncertain how prices will develop over time. However by choosing a fixed date, costs can be adjusted when prices stabilize over time by comparing these to the ones at the fixed date.

For the projection of the costs over time it is assumed that the costs occur instantaneous at the end-of-service life. Rijkswaterstaat does not use depreciation of value over time. Furthermore, even though costs like design and preparation costs are made before the moment of replacement the costs are projected at one specific year.

Finally agreed upon extra costs by the asset owner were added. For durability like the use of sustainable materials etc. 2% is added to the total amount. For diverting traffic while executing measures at our main road network 7% is added to the total estimated costs for renovating or replacing parts of the main roadwork. As there is no agreement on costs for traffic while working on waterway network, no cost were taken into account for this. This all results in a baseline as is shown in Figure 3.

Figure 3. The estimated baseline fur funding.

4.2 Uncertainties

Experience with renovation of replacement projects is still limited and key figures have yet to be derived. It is acknowledged however that costs can differ. For example, having to work within an existing infrastructure constraints an optimal design. Next to these there are developments that will take place in the foreseeable future, like more use of IT, bundling construction of several objects in one portfolio and incorporating resilience to climate change. Also, due to new regulations, new objects like bridges should be rebuild wider than they were, with additional costs for the adjacent road infrastructure. For these expenses Rijkswaterstaat experts estimated percentages to add on to or subtract from the baseline. However, since they are less predictable and depend on future decisions they were not added to the baseline itself. Depending on the type of assets the percentages add up to 70%. To manage expectations, innovations are only taken into account as proven technology, at which point they are incorporated into the baseline.

There are two other significant uncertainties that influence the total expenditure. For both these uncertainties scenario analyses where done. The first significant uncertainty is renovation instead of replacement at the end-of-service life or a whole object. This choice depends on many factors which are only partly under the control of Rijkswaterstaat. A scenario analysis for bridges shows a decrease in needed funding of 100 to 550 million euros per decade.

The second significant uncertainty are those objects that have to fulfil a new demand. These demands can occur before the end-of-service life or when end-of-service life is reached. Historically, 88 percent of the replaced bridges were replaced as part of an investment in infrastructure improvement, like road widening (Rijkswaterstaat 2026), and therefore financed through a different source of funding. Whether this will continue in the future is unknown. There are

limiting factors for new functions, like saturation of the demands on the infrastructure and the current nitrogen crisis. Either way, these measures are funded from a different source and impact the estimation for replacement and renovation. A scenario analyses for fixed objects shows a decrease of the total estimate up to 15%.

In the report on the estimation we did not add up these uncertainties. To estimate the total costs of investments we only take the uncertainties into account that enlarge the estimate. The decisions to renovate or replace and the decisions to add new demands are made outside of Rijkswaterstaat and therefore we can only partly influence these decisions.

4.3 *Future trends*

The last category are uncertainties that we are not yet able to express in costs, like climate-adaptation, truck platooning or other developments that are awaiting policy changes from the government. These costs were not taken into account in the estimate.

5 COMPARISON TO PREVIOUS ESTIMATE

As stated in 2022 a big step was made to make the process reproducible. Before 2022 a bandwidth of 50 % was used to take uncertainties into account. In 2022 this bandwidth was broken down into the different components some which were added to the baseline, like the percentages for durability and diverting traffic. Many of the other component we described in paragraph 4.2. Also some objects that have missing data were left out altogether in the 2022 version. This makes a comparison between the estimate of 2022 and earlier estimates difficult or even impossible.

6 CONCLUSIONS

The estimation process to determine the needed funding for renovations and replacements is still developing and has come a long way. In 2022 the process was adjusted to be more reproducible which led to a different approach than before and makes a comparison to previous estimates difficult.

To further improve the estimation, steps can be taken to collect more data on the objects and incorporate all objects that are in need of renovation or replacement in the next 25 to 30 years. Also key figures for determining the costs need to be based on renovations and replacements instead of new constructions. It can take several years of experience with renovations and replacements to build a costs database to extract key figures from.. Furthermore, more methods to determine the end-of-service life need to be developed. Not only funding, but also staff is needed at Rijkswaterstaat and our contractors to execute the necessary measures. As there is a shortage of staff, this will limit to ability to execute the needed measures and therefore influence the needed budget.

How to translate the estimate and the remaining uncertainties into government funding is yet to be established in conjunction with the policy department of the Ministry of Infrastructure and Water Management.

Plannability of maintenance in life-cycle decision making for infrastructure

J.D. Bakker & R. Treiture

Rijkswaterstaat, Utrecht, The Netherlands

ABSTRACT: Most infrastructure management systems include maintenance planning. Traditionally these maintenance plans are generated based on condition based inspection procedures. In the past decades, infrastructure management organizations like Rijkswaterstaat have moved towards a more tactical maintenance planning, where maintenance and replacement measures are planned at forehand based on known object behavior, and inspections are used to verify and to adjust the maintenance plan based on observations. Practice shows however, that not all maintenance can be planned at forehand. For the long term planning, it is important to have some idea of the plannability of maintenance. This is also relevant for estimation of the expected performance. This paper describes how Rijkswaterstaat has come to estimates of the ratio between regular, plannable periodic maintenance and more incident driven maintenance, and how this can be used in performance management, maintenance planning and end of life evaluations.

1 INTRODUCTION

1.1 *General*

This paper deals with plannability of maintenance. Plannability is a very important aspect for maintenance managers working with life-cycle maintenance plans. A considerable part of the maintenance is initiated by random events, in time and place. This issue is seldomly explicitly dealt with. Sometimes the expected effect of unplanned maintenance is neglected in maintenance plans, or modelled as planned maintenance, both leading to an unreliable maintenance plan. This paper deals with this issue, from the experience of Rijkswaterstaat. Rijkswaterstaat uses life-cycle maintenance plans since a few decades. In the recent years the awareness of the plannability issue grows. This paper deals with the recent insights on how to look at plannability issues, and describes the first steps Rijkswaterstaat is making on this issue. After a brief introduction on Rijkswaterstaat in chapter 1, chapter 2 will explain the different aspects on (un)plannability of maintenance from the experience of Rijkswaterstaat. Chapter 3 describes the use of life-cycle maintenance plans at Rijkswaterstaat, and explains where plannability is an issue and how Rijkswaterstaat takes a first step in dealing with this. Chapter 4 deals with the conclusions and the way forward.

1.2 *Rijkswaterstaat*

Rijkswaterstaat is a government agency within the Dutch Ministry of Infrastructure. Rijkswaterstaat maintains and operates 3 national networks: the Main Water System (transport of water to the sea, and along the sea-shore), the Main Waterway System (transport over water, ships) and the Main Road Network (road traffic). These transport networks need supporting infrastructure to be able to deliver performance: All these infrastructure are assets, owned by the government but maintained by Rijkswaterstaat.

1.2.1 *Responsibilities and finance structure*

Rijkswaterstaat is financed separately for new construction, large scale maintenance and replacement projects, and the regular maintenance works. Both the new construction and the large scale reconstruction and replacement works are financed project wise (Klanker et al., 2016). To finance the regular maintenance works (all those activities needed to maintain the required performance levels) Rijkswaterstaat agrees every 4 years with the ministry on a Service Level Agreement (SLA) that defines the performance to be delivered for an agreed maintenance budget (van der Velde et Al, 2012). This SLA-period will increase to 8 years in the near future. This SLA requires a solid financial justification methodology.

1.2.2 *Service level agreements for asset management*

The SLA contains a set of Performance Indicators for a delivered outcome, and both a long term and a short term cost estimate of the needed budget to deliver this performance. The justification for this cost estimate is based on Object Maintenance Regimes (OBR) for the long term, and explicit maintenance plans for the short term. The OBR describes life-cycle maintenance strategies for different asset types. Based on these OBR's an estimate of long term budget need is made based on unit prizes (P) per type of asset * the quantity (Q) of these assets.

Short term budget needs (1-6 years) are based on actual life cycle maintenance plans for individual structures. Even though the assumptions for short term maintenance needs are based on the same OBR's, the individual maintenance plans may differ from the long term average. Typical reasons are:

- On object level the distribution of cost in time is not even. Maintenance needs may vary considerably from one year to the other;
- Maintenance backlog may cause additional cost in the short term planning;
- Inspection leads to a more precise planning than the long term average expectations;
- The short term planning consists of actual planned projects rather than individual long term average maintenance activities.

1.2.3 *Plannability of maintenance activities*

Until recently, both the OBR's and the life-cycle maintenance plans presumed predictable behavior in time. The assumption was, that based on the construction type and the used materials a maintenance prognosis could be generated, predicting all the needed maintenance activities in time. Inspection would predominantly be needed to justify the exact moment of maintenance.

Practice shows however, that inspections also lead to new maintenance activities, that were not predicted before in the OBR's or in the life-cycle maintenance plans (Bakker & Klatter, 2012). Neglecting this more or less “unplanned maintenance” can lead to an under-estimation of the necessary budgets on the long term and to an unstable maintenance programming, because the “new facts” that emerge from the inspection often lead to both constant replanning and budget shortfalls. Therefore the realization came that some sort of budget reservation was needed both in the OBR's and in the short term maintenance planning to deal with these uncertainties. Until recently, the only reservations taken into account were those for calamities that need immediate repair.

First efforts at Rijkswaterstaat to quantify the financial impact of unplanned maintenance have led to (conservative) reservations in the OBR's and in the life-cycle maintenance planning. But more detailed studies still need to be done to actually quantify the financial impact more precise. First step will be to describe the logic and philosophy on dealing with planned and unplanned maintenance. This paper does so. Chapter 2 describes this logics, based on the findings at Rijkswaterstaat. Chapter 3 will give a state of the art on how Rijkswaterstaat deals with the plannability of maintenance at this moment. Chapter 4 deals with the evaluation and conclusion.

2 THE CONCEPT OF PLANNABILITY EXPLAINED

2.1 *Life-cycle maintenance plans*

2.1.1 *General*

Traditionally maintenance managers rely on inspections exclusively for their maintenance planning. In recent decades the use of life-cycle maintenance plans increases in popularity. A life-cycle maintenance plan is a plan that shows all the expected maintenance activities in time. Such plan can be based on general expectations on ageing of elements in structures over time, and usually has some form of justification, for instance general reference maintenance strategies and cost justification. More complex maintenance plans have explicit LCC-optimization tooling and explicit simulation capability on expected performance effects of maintenance scenario's. Life-cycle maintenance plans can be updated based on inspections.

2.1.2 *Structures*

If periodic inspection are the exclusive source for maintenance prognosis, maintenance will be reactive, with a limited capability to look forward in time. This is why maintenance managers nowadays try to combine maintenance activities of different assets as effective as possible, and therefore an insight of the expected maintenance needs for at least 6 years ahead or longer is needed.

For civil structures the use of condition based maintenance is still quite common, because:

- Probability of detection is generally high: In most cases risks are well detectable, if inspection is done with the right focus. A good risk inventory before inspection is generally sufficient to focus inspection at such way that a reliable prognoses of future activities can be made up to 4 years ahead, and rough estimates up to 10 years ahead.
- The time between the first detection of a damage indicator and the latest moment of repair is generally long; For instance, concrete reinforcement corrosion often takes decades to develop from the first damage detection to actual failure (providing the indicator can be detected);
- Failure seldom happens suddenly. In most cases structures give clear warning sighs like deformation or cracks long before actual failure occurs.

Nevertheless, for civil structures the need for life cycle maintenance planning rather than purely condition based maintenance prognosis increases, because:

- Purely condition based maintenance tends to be reactive, and often lacks a life cycle optimal maintenance strategy.
- Large scale maintenance projects sometimes take 5 to 10 year preparation time. Maintenance managers try to combine as much as possible maintenance in one project. This is hard to do without at least some form of a lifecycle plan;
- Condition based data only is an insufficient base for long term maintenance agreements. For instance: Service Level Agreements between Asset Owners (like ministries) and Asset Managers (like government agencies);
- Only condition based information is insufficient to make a reliable cost estimate for long term maintenance contracts (for instance Design, Build, Finance and Maintain contracts)
- Only condition based information is insufficient to make lifecycle comparison between replacement scenario's and maintenance scenario's;
- Only condition based information provides information on maintenance need, but does not provide a good basis to define a maintenance backlog, because a reference is missing (maintenance backlog starts from the moment that a structure is not maintained at the economical most optimal moment, not when the condition is already bad).

2.1.3 *Electrical and mechanical components*

There is a big cultural difference between a typical “electrical and mechanical maintenance engineer” and a typical “civil maintenance engineer”. Many electrical and mechanical maintenance engineers work in the process industry, where “time is money”. The electrical and mechanical components are performance killers, leading to downtime if one component

suddenly fails, or if machines need to be taken out of production for maintenance. Not surprisingly the process industry has been upfront in their aim to optimize maintenance and maximize productivity. Condition based maintenance is less common for electrical and mechanical components. There are some good reasons why:

- The probability of detection is not high: It takes high inspection intervals or intense monitoring to detect failing components timely;
- Inspection induces an additional risk of failure: If components need to be taken apart in order to do a good inspection, there's always an additional risk of failure during inspection and right after inspection;
- The time between detection of a failure indicator and the time to repair is often too short to plan maintenance efficiently with a minimal downtime;
- If a component shows unplanned failure, this often directly leads to functional failure.

Not surprisingly life-cycle maintenance plans are common practice in the electrical and mechanical engineering. So called “planned maintenance” is a leading strategy for these types of components. Replacement is often done time-based or usage-based, (long) before actual failure is expected. Maintenance can be planned years ahead, based on general schedules, doing as much as possible in a minimal downtime. Usually not all components are replaced time-based or usage-based. Those elements that are non-critical (for instance in case of redundancy) are replaced correctively, after failure. The choice between corrective and preventive maintenance, and the optimization of life-cycle maintenance plans with a minimal downtime is a typical job for the maintenance engineer.

2.2 *Statistical predictability versus plannability*

2.2.1 *General*

Life-cycle maintenance plans show their value for those maintenance activities that are “plannable”: Those activities that can be predicted in time and cost. In this chapter we will focus on plannability over time, and discuss how to deal with those maintenance activities that can statistically be predicted, but cannot be planned in time in life-cycle maintenance plans.

2.2.2 *Maintenance strategies for plannable maintenance events*

Most life-cycle maintenance plans and maintenance optimization models on the market are dealing primarily with plannable maintenance events and corrective maintenance events. The assumption is that there are no random events, and all maintenance decisions are initiated by aging processes with a predictable maintenance need in time. Aging can be either chemical or mechanical, or a combination of both. Either based on statistical data or based on theoretical modeling of the aging effect, it is possible to make maintenance strategies that can be planned in a life-cycle maintenance plan. Depending on the accepted risks and the options to quantify the aging (inspection, monitoring, prediction modeling) the maintenance measure can be taken either

- 1) long before failure (time- or use dependent preventive maintenance);
- 2) at an optimized intervention level (condition based or predictive) or
- 3) after failure (corrective maintenance).

Preventive maintenance is perfectly plannable in a life-cycle maintenance plan based on fixed maintenance intervals. Condition based or predictive maintenance is plannable too, based on expected maintenance intervals (from theory and practical experience), but the planning needs to be adjusted based on inspection. Corrective maintenance usually presumes direct replacement after failure. Therefore, failure induced maintenance cannot be planned. An age-dependent financial reservation can be made tough.

In many cases failure of a component does not directly cause failure of the complete functionality. For instance, if 3 road lanterns have failed, spread out over a row of 25 lanterns, the total road-lightning may still be sufficient. In this case the failure of 3 lanterns is not considered to be corrective maintenance. “3 failed lanterns” can be an intervention level for condition based maintenance, and can be considered as plannable, since the lightning system has not failed yet.

Life cycle maintenance plans need to be explicit on the related maintenance strategy, because the interpretation in the planning differs: A preventive replacement 10 years from now can be planned accurately, but a corrective replacement 10 years from now is merely a financial reservation: in practice the actual replacement may be earlier or later, directly after failure.

2.2.3 Random maintenance events: An example

Some maintenance and repair activities cannot be planned in advance. For instance, if a viaduct is damaged in a collision with a vehicle. If this happens, repair will be needed. If the probability is 1 to 50 each year for a viaduct to be involved in some sort of collision, this does not result in a plannable maintenance activity every 50 years. The cost of this repair may vary from €1.000,- to €1.000.000,-. Still yet, for each bridge it's possible to make a statistical prediction of the probability of collapse per year and the expected cost. If a bridge stock includes several thousand of viaducts, this statistical prediction can be used to make a yearly reservation for collision risk. But this does not lead to a plannable maintenance action, up until an individual bridge is involved in a collision. Cost of collision are statistically predictable, but the maintenance is not plannable.

2.2.4 Randomness of sudden external events

Collision is a sudden random event. Sudden random events are not plannable. Only after an event has occurred, the needed counter measure can be planned. Sometimes the probability of a random event is time dependent. In case of traffic collision: If traffic grows, and the amount of special transports and high vehicles grows, the probability of collision grows. Likewise, risks of damage due to overloading increases as the traffic becomes heavier.

Many sudden random external events have some sort of time dependent probability. Therefore, it is likely for structures that the risks on random events increase while the structure ages, for instance because of changing surroundings.

Some random external events only effect aged structures. For instance, an old open asphalt pavement is very sensitive for frost. The probability of needed repair and the amount of repair depends strongly on the age of the pavement. Still yet, repair of the pavement is only needed if it freezes.

2.2.5 Randomness in maintenance and repair needs due to human errors in design, construction and maintenance

Most building codes are based on probabilistic assumptions. Usually, these building codes assume an uncertainty in material strength and an uncertainty in stresses due to loads. These calculations do not quantify the effect of human error, because it is challenging to predict what this will be. The examples are numerous, even for our most common materials:

- Some typical examples for concrete structures: badly placed reinforcement bars, forgotten shear reinforcement, gravel nests, insufficient concrete cover, badly injected post-tensioning ducts etc.
- Some typical examples for steel structures: improper welding (too hot, too thin, damage of surrounding coating), galvanic corrosion, local peak stresses in orthotropic structures, etc.
- Electrical and mechanical components: effects of leaking water (causing a short circuit), bad electric contacts, insufficient cooling, oil leaks, eccentric mechanical power transfer, etc.

These random flaws in design, construction and maintenance can have a variety of possible effects, on both functionality and maintenance cost. As long as these flaws are hidden, it is not possible to plan maintenance actions in time to deal with the effects. Similar to the external events, the only way to take these effects into account is to make a financial reservation, based on statistic information on probability of occurrence and the spread in possible cost effects.

Time dependency can be the case: Some effects will typically show in the first years after design. Other effects will reduce the technical life. A typical example are common problems in orthotropic bridge decks. The fatigue life is shortened drastically due to local high steel stresses in the orthotropic plates.

Structures are usually constructed in such way that warning signs can be seen long before failure. If a structure reaches the so-called "Usability Limit State (ULS)", usually clear

deformations can visually be detected. A sudden failure without any warning signs is very uncommon for structures. For electrical and mechanical components random sudden failure is much more common.

Random flaws in design, execution and maintenance are either detected timely in condition based monitoring or repaired after failure as corrective maintenance.

2.3 *Creating Life Cycle Maintenance plans combining plannability and statistical predictability*

Generally speaking, there are three options for cost estimates in a maintenance plan:

1. A planned activity with a cost estimate at a certain point in time: Both the year the maintenance activity is needed and the cost are known.
2. An expected activity with cost estimate, with an uncertainty on the exact needed moment: Based on the expectation a budget reservation can be made at a certain point in time, but the activity cannot be planned.
3. A random activity with a probability per year.

The plannability can be different for the short term planning than for the long term. The table below proposes a categorization for plannability of maintenance in short and long term maintenance plans:

Table 1. Categorization of plannability of maintenance.

Nr	Initiator	Example	Maintenance strategy	Plan-ability	Short-term planning	Long-term planning
1	Regular ageing	Electrical components	Preventive (planned) maintenance	++	Cost planned in maintenance plan in the planned year	Cost planned in maintenance plan in the planned year
2	Regular ageing	Coating on steel	Condition based Maintenance	+	Cost planned in maintenance plan based on condition data	Cost expectation and estimated year in maintenance plan based on averages
3	Regular ageing	Redundant battery	Corrective maintenance	-	Financial reservation in expected year of failure	Cost expectation and estimated year in maintenance plan
4	Random events (timely Warning)	Reinforcement corrosion	Condition based maintenance	0	Age dependent financial reservation	Age dependent. financial reservation.
5	Random events (time dependent, sudden)	Frost damage on aged pavement	Corrective maintenance	-	Age dependent financial reservation	Age dependent financial reservation
6	Random events (sudden)	Vehicle collision; Shortcut in electrical Component	Corrective maintenance	-	Financial yearly reservation	Financial yearly reservation

2.4 *Life cycle planning considering random events*

Looking at the table above, it becomes clear that a life cycle planning should account explicitly for all these types of cost expectations, both for the short term as for the long term. Not everything is plannable in a sense that it is known what activity will be done in what year. But the unplanned part can still be estimated explicitly. Clear distinction should be made between the plannable activities and the expected activities, both in financial reservation and in maintenance planning and contracting.

3 CASE RIJKSWATERSTAAT: FIRST STEPS IN DEALING WITH PLANNABILITY FOR STRUCTURES

3.1 *Initiation of the discussion on plannability*

In 2020-2022 there has been an internal and an external audit at Rijkswaterstaat to look at the reliability of the financial justification of short term and long-term budgets. This has led to major improvements in the complete justification system. But one of the tough to answer questions from the auditors was about uncertainties in the planning. The auditor raised questions on the budgetary impact of incidental maintenance activities. So far there was no research done to quantify this. Not for all types of assets there was structured data to answer this question, but for structures there was a good dataset available.

3.2 *Identifying plannability in the maintenance information systems*

Rijkswaterstaat has different software systems for different asset types. The system for structures (like bridges, viaducts, locks, weirs etc.) is called DISK. DISK contains the decomposition of all these structures in Building Objects, Elements and Building parts. The life-cycle maintenance plan contains maintenance strategies on element level (Bakker & Klatter, 2012). Examples of elements are the bridge deck, the pavement, the supports, the joints etc. For each of these elements there are standardized maintenance strategies. These are used to build up the maintenance plan.

A standard maintenance measure has a name, an interval, a unit and a price per unit. To make a maintenance measure in the life-cycle maintenance plan the amount of unit is added, and the latest year. For instance: Bridge deck - Concrete repair under bridge – every 30 years – 17€/m² Amount: 360 m², last year of previous execution: 2010; expected new year: 2040. During inspection an inspector will advise if both cost and expected year are still correct. But he can also find something unexpected. Then he will make an extra maintenance measure. For instance: the concrete is damaged due to collision with a vehicle. Then the inspector will make a ‘one-time maintenance measure’, containing a description, a cost estimate, and an advised and latest year of execution. For instance: bridge deck - repair of collision damage - €10.000,-, - 2023-2024. In this way the standard maintenance measures can be distinguished from the incidental ones: The incidental maintenance measures have no interval. All data from DISK is periodically exported to the planning system (RUPS)

3.2.1 *Research methodology*

Imperfect data had to be analyzed to quantify the (minimal justifiable) needed reservations for the unplanned maintenance. The planning system was used as historical data source. Only those maintenance measures identified as “obviously unplanned” would be taken into account.

A representative dataset was analyzed by 2 specialist independently. All maintenance measures with an interval were considered as “planned”, so the focus was on those measures with no interval. The 2 specialists, and each independently, identified the “obviously unplanned maintenance”, that was beyond doubt not covered in some way by our standard maintenance scenario’s. After rating the maintenance activities independently, the 2 specialists compared the results, and discussed the differences to come to a shared result.

Based on this analyses the conclusion was that at least 20% of all maintenance was clearly unplanned, compared to the maintenance strategies that are covered in the OBR. The real number was likely to be much higher, but could not be proven based on the available data.

3.2.2 *Taking account of the unplanned maintenance*

Based on the analysis result, Rijkswaterstaat raised the long-term cost estimates for structures by 20% to cover the uncertainty related to the unplanned maintenance. This figure was incorporated in the OBR. For the short-term planning also a reservation for unplanned maintenance was made in the programming. As explained in paragraph 2, most unplanned maintenance activities don’t need to be performed directly once the first indicators are observed. However, the uncertainty decreases in time, as inspection data detects the first signs of unplanned events. Therefore, it is presumed that the uncertainty is time dependant: for t+1: 5% for t+2: 10%, for t+3: 15%, and for t+4: 20%.

3.2.3 Further indicators

This 20% figure is a very conservative figure, because it had to be justifiable in an audit. In practice this figure is probably much higher. The table below shows another indicator. In DISK inspectors are asked to classify the damage to a root cause. The table below shows a limited dataset from DISK from one region. It can be seen that inspectors rate only about 35% of the encountered damages to regular aging. Clearly human error plays a major role in maintenance in practice.

Table 2. Causes of defects.

Damage initiator	Number of registrations
Normal aging	1750
Unknown/don't know	874
Flaw in design	300
Flaw in maintenance	122
Flaw in execution work during construction	402
Flaw in execution work during maintenance	1331
Excessive loads or usage	145
Total	4924

The big difference between the 20% uncertainty in maintenance cost and the $(100\%-35\%)=65\%$ of the damages related to other things than regular ageing, can have different reasons:

- Not all damages have the same cost effect. Those related to regular aging may have a relatively large cost effect;
- The 20% is known to be conservative.
- Some maintenance is considered to be plannable but is actually an estimate for random events. Take the example of concrete maintenance discussed above: Concrete is designed to last 100 years without damage initiation. Therefore an experience figure of maintenance every 30 years cannot be correct. Practically this figure represents the effect of all sorts of different unplanned maintenance events.

4 EVALUATION AND CONCLUSIONS

Life-cycle maintenance planning becomes more common nowadays. In these plans maintenance is often considered to be plannable, with normal aging as leading. However, one should question how well this assumption fits practice for instance with civil structures. This paper shows the importance of that discussion. Wrong assumptions lead to unreliable long term maintenance prognoses and unstable short term maintenance planning. From scientific perspective much more research should be done on this topic. Most research nowadays focusses on predictive, time dependent behavior leading to plannable maintenance. Based on the findings in this paper, focused research is recommended on plannability of maintenance. A possible research item might be the applicability of models used by insurance companies to deal with uncertainties related to unplanned maintenance, for instance models for health insurance.

ABSTRACT: Predictive digital twins can support asset managers in assessing the end-of-service life phase of infrastructure. This paper reports on the development of a standardized Digital Twin System Architecture integrating various system layers, which can help asset managers in effectively and efficiently deploying (new) digital technologies to manage their asset networks. A Field-Lab in the Moerdijk bridge region allowed to perform the experiments, research and development of relevant building blocks towards the implementation of this digital twin architecture for steel bridges. This includes the chain from sensor-data, data-management, data-processing towards 3D visualization in a geospatial environment.

1 INTRODUCTION

1.1 *The Renovation & Replacement research program*

Rijkswaterstaat is the executive agency of the Ministry of Infrastructure and Water Management in The Netherlands that manages and develops the main road and waterway network plus the main water systems. These networks include 178 steel bridges amongst many other structures, roads and waterways. The majority of these objects have reached their designed lifespan and need to be replaced or renovated in the upcoming decades. It is important that these measures are timed well: too late and the network cannot be used due to safety concerns, too early and unnecessary destruction of capital will occur. As the wave of upcoming replacements will require a great effort of Rijkswaterstaat and other involved parties (e.g. engineering firms, contractors), an optimal order of measures is required. Since the degradation of an object may have been different than expected (e.g. due to higher traffic loads), it is not justifiable to simply use the initially established end-of-life. For that reason, a research program was started. One of the avenues to explore is how data and digitization can be used to more efficiently predict the end-of-service life. A complete re-calculation of a bridge takes time and effort. Therefore, the process for steel bridges is threefold. At this moment expert-judgement and quick scans are used to determine the order of the re-calculations. By using sensors and predictive digital twin techniques we aim to accelerate the calculations and make them more accurate. Throughout the infrastructure sector (and other sectors) many definitions of digital twinning are used. In the framework of the long term end goal of this research a predictive digital twin of a bridge is defined as a digital replica of the physical bridge that contains, connects and carries various types of relevant data and simulation tools over the whole life cycle of the bridge. The digital twin is connected to the physical bridge through data, e.g. inspection data and/or (near real-time) monitoring data about the current state of the bridge, and contains models to transfer these data into predictions regarding structural safety and technical end-of-life. The digital twin also contains a visualization tool to

retrieve information and insights in a user-friendly way. This definition is based on the work of Cambridge Centre for Smart Infrastructure and Alan Turing Institute (Ye et al 2019).

2 TOWARDS DIGITAL TWINS FOR END-OF-SERVICE LIFE PHASE

2.1 *Vision on application of digital twins*

Over the last decades, academia, engineering companies and asset managers have started to adopt a variety of digital technologies (e.g. models, sensors, data-analysis methods) to address end-of-service life questions for infrastructural objects like steel bridges. For example, there are detailed finite element models (FEM) to calculate the stress levels in bridge components. Another example are advanced fatigue crack growth models that can be updated by inspection and sensor data to monitor real-time loads and stresses on bridges. Until a few years ago, most of these methods were predominantly based on expert knowledge. During the last years, however, the availability of data, data-driven methods, computational power and visualization technology has increased rapidly. This raises the question how these digital technologies can be effectively and efficiently applied for the end-of-service life challenges of asset-managers.

Digital twinning is one of the upcoming data-driven approaches that is receiving increasingly more interest. A digital twin bridges the gap between the physical and the digital by bringing real world data and models in a virtual environment. Such a virtual replica of the physical world can facilitate data-driven working and lead to more efficient decision-making and asset management in an ever digitizing society.

In the built environment, digital twins are starting to receive more interest, being mainly useful for inspection purposes (Pan & Zhang 2021) and predictive maintenance, especially when combined with sensor data and model results (Khajavi et al 2019). Building information models (BIM) can play an important role in digital twins, as these models hold detailed information on the properties of all components of a construction on an architectural level (Lu et al. 2019, Menassa 2021).

The aforementioned examples feature digital twins of a single physical system. A next step is to develop comprehensive digital twins that bring together data from multiple physical systems. An example of this upscaling are Digital Twins for the Physical Living Environment (DTFL), which integrate geospatial data of physical and geographic objects on a regional scale along with data of the dynamic processes (e.g. through sensor data) that are taking place.

The incorporation of BIM models in the wider context of a DTFL remains relatively unexplored. Importing a BIM model into a DTFL is challenging as it requires accurate geospatial positioning of the BIM model. This is complicated as BIM models are often stand-alone models that lack georeferencing. Bringing a BIM model into a DTFL can have great added value for a construction or infrastructure object. For example, the interaction can be established between the model and factors like subsurface, weather or real-time traffic flow. Also, it can facilitate assessing the impact of planned construction work on the external living environment.

2.2 *Standardization of architecture*

A standardized Digital Twin System Architecture (Figure 1) is essential to efficiently develop and apply current and future digital technologies. Creating object specific DT's from a standardized architecture/framework will prevent the need to start from scratch with each new digital twin and it allows to create digital twins for specific types of assets and problems in a flexible and repeatable way. It also contributes to standardization and interoperability amongst the many stakeholders involved in life cycle of the asset. The system architecture consists of various building blocks like data, models and visualization. Decoupling of system layers and standardization of the interfaces will prevent vendor lock-in. This way, digital twins of assets can become a an instrument to better retain information and insights throughout the (remaining) life cycle.

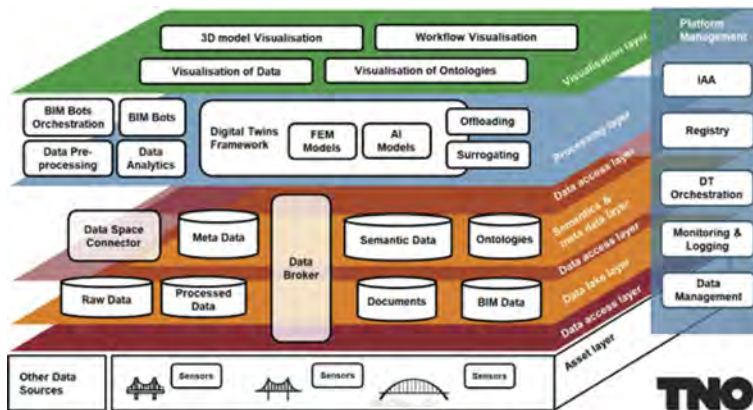

Figure 1. Standardized Digital Twin System Architecture.

3 USE CASE END-OF-SERVICE LIFE PHASE STEEL BRIDGES

3.1 Use case Field-Lab Moerdijk bridge

Rijkswaterstaat and TNO started a Field-Lab in the Moerdijk bridge region to facilitate collaborative experiments, research and development towards the implementation of Digital Twins for the end-of-service life phase of steel bridges. For this stage in the life cycle structural safety and fatigue (crack growth at specific hotspots in the steel structure due to cyclic loads) are important risks. The current practice at Rijkswaterstaat is to manage these risks with various types of inspections, structural assessments and continuous monitoring (Paulissen et al, 2018). The data and models involved in in this Field-Lab have been used as input for the experiments within the Digital Twin System Architecture and building blocks for steel bridges.

This chapter of the paper summarizes the progress so far. The focus was mainly on the modelling and visualization of data. A DTFM portal was developed to visualize both the data and models results of the bridge within a geospatial context (see 3.5). Furthermore we have prototyped two data management solutions (3.2) and applied three distinct analytical approaches to model stresses on the bridge (3.3).

3.2 Building blocks

On the **Asset layer**, a monitoring system was used that continuously records the dynamic strains resulting from trucks. The sample rate of the recordings is 100 Hz to capture the effect of individual truck wheels. Besides these continuous monitoring, a controlled load experiment was done to record the effect of a known load on the bridge. This type of monitoring can be used to calibrate the structural analysis models. The calibration is done by comparing the recorded load effects to assumptions from assessment standards. In the context of the Digital Twin development, the data were used as input for the Data -and Processing layer.

3.3 Data management

On the **Data layer**, two data management solutions were investigated and prototyped. The first focuses on robust and efficient storage and handling of large-scale time series datasets. This was done using Microsoft Azure Cloud storage and TimescaleDB, which is a database based on PostgreSQL. Once uploaded to the database, the data can be handled, queried and visualized much quicker than traditional CSV-files. TimescaleDB also allowed for easy interfacing with analytical tools and dashboarding software. The second solution holds a more broad oriented data management system that focuses on registering and organizing

various types of datasets along with the relevant metadata in a single portal. The prototype is based on the open-source data management system CKAN. The prototype includes links to geometric datasets and models (i.e. point clouds & BIM), inspection data, time series data and a structural analysis models. Both data management solutions aim to make data available in a Findable, Accessible, Interoperable and Reusable way. This is important for being able to make more efficient use of the available data for the life cycle asset-management. It also contributes to innovation once datasets become more easily accessible to organizations doing R&D.

3.4 *Data processing*

On the **Processing layer**, three data-analysis tools were investigated.

Bridge Weight in Motion (Rodenburg et al, 2022), is an analysis tool that extracts truck load parameters (e.g. axle configurations, axle loads and gross vehicle weights) from the monitoring system as described before. This is important information to determine the loads that need to be assessed to determine the structural safety and fatigue life of the bridge. In current practice, this is done based on generic load models from European and National standards (e.g. Eurocodes including National Annexes). This results in uncertainties and possibly over-/underestimations of the loads that are used for the assessment of the bridge. Integration of this tool in a Digital Twin environment contributes to effectively determining bridge specific traffic loads, which can be used for the structural assessment and efficient long term monitoring of traffic loads on the bridge.

The second analysis tool is **ProbEye**, an open-source parameter estimation tool developed by TNO and the German knowledge institute Bundesanstalt für Materialforschung und -prüfung. The tool combines a model, prior knowledge about its input parameters and measurements to obtain the probability density function of model parameters (Vereecken et al, 2022). It explicitly accounts for model uncertainties and measurement inaccuracies. As such, models can be made more accurate by making use of measurement data. In the case of the Moerdijk bridge, the tool was used to calibrate structural assessment model constructed in FEA software DIANA. This models calculates the deformations, forces and stresses in the bridge structure. Because the method requires many model evaluations, computation time is a specific challenge. This is was overcome by surrogate modelling and parallel computing in the cloud. The latter was done in close collaboration with DIANA. Integration of this tool in the Digital Twin results in more accurate structural analysis models .

The third tool is **continuous automated analysis** and converts continuous monitoring data into interpretable parameters for assessing the structural safety and fatigue life of the bridge. This involves filtering, data cleaning, temperature correction and conversion of measured quantities (strains) into relevant quantities for structural assessment. The tool is directly interfaced with the Timescale database such that the analysis is automatically done when new data are uploaded in the database. This is valuable for continuous (trend) monitoring of traffic load effects during the life cycle of bridges.

3.5 *Visualisation of a DTFL*

For the **Visualisation layer**, we have focused on implementing the steel bridge in a comprehensive DTFL. A DTFL requires a 3D environment that integrates data in a geospatially accurate way. The open-source software library CesiumJS is a state-of-the-art tool that is becoming increasingly popular to visualize DTFLs. The CesiumJS software allows for displaying geospatial data in a full 3D environment in a web browser. As part of this study, we developed a generic Cesium-based application and interface that can be reused for different purposes.

Within a Cesium-based viewer, data can be displayed both as 2D map layers (e.g. WMS services) or 3D physical objects. For running in a web browser, the application is easily accessible for a wide public. At the same time, visualizing a 3D digital twin in a browser while maintaining a satisfying performance level is challenging when dealing with large quantities of data. Browser

cache and performance can easily be overloaded. An important way to prevent this is through 3D tiling, which is a technique to subdivide 3D objects in a set of numerous tiles.

3D Tiles is an open standard of the Open Geospatial Consortium (OGC) and designed for streaming large 3D geospatial datasets. By using 3D tilesets, only the data that are close to the user's viewpoint are requested and visualized in the web application. In that way, the user only retrieves the necessary data, optimizing the performance of the application.

The conversion of data for display in the digital twin requires two main processing steps. First, the data is processed to 3D objects through a mesh tessellation or triangulation and set to the specific geodetic system for Cesium (EPSG: 4978). Secondly, the 3D objects are converted into a 3D tileset. This processing pipeline is not yet standardized and can vary substantially between different data types like point clouds, BIM models or other custom 3D objects. Especially for BIM, there is a large variety of file formats, which complicates the establishment of a uniform data processing protocol.

The digital twin environment that we developed includes a number of nation-wide data sets for the Netherlands. Within the Netherlands, a wide variety of data is openly available in a number of key registries. We processed a set of these data sets into the viewer, including all buildings and trees. Furthermore, a nation-wide digital elevation model (DEM) is available and can be loaded into the Cesium environment as a tiled mesh to visualize the terrain in 3D. Any map layers are then draped over the 3D terrain.

The visualization platform provides a custom user interface, which allows users to intuitively switch between different map layers, data sets and model results. The so-created digital twin infrastructure can be used for variable applications in the field of the physical living environment.

For the Moerdijk bridge, we used the Cesium-based web application to visualize the results from FEM. The Moerdijk bridge itself is visualized in the viewer as a BIM model, which was available in Revit file format (.rvt) (Figure 2). The elements of the BIM model were first converted into 3D geometries using FME while retaining the BIM attributes and then stored in a PostgreSQL database. Subsequently, a 3D tileset of the BIM model was generated using the tool pg2b3dm and stored in a cloud-based service. A separate 3D tileset was generated for nine different structural elements of the bridge to enable visualization of distinct parts of the construction. The subdivision consisted of the vertical web, inclined web, top flange, bottom flange, overlay, diaphragms, cantilever beams, cantilever beam sidewalls and top stiffeners.

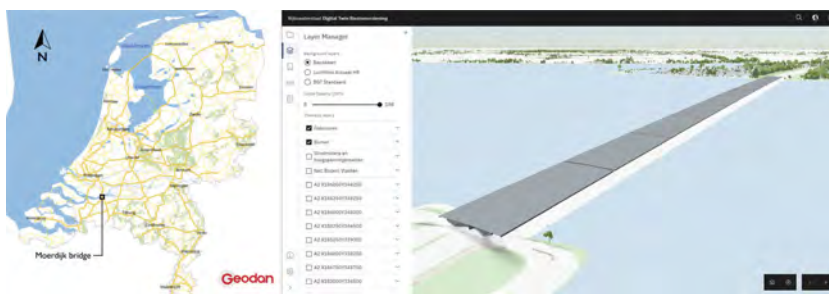

Figure 2. Location of the Moerdijk bridge in the southwest of the Netherlands (left) and the BIM of the bridge positioned in the digital twin environment (right). A user interface allows for selecting which data are being visualized.

Model results from the FEM were projected directly on this detailed representation of the bridge from the BIM model (Figure 3). Multiple FEM model results can be attached to a single element so that it is possible to dynamically switch between them. The precise model outcomes for each component of the BIM model can also be retrieved by clicking on a specific structural element to get the corresponding object information.

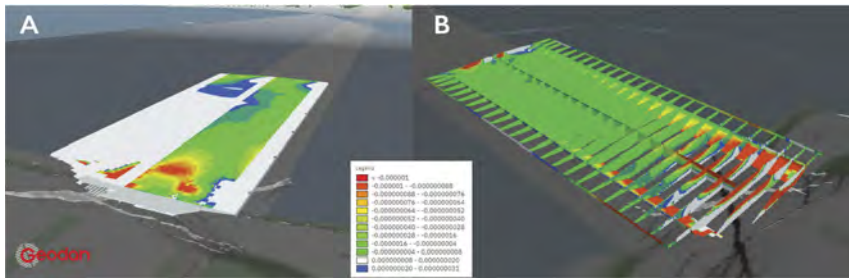

Figure 3. Results of the FEM for a truck passing over the Moerdijk bridge are visualized in the digital twin for one bridge section. A. FEM results for the overlay displayed within the entire BIM. B. FEM results displayed on only the vertical web, inclined web, diaphragms, cantilever beams and sidewalls. The other bridge elements are hidden to have a clear view of the internal structure of the bridge.

In addition to the model results, inspection photos of the bridge can be retrieved from the digital twin. The locations where photos are taken are indicated by an arrow symbol, whose orientation corresponds to the direction in which the photo was taken. The corresponding image file can be retrieved by clicking on the arrow symbol. The entire set of inspection photos comprises more than 19.000 files. Visualization and retrieval of photos from the digital twin helps to maintain a clear overview of the available images.

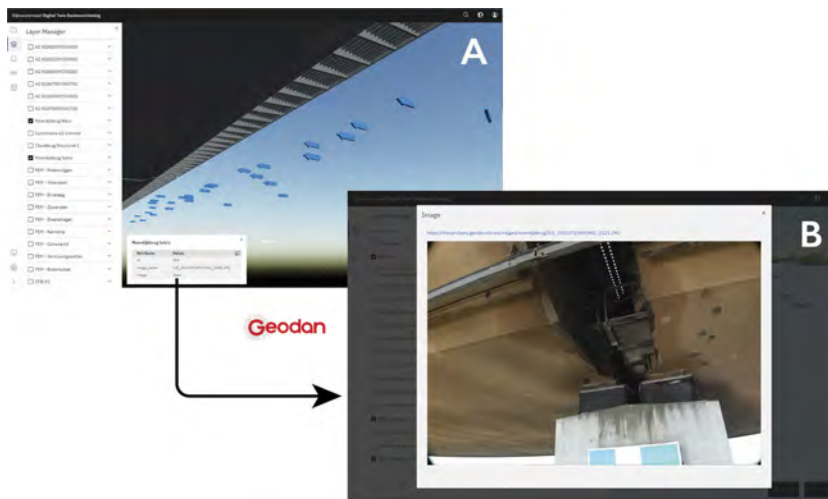

Figure 4. The BIM of the Moerdijk bridge viewed from below. The arrows indicate the position and direction of photos taken during inspections. The photos can be retrieved by clicking on the corresponding arrows.

4 CONCLUSIONS

The digital twin of the Moerdijk bridge presents a first step towards developing a virtual environment for managing the end-of service-life phase of the bridge. At the moment, the prototype offers the BIM integration along with two data sources: a set of FEM results and georeferenced inspection photos. Visualization of the FEM in the digital twin environment can facilitate the monitoring and prediction of the structural safety and fatigue life of the structure through time.

The developed digital twin offers a platform to incorporate a wide variety of other additional data types that may be of interest for monitoring purposes. For instance, 3D meshes

obtained through laser scanning or photogrammetry techniques may have added value for the detection of fractures and deformations. Another important aspect for bridge monitoring would be the time component. Real-time information from sensors (e.g. strain monitoring) and results of data-analysis (e.g. fatigue spectra, traffic loads) can be incorporated into the digital twin through API implementation, while time sliders can add a 4D component to the viewer to gain insight into changes in the bridge through time. Displaying a high-performance digital twin in a browser was long considered impossible, but is now becoming achievable thanks to state-of-the-art software libraries like CesiumJS.

By bringing together relevant data from multiple sources, the digital twin can provide a comprehensive overview of the current state and potential risks. This can lead to better decision-making and cost reductions regarding the maintenance of infrastructure objects.

So far we have adopted a wide approach, to be able to test a broad spectrum of techniques. In due time cost-effectiveness analyses will be made so the best tools can be selected. We will also take the possibilities of implementing the necessary processes into account. For example a technique to determine parameters for re-calculations that cannot be widely used by engineering companies in their assessment of an object is less likely to be used in the long term.

The next goal is that the digital twin platform for the Moerdijk bridge can be easily reused for other infrastructure objects. The use of a standardized Digital Twin System Architecture can contribute to the effectiveness and efficiency of further developing and applying this potential.

So far we have learnt that the main challenges to achieve this mainly revolve around standardization and interfacing. Much of the data processing has to be automated to expand the implementation of the digital twin infrastructure. For example, the transfer of FEM results into the viewer is still manual work at the moment. Ideally, however, FEM results are directly coupled to the digital twin. This automatization would facilitate model results to easily be reflected in the viewer. Furthermore, as more data become available, model results may be updated through machine learning algorithms. Such model updates must also be able to be fed back easily into the viewer (top layer in the suggested system architecture from Figure 1).

Altogether, the entire spatial data infrastructure has to mature, from data storage to data management, supported data types, data processing and user interfaces. Only then it can effectively be deployed in the working processes of the bridge managers. Nevertheless, the developed prototype shows the potential of a geospatial digital twin portal for bridge managing purposes.

Another lesson is that it might be better to gather different companies and stakeholders at the start of building a digital twin. With our current DT each stakeholder started in their own area of expertise and these data sources had to be merged together in a later phase.

In a later phase we aim to use the digital twin for the maintenance during the total life span.

Furthermore, while the initial development was focused on technical users (structural engineers, technical advisors), the imaginable uses of digital twins are broader. In future, it may be extended to other users (decision makers, modelers, etc.).

Numerical investigation of the effects of graphene on the mechanical properties of fibre reinforced cementitious matrix composite

X.M. Zhu, M.N. Su & Y.C. Wang

School of Engineering, The University of Manchester, UK

ABSTRACT: In this study, graphene is introduced to the cementitious matrix to improve not only the mechanical properties of the matrix but also the bonding properties. This study proposes a finite element model for graphene modified FRCM composite and validates the model by comparison against experimental results. Results showed that the increase of the mortar stiffness due to the introduction of graphene would lead to the increase of the elastic stiffness but the decrease of the strain of the composite. The stronger interfacial bonding brought by graphene would result in less strain developed at the cracking development stage. Graphene also led to more in-depth penetration of matrix into fibre bundles, which increases the ultimate strain of the composite. In addition, the constitutive models generated from parametric study were also used to assess two existing analytical models.

1 INTRODUCTION

Fibre reinforced cementitious matrix (FRCM) composite have been proved a successful alternative solution of fibre reinforced polymer (FRP) in structural strengthening field recently (Zhu et al., 2018; Su et al., 2019a, b). FRCM composite is composed by one or more fibre reinforcement layers embedded in cementitious matrix. The use of organic resin matrix for FRP is replaced by inorganic cementitious matrix in FRCM to improve the compatibility between fibre and matrix (Feng et al. 2020a). Although FRCM composite is capable of improving the confinement, shear and flexural capacity of structural members, the issue of weak bonding at the fibre-matrix interface is still a concern (Feng et al. 2020b; Zhu et al. 2021). The typical failure of FRCM composite is a combination of slippage between fibres as well as partial fracture of fibres. This is due to the partially penetration of cementitious matrix into carbon fibre bundles; only the fibres directly bonded matrix (i.e. external fibres) would fracture while the internal fibres are pulled out. The penetration of matrix determines the proportion of external part of carbon fibres and largely determines the ultimate strengths of the FRCM composite.

Great efforts have been made by adding graphene nanoparticles into the cementitious matrix to enhance the matrix properties (Yang et al. 2017; Li et al. 2017). This idea is now applied to FRCM composite. Compared to the traditional FRCM composites, the introduction of graphene into the FRCM composite (Gr-FRCM) is expected to (a) enhance the mechanical properties of the cementitious matrix, (b) improve the fibre-matrix interfacial bonding and (c) increase the penetration of cementitious matrix into fibre yarns. This study aims to understand the effects of graphene on the tensile behaviour of FRCM composite plates. Thus, the study will firstly develop a finite element model on FRCM composite plates and validated against test results; secondly, the validated model will be used to carry out a parametric study to examine the effects of key parameters; finally, the newly generated results will be compared to analytical models.

2 FINITE ELEMENT MODELLING

2.1 Model development and validation

The geometry of a typical Gr-FRCM composite sample under tension is shown in Figure 1(a). The composite is comprised of one layer of carbon fibre mesh embedded in graphene modified cementitious matrix. The sample is designed with a gauge length of 220 mm and clamping length of

140 mm at each end. The thickness of matrix layer is 5 mm. Geometries of the carbon fibre mesh is presented in Figure 1(b), which is made in form of bidirectional grid with a uniform bundle width of 3 mm, and the gap between two adjacent fibre bundles is 7 mm and 6 mm in warp and weft directions, respectively. The thickness of the fibre mesh is 0.154 mm. The total width of the Gr-FRCM sample is 50 mm and each specimen contains five longitudinal fibre bundles.

Figure 1. Geometry of Gr-FRCM sample and fibre mesh.

The main material properties used in the finite element models are summarized in Table 1, which were corresponded to matrix with 0% (G0), 0.035% (G1) and 0.07% (G2) graphene (percentage of cement weight). The properties include the Young's modulus E_m and the tensile strength f_{mc} of matrix, the Young's modulus E_f and the tensile strength f_{fu} of carbon fibre mesh, as well as the shear stress-slip stiffness k_s , the shear strength τ_s and the fracture energy G_s of fibre-mortar interface. A simplified bilinear response of interface traction separation relationship is defined to simulate the mechanical interaction between the mortar and fibre. The damage initiation is defined using the maximum nominal stress criteria, and the damage propagation is captured via fracture energy with linear softening.

Table 1. Material properties for the Gr-FRCM composite model.

	E_m (MPa)	f_{mc} (MPa)	E_f (MPa)	f_{fu} (MPa)	k_s (N/mm ³)	τ_s (MPa)	G_s (N/mm)
G0	47900	4.19	79770	1931	14.23	2.35	1.62
G1	55800	4.38	79770	1931	19.99	2.59	1.72
G2	59752	4.67	79770	1931	20.72	2.95	1.80

The boundary conditions are set by restraining horizontal and vertical movement and rotation of all external nodes at the bottom surface of mortar. A vertical displacement load is applied on the upper surface of the matrix. Meanwhile, in order to simulate the clevis gripping test setup, only elastic properties are applied to mortar and fibre mesh at both ends, to allow the damage of the composite occurring within the gauge length. The mortar and fibre mesh parts are both built using 3D linear brick elements with eight nodes (C3D8R), in order to reduce integration and hourglass control. The mesh sizes of 5 mm and 3 mm are employed for mortar and fibre mesh, respectively. Thus, a total of 1000 solid elements and 2222 nodes are formed within mortar part, meanwhile, a total of 968 elements and 2896 nodes are generated within the fibre mesh.

Typical force-deformation curves of Gr-FRCM composite obtained from finite element modelling are compared with experimental results for specimens G0, G1 and G2, as shown in Figure 2 and Table 2. The comparison shows that the two results are in good agreement, and the numerical model is able to capture the full tensile behaviour of Gr-FRCM composite from mortar cracking to the ultimate.

3 PARAMETRIC STUDY

Compared with the conventional FRCM composite, graphene could enhance FRCM composite by improving the mechanical properties of the cementitious matrix, the fibre-matrix interfacial bonding and the penetration of cementitious matrix into fibre yarns, which will enhance the utilization efficiency of fibre at ultimate of the composite. Therefore, the parametric study would

Table 2. Comparison between test and FE modelling results.

Samples	Elastic modulus (MPa)		Cracking force (kN)		Cracking deformation (mm)		Ultimate load (kN)		Ultimate displacement (mm)	
	Test	FE	Test	FE	Test	FE	Test	FE	Test	FE
G0	95	93	2.45	2.18	0.023	0.021	2.81	2.98	1.51	1.45
G1	100	109	2.67	2.29	0.022	0.019	2.92	3.11	1.54	1.55
G2	104	110	2.75	2.31	0.019	0.020	3.21	3.19	1.54	1.56

focus on the key parameters influenced by the introduction of graphene, including the tensile strength f_{mc} and modulus E_m of matrix, the shear stress-slip stiffness k_s , the shear strength τ_s and the fracture energy G_s of fibre-mortar interface, as well as the thickness of external fibre layer t_f .

Based on current theories (Filippou & Chrysostomou 2020, Larrinaga et al. 2013), the stress-strain curves of FRCM composite can be simplified into an analytical model with three phases, as shown in Figure 3. Phase I of the curve represents the elastic behaviour when fibre and matrix work together to resist external loads, ending up with the initial cracking (section OC). Phase II refers to a period of crack development from initial cracking to the maximum number of cracks on matrix, during which the fibres experience a certain level of interfacial debonding and/or slip-page (section CT). Phase III is the post-cracking stage from the completion of multi cracking to the ultimate failure, at which the resistance was mainly provided by carbon fibres (section TU).

Figure 3. Typical stress-strain relationships of FRCM composite under tension.

3.1 Effects of matrix properties

Figure 4 shows a comparison between tensile stress-strain curves of FRCM composites with three different types of matrix; the properties of specimens are listed in Table 3. The stress is derived by dividing the total force by cross-section area of the fibre mesh, and the strain is

calculated based on the deformation within the gauge length. It indicates that the modulus E_m and tensile strength f_{mc} of matrix mainly influences the first two phases. The greater value of E_m (i.e. a rise of 46% from M1 to M3) results in the increase of the elastic stiffness (35%) of the composite at Phase I and slightly improved stiffness (9%) of the composite at Phase III, but the decrease of the strain (41%) developed at Phase II (see Figure 5). In addition, when the tensile strength f_{mc} is enhanced, the stress of FRCM developed at the ultimate failure is increased; for instance, from M1 to M3, the ultimate failure stress is increased by around 22% (see Figure 4).

Table 3. Material properties for three types of mortar.

Mortar Type	E_m (MPa)	f_{mc} (MPa)
M1	40482	4.19
M2	46828	4.29
M3	75754	5.95

Figure 4. Stress-strain curves of FRCM composite with different mortar properties.

Figure 5. Effects of mortar modulus on the elastic stiffness and strain of Phase II.

3.2 Effects of fibre-mortar interfacial properties

Since different graphene dosage will result in different interfacial bonding strength between mortar and fibre, three key parameters relating to interfacial bonding (i.e. the shear stress-slip stiffness k_s , the shear strength τ_s and the fracture energy G_s) are examined, as listed in Table 4. The interfacial properties were carefully chosen herein to cover both weak and strong interface cases.

Table 4. Parametric study on different fibre-mortar interfacial properties.

Sample label	k_s (N/mm ³)	τ_s (Mpa)	G_s (N/mm)
Int01	1.42	0.24	0.16
Int05	7.12	1.18	0.81
Int08	11.38	1.88	1.30
Int1	14.23	2.35	1.62
Int2	28.46	4.70	3.24
Int3	42.69	7.06	4.86
Int5	71.15	11.76	8.11
Int10	142.30	23.52	16.21

The stress-strain curves of FRCM composite with relatively weak and strong interface are presented in Figure 6(a) and (b), respectively. To better present the effects of interfacial properties, the relationships between the strain developed at Phase II and the shear stress-slip stiffness k_s of each sample are plotted in Figure 7. It can be seen that the FRCM composites with weak interface experience a longer period of curve fluctuation (Phase II) generally, which is caused by more fibre mesh slippage after cracks occurs at the surrounded matrix. For example, with an 60% increase in shear stress-slip stiffness from Int08 to Int2, the strain of Phase II decrease 13%. FRCM composite sample Int01 failed much earlier than other samples, because the very weak interfacial bonding makes the embedded fibre slip severely after mortar initially crack and fibres unable to further resist external loads after the failure of matrix. On the other hand, the FRCM composites with strong interface limit the strain development of Phase II. With the further increase of interfacial properties, the strain developed at Phase II were almost the same at 0.0075 (see Figure 7). With strong interfacial properties, the strain developed at Phase II is due to the mortar cracking alone without the fibre slipping according to the numerical model results. The prohibition of fibre slippage makes the stress more efficiently transfer between mortar and fibre till the number of mortar cracks becomes stable.

Figure 6. Stress-strain curves of FRCM composite with different interfacial bonding.

3.3 Effects of amount of external fibres

As mentioned earlier, introduction of graphene could accelerate the hydration reaction and promote the generation of hydration products inside of carbon fibre bundles. Thus, four different thickness of external fibre layers t_f are considered in this parametric study, as shown in Table 5. Figure 8 presents the comparison results among stress-strain curves of these samples. Values of the cracking stress f_c , the strain developed at Phase II ε_T and Phase III ε_U are extracted and summarized in Figure 9. It is concluded that the number of external fibres affects (a) the cracking stress of the FRCM composite at the end of Phase I, (b) the strain developed at Phase II and (c) the strain at ultimate at Phase III. Specifically, when the thickness of external fibre triples from 0.167 mm to 0.502 mm in the models, the composite cracking stress is decreased by 69% from 927MPa to 269MPa (see Figure 9(a)), the strain of Phase

Figure 7. Effects of interfacial properties on the strain developed at Phase II.

II is decreased by 54% (from 0.0106 to 0.0048), while the ultimate strain is increased by 17% from 0.019 to 0.023 (see Figure 9(b)).

4 ANALYTICAL MODELS

The comparison between modelling results and theoretical calculation results by the classical ACK model (Aveston 1973) and a model based on cracking theory in EC2 (Larrinaga et al.

Figure 9. Effects of thickness of external fibre layers on the (a) cracking stress and (b) strain.

2013) is carried out. A typical numerical curve (Sample Int08) presented in Section 3.2 is used to for comparison, as shown in Figure 10.

Figure 10. Comparison on stress-strain curves obtained from FE modelling and two analytical models.

It is shown that both analytical models can predict the elastic stiffness and the cracking stress of Phase I, but fail to accurately predict the strain and stress developed at Phase II and Phase III. To be specific, the strain developed at Phase II is around 0.011, while the ACK model and EC2 model underestimate it as 0.007 and 0.004, respectively. The stress developed at Phase II gets increased compared with the cracking stress, but both models overlook the stress growth at Phase II. For the ultimate point, which is around 0.021 for strain and 2004 MPa for stress in the FE curve, the ACK model is 5% underestimation of strain and 6% underestimation of stress, but the EC2 model significantly underestimate the strain and the stress by 29% and 12% respectively. For ACK model, the underestimation may come from its assumption of a constant shear bonding strength between the fibre and mortar during the damage interaction phase, while this bond strength increases due to fibre slippage as shown in numerical curves. The EC2 model was developed based on the cracking pattern of reinforced concrete, which could be different for the cases for FRCM composite plate as the bonding mechanism of cement/reinforcement is apart from that of cement/fibres.

5 CONCLUSIONS

This study investigates the tensile behaviour of graphene enhanced fibre reinforced cementitious matrix (FRCM) composite plate by numerical study. A finite element model was built and validated based on the experimental results of graphene modified FRCM composites. Upon validation, a parametric study is performed focusing on the key parameters related to the mechanical properties brought by the introduction of graphene, including the tensile strength and modulus of mortar, the shear stress-slip stiffness, shear strength and fracture

energy of fibre-mortar interface, as well as the amount of external fibre layer directly bonded with matrix. The effects of these parameter on the constitutive model of FRCC composite were investigated. Results showed that:

- The increase of the mortar stiffness (+46%) would lead to the increase of the elastic stiffness (+35%) but the decrease of the strain (-41%) of the composite, while the tensile strength of mortar was beneficial for the deformation of the FRCC composite.
- The interfacial property had a significant impact on curve profile of Phase II: stronger interfacial bonding in general would result in less strain developed at Phase II.
- When the number of external fibres directly bonded with matrix became triple, the cracking stress and the strain developed at Phase II were found to decrease approximately 70% and 54% respectively, but the ultimate strain of the composite was increased by more than 15%.
- In addition, the curves generated from the numerical model were also compared with two existing analytical models (i.e. the ACK model and the EC2 model). Both models underestimated the ultimate strain and stress of the composite. In order to improve the accuracy of analytical models, parameters corresponding to interfacial properties and external fibres are suggested to be included in the analytical model.

Experimental behavior of FRCM-confined concrete under high temperature

F. Faleschini & C. Pellegrino
University of Padova, Padova, Italy

K. Toska
CY Cergy Paris Université, Neuville-sur-Oise, France

ABSTRACT: The paper investigates the behavior of concrete confined through FRCM (Fiber Reinforced Cementitious Matrix) composites subjected to high temperatures. Small scale cylindrical specimens (150x300 mm) were confined using two types of carbon fiber (dry and resin impregnated). For the sake of comparison two layers of FRCM were applied to all confined specimens. After curing, cylinders were exposed to four ranges of increasing temperatures being 20°C (ambient), 80°C, 100°C and 250°C and then tested under cyclic loading. The experimental results show that thermal stress significantly influences the confinement effectiveness of FRCM composites. Exposure to high temperatures reduces the ultimate confined strength and strain. For specimens confined with resin impregnated fibers, the observed stress-strain trend of confined elements tested after high temperatures exposure significantly differs from specimens tested under standard ambient conditions.

1 INTRODUCTION

Composite materials have been widely used in structural engineering to strengthen and upgrade existing concrete or masonry structures. Among others, fabric reinforced cementitious composites are gradually substituting the use of fiber reinforced polymers (FRPs) in the construction industry. This is mainly due to a better performance of FRCM composites in terms of durability and a higher compatibility with concrete and masonry substrates, because they replace the use of polymeric resins as a binding phase in favor of cementitious matrices, suitably added with substances aimed at improving their interaction with the resistant phase and support (Papanicolaou et al. 2008, Harajli et al. 2010). The cement-based matrix of the composites offers some advantages in comparison with the epoxy-based matrix of FRPs such as: easier application, especially onto rough and irregular surfaces like in old masonry (Mazzotti et al. 2015) or concrete construction, better bond behavior at high temperatures (Tetta & Bournas 2016, Raoof & Bournas 2017) and higher physical and chemical compatibility with the concrete or masonry substrate (Donnini & Corinaldesi 2017).

The beneficial effects from these features compensate the lower effectiveness of cementitious composites than FRPs (Donnini et al. 2019). Confinement of axially loaded concrete columns through FRCM jacketing is one of the main applications of the composite. Bournas et al. (2007) compared the confinement effectiveness of FRP and FRCM composites on small scale concrete specimens. Toska & Faleschini (2021) experimentally investigated the effect of cyclic loading and of different bonding conditions on the confinement effectiveness of FRCM composites (Toska et al. 2023). The ability to enhance seismic performance of FRCM jacketing was also experimentally investigated for undamaged and damaged reinforced concrete columns subject to cyclic horizontal loading (Bournas et al. 2009, Toska et al. 2022).

However, cementitious composites are relatively recent and further research is still needed to understand their behavior. One of the still little studied aspects concerns the effect of high temperatures on the behavior of composites and the effectiveness of the interventions in which these materials are applied when exposed to high thermal stresses. Some researchers have compared the loss of strength of FRCM or TRM cementitious composites with those of FRP ones by means of tensile tests on specimens conditioned to thermal stress (Donnini et al. 2017, Messori et al. 2019). As expected, the results show a clear better resistance to high temperatures for the FRCM composites although, after a certain temperature, a decreasing trend in the tensile strength of the tested specimens is observed as the temperature increases. Recently, Kapsalis et al. (2021) published an extensive review on experimental investigations dealing with the behavior of textile reinforced concrete subjected to high temperatures. The same authors later on investigated the performance of textile-reinforced concrete after fire exposure (Kapsalis et al. 2022). TRC specimens with various reinforcement (carbon or glass fibers, uncoated or coated textiles) were casted and subjected to temperatures up to 700°C. The residual tensile capacity of the exposed specimens is analyzed and the results showed that the use of uncoated carbon fibers is the most promising solution to maintain a high residual capacity after fire exposure.

Regarding the behavior con FRCM-confined concrete under high temperature, Trapko (2013) investigated the effectiveness of confinement using FRCM composites in comparison to those confined through FRPs when subject to high temperatures. However, the investigated temperature range varies only from 40 °C to 80 °C. Ombres et al. (2021) investigated confinement through PBO-FRCM composites subject to temperatures ranging between 20 °C and 200 °C. The test results evidenced that the thermal conditioning affected both the mechanical properties of the FRCM materials and the effectiveness of the concrete confinement.

In this context, the present study investigates the performance of FRCM confined concrete subject to temperatures varying from ambient to 250 °C. Cylindrical specimens were confined with two types of FRCM jackets that differ from the carbon fabric applied: dry and epoxy resin coated.

2 EXPERIMENTAL PROTOCOL

2.1 *Materials and specimens*

In the presented experimental campaign, small scale specimens with $b \times h$ dimensions 150 x 300 mm were casted using the same concrete batch. For the FRCM composite, the reinforcement consists in two types of carbon fabric: one in dry condition and the other coated using an epoxy-resin solution. The inorganic matrix consists in a premixed fiber reinforced cementitious mortar with a compressive strength of 25 MPa and flexural strength of 4.8 MPa. All materials were provided by the same manufacturer. The properties of the carbon fiber are shown in Table 1. For the sake of comparison and based on the previous experience of the authors, all specimens were confined using two FRCM layers.

Confinement was applied following always the same protocol. First the concrete specimen was damped with water to avoid water absorption from the FRCM composite, a first layer of mortar (3-4 mm thick) was applied around the cylinder and above it the carbon fabric was wrapped gently pushing it into the matrix. Then a second layer of mortar and then fabric was applied repeating the same procedure. The last layer was covered with the last mortar application. Carbon fabric was applied continuously with a final overlapping length of 200 mm.

Table 1. Properties of carbon fibers.

Fiber type	t_f (mm)	E_f (GPa)	f_f (MPa)	ε_f (%)
Carbon	0.047/0.061	240	4900	1.80

Figure 1. Application of the confining FRCM jacketing on the cylindrical specimens.

After FRCM jacketing application specimens were left curing for at least 90 days and then, before axial compression testing, they were exposed to increasing temperature levels being: 20 °C (ambient), 80 °C, 100 °C, 250 °C. Only specimens confined with coated carbon fibers were exposed to the 80 °C temperature. This aimed to investigate if the epoxy coating would undergo any degradation even for temperatures lower than 100 °C, given the poor behavior of organic matrixes at high temperatures. Specimens features are summarized in Table 2.

Table 2. Specimens' features.

Specimen	D (mm)	l_b (mm)	t_f (mm)	Fabric	T (°C)	Layers

2CR_250_1	150	200	0.061	Coated (Epoxy Resin)	250	2

2.2 Test setup and loading protocol

After the temperature exposure, specimens were axially loaded adopting a cyclic loading protocol. The tests were carried out using a universal loading machine under displacement control mode. Single compressive cycles were performed using a displacement rate of 0.6 mm/min was used for both loading and unloading paths. To avoid the complete unloading of the specimens and undesired movement of the specimens itself or of the instrumentation a small axial load of about 0.5 MPa was maintained during the unloading cycles. Before loading, both the upper face of the specimens was capped with high-strength mortar to ensure a proper distribution of the axial loading.

The axial load was acquired continuously during the test, using the 600 kN load cell of the universal testing machine. Axial strains were monitored using three linear voltage displacement transducers (LVDTs), that acquired the displacement between the top and bottom plates. LVDTs were installed equally spaced at 120°. Figure 2 shows a reference specimen and the instrumentation disposition during the testing.

Figure 2. Test setup.

3 RESULTS

3.1 Failure modes

Specimens confined with dry and coated carbon fabric showed different crack pattern and failure modes while no significant differences were observed in the crack pattern of the confined specimens when exposed to different temperatures. First, small vertical cracks were observed in the confinement jacket when the axial load was near the initial unconfined strength for all tested specimens. After an initial homogeneous crack distribution, a main crack, generally near the overlapping end, propagates until failure is reached. For specimens confined with epoxy resin coated carbon fabric, the failure was more abrupt and is characterized by wider crack openings and also spalling of the external mortar layer.

3.2 Axial stress-strain behavior: Dry vs resin impregnated carbon fiber

All specimens were tested under a cyclic compression loading protocol, however, for the sake of simplicity, only the envelope curves will be considered in this section. The initial concrete strength was evaluated on two specimens and the unconfined axial stress-strain curves together with the failed specimens after testing are shown in Figure 4. The unconfined compressive strength is 20.6 MPa while the axial strain at peak stress was about 0.36%. At ambient temperature, specimens confined with dry carbon fabric displayed a similar behavior to what previously observed by some of the authors in a previous work (Toska & Faleschini, 2021). The first peak, reached at strain values close to those observed for unconfined concrete, is followed by a slight strength decrease which in turn is followed by a new stress increase or by an almost constant strength until failure. On the other hand, for specimens confined with coated carbon fibers the softening phase was not observed and the stress-strain curves were characterized by a hardening trend until failure. Carbon fabric coated in epoxy-resin performed better both in terms of axial strength and axial strain capacity. For normal ambient temperature this

Figure 3. Final crack pattern for a) C_20_2C, b) C_250_2C, c) C_20_2CR and d) C_250_2CR.

Figure 4. Axial stress-strain curves for specimens confined with dry and pre-impregnated fabrics at different temperature steps: a) ambient, b) 80 °C, c) 100 °C and d) 250 °C.

is in line with what previously observed by some of the authors in (Toska et al. 2023). The better behavior of coated carbon FRCM jacketing, in terms of confined peak strength and strain, surprisingly, was maintained also for the higher temperature steps. Strength enhancement, results about 19%, 17% and 27% more effective for coated cases respectively for ambient, 100 °C and 250 °C. Since specimens are tested after cooling down, investigating their residual capacity, the better performance of jackets with coated fabrics is believed to be due to melting and re-hardening of the polymeric coating of the fabric that results in a better fiber-matrix bond. Similar behavior was observed also on pullout test by de Andrade Silva et al. (2014) for temperatures up to 200 °C.

3.3 Influence of high temperature

Figure 5 Compares axial stress-strain curves for confined concrete through FRCM composite with dry carbon fabric. Both curves, for specimens exposed at 100 °C and 250 °C, result significantly different from the one for ambient temperature. The effect of high temperature is significant already at 100 °C. Strength enhancement at the first peak (at axial strain near to that of unconfined concrete), that is very clear and significant for specimens at ambient temperature, is not present after high temperature exposure. Confined strength results 26.4 MPa for ambient temperature specimens, 23.5 MPa after 100 °C exposure and 21.4 MPa after 250 °C exposure. Ultimate axial strain at 100 °C is about 1%, resulting slightly higher than at ambient temperature (about 0.9%) and at 250 °C (about 0.8%).

Figure 5. Axial stress-strain curves for specimens confined with dry carbon fabric.

Specimens confined with coated carbon fabric also experienced a significant performance reduction when exposed to high temperatures. Confined peak strength decreased from 30.7 MPa at ambient temperature to 27.5 MPa after 250 °C exposure. At 80 °C, strength remained similar to the unconditioned one (about 30 MPa), while at 100 °C peak strength was almost the same as the one recorded at 250 °C (about 28 MPa). The ultimate axial strain capacity remained relatively high, varying between 1.2% and 1.4%. Even though peak strength degradation was low (about 10%), axial stress-strain curves (Figure 6) differ significantly for the different temperature steps. As observed for the dry-fabric cases, strength enhancement at the first peak (following the first branch of the stress-strain curve) is gradually reduced as temperature gets higher, moving the inflection point of the hardening branch lower for each step.

Figure 6. Axial stress-strain curves for specimens confined with coated carbon fabric.

4 CONCLUSIONS

The present work investigates the behavior of FRCM confined concrete when exposed to high temperatures. Small scale cylindrical concrete specimens were casted and confined using two types of carbon FRCM composites, that differ on the initial treatment of the fabric: dry and epoxy resin coated were tested. After 90 days of curing from the jacketing application, specimens were exposed to increasing temperature steps: 20 °C (ambient), 80 °C, 100 °C and 250 °C. After cooling down, the specimens were tested under compressive cyclic behavior to investigate their residual strength and strain capacity. Results show a significant change in the axial stress-strain behavior after high temperature exposure. Epoxy coated FRCM jackets performed better than dry ones at all temperature steps, both in terms of strength enhancement and axial strain capacity. Between ambient and maximum considered temperature (i.e. 250 °C), 19% strength reduction was observed for dry carbon FRCM while only 10% for coated ones.

Retrofit of RC bridge half-joints: Applications and remarks with emphasis on post-tension techniques

G. Santarsiero, V. Picciano, A. Masi & G. Ventura
School of Engineering – University of Basilicata, Potenza, Italy

ABSTRACT: Due to their advantages, many reinforced concrete road bridges were built according to the Gerber scheme in which the so-called half-joints represent a key structural component. Besides their advantages, some drawbacks can be found in this type of bridge, mainly related to the deterioration process of the half-joints that leads to reinforcement corrosion and consequent concrete cracking and spalling. Therefore, many bridges may need over time specific retrofit interventions to guarantee the required level of safety. This paper first describes the retrofit techniques currently available in the literature. Numerical simulations are then carried out to investigate the effectiveness of a specific technique based on post-tensioning. Refined nonlinear finite element models were used to characterize the post-tension effects on the load-bearing capacity of a case study half-joint also in presence of simulated chloride-induced corrosion, and to outline the optimal prestress level to be used to obtain the wanted performance improvements.

1 INTRODUCTION

In the past, the Gerber scheme was widely used for the construction of reinforced concrete road bridges due to its advantages in terms of both stress distribution and the related statically determinate conditions. According to this scheme, the cantilever and the simply supported spans are connected to each other through the so-called half-joints, which represent a key component of these bridges (Kun et al. 2015).

Despite the advantages, a frequent problem related to this kind of bridge is the malfunctioning of drains, which causes seepage across expansion joints (Lee 1994). In particular environmental conditions, the presence of chloride ions may enhance the degradation phenomena leading to reinforcement corrosion and consequent cracking and spalling of concrete (Gjørøv 2009), especially in the cantilever part (Figure 1).

Another issue is related to the very narrow space in correspondence with the joints' position, which causes difficulties in inspections leading to incorrect quantification of degradation (Desnerck et al. 2018). In the literature, two cases of bridges' collapse are related to the half-joint failure. The first is the de la Concorde overpass collapse in 2006, a bridge situated in Laval (Canada). The other case is related to the Gerber bridge overpass in Annone Brianza (Italy), which collapsed in 2016 following the passage of a 108-ton truck. In both cases, the deterioration of the half-joints and damage already present on the bridge coupled with some design and construction flaws were responsible for the collapse (Mitchell et al. 2011, Di Prisco et al. 2018).

For this reason, the assessment of these structural components, also accounting for degradation modelling, coupled with rehabilitation, through careful planning and design of the interventions by the bridge owners and practitioners, are crucial, in order to increase their structural performance and therefore to extend the lifespan of bridges.

To this end, this paper first reports a brief review of the currently available intervention techniques for bridge half-joints, accounting for both previous experimental studies in the literature and interventions carried out on existing bridges. Through the analysis of each technique's main advantages and disadvantages, it is possible to identify the one which results the

least disruptive and expensive and the most easily applicable. This is the post-tension technique, based on the use of external high-strength post-tensioned rods, which are restrained on the top and the bottom of half-joint's surfaces through steel plates.

Therefore, the paper presents an application of this technique to half-joints of a case study bridge, the Musmeci bridge in Italy (e.g. Marmo et al. 2019), in which, through nonlinear numerical simulations, the performance improvements at both serviceability and ultimate limit state have been evaluated, accounting for the variation of the prestress applied and also considering the presence of different chloride-induced corrosion scenarios.

2 REVIEW OF THE AVAILABLE RETROFIT OPTIONS FOR HALF-JOINTS

When it comes to bridge half-joints, there can be several reasons for which repair or strengthening interventions are needed: increased traffic loads compared to the time of design and consequent increase in strength demands; decrease in concrete and reinforcement's strength due to the accumulation of decay; the presence of widespread cracks which may cause a loss of serviceability or, in extreme cases, the collapse of the structure. As a result, researchers have developed and studied different techniques to account for all these aspects.

In the literature, there are techniques developed and tested on the half-joints properly belonging to bridge structures, and techniques more suitable for dapped-end beams often used on the roofs of industrial buildings or in the floor systems of buildings used for parking or otherwise prefabricated. In addition, the various techniques differ from each other in the particular materials used, in the different performance objectives, or even in the different installation configurations taking into account the geometry of the structural element at hand.

Among the available retrofitting techniques, a rather invasive intervention consists of joining the cantilever and suspended span in such a way as to completely change the bridge's statically determined scheme to one of a continuous bridge. This intervention has been developed and patented by Fukuoka (1999) and the connection is made through the use of horizontal high-strength steel bars restrained to the existing concrete of the half-joints. In addition to being very invasive, the intervention is also very costly since new bearings must be placed on the piers to allow the absorption of thermal expansions.

On the other hand, a non-invasive and easy technique consists of the use of high-strength post-tensioned bars installed along the undapped part of the half-joints in a vertical or inclined direction, in order to increase the load-bearing capacity of the half-joint. The only installation operation consists of drilling holes on the side of the joints, through the curb or transverse beam, if present, for the positioning of the bars (Figure 2). Such an intervention was carried out on the existing Scafa bridge located in Fiumicino (Italy) (Alessandrini & Burba 1994) and the PRC Gerber bridge on the Po River near the town of Pieve Porto Morone (Italy) (Di Prisco 2019).

The main objective of this technique is to provide an increase in the load-bearing capacity of the half-joint and, in addition, the prestressing action also favours the limitation of cracks during service conditions. In order to quantify the performance gains offered by the technique, Atta & Taman (2016) carried out an experimental tests campaign on Gerber beams in which the post-tensioned bars were installed in different configurations and positions. In particular, they

showed that the three configurations illustrated in Figure 2 exhibited improved behaviour by providing strength gains of 81%, 65%, and 83%, respectively, with respect to the beam without intervention.

A technique able to intervene on the deteriorated concrete of the half-joint, provide an increase in strength and, at the same time, provide protection against long-term degrading agents consists in the realisation of a steel jacketing system bonded to the lateral surfaces of the half-joint through the use of transversal bars. Such an intervention was carried out on the Generale Franco Romano viaduct in the Piedmont region (Italy) (Lafranconi et al. 2018). The increase in load-bearing capacity can be provided by the installation of post-tensioned vertical bars restrained above and below the saddle, as shown in Figure 3a. The only disadvantage of the technique is that the intervention is mainly carried out along the lateral surfaces of the half-joints, which are not always accessible due to the presence of a connection curb or the transverse beam connecting the deck's girders.

Finally, there are techniques in the literature based on the use of composite materials in the form of plates, laminates or fabrics bonded externally to the surfaces of the half-joints (Figure 3b). The most commonly used solutions are carbon fibre-reinforced polymer (CFRP) or fibre-reinforced polymer (FRP). The advantage of these materials lies primarily in their ability to provide strength improvements while occupying very small volumes, which makes them suitable for Gerber saddles. Some authors have tested the performance of these materials by carrying out experimental campaigns on dapped-end beams used in precast buildings. In particular, Taher (2005) analysed the performance of different configurations of CFRP laminates, differing in the inclination of the laminates with respect to the beam axis or in the installation position, obtaining an increase in strength in the range of 17-42%. Nagy-György et al. (2012) performed experimental tests using FRP plates or fibres in different configurations, obtaining that the highest performance was provided using a combination of vertical and inclined fibres. The disadvantage of using composite materials is mainly related to their excessive cost. Furthermore, the application of materials on the side surfaces of the half-joints is not always permitted due to the structural constraints mentioned above.

Figure 2. The most performed post-tensioned solutions tested by Atta & Taman (2016).

Figure 3. a) Schematic view of the jacketing system, adapted from Lafranconi et al. (2018) and b) different configurations of externally bonded composites (Taher 2005, Nagy-György et al. 2012).

2.1 Remarks on the choice of the optimal intervention

If we want to compare the techniques described above, in addition to the advantages and disadvantages of each one, we have to analyse further aspects related mainly to the construction in place. In particular, Santarsiero et al. (2023) compared the techniques taking into account

several aspects: the construction costs; the disruption caused to the bridge and road traffic; the need to lift the suspended span; the need to carry out repair work before the actual intervention; and, finally, also considering the performance improvement by comparing the half-joints' failure modes before and after the intervention.

What emerges is that the techniques which require the lifting of the suspended span (i.e. jacketing and application of composites) are the most expensive and disruptive. In contrast, the post-tensioning technique is the least invasive, the most economical and adaptable to the different geometric configurations present in existing bridges.

In fact, in the majority of cases, the deck of a Gerber bridge is in the configuration illustrated in Figure 4, in which the girders are connected by a transverse beam and/or a curb at the dapped-ends. This configuration impedes the realisation of all those techniques which work on the lateral surfaces of the beams. Therefore, it is very important to assess the feasibility of an intervention, i.e. its applicability in reality, when one is called upon to choose between different types.

Figure 4. Typical Gerber bridge deck configuration and applicability of the post-tension intervention technique.

3 POST-TENSION TECHNIQUE: NUMERICAL SIMULATION

In order to deepen and quantitatively evaluate the performance improvements provided by the post-tension technique, this section describes a numerical simulation carried out by nonlinear finite element analyses. The intervention is applied on a half-joint belonging to the bridge on the Basento river in Potenza (Italy), carefully described in previous articles (Santarsiero et al. 2021, Marmo et al. 2019), designed by Sergio Musmeci matching older codes (Circolare n. 384 del 1962). It is worth reminding that the bridge's RC box deck is 16 m wide and supported by the vault every 17.30 m for a total length of 300 m. Moreover, the deck is provided with suspended spans (10.38 m long) connected by half-joints which are shown in detail in Figure 5a.

Numerical simulations were carried out using the finite element software ATENA (Červenka et al. 2021), which is able to accurately reproduce the reinforced concrete structures' behaviour according to the nonlinear fracture mechanics theory (Bazant & Oh 1983). In particular, it is possible to simulate the nonlinear behaviour of concrete both in compression (crushing) and in tension (cracking). Further details on the constitutive models used are provided in a previous article by Santarsiero et al. (2021). The main results of the numerical simulations are here briefly summarized as they are widely described in Santarsiero & Picciano (2023).

Figure 5b shows the FEM model of the studied half-joint in the presence of intervention. Within the analyses, the presence of degraded conditions due to chloride-induced corrosion was also simulated. In fact, the software makes it possible to simulate the chloride ions ingress into the concrete and the initiation and propagation of reinforcement corrosion through a refined mechano-chemical model (Červenka et al. 2017), which takes into account the acceleration of the phenomenon induced by the presence of concrete cracks caused by the loads acting on the half-joint.

In particular, the model is based on the 1D chlorides diffusion process within the concrete, modelled through Fick's second law (Zhang et al. 2010) accounting for three fundamental

parameters: the surface chlorides concentration C_s (as % of cement mass), the chloride diffusion coefficient D_{ref} (m^2/s) and the critical chloride content C_{crit} (as % of cement mass).

In the previous study by Santarsiero et al. (2021), the significance of the three parameters was investigated in detail and, in particular, analyses were carried out with different combinations of their values in order to identify the one which produces the worst effects in terms of corrosion and loss of bearing capacity.

Therefore, in this study, in order to analyse the ability of the post-tension-based intervention to improve the condition of a severely degraded half-joint, a triad of values was deterministically selected based on literature data (Angst 2019, Bertolini et al. 2004, Hájková et al. 2018, Van der Wegen et al. 2012) relating to aggressive environmental conditions concerning road bridges in harsh climates exposed to de-icing salts.

Evaluating the nonlinear concrete and steel behaviour, the design strength values calculated according to the Italian Guidelines (Ministry of Infrastructure, CSLP 2020) were used. The design strength of the analysed concrete structure is $f_{cd} = -17.24$ MPa (Santarsiero & Picciano 2023). As a function of the latter value, the other material properties required for the numerical simulations were calculated. In particular, $f_{ctd} = 1.59$ MPa, $E = 29,253.88$ MPa and $GF = 1.31E-4$ MN/m (Fib, Fédération Internationale du Béton 2010).

Similarly, the reinforcement properties were calculated: the design yielding stress is the same as the characteristic one $f_{yd} = f_{yk} = 375$ MPa, as the former can be obtained by the ratio between the latter and the maximum value of confidence factor, $CF = 1$, depending on the achieved knowledge level (Ministry of Infrastructure 2018); the failure stress is equal to $f_{td} = 460$ MPa and the failure strain ε_t is set to 18%.

As for the intervention, this is carried out according to configuration No. 2 tested by Atta & Taman (2016) (illustrated in the central scheme of Figure 2), through the use of two external 26.5 mm diameter high-strength Dywidag-type steel bars, equipped with corrosion protection system, with yielding stress $f_y = 950$ MPa and failure stress $f_t = 1050$ MPa. The bars were restrained at the top and bottom (Figure 5b) through two S275JR ordinary steel plates (EN 1993-1-1 2005, Ministry of Infrastructure 2018) 500 mm wide, 150 mm long and 100 mm thick.

11 analyses were performed taking into account the variability of two parameters in particular: the corrosion period (t_{corr}) and the prestress value applied to the external bars (σ_p). With regard to the first parameter, a corrosion period of 45 years was considered, which would correspond to the current state of the bridge taking into account that it was completed just 45 years ago; and a period of 95 years, in order to assess the effect of the intervention following a further 50 years of corrosion. Concerning the second analysis parameter, the prestress value was varied in terms of percentages with respect to the yield strength of the external bars, considering the following four cases: $0.05f_y$, $0.15f_y$, $0.30f_y$, $0.40f_y$.

Ultimately, the following analysis intervals can be distinguished in each of the performed analyses: a first interval, identical to all the analyses, in which the half-joint is loaded by the vertical reaction, at the intermediate point of the nib, equal to 270 kN (relative to the permanent structural and non-structural loads transferred by the suspended span); a second interval in which the chlorides ingress, which is a function of the cracks generated in the previous interval, and the effects in terms of corrosion and consequent load-bearing capacity reduction are simulated, accounting for the two selected periods; a third interval in which the post-tension intervention is made active by applying the selected prestress values in the external bars; and, finally, a last interval in which, through a displacement control analysis, the half-joint is brought to failure to assess the ultimate capacity P_u .

4 ANALYSIS OF RESULTS

This section describes the main results of the performed numerical analyses, referring to the recent work by Santarsiero & Picciano (2023) for a more in-depth discussion. In particular, the performance of the post-tension intervention was analysed at both the serviceability (SLS) and ultimate limit state (ULS) as a function of the applied prestressing.

Concerning the performance improvements at SLS, the cracking load P_c was monitored for each of the analyses. The latter represents the load at which a limit crack width of 0.20 mm is

Figure 5. a) Musmeci bridge's half-joints (dimension in cm) and b) FEM model (dimension in mm).

reached as reported within the current codes (Ministry of Infrastructure 2018, EN 1992-1-1 2004) depending on the aggressiveness of the environment and the corrosion sensitivity of the reinforcement bars. As shown in Figure 6a, the cracking load of retrofitted models increases, with respect to the as-built corroded ones, with an almost linear trend as the prestress in the bars increases. In particular, there is a significant enhancement for prestressing values of $0.15f_y$ or more. Furthermore, ΔP_c values are greater for analyses with 95 years of corrosion than for those considering 45 years, especially for high post-tension values. Ultimately, the half-joint's conditions at the serviceability limit state improve due to the intervention, which reduces the cracks' width and, thus, also limits the ingress of degrading agents.

Figure 6b shows the variation of the ultimate load P_u as a function of the applied post-tension. As can be seen, the load-bearing capacity of the half-joint is not greatly affected by the tendons' prestress, showing a significant improvement even for low post-tension values. Furthermore, a greater increase in P_u is obtained after 45 years of corrosion, with an average ΔP_u equal to 25%, compared to the average increase of 18% in the case of 95 years of corrosion. In fact, in the latter case, the reinforcement is more corroded, limiting the increase in load-bearing capacity offered by the intervention.

Thus, the post-tensioning intervention makes it possible to recover the share of load-bearing capacity lost due to reinforcement corrosion as a result of 95 years of chloride pollution. In fact, the ultimate capacity assumes the same value as the as-built condition, as can be also seen from the load-deflection curves of the retrofitted (coloured-dashed lines) and as-built (black continuous line) models in Figure 7b. In the case of a 45-year corrosion simulation, it provides an increase in performance, which is also higher than that of the as-built condition (Figure 7a).

In order to generalize the results here obtained, the effects of the reinforcement layout were investigated in Santarsiero & Picciano (2023), in which the same analyses were performed considering the absence of the inclined bars depicted in Figure 5a. It has been observed that post-tension interventions are able to provide an even more significant performance enhancement when inclined bars are absent, in terms of both cracking load and ultimate load improvement.

Figure 6. Cracking load (a) and ultimate load (b) improvements for retrofitted models with respect to as-built corroded conditions after 45 and 95 years, as a function of the applied prestress values.

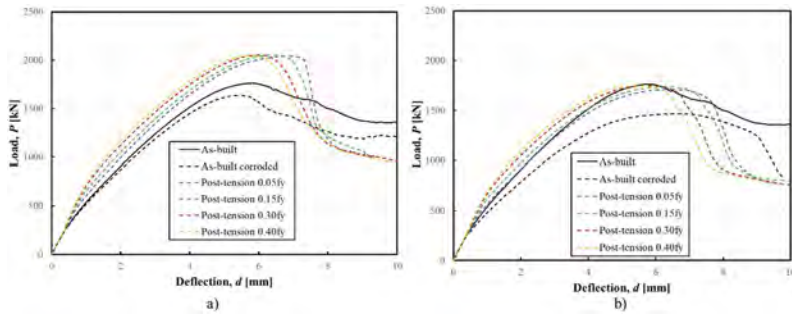

Figure 7. Load-deflection curves of the performed analyses after (a) 45 and (b) 95 years of corrosion.

5 CONCLUSIONS

This paper firstly reports a review of the currently available retrofitting techniques for half-joint bridges, with a specific focus on post-tension techniques, which have a higher ease of application when curb and transverse beams are present close to the bridge half-joints. Hence, post-tension is the most suitable technique to improve the load-bearing capacity of reinforced concrete half-joints. Subsequently, the results of a numerical investigation carried out on an existing bridge half-joint have been described. Results point out the effect of the installation of post-tension rods to improve the serviceability and ultimate capacity, also considering the effect of corrosion due to chlorides. The analyses demonstrated that cracking load values are almost linearly dependent on the prestress values imposed on the rods with a great benefit to durability enhancement due to the smaller crack width in the post-intervention condition. As for the ultimate load capacity, the prestress value shows a lower influence. In fact, also small prestressing values provide a significant increase in the load-bearing capacity. Finally, it has been found that, if the intervention is carried out after 45 years of simulated corrosion, evident advantages in terms of capacity improvement can be obtained, contrarily to what is found intervening after 95 years, when the heavier degradation effects, occurred on steel reinforcement, limit the recovery of load-bearing capacity.

ACKNOWLEDGMENTS

This study was partially developed under the financial support of the Italian Department of Civil Protection, within the ReLUIS-DPC 2022–2024 project (WP5, Task 5.4 “Upgrading and retrofitting interventions of existing bridges”). This support is gratefully acknowledged.

Enhancing Textile Reinforced Concrete materials by admixing short dispersed fibres

E. Rossi & N. Randl

Carinthia University of Applied Sciences, Spittal, Austria

ABSTRACT: Textile Reinforced Concrete (TRC) is a material consisting of a high-performance fabric embedded in a cementitious matrix. It has been widely studied for new thin-walled structures and strengthening and retrofit applications. The low tensile strength of the cementitious matrix often limits the full utilization of the material. The splitting forces generated by the loaded fabric often result in spalling of the cementitious matrix with consequent loss of functionality of the material. This problem can be overcome by admixing short dispersed fibres in the cementitious matrix. The resulting material is named Fibre/Textile Reinforced Concrete (F/TRC). An overview of the state of the art on experimental tests that highlight the difference in performance between F/TRC and TRC materials is presented. It can be seen that short dispersed fibres play a fundamental role in achieving higher performances. The results highlight how they influence the failure mode, the crack pattern, and the stress transfer.

1 INTRODUCTION

Textile Reinforced Concrete (TRC) is a relatively new layered concrete composite material consisting of high performance fabrics, generally made of carbon, AR-glass, basalt, or synthetic fibres, embedded in a fine-grained cementitious matrix. This material is often addressed also as Textile Reinforced Mortar (TRM) or Fabric Reinforced Cementitious Matrix (FRCM). It has been used to produce thin walled elements both for structural and non-structural use (Hegger & Voss 2008, Botelho Goliath et al 2021), and for structural strengthening applications (Nobili & Falope, 2017, Koutas et al. 2019, Adam et al. 2020). The success of TRC as a strengthening material has to be sought in its high compatibility with concrete and masonry substrates, and to the capability of overcoming some of the limitations of more traditional FRP applications, such as poor behaviour on wet surfaces and at high temperatures.

The relatively brittle nature of the matrix used to produce TRC can however result in premature failure, thus preventing a full utilization of the high-strength fabrics. This phenomenon is particularly evident in the case of splitting or splitting-related failure of TRC elements. It is a consequence of the stress transfer between the fabric's rovings and the surrounding cementitious matrix and is enhanced by the variable geometry of the rovings themselves and the reduced concrete cover (Preinstorfer & Kollegger 2020, Preinstorfer & Kromoser 2020, Tekle et al. 2021, Beßling & Orlowsky 2022). The same phenomenon, i.e. splitting of concrete, is a limiting factor for the full utilization of the anchored material's strength whenever the end anchorage of a reinforcing bar, cast-in (García-Taengua et al. 2014) or post-installed (Randl & Kunz 2014), has to be designed for small concrete covers. An effective way to overcome such limitation in TRC applications consists in the introduction of short dispersed fibres in the cementitious matrix, thus increasing its tensile properties. The resulting material, named Fibre/Textile Reinforced Concrete (F/TRC) (Rossi et al. 2021b), is able to exhibit strongly improved performances both at the material level and structural level (Barhum & Mechtcherine 2013; Dong et al. 2020, 2021, Dinh et al. 2021). The present article summarises some of the results of the CON_FIT

project and discusses the enhanced properties of F/TRC against more traditional TRC, both at the material level, through experimental testing of small TRC and F/TRC specimens, and at structural level, when these materials are used for strengthening purposes. The focus will be on two main aspects: change in the failure mode, which generally results in a better utilization of the high performance fabrics and change in the crack pattern, which can significantly orient design choices at Serviceability Limit States (SLS).

2 CHANGE IN FAILURE MODE

The most noticeable effect of the introduction of short dispersed fibres in the cementitious matrix of TRC is the change in failure mode. The increased tensile properties of the matrix are able to absorb the tensile stresses generated by the splitting forces, ultimately leading to a change in the failure mode and, consequently, higher performances of the material. At the material level, this was observed on tensile tests performed on lap-spliced textiles (Rossi et al., 2021c). The tested specimens consisted of Ultra High Performance Concrete (UHPC) internally reinforced with fully epoxy-impregnated carbon textiles. The textile was arranged in order to have a connection between the top and bottom parts of the plates through the overlap of two rovings. Furthermore, a notch was cut in the plate, around the lap-spliced connection, to force the first crack to appear in that specific region. While several different geometries were tested, the comparison between TRC and F/TRC was performed on asymmetric configurations with an overlapping length of 100 mm. The F/TRC was produced admixing 2 vol% of steel fibres having a length of 5 mm and a diameter of 0.15 mm (aspect ratio: 33.3). As can be seen in Figure 1, the splitting failure of the TRC specimen caused the loss of the concrete cover over the overlapped textile. The F/TRC specimen, instead, failed by textile pull-out. This, in turn, resulted in a higher load carrying capacity of the F/TRC specimens which failed,

Figure 1. Comparison of TRC and F/TRC failure modes in lap splice tests.

on average, at a load of 21.7 kN, compared to the TRC specimens, which failed on average at 14.4 kN.

A similar behaviour was also observed when TRC and F/TRC solutions were used to strengthen Reinforced Concrete (RC) beams in bending (Rossi et al. 2021b) and in shear (Rossi et al., 2022). In the case of strengthening in bending, RC beams having a cross section of 220x450 mm and a length of 2.5 m were strengthened in the tensile zone using a carbon textile fabric embedded in different cementitious matrices and using different typologies and arrangements of mechanical anchoring solutions. The direct comparison of TRC and F/TRC consisted of a single textile layer embedded in a UHPC matrix and without the use of mechanical anchorage devices. The F/TRC was made admixing 2.5 vol% of the same steel fibres mentioned in the previous case. In this case, both specimens failed due to rupture of the textile, thus achieving similar performances. Nevertheless, the F/TRC-strengthened element showed a slightly higher maximum load carrying capacity (370.5 kN) than its TRC-strengthened counterpart (362.1 kN). Also the failure mode was somehow different; while the F/TRC strengthened specimen showed rupture of the textile in a single longitudinal position, the TRC counterpart exhibited rupture of the rovings in different locations accompanied by a substantial loss of the UHPC cover in a rather diffuse area (Figure 2 left).

In the case of shear strengthening, the effect of short dispersed fibres is even more evident. In that context, one should note that apart from the other mentioned effects of adding fibers, they also contribute strongly to the shear resistance of a high strength concrete materials (Randl et al. 2018), which applies also to layers of new concrete subsequently attached to the web. The specimen consisted of 6.3 m long RC T-beams with a 220x450 mm web and a flange of 600x150 mm. The shear reinforcement, in the form of closed Ø10 stirrups spaced at 100 mm along the whole length of the beam in the flange. The same diameter and spacing was adopted also in the web but the shear failure zones were cast without stirrups. The shear span was 1.3 m long resulting in a span-to-effective-depth ratio of 3.47. The specimens were strengthened with carbon textile arranged in different configuration and embedded in a pre-mixed HPC matrix. The F/TRC strengthening elements were prepared as in the case of the bending beams i.e., 2.5 vol% of short steel fibres. The comparison of the TRC and F/TRC strengthening solutions was performed on a 2-layer side bonded setup. The TRC strengthening solution failed due to interlaminar shearing i.e., formation of a planar crack along the plane of the textile, at a load of 397.9 kN, while the F/TRC solution failed due to debonding at a load of 518.7 kN. The two different failure modes are visible in Figure 2 right.

Figure 2. Comparison of TRC and F/TRC strengthening solutions failure modes in flexural (left) and shear (right) beam tests.

3 CRACK PATTERN

The presence of short dispersed fibres in F/TRC materials and F/TRC-strengthened elements plays also a role in the resulting crack pattern. Mészöly et al. (2020) performed a study on the behaviour of TRC and F/TRC plates in bending. The plates were prepared using a UHPC matrix reinforced either with AR-glass or carbon. The F/TRC was produced using 2 vol% of steel fibres having a length of 15 mm and a diameter of 0.2 mm. The results of the tests showed the superior performances of F/TRC which exhibited a higher cracking load, as well as reduced crack opening combined with a more diffuse crack pattern (Figure 3).

Figure 3. Comparison of the crack patterns of TRC and F/TRC at 1 mm crack opening (modified from Mészöly, Ofner and Randl, 2020).

When this kind of materials are used as strengthening elements, instead, an opposite behaviour can be observed. In a follow-up study on the effect of TRC and F/TRC strengthening elements upon flexural RC beams (Rossi et al 2021a) focused on the evolution of the crack pattern, it was observed that F/TRC strengthening, compared to TRC, would result in an increase in the cracking load for smaller cracks (0.1 – 0.2 mm) but not for larger cracks. Furthermore, before yielding of the longitudinal reinforcement, it would result in an overall reduced number of smaller cracks, while the larger ones tended to be less affected. After reaching the yielding load, instead, the crack opening rate of the TRC-strengthened specimen would strongly increase, while, with F/TRC, it seemed substantially unaffected. The average and maximum crack opening did not show significant differences. Analogous behaviours were observed also when strengthening RC beams in shear and RC column stubs in compression.

In the case of shear strengthening of RC beams (Rossi et al. 2022), the TRC strengthening element exhibited, at the maximum load, a rather diffuse crack pattern characterized by a strong concentration of diagonal cracks spanning from the support to approximately 1/3 of the shear span. Furthermore, subvertical cracks were visible at a regular spacing along the rest of the strengthening layer. The F/TRC strengthened element, instead, showed only limited cracking. Few diagonal cracks were located at approximately 1/3 of the shear span towards the support, and subvertical cracks were barely observable (Figure 4). Thus a more efficient crack control can be achieved compared to other shear strengthening methods (Randl & Harsányi 2018).

Similar results were also observed when TRC and F/TRC were used to strengthen RC columns (Mattarollo et al. 2022). The test specimens consisted of short circular column stubs externally confined with carbon or basalt TRC or F/TRC. The RC column stubs were 675 mm high and had a diameter of 200 mm. The strengthening solutions consisted of a continuous textile sheet, either of carbon or basalt, wrapped around the specimen in a 2-layer configuration and embedded in a HPC matrix. The steel fibres used to produce F/TRC were 5 mm long with a diameter of 0.15 mm and admixed in a 2.5 vol% ratio.

The specimens confined with TRC failed at an average load of 1145 kN and 1177 kN for basalt and carbon, respectively. The crack pattern of these specimens was characterized by the presence of many cracks, most of which were running along the whole height of the specimens. The F/TRC strengthened specimens, instead, failed at an average load of 1353 kN and 1368 kN for basalt and carbon, respectively. In this case the crack pattern featured a reduced

Figure 4. Comparison of the crack patterns of TRC and F/TRC shear strengthening at maximum load (modified from Rossi *et al.*, 2022).

number of cracks, which mostly were running from either the top or bottom of the specimens till approximately the middle. (Figure 5).

Figure 5. Comparison of the crack patterns of carbon TRC and F/TRC used to confine RC columns.

4 CONCLUSIONS

Fibre/Textile Reinforced Concrete (F/TRC) can overcome the limitations of traditional TRC related to its brittle matrix. The admixture of short dispersed fibres improves the tensile behaviour of the cementitious material, thus preventing or strongly limiting undesired phenomena such as premature splitting and interlaminar shearing. This, in turn, affects the failure mode and, consequently the overall performance of these materials enabling a higher utilization of the high-performance reinforcement. Within the CON_FIT project, F/TRC elements were

casted using short steel fibres admixed in High- and Ultra-High- Performance Concretes, and different type of fabrics. Compared to TRC, F/TRC exhibited better performance both as a material and when used to strengthen RC elements. It showed its capability of effectively preventing splitting phenomena, which resulted in more favorable failure modes and, consequently, in higher maximum loads. Furthermore, it had a strong influence on the crack pattern. At the material level it tended to reduce the maximum crack opening and increase the total number of cracks. When used as a strengthening solution, instead, it showed a tendency to reduce the overall number of cracks and increase the cracking load.

Shear strengthening with F/TRC: Experimental investigation on real scale RC beams

E. Rossi & N. Randl

Carinthia University of Applied Sciences, Villach, Austria

ABSTRACT: Shear strengthening of existing structures is a key activity in ensuring adequate safety. Shear deficient Reinforced Concrete (RC) elements exhibit rather brittle failures which can lead to disastrous consequences. Furthermore, even elements which are not prone to shear failure might require installation of shear strengthening solutions, for example after a bending capacity enhancement intervention. Among the different shear strengthening methods available today, the use of Textile Reinforced Concrete (TRC) was given particular attention by both scholars and practitioners due to its compatibility with the substrate material and the overcoming of the intrinsic limitations of Fiber Reinforced Polymer (FRP) solutions. An enhanced version of TRC, named Fibre/Textile Reinforced Concrete (F/TRC) and consisting in the admixture of short dispersed fibres in the cementitious matrix of TRC material, was recently developed and showed high potential as a strengthening material. The use of F/TRC as shear strengthening method was tested in the structural laboratory of Carinthia University of Applied Sciences on real scale RC beams. The effect of these strengthening solutions was evaluated in detail using a Digital Image Correlation (DIC) system. The present article describes the strengthening potential of these solutions and provides insights on the progression of the different observed failure modes, including debonding and interlaminar shearing.

1 INTRODUCTION

Structural strengthening is a key activity in the modern construction sector. The continuously aging structures, the increase in loads such as traffic, and the increased frequency of extreme events related to climate change are the main drivers of this activity. Particularly important, in this context, is shear strengthening due to the brittle nature of shear failure. Furthermore, even structural elements which are not prone to shear failure might need to be strengthened in shear in order to avoid vulnerability shifts consequent to other strengthening operations such as flexural strengthening. Different strengthening solutions against shear have been studied in the recent past, including post-installed reinforcing elements (Randl & Kunz 2009, 2014), Fibre Reinforced Plastics (FRP) and innovative anchor solutions (Randl & Harsányi 2018), and especially Textile Reinforced Concrete (TRC) (Brückner et al. 2006; Escrig et al. 2015; Tetta et al. 2016; Adam et al. 2020; Pohoryles et al. 2021; Rossi et al. 2022). This material, also known as Textile Reinforced Mortar (TRM) or Fabric Reinforced Cementitious Matrix (FRCM), is a high performance cementitious composite consisting of one or multiple layers of high strength fabrics, generally made of carbon, AR-glass, or basalt fibres, embedded in a cementitious matrix. Fibre/Textile Reinforced Concrete (F/TRC) is, instead, an enhanced version of TRC materials which is able to overcome the limitations related to the low tensile performances of the cementitious matrix by admixing to it short dispersed fibres, thus preventing undesired failure modes such as splitting and interlaminar shearing (Rossi et al. 2021a, b, Rossi et al. 2022). These materials have been used to produce thin-walled structural elements (Hegger & Voss 2008; Botelho Goliath et al. 2021) as well as strengthening solutions for

existing structures (Nobili & Falope 2017; Koutas et al. 2019; Furtado et al. 2020; Li et al. 2021). It is also well known that short dispersed fibres can contribute strongly to the shear resistance of a high strength or ultra-high performance concrete (Randl et al. 2018), which applies also to layers of new concrete subsequently attached to the web.

The present work focuses on experimental tests of TRC and F/TRC shear strengthening solutions applied on real-scale Reinforced Concrete (RC) T-beams. The different behaviour of the two materials will be analysed in terms of increase in the load carrying capacity and change in failure mode. Through the use of the results obtained from the Digital Image correlation (DIC) monitoring system, an analysis of the debonding and interlaminar shearing phenomena is performed. In particular, the results shown hereafter will complement a previous research campaign (Rossi et al. 2022) by enabling important considerations on the efficiency of the strengthening solutions and highlighting the differences between the observed failure modes.

2 MATERIALS AND METHODS

The specimens consisted in 6.3 m long T-beams having two shear deficient zones, one at each end of the beam. The width of the cross section was 220 mm in the web and 600 mm in the flange. The total height of the beam was 450 mm, 150 of which in the flange. Each beam had 2 shear deficient zones. In the presented cases, the shear deficient zones had no stirrups in the web. The rest of the beam was reinforced with Ø10 stirrups spaced at 100 mm. The longitudinal reinforcement consisted of 8 Ø10 rebars in the flange and 6 Ø30 rebars in the tensile zone of the web, arranged in two layers. The beam was designed to be tested in a three point bending configuration with a total span of 3.9 m and a shear span of 1.3 m, resulting in a shear span to effective depth ratio of approximately 3.5. A schematic representation of the beams can be seen in Figure 1.

The concrete used to cast the beam was a C40/50 with a mean cube compressive strength of 60.7 MPa. The steel for the longitudinal and transversal reinforcement was a B 550B.

Figure 1. Geometry of the beam specimens (modified from Rossi et al. 2022).

Several strengthening solutions were tested during the experimental campaign. They were all designed in a way to prevent or delay the formation and propagation of typically observed shear cracks in such type of T-beams (Stoerzel et al. 2015). The present work focuses on 4 different side-bonded solutions: S1 – a single layer TRC strengthening; S2 – a double layer TRC strengthening; FR-S1 – a single layer F/TRC strengthening; FR-S2 – a double layer F/TRC strengthening. Each strengthening solution employed a high performance cementitious matrix, admixed with 2.5 vol% of short dispersed steel fibres in the case of F/TRC solutions, and a fully impregnated carbon fabric. The cementitious matrices had a cube compressive strength of 90.6 MPa and 90.3 MPa, tested on 100x100x100 mm specimens, and a flexural tensile strength of 7.1 MPa and 18.8 MPa, tested on 40x40x160 mm prisms, for TRC and F/TRC respectively. The carbon fabric was characterized by rovings having a cross-sectional area of 3.62 mm² and a spacing of 25 mm from their axis. The tensile strength of then longitudinal and transversal rovings was 3100 MPa and 3300 MPa, respectively ('solidian GRID Q142/142-CCE-25 Technical Data Sheet').

The tests were performed in displacement control with a speed of 0.5 mm/min. The testing and measurement equipment consisted of a 2.1 MN hydraulic cylinder with a resolution of 0.01 kN, a two-system stereo DIC photogrammetric equipment and an LVDT used to monitor the deflection of the beam.

3 RESULTS AND DISCUSSION

All the specimens failed in shear, signaled by the presence of one or more diagonal cracks running from the support to the load introduction. The results of the tests, in the form of Force-Deflection curves can be seen in Figure 2. The reference beam started to fail at approximately 250 kN, when the web was fully cracked. At this stage, however, the shear cracks did not yet propagate to the flange. The beam was thus able to carry additional load, reaching a maximum of 291.7 kN when the diagonal crack propagated in the flange towards the load introduction. Specimen S1 failed at 358.5 kN, recording a maximum load increase of 22.9%, due to interlaminar shearing i.e., formation of a crack in the plane of the textile which separated the textile fabric from the rest of the structure. Specimen S2 exhibited a similar behaviour, failing due to interlaminar shearing at a load of 397.8 kN (36.4% increase in maximum load). This specimen, however, exhibited a rather horizontal branch of the force deflection curve, characterized by the presence of several drops in load. This was attributed to the capability of the 2-layer configuration to redistribute some of the stresses between the two layers. Specimen FR-S1 recorded a maximum load increase of 46.5%, corresponding to a maximum load of 427.3 kN. This specimen exhibited a mixed failure mode. On the side where the DIC measurement was taking place, extensive debonding in the central strengthened region could be observed. On the other side, instead, a clear shear crack was visible and, upon further inspection, pull-out of the textile fabric was observed. Specimen FR-S2 failed due to debonding of the strengthening layers at a load of 518.7 kN, corresponding to a maximum load increase of 77.8%. A summary of the test results can be found in Table 1. Focusing on the effect that 2-layers configurations (S2 and FR-S2) have on the overall capacity increase and comparing them with 1-layer configurations (S1 and FR-S1), an interesting behaviour arises. S1 strength increase accounts for 66.8 kN while S2 accounts for 106.1 kN. The ratio between the two is 1.59, showing a less than linear contribution of the additional layer. Similarly FR-S1 provided a strength increase of 135.6 kN while FR-S2 of 227.0 kN, corresponding to a ratio of 1.67. While these four tests alone are not enough to define a law correlating the strength increase to the number of layers, the relative low difference observed in the two cases hints to the fact that the contribution of the additional layer is strongly reduced, at least in side-bonded configurations, and might account for approximately 60%.

Figure 2. Force-deflection curves of specimens (data partly from Rossi et al. 2022).

Table 1. Overview of testing program and results.

Specimen	Strengthening material	N° of layers	Maximum force [kN]	Deflection at maximum force [mm]	Performance increase [%]
Reference	-	-	291.7	11.8	-
S1	TRC	1	358.5	7.7	22.9
S2	TRC	2	397.8	12.9	36.4
FR-S1	F/TRC	1	427.3	11.4	46.5
FR-S2	F/TRC	2	518.7	14.0	77.8

To better analyse the failure modes that were observed during testing, with special reference to interlaminar shearing and debonding, the out-of-plane displacement (OOP) was measured with the aid of the DIC measurement. Such results can be seen in Figure 3. The plotted results refer to a post-failure condition of the beams, corresponding to a load decrease of approximately 10% of the maximum load. As it can be seen, specimens S1 and FR-S1 showed a very similar pattern of OOP. In both cases OOP was located in the same region i.e., bottom central part of the strengthened region progressing upwards towards the flange. In the case of specimen S1, the OOP shows high values around the shear crack which tend to concentrate in the bottom part and diminish further away from the crack itself. Specimen FR-S1, while exhibiting a similar pattern, is characterized by a more diffused distribution of high OOP which tends to diminish in a longer distance from the maximum. This difference, combined with the force-deflection results, shows that F/TRC is able to retain its strengthening capability even when part of the layers are debonded from the existing structure. This interpretation is confirmed by the results of specimens S2 and FR-S2. In this case, the maximum OOP was located in different points for the two beams. In the case of S2, the OOP is concentrated in the top left area of the strengthening layer (near the support) and, once again, around a shear crack. In the case of FR-S2, instead, the OOP is the highest in the bottom right corner (under the load introduction) and propagates along nearly the whole length of the strengthening layer. Specimen FR-S2, however, despite having a significant portion of the F/TRC layer debonded from the substrate, was able to contribute to a performance increase more than three times than what was obtained with specimen S2.

Focusing on the specific patterns of OOP that the different solutions exhibit, some interesting considerations can be formulated. Comparing S1 and S2, it can be seen that, in both cases, the OOP tends to concentrate around the main diagonal shear crack, which however shifted towards the left side in specimen S2. The addition of the second textile layer, however, resulted in a more diffuse propagation of the interlaminar shearing phenomenon, probably due to internal stress redistribution. Comparing FR-S1 and FR-S2, instead, a significant change in behaviour is observable. As already mentioned, FR-S1 showed a concentration of OOP around the main shear cracks, albeit more diffused than S1. FR-S2, contrarily, showed that OOP was concentrated at edges of the strengthening layer. This difference hints at the fact that, most probably, the combined effect of the 2-layer configuration, together with the increased performance of F/TRC, can effectively bridge across the main shear crack, shifting the main vulnerability to other stress concentration areas, such as the corners of the strengthening layer.

4 CONCLUSIONS

An experimental campaign was performed at the structural laboratory of Carinthia University of Applied Sciences testing different TRC of F/TRC shear strengthening solutions. The tests highlighted how the different materials and configurations contribute to increasing the load carrying capacity of the strengthened element. Different failure modes were observed, including interlaminar shearing and debonding. In the case of side-bonded strengthening solutions, TRC elements always failed due to interlaminar shearing. The use of F/TRC materials could effectively prevent this failure mode. This resulted in a higher load carrying capacity. The

Figure 3. Out-of-plane displacement of the strengthening solutions.

presence of an additional textile layer, independently of the employed material (TRC or F/TRC) showed a less than linear increase in the additional load carrying capacity. Furthermore, with the aid of DIC measurement, it was possible to observe that TRC interlaminar shearing failure was located in the surroundings of shear cracks and led to failure of the specimen when the phenomenon interested a relatively contained part of the element. Contrarily, F/TRC side bonded solutions show a good stress redistribution capability, enabling the specimen to still be able to carry loads even when significant parts of it were debonded from the substrate. Such phenomenon even led to a vulnerability shift for the 2-layer F/TRC strengthening solution, where the debonding was concentrated in the corner of the strengthening solution instead of being around the main shear crack.

State of the art in flexural prestressing of RC members with SMA materials

J. Rogowski & R. Kotynia

Department of Concrete Structures, Lodz University of Technology, Lodz, Poland

ABSTRACT: Prestressing concrete is a great technique to improve the serviceability state of RC members subjected flexure. Relatively new materials such as iron-based shape memory alloys (FeSMA) can be a great alternative for conventional prestressing system. Using the shape memory effect, concrete members can be prestressed without the need of hydraulic jacks, ducts or anchor heads. The flexurally strengthened members exhibit higher cracking load, initial stiffness and reduced deflections with simultaneous ductile behaviour up to failure that is usually due to concrete crushing. In the paper, a brief description of FeSMA including utilization of shape memory effect for prestressing and tensile behaviour of materials is presented. The existing prestressing systems for flexural strengthening of RC members are described. Previous studies based on flexural strengthening using prestressed memory steel are revised, summarized and discussed. Selected real-life implementation is described to confirm the practicality and feasibility of the strengthening using FeSMA systems.

1 INTRODUCTION

The number of existing reinforced concrete structures that need to be strengthened is constantly increasing. The need for retrofitting may be caused by the deterioration of structures, changes in usage, increasing design requirements or design errors. Traditional methods of strengthening include, for instance, additional concrete layer in the compression zone or externally added steel reinforcement. These methods, known as passive strengthening, mainly improve the load-bearing capacity and do not affect significantly the serviceability limit state. One of the most effective methods to reduce deformations and crack widths of RC members is prestressing of concrete. However, existing strengthening techniques with prestressed carbon composites require complex mechanical anchorage and additional special devices such as hydraulic jacks that increases significantly the overall costs of strengthening. Prestressing CFRP systems are in most cases bonded to the concrete surface using epoxy and their ultimate load is limited due to the bond strength. Additionally, a sudden failure due to delamination is a common failure mode (Kotynia 2019). Hence, new methods of active strengthening are still in demand and developed.

Prestressing using shape memory alloys (SMA) should be considered a promising alternative for the existing prestressing methods of existing concrete members. These metallic alloys have unique abilities that allow them to return to their initial shape after having been permanently deformed. The ability to recover inelastic deformations occurring automatically by unloading is called superelasticity. If the return to the predefined shape has to be activated, e.g. upon heating, the phenomenon is called the shape memory effect (SME). Some mechanical stress appears in the material if the deformation recovery is restrained. The stress obtained after heating the material to a certain temperature and cooling it down is called recovery stress and can be used for prestressing some concrete members.

The superelasticity is characteristic of the most popular nickel-titanium based alloys (NiTiSMA). Their applications have been limited in the civil engineering industry due to their

high material costs, however, they have already confirmed their potential for retrofitting concrete members and can be used as dampers, actuators or self-centering elements (Mohd Jani et al. 2014). An iron-based shape memory alloys (FeSMA) seems to be a more suitable material for structural retrofitting not only due to a reasonable production cost but also higher Young modulus and relatively low temperature of activation (Leinenbach et al. 2012). SME can be used for flexural strengthening of RC beams or slabs, shear strengthening or active confinement of RC columns. Overall state of the art in the topic of strengthening and self-centering of concrete structures was summarized in a review by (Raza et al. 2022).

This paper is focused on the topic of flexural strengthening of RC structures with prestressed FeSMA materials and provides a background for future research. The key parameters of memory steel and prestressing systems are briefly described. The previous experimental studies with flexurally strengthened RC members using FeSMA are summarized, important results from the research are discussed and recommendations for future research are highlighted.

2 DESCRIPTION OF IRON-BASED SHAPE MEMORY ALLOYS

2.1 *Prestressing systems*

The method of prestressing concrete structures using FeSMA reinforcements is quite similar for all technique of strengthening. This method of prestressing is characterized by ease of applications and does not require hydraulic jacks, anchor heads or ducts. A bar, strip or wire made of memory steel is initially prestrained (permanently elongated) at room temperature. The prestrained reinforcing material is then applied to the concrete surface or embedded in concrete. The FeSMA reinforcement has to be fixed to the concrete member to restrain the deformation. The reinforcement is then heated to activate the shape memory effect. Various heating systems may be used to provide heat supply: gas torch, infrared heating, electrical resistive heating. Since the deformations of FeSMA materials are restrained, the recovery stress develops in the memory steel. The force is transferred to a concrete member through anchorage system or bonding between FeSMA and surrounding materials and prestress occurs in the concrete. The prestressing force depends on the recovery stress of the alloy that for different Fe-Mn-Si alloys are in the range of 130–580 MPa (Cladera et al. 2014). The recovery stress highly depends on composition of the alloy, thermomechanical training, level of initial prestraining, and temperature of activation. (Michels et al. 2018b) indicated that increasing the maximal temperature during activation provides higher recovery stress. However, the high temperature inside the concrete or cementitious grout may lead to deteriorating its mechanical properties, so the recommended temperature is in range 160 – 350°C. Based on the previous research studies the optimal level of prestraining is in range 2 – 4 % (Michels et al. 2018b, Shahverdi et al. 2018). In general, the recovery stress is much lower than the initial prestress in the CFRP reinforcement and the prestressing force for FeSMA system would be from two to four times lower than for the CFRP prestressing (assuming a similar cross-section area of reinforcements for both systems) (Rogowski & Kotynia 2022).

The following prestressing systems should be highlighted (Schranz et al. 2019):

- externally applied reinforcements (EAR). The most common is prestressing using unbonded FeSMA strips that are fixed to a concrete member with anchoring device (Strieder et al. 2019) or using direct fastening system (Michels et al. 2018a). The latter method is based on fixing the strip to concrete by installation the nails in the pre-drilled holes using powder-activated tools. The strip is not in contact with concrete between the end anchorages and acts as an external unbonded tendon during loading the structure.
- near-surface mounted (NSM) reinforcements. The FeSMA strips or bars are inserted into the concrete grooves which are filled with cementitious mortar (Shahverdi et al. 2016b, Schranz et al. 2021). The reinforcement may be additionally fixed using end-anchorages (Rojab & El-Hacha 2017a).
- bars embedded in the shotcrete layer (Shahverdi et al. 2016a).
- bars as longitudinal tensile reinforcements mounted before casting of concrete member (Yeon et al. 2022).

2.2 Tensile behaviour

Stress-strain behaviour of memory steel is similar to a conventional steel. The behavior of SMA during unloading is nonlinear. FeSMA exhibit ultimate strength of 680–1000 MPa with ultimate tensile strain equal to 16–50% (Shahverdi et al. 2018). In contrast to composites, they are fully isotropic materials. The initial Young modulus of FeSMA is about 170 GPa and is lower than steel and the high modulus CFRP. It should be emphasized that elastic modulus depends on actual state of alloy. It is about 25 – 50% lower after activation than in elastic state (Shahverdi et al. 2018, Yang et al. 2021). Moreover, stress relaxation occurs in the FeSMA materials. A decrease of 10% in recovery stress was observed after 1000 h by (Michels et al. 2018b). During the life cycle of the structure, the total relaxation losses are estimated at 15 – 20%. Re-heating of FeSMA to the activation temperature and cooling to the ambient temperature (multiple activation) can retrieve a significant part of the prestressing losses (Hosseini et al. 2018).

3 LITERATURE REVIEW

Experimental research studies dedicated to flexural strengthening using iron-based shape memory alloys are summarized in Table 1. It contains information about steel reinforcement ratio, ρ_s , FeSMA reinforcement ratio, ρ_{SMA} , ductility index, I_D , and cracking load increment, ΔP_{cr} , that are calculated as follows:

$$\rho_s = \frac{A_{s,t}}{A_c} * 100\% \quad (1)$$

where $A_{s,t}$ = area of tensile steel reinforcement; A_c = cross-section area.

$$\rho_{SMA} = \frac{A_{SMA}}{A_c} * 100\% \quad (2)$$

where A_{SMA} = area of FeSMA reinforcement; A_c = cross-section area.

$$I_D = \frac{d_{ult}}{d_y} \quad (3)$$

where d_{ult} = deflection at ultimate load; d_y = deflection at yielding load.

$$\Delta P_{cr} = \frac{P_{cr,str} - P_{cr,ref}}{P_{cr,ref}} * 100\% \quad (4)$$

where $P_{cr,str}$ = cracking load of strengthened beam; $P_{cr,ref}$ = cracking load of reference beam.

RC beams strengthened with FeSMA strips as NSM reinforcements were investigated by (Shahverdi et al. 2016b). The FeSMA strips were prestrained up to 2% and glued with cement-based mortar in grooves (without end anchorages). The strips were activated by resistive heating for 3 beams, while they remained inactivated in one beam. Bonding strength between glued with cement-based mortar FeSMA strips and concrete was sufficient to transfer the prestressing force. The prestressed beams exhibited a higher cracking load by 80% compared to the non-prestressed beam and lower mid-span deflections (up to a load of ~12 kN)). As could be expected, prestressing did not increase the ultimate load in comparison to the nonactivated beam. Two of the activated beams failed due to strip rupture, however they experienced significant deflections of more than 1/40 of the span length. The long-term behaviour of similar beams (activated and nonactivated) was studied by (Shahverdi & Czaderski 2019). The beams were loaded (until more than their cracking load) using a concrete block in May 2015 and their mid-span deflection and crack propagation have been monitored for about 4 years. The mid-span deflection has increased from 4.3mm to 10.2mm in the activated beam and from 7.3mm to 13.2mm. Since both beams presented similar behaviour, the study noted that the stress relaxation (reduction in prestressing force) is not significant.

The application of FeSMA bars embedded in a shotcrete layer for flexural strengthening of RC beams was investigated by (Shahverdi et al. 2016a). The bars were initially prestrained to 4%, then fixed by mechanical hooks to the roughened bottom side of the beams and activated by resistive heating at 160°C. The beam with 2 FeSMA bars exhibited about 240 and 80% higher cracking load compared to the reference beam and a beam strengthened with 2 steel bars, respectively. However, the cracking load (determined using digital image correlation measurements) was lower for the beam with 4 FeSMA bars compared to the one with only 2 bars. It could be caused by shrinkage cracks of the shotcrete layer prior to the loading and should be further investigated to develop this technique. Nevertheless, load at midspan deflection of 4mm (corresponding to the serviceability limit state) increased by 63 and 165% compared to the reference beam for the beams with 2 and 4 bars, respectively.

Ribbed FeSMA bars were used for strengthening of two-field RC slab subjected to flexure with one part acting as a cantilever. Two system of strengthening were used. In the first (denoted as CR), the bars were placed in a roughened surface of beam and anchored at their ends over a length of half meter with grout. For other slabs (denoted as NSM), the bars were mounted as NSM reinforcement with the anchorage zone of 600mm performed by filling the grooves with cementitious mortar. After activation at 200°C using a resistive heating device, the remaining length between the anchorages was filled with the grout or mortar. The effectiveness of prestressing was confirmed by an increase in the cracking load (76 – 94% and 232 – 265% compared to the reference slab and non-activated slab with NSM bars, respectively) and a decrease in the length of the cracked zone between the outermost bending cracks in comparison with non-prestressed beams. Longitudinal cracks developed in the concrete cover during loading, but their width was negligible compared to the transverse bending cracks. The bond strength of FeSMA bars and surrounding materials was sufficient to avoid premature bonding failure – the slabs exhibited high ductile behavior up to fail due to the crushing of concrete.

Series of studies with FeSMA smooth bars as NSM reinforcements were conducted by Rojob & El-Hacha. The bars were initially prestrained to 6%, grooved into the tension side of the beams, end-anchored with steel plates, and heated up to 300 – 350°C using heating tapes or a rosebud torch. Finally, the grooves were grouted after cooling the bars to room temperature to create a bond between the concrete and bars. (Rojob & El-Hacha 2017a) indicated that in comparison with the reference beam, the cracking load increased by 111 and 142% for beams with FeSMA bar without and with additional thermomechanical training, respectively. (Rojob & El-Hacha 2017b) tested different anchorage systems where the bar was bent 90° angle at both ends, and the ends were inserted into pre-drilled holes that were then filled with epoxy. Compared to the previous anchorage solutions, a drop in the strain was clearly noticeable which could lead to a reduction of prestressing force transferred to the beam. Hence, only a 20% increase in cracking load was achieved. In both studies, the anchorage setting during the loading tests was observed (resulting in a relaxation of bars) and the debonding between the FeSMA bar and grouting material was noticed at higher loads (about the yielding load). The fatigue behaviour of RC beams with prestressed FeSMA bars was studied by (Rojob & El-Hacha 2018a). At low levels of fatigue load, corresponding to stress levels in the tensile steel reinforcement (of reference beam) equal to 0.29 and 0.53 of yield strength, the strengthened beams exhibited better performance than the reference beam. At higher levels of fatigue load, the deterioration in the bond between the FeSMA bar and surrounding grouting material resulted in the loss of strain in the bar started occurring. In consequence, the continued degradation led to the rupture of bars at the anchorage zone after 5.5 million load cycles. The performance of RC beams exposed to freeze-thaw cycles and sustained load (50% of ultimate capacity of the unstrengthened beam) was investigated by (Rojob & El-Hacha 2018b) and compared to the non-exposed beams. After the application of freeze-thaw cycles, the grout was completely spalled, hence FeSMA bar acted as an unbonded prestressed tendon. Reduction of 19 and 12% in the yielding and ultimate load due to the deterioration in the stiffness was noticed for the prestressed beam exposed to freeze-thaw cycles. The exposure did not affect the ductile behavior of the beams until failure. In all presented studies, the smoothness of the bars resulted in a lower bond strength of the bar and surrounding grout.

FeSMA strips were used as NSM reinforcements for flexural strengthening of RC beams in a study conducted by (Hong et al. 2018). The strips were prestrained to 2 or 4%, inserted in grooves cut in the concrete cover that was then filled with the rapid hardening cement mortar (90% of the length of strips was embedded). Activation of the strips was performed using resistive heating to the temperature of 160°C. The recovery stress resulted in the upward displacement of beams that was greater for the higher value of initial prestraining. Activation of FeSMA strips increased the cracking load of prestressed beams by 16 and 35% compared to the beam with non-activated strips and improved flexural rigidity. However, the behaviour of beams was still ductile up to fail due to the crushing of concrete. (El-Hacha & Rojob 2018) investigated large-scale RC beams strengthened with NSM FeSMA strips that were prestrained to 3% and activated at 150°C using heating tapes. The strips were end-anchored and the grooves were filled with adhesive after cooling the strips down to room temperature. The

beam with 7 activated strips showed 59% increase in the cracking load compared to the reference beam. The cracking loads of beams with 5 activated and non-activated strips were close (the difference of less than 3% was not explained by the authors) but the prestressed beam exhibited higher stiffness up to the yielding load. Finally, the prestressed beams were compared with beams strengthened using NSM CFRP – the FeSMA beams exhibited only slightly lower strength but significantly higher ductility.

Externally applied and unbonded FeSMA strips were used for active strengthening of RC beams by (Michels et al. 2018a). The FeSMA strips were prestrained to 2%, mechanically anchored to the concrete beam with the direct fastening method and activated by resistive heating at 160°C. The beams prestressed with FeSMA strips exhibited higher cracking load and enhanced stiffness compared to an unstrengthened beam and a beam passively strengthened with CFRP strip. Moreover, the FeSMA beams retained ductile behavior and failed due to the concrete crushing after steel yielding. A slightly lower ultimate concrete compressive strain value equal to 2.5‰ was measured that is in line with knowledge for unbonded external prestressing tendon, as a result of more concentrated beam rotation occurring within the maximal bending moment zone (Michels et al. 2018a). FeSMA strips were also used for the flexural strengthening of RC beams (Strieder et al. 2019). The strips were end-anchored to the beam with a special clamping device and thermally activated at 200°C by sequentially infrared heating. Sequential activation of strips does not influence the failure mode of the beam but has an impact on the level of prestress (usually higher temperature of activation could be required). The cracking load and initial stiffness of the prestressed beams were significantly higher compared to the reference beam and a beam strengthened with a passive steel strip. One of the beams was then loaded to 30kN, unloaded and reactivated at 350°C before loading up to failure to simulate behaviour of a damaged beam strengthened with FeSMA. The structural behavior of this beam remained ductile up to failure

(Hong et al. 2022) and (Yeon et al. 2022) used FeSMA rods as tensile reinforcement of concrete beams and slabs, respectively. The effect of FeSMA area, activation and additional end-anchorage were investigated. The rods were prestrained to 4% and activated at 160°C by resistive heating. Both beams and slabs exhibited ductile behavior up to failure due to concrete crushing after yielding of FeSMA reinforcements. Activation of rods significantly increased cracking loads but the ultimate loads remained at the same level. The greater number of rods, the higher prestress of specimens (was observed as the greater camber of beam or slab during the activation process) that resulted in higher cracking load increment compared to the non-activated specimens with the same reinforcements. The beam with activated rods without anchoring devices exhibited similar behaviour (including initial camber, cracking load and ultimate load) indicating that the bonding strength between concrete and FeSMA reinforcements was sufficient to prevent prestress loss due to slippage.

4 PRACTICAL IMPLEMENTATION

The first practical implementation of flexural strengthening with prestressed FeSMA strips took place in 2017 in Villigen, Switzerland (Michels et al. 2018a). The change of the static system caused by the removal of load-bearing wall resulted in the need of additional reinforcement. The combination of three strengthening methods was used to ensure minimal loss of room height and guarantee a satisfying behavior at the serviceability and ultimate limit state. The slab was strengthened by a steel girder installed between two supporting walls. The lack of lower flexural steel reinforcement above the removed wall was covered by applications of 12 CFRP strips. 14 FeSMA strips was applied in the perpendicular directions to the girder to deliver the prestressing in the slab and cover serviceability requirements. The FeSMA strips were fixed with nails using a direct fastening system and activated by resistive heating at 160°C.

5 CONCLUSIONS

In the paper, the state of the art in the topic of flexural strengthening using prestressed FeSMA materials is presented. The literature review shows that prestressing with FeSMA can be an

interesting alternative to conventional prestressing systems. The shape memory effect exhibited by FeSMA can be used to prestress RC slabs and beams. The effectiveness of flexural strengthening was confirmed both in experimental tests and practical implementation. FeSMA materials for flexural strengthening can be used as: externally applied or near-surface mounted reinforcement, embedded in a shotcrete layer or a tensile longitudinal reinforcement. All techniques of strengthening are much easier to perform in comparison with prestressing using CFRP materials.

The activation process is carried out by heating to the temperature in the range of 160 – 350°C. It can be performed using various methods including: heating using a gas burner, infrared heating or electrical resistive heating. The heating method may affect the prestressing level that is also highly dependent on composition of the alloy, initial prestraining and activation temperature. In general, the recovery stress are in the range of 130–450 MPa that resulted in 2 – 4 times lower prestressing forces in comparison to prestressing with CFRP materials.

The activation of SMA improves the structural performance of RC members especially in serviceability states. The prestressed beams and slabs exhibited greater cracking and yielding load, higher initial stiffness of the beams and reduced deflections. However, the behaviour of members prestressed with FeSMA is ductile up to failure that is caused in most cases by crushing of concrete after steel yielding. The ductility index for beams strengthened with FeSMA remains high and is similar to under reinforced concrete beams. Strengthening with FeSMA materials can be combined with other strengthening techniques e.g. with non-prestressed CFRP strips to provide maximum gains in both serviceability and ultimate limit states.

The elasticity modulus of FeSMA is dependent on the actual state of the alloy and the initial value is 30 – 50% higher than the value after activation –the latter value should be used for design purposes. The FeSMA is also affected by stress relaxation. The prestress loss due to relaxation is estimated to be about 15 – 20% in the life cycle of structure. Multiple activation allows to retrieve part of this loss.

The following recommendations should be considered in future research to develop the knowledge of prestressing RC members using FeSMA:

- effects of various heating methods and multiple activations on the prestressing level of FeSMA;
- prestress losses (including loss due to the slippage at anchorages) and long-term behavior of FeSMA used for prestressing of RC structures;
- development of more accurate methods of determining recovery stress after application of FeSMA materials to RC structure;
- combination of strengthening using prestressed FeSMA and non-prestressed CFRP materials.

FRP shear dowels - Experimental investigation

Đ. Čairović, M. Zlámal, J. Venclovský & P. Štěpánek
Brno University of Technology, Brno, Czech Republic

ABSTRACT: Main aim of this paper is to present extensive experimental investigation and define different load-bearing mechanisms, in cases when FRP shear dowels were provided as the reinforcement crossing the interface. More precisely, research was focused on use of non-corrosive GFRP (Glass-Fibre Reinforced Polymer) rebars as durable alternative to commonly used steel dowels, with a potential to significantly reduce life-cycle costs connected with maintenance of the structures.

1 INTRODUCTION

The need for strengthening of existing concrete structures has become more pronounced over the last decade, since a great number of buildings and engineering structures across Europe is reaching their design life span. Demolition and replacement of those structures with newly built is mainly cost inefficient and has higher negative impact on environmental and social aspects of the civil engineering sector. Therefore, strengthening of those structures is usually recommended, since it can extend their life, while at the same time ensuring the serviceability requirements and the safety of all users.

In cases of structural repairs, placing an additional concrete layer over existing structures is one of the most common types of structural strengthening. But whenever new concrete is cast against existing hardened concrete layer, concrete-to-concrete load transfer becomes relevant, since monolithic behaviour of composite structure needs to be ensured.

Strength of the interface is generally governed by the properties of adhesive bond or amount of the reinforcement crossing the interface. If adequate surface preparation cannot be realized, or adhesion is insufficient, shear dowels must be provided.

In order to fully utilize shear reinforcement, it has to be assumed that adhesive bond is lost, and that crack will appear along the interface. Especially in the cases of vertical interfaces, those cracks can be main cause of many durability issues like corrosion of the reinforcement. For that reason, performance of FRP (Fibre Reinforced Polymers) shear dowels was investigated, representing durable alternative to commonly used steel dowels (Čairović *et al.*, 2021).

2 EXPERIMENTAL INVESTIGATION

As described above, behaviour of the reinforced concrete-t-concrete interfaces is rather complex problem, and its resulting strength is governed by different, mutually affected load-bearing mechanisms. For that reason, experimental investigation was divided into 3 dedicated tasks:

- To obtain shear strength of GFRP reinforcement,
- To assess strength of the interface with GFRP reinforcement and
- To assess strength of the interface with typical steel reinforcement, to serve as reference.

2.1 Shear strength of GFRP rebars

Shear strength of commonly used steel reinforcement can be estimated by for example von Mises failure hypothesis (Randl, 2013), where the magnitude of the shear yield stress is $\sqrt{3}$ -times lower than the tensile yield stress in the case of simple tension. For reinforcement grade B500 B, corresponding shear strength will be approximately 320 MPa. Somewhat higher value of 420 MPa was obtained experimentally but still, it can be stated that abovementioned approximation provides reasonable results.

This cannot be applied for FRP reinforcement, due to its un-isotropic character. Also, somewhat lower values of shear strength can be expected, since best properties of the FRP rebars can be obtained in longitudinal direction i.e., direction of load-bearing fibres. Transverse shear strength of FRP rebars can be evaluated by standardized test methods, using double shear test machine (ACI 440.3R, 2004; ISO 10406-1, 2015), presented in Figure 1. Specimen is sheared on two planes by two blades converging along the faces perpendicular to its axial direction. Typical failure of specimens is presented in Figure 2.

Figure 1. Transverse shear test: experimental test setup (right).

Figure 2. Transverse shear test: failure of GFRP specimen (left) and B500 B steel specimen (right).

Experimentally obtained values of transverse shear strength and basic mechanical properties of the rebars used in this experimental investigation are summarized in Table 1. below.

Even thou tensile strength of used GFRP was much higher, oppose to steel reinforcement, ultimate shear strength of 180 MPa was obtained. This value is even lower, comparing to the steel reinforcement, since as it was already stated, loading direction in case of transverse shear is perpendicular to the direction of the fibres and this mechanical property is mainly governed by the properties of matrix. For that reason, steel rebars 8 mm in diameter were substituted with 10 mm GFRP bar, leading to similar shear resistance.

Table 1. Mechanical properties of FRP and steel reinforcing bars.

	Yielding strength f_y [MPa]	Ultimate tensile strength f_u [MPa]	Ultimate shear strength τ_s [MPa]	Modulus of elasticity E [GPa]
Steel B500 B	548	645	420	200
GFRP	-	1080	180	52

2.2 Interface shear strength

To evaluate performance of GFRP (Glass Fibre Reinforced Polymers) rebars as a shear reinforcement for concrete-to-concrete interfaces, push-off tests were performed (Ćairović *et al.*, 2021). This test configuration is mainly used to characterize the shear strength of reinforced interfaces. In fact, test configurations in this category uniquely allow the use of shear reinforcement that crosses the interface, either perpendicularly or inclined.

Dimensions of the specimen were $400 \times 400 \times 300$ mm, while both concrete layers had the same thickness of 150 mm. Specimens were performed in 3 stages: casting of the substrate layer, post-installation of the shear dowels and casting of the overlay, as presented in Figure 3.

Figure 3. Stages of specimen preparation: a) casting of the substrate layer; b) post-installation of the shear dowels; c) casting of the overlay.

In cases when shear dowels were provided, either GFRP 10 mm in diameter or steel reinforcement B500 B 8 mm in diameter was used. Based on reinforcement provided, 4 different series can be defined: with 2, 4, 8 and 16 rebars. Orientation of the reinforcement is shown in Figure 4. Each series also included one referential specimen, without any reinforcement crossing the interface.

In all the cases, distance of the bar from the edge was at least 50 mm. This distance, larger than 5 diameters, should ensure that splitting of the concrete cover will not likely occur

Figure 4. Orientation of the reinforcement for different series.

(for more information see for ex. (Vintzēleou and Tassios, 1986)). Anchorage length of 100 mm was chosen, and being larger than 10 bar diameters it should be sufficient, since according to (Randl, 2013) no influence on the magnitude of the shear resistance have been observed for anchorage depths of $6 \varnothing$ or more.

Seven days after casting of the substrate layer, 14 mm and 16 mm diameter holes were drilled for steel and FRP reinforcement, respectively. Afterwards, shear dowels were bonded using commercial epoxy adhesive, following by placing of the overlay concrete.

Concrete mixtures for both concrete layers have been adjusted, to realistically reflect possible in-situ applications. For that reason, mechanical properties of substrate layer are significantly lower, comparing to the overlay. It corresponds to the situation when old concrete structure is strengthened by additional concrete layer.

In addition to reinforcement properties summarized in Table 2, mechanical properties of hardened concrete were also experimentally obtained.

Table 2. Mechanical properties of the concrete.

	Mean cubic compressive strength $f_{cm,cube}$ [MPa]	Mean splitting tensile strength f_{ctm} [MPa]
Substrate concrete	23.5	2.1
Overlay concrete	77.6	3.6

Testing presented in Figure 3, occurred 28 days after overlay was cast. Supporting and loading beams were carefully aligned and placed approximately 5 mm from the interface plane. Specimen was also anchored to the column, 100 mm below top surface.

Figure 5. Push-Off Test setup: scheme (left) and experimental test setup (right).

Experimentally obtained values of ultimate applied loads and corresponding interface slips are summarized in Table 3, below (see Section 4 for definitions of ultimate forces). Labelling of series corresponds to material of the reinforcement and number of provided rebars (for example F2: FRP reinforcement, 2 rebars).

Based on obtained results and its mutual comparison presented in Figure 6, it can be stated that, even though somewhat higher values of shear slips were observed if FRP reinforcement was used, it represents good alternative to traditionally used steel reinforcement.

3 RESULTS AND DISCUSSION

In (fib, 2013) two bond-slip behaviours have been distinguished, corresponding to ultimate strength of the interface and its main contributors. In accordance with presented behaviour, three ultimate resisting forces have been presented in Figure 6, and defined as follows:

Table 3. Push-Off Test Results.

Series	Reinf.	Ø [mm]	No. of bars [-]	ρ [%]	F _{MAX,0} [kN]	w ₀ [mm]	F _{MAX,I} [kN]	w _I [mm]	F _{MAX,II} [kN]	w _{II} [mm]
REF	-	-	-	0.0%	117.6	-	-	-	-	-
S2	B500 B	8	2	0.6%	198.9	0.021	-	-	70.4	5.358
S4	B500 B	8	4	1.3%	118.4	0.031	113.4	0.387	135.3	14.331
S8	B500 B	8	8	2.5%	211.4	0.038	280.6	0.153	229.6	8.532

Figure 6. Typical Force-Slip diagrams for interfaces with FRP (left) and steel (right) reinforcement.

- $F_{max,0}$ corresponding to brittle failure mode typical for interfaces without shear reinforcement,
- $F_{max,I}$ represent ductile failure mode and contribution of reinforcement, friction and mechanical interlocking and
- $F_{max,II}$ observed during kinking of the reinforcement.

For the purposes of this experimental study, force $F_{max,II}$ can be neglected, since kinking effect occurs together with extensive deformations of the interface, therefore it is not relevant for design purposes. Opposite to $F_{max,II}$, force $F_{max,0}$ occurs at relatively low slips and describes brittle interface failure. Even though it is relevant for the design of concrete-to-concrete interfaces in general, behaviour of the interfaces without shear reinforcement is out of the scope of this paper.

According to (fib, 2013), strength of the interfaces intersected by steel dowels τ_{Rdi} can be estimated as follows:

$$\tau_{Rdi} = c_r \cdot f_{ck}^{1/3} + \mu \cdot \sigma_n + \kappa_1 \cdot \rho \cdot f_{yd} (\mu \cdot \sin \alpha + \cos \alpha) + \kappa_2 \cdot \rho \cdot \sqrt{f_{yd} \cdot f_{cd}} \leq \beta_c \cdot \nu \cdot f_{cd}. \quad (1)$$

where c_r = the coefficient for aggregate interlock effects at rough interfaces; f_{ck} = characteristic value of cylinder compressive strength of concrete; μ = coefficient of friction; σ_n = the (lowest expected) compressive stress resulting from an eventual normal force acting on the interface; κ_1 = the interaction coefficient for tensile force activated in the reinforcement or the dowels; ρ = the reinforcement ratio of the reinforcing steel crossing the interface; f_{yd} = design yield strength of reinforcing steel in tension; α = the inclination of the reinforcement crossing the interface; κ_2 = the

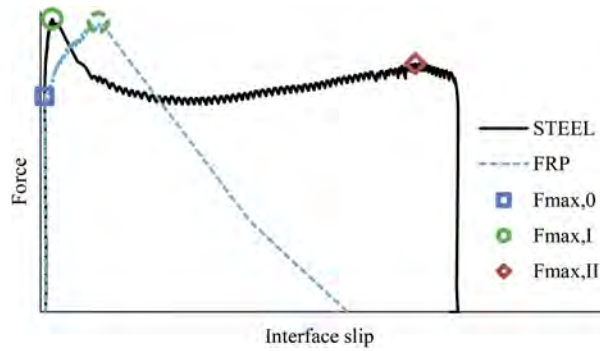

Figure 7. Typical force-slip behaviour of reinforced interfaces.

interaction coefficient for flexural resistance; f_{cd} = design value of cylinder compressive strength of concrete; β_c = the coefficient for the strength of the compression strut and ν = reduction.

First part of the equation corresponds to aggregate interlock at rough interfaces. As recommended, value of the coefficient c_r for smooth interfaces is assumed to be zero.

Second part describes the dry friction, caused by normal stress acting perpendicular to the interface plane and could be neglected for the purposes of this investigation. Regardless, it is assumed that recommendations listed in (fib, 2013; Randl, 2013) are applicable. Based on previous observations and recommendations available in the literature (Čairović *et al.*, 2016, 2019; Čairović, 2021), it could be stated, that even though recommended value of coefficient of friction μ is 0.6, somewhat higher values are usually obtained.

Third part represents friction caused by clamping forces and it depends on interaction coefficient κ_1 , yielding strength of the steel and the reinforcement ratio. Since yielding of the bars will not occur if FRP reinforcement was used, last part of the equation corresponding to flexural resistance of the reinforcement can be omitted i.e., value of interaction coefficient for flexural resistance κ_2 can be set as zero. Correspondingly, value of κ_1 can be adjusted and instead of 0.5, recommended for interfaces other than very smooth, 1.0 can be used since no interaction is expected and full contribution of dowel action can be assumed.

Hence, if FRP rebars were used as shear dowels, following modified design equation can be used for estimation of interface strength:

$$\tau_{Rd,FRP} = c_r \cdot f_{ck}^{1/3} + \mu \cdot \sigma_n + \rho \cdot \tau_s(1 + \mu) \leq \beta_c \cdot \nu \cdot f_{cd} \quad (2)$$

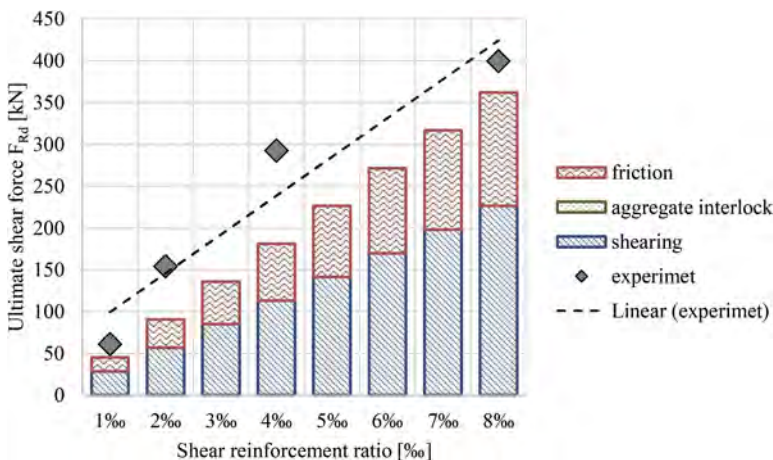

Figure 8. Dependence between interface strength and reinforcement ratio.

In general, good correlation between experimentally obtained results and the resulting interface strength determined using abovementioned Equation (2) was obtained, as presented in Figure 7. Presented analytical approach slightly underestimates interface strength. One of the main reasons is, as stated above, that a somewhat higher contribution of friction was usually observed.

It has to be stated, that experimentally obtained dependence between interface strength and reinforcement ratio shows non-linear character. For that reason, it is not recommended to use the proposed equation for the estimation of strength for the interfaces with reinforcement ratio outside of the scope of this experimental investigation.

4 CONCLUSIONS

Based on extensive experimental study presented above, following conclusion could be drawn:

- Performance of the concrete-to-concrete interfaces reinforced with GFRP rebars has been experimentally validated and in general shows good behaviour, comparable to the interfaces with traditional steel reinforcement;
- Analytical approach has been presented, allowing the design of the interfaces reinforced with FRP rebars and extension of the application fields of this durable and environmentally friendly material;
- Further research, including different types of reinforcement, concrete classes and/or surface preparation methods is necessary to confirm presented results and allow structural applications of FRP dowels and use of presented analytical design approach in everyday practice.

Extensive numerical analysis, aiming to detailly investigate load-bearing mechanisms and strength of the interfaces intersected by FRP and steel dowels, has been carried out at present and it will be presented in future contributions.

ABSTRACT: In the current research the interface response of Carbon Fiber Reinforced Polymers (CFRP) adhesively bonded on concrete substrates is investigated considering two scenarios with and without corroded reinforcement. The investigation includes Near Surface Mounted (NSM) CFRP strengthening schemes embedded to concrete using two-component epoxy adhesive layers, a conventional and a toughened one. The bond-slip behavior of the interfaces between the concrete and FRPs was investigated with a modified double shear test configuration. The experimental results indicate a different effect of the toughened adhesive on the response of the interface as the interface is not affected by corrosion. The crack propagation of the interface is depicted by two different distinct branches, a fully elastic up to the peak shear stress-strain, and a quasi-stable branch up to final pull out of the composite. The reduced stiffness and high energy absorbing capacity toughened adhesive epoxies are proven to be optimal retrofitting solutions for concrete applications.

1 INTRODUCTION

Structures often suffer from exposure to extreme corrosive environments leading to a decrease in their structural performance and safety. Therefore, retrofitting solutions using bonded composites such as Fiber Reinforced Polymers has attracted a lot of interest resulting in a technological advancement of structural refurbishment. The efficiency of the retrofitting measures depends mainly on the response of the interface between the concrete substrate and the composite (Mehta, & Monteiro. 2014); (Siddika et al. 2019).

The FRPs are applied on an adhesive layer, mainly epoxy adhesives for structural applications. This kind of strengthening enhances the deformability of the strengthened structure without increasing the stiffness of the member or changing the geometry of the elements (Heiza et al. 2014); (Siddika et al. 2019). The integrity of the concrete substrate and the type of epoxy adhesive used influence the bonding of the strengthening measure and the level of integration into concrete. Standard epoxy adhesives normally show high tensile modulus and result in brittle fracture of the matrix. Lately, toughened epoxy adhesives are developed having lower stiffness and higher fracture energy due to rubber-like nanoparticles of their matrix. These adhesives are mainly designed for dynamic loads (Kasper 2019); (Achillopoulou et al. 2021); (Achillopoulou et al. 2022).

The objective of this research paper is to explore the application of such adhesives to FRP measures for concrete solutions. To address this objective, the interfacial response of FRP and

concrete substrate is investigated experimentally. Due to the brittle behavior of concrete, there was a focus on the examination of the limitation of the substrate's crack propagation by comparing conventional and toughened retrofitting systems. Cracking schemes created to the interface due to the initial stage of corrosion are also examined. The interaction of the concrete substrate with the epoxy adhesive layer is studied by conducting double-lap shear tests. The toughened adhesives are expected to absorb more energy before debonding while having a lower modulus of elasticity (Kasper 2019); (Achillopoulou et al. 2021); (Achillopoulou et al. 2022).

2 EXPERIMENTAL INVESTIGATION

The current study was supported through an experimental campaign. The campaign has two phases: a) laboratory accelerated corrosion simulation and b) shear testing. The wider experimental campaign includes commercialized FRP systems (Near Surface Mounted bars-NSM) applied in concrete substrates containing health or corroded reinforcement using three different adhesive layers, one of which is toughened (Sikadur®-370), while the rest two are compatible.

2.1 *Materials*

Nine concrete blocks with dimensions 150x150x250mm were prepared according to (ACI 1991); (EN1008 1995); (Su et al. 2001) with 28-day compressive strength of 37.5MPa corresponding to a tensile strength of 3MPa. All blocks contained steel rebar ($f_{sy}=500\text{MPa}$) of 18mm diameter in the middle of the cross-section placed longitudinally to the concrete block. CFRP NSM (Sika® CarboDur® S: density $\rho=1.6\text{kg/L}$, tensile strength $\sigma_u=3100\text{MPa}$, modulus of elasticity $E_{0.05-0.25\%}=170\text{GPa}$, tensile strain $\epsilon_{EAB}=1.8\%$) were bonded symmetrically on opposite sides of the concrete blocks at a bond length equal to 200mm.

The NSMs are embedded on the concrete cover in a groove opened using a diamond cutting wheel. The groove's depth was equal to 3.3mm. The systems were applied with a dry layup process and according to the technical specification of the manufacturer. The interfaces were treated properly to have a laitance contaminant-free, open-textured surface and were cleaned with air pressure to remove loose material, dust and rust. The two components' epoxy adhesives were mixed according to the manufacturer's recommended ratio and time (3:1 for Sikadur®-30, 4:1 for Sikadur®-330 and 100:74 for Sikadur®-370). Before the application of the FRPs to the groove, the specimens were cleaned with a grease-free, solvent-based cleaning agent (Sika® Colma Cleaner). The composites were left to cure at ambient conditions (20°C, 50% relative humidity-RH) for at least a week before testing.

2.2 *Accelerated corrosion*

The concrete prisms were exposed to cycles of wet and dry conditions. They were submerged in a tank containing a NaCl-water solution of 3.5-5% weight concentration (Figure 1a), which covered one third of the cross-section size of the concrete blocks (van Zijl & Paul 2018); (Batuwitige et al. 2017). A continuous power supply ($\approx 1\text{mA}$) (Batuwitige et al. 2017) wired in the steel rebars for about three weeks was used to create a low ratio of corrosion equal to 6% of the steel rebar cross-section. After three weeks, the prisms were cured to dry conditions in the lab.

2.3 *Experimental configuration*

Various experimental setups of double lap tests exist in the international literature (Mukhtar & Faysal 2018). These configurations permit the direct examination of the shear stresses of the interface and the bonding capacity of the materials. This study uses the double lap shear test (Figure 1b) modified by Achillopoulou (2021). In this setup, the FRPs are gripped using steel plates that are supported to a rigid steel frame from which the concrete block is hanged. The hollow support permits relative slips between the concrete block and the FRPs if a compression load is applied to the concrete block. The steel plates were further altered to fit the cross-section shape of the FRPs and also to reduce their potential slip during the test by formulating a wedge

Table 1. Mechanical properties of epoxy adhesive layers and FRPs.

Type	ρ^* [kg/L]	σ_u^* [MPa]	E^* [GPa]	ε^* [%]
Sikadur [®] -30	2	26	9500	0.3
Sikadur [®] -330	1.4	29	4000	1
Sikadur [®] -370	1.7	30	5000	2.5
Sika [®] CarboDur [®] -S	1.6	3100	170	1.8

* Where ρ is density, σ_u is tensile strength, E is the modulus of elasticity within values 0.05-0.25% and ε is tensile strain (EAB).

(Figure 3a, b, c). For the case of NSM, the experimental setup practically simulates the pull-out tests aimed to characterize bonding. The tests were performed on a compression machine at a speed of 1mm/min at room temperature (20°C). The measurements of the deformation of the central part of the CFRP were recorded using a high accuracy laser sensor. Also, two Linear Displacement Transducers (LDVT) with a maximum capacity of 100mm, were used to measure the displacement of the upper level of the concrete block and the grips.

Figure 2. Experimental campaign: (a) accelerated corrosion, (b) double lap (DL) setup.

3 RESULTS

3.1 Experimental results

The bond level is measured up to the stress level needed so the NSM bars are pull-out. The results are presented in shear stress-shear deformation diagrams for the three different adhesives used for the healthy and corroded substrate. Table 2 below contains the characteristic values of the experimental results, the mean values and errors. All tests presented a similar response. An initial branch with small stiffness variations up to the maximum point is noted for all adhesive layers used (Figure 4), followed by an abrupt reduction and subsequently a remaining load. The peak point is related to the ultimate strain limit of the adhesives. At those instants the curve reaches the peak and then becomes non-linear. The extensive slip is denoted by a practically stable load level due to the mechanical interlock of the materials.

Figure 3. Altered gripping steel plates: (a) gripping profile, (b) gripping end, (c) wedge shape.

According to test results for the healthy concrete substrate (Figure 4a, b, c), all adhesives presented the same levels of stresses without any significant variations (5-12%). The strain levels were similar for the conventional Sikadur®-30 and the toughened Sikadur®370 adhesive. Even though, the modulus of elasticity of the toughened epoxy is almost half of that of the conventional adhesive, its high deformability is dominant in shear stress distribution along the interface. If compared with Sikadur®-330, which has an intermediate level of mechanical properties, the performance of the toughened layer is also enhanced, in terms again of strain levels before the final pull-out. The transition point is presented in early strain levels for Sikadur®-370. The epoxy is activated earlier and bears the strains before bonding is completely lost and interlocking of materials is only acting. This means that in all cases, the toughened epoxy absorbs the highest percentage of energy before failure. Compared to Sikadur®-330, the toughened epoxy absorbs almost 70% higher energy, whereas, the energy closes to Sikadur®-30 epoxy. The remaining stress level is similar in all cases.

The second series of tests examined the effect of corrosion in early stages on the bonding of the NSMs. The compatible adhesives Sikadur®-30 and Sikadur®-330 presented a slightly different response compared to the healthy specimens. For this scheme (Figure 4d, e), both adhesives presented a reduced (5%) initial stiffness, different though stress-strain field. For the case of Sikadur®-30 stresses are 15-25% lower when the substrate is corroded, noted 15-45% lower levels of strains. The intermediate adhesive layer Sikadur®-330 presents similar stresses in both substrate schemes, though the peak point occurred in lower strains some of them even 70% lower. Regarding the toughened adhesive Sikadur® -370, the response was slightly different and practically there is no significant influence of the corrosion products on the bonding capacity of this category. In fact, the curve is also less steep after the peak point (Figure 4f) denoting a different scheme in crack propagation on the substrate before pull-out. In terms of energy, the NSM embedded using the toughened epoxy Sikadur®-370 presented higher energy than all.

3.2 Failure modes

At end of the tests, differences were also reported regarding the failure modes between the compatible and toughened adhesives used to embed the NSMs. Those differences are related

to the microstructure of the adhesives. The stress and strain profiles are not constant along the NSM- concrete interface, presenting stress concentration at the extremities. After the loss of bonding depicted with the abrupt loss of shear stress, the progressive detachment corresponds to the post-linear stage shown in the shear stress-strain curves (Figure 4). In that stage, the NSM and concrete continue to interact due to interlocking and friction. The compatible adhesives Sikadur®-30 and Sikadur®-330, exhibited a rather mixed failure that is adhesive-

concrete interface failure. The loss of bonding was accompanied by measurable slip at the NSM strip (Figure 5b). For the case of Sikadur®-370, the failure differs. At the end of the tests, the failure observed was associated with the concrete local plastification (Figure 5c). An adhesive to concrete interface failure was noted, since a concrete cone breakout was detached at the loading end together with the NSM strip followed by slip. This variation is related to the structure and technology of the epoxy itself. The initial design of this adhesive includes rubber-like nano-particles that permit the adhesive to absorb more energy and let the propagation to occur in a larger area. In the case of the toughened epoxy, the cone size is comparatively larger (Figure 6c, d). The cone is formatted at an angle of 45 degrees and its depth is almost 20% of the bonded length of the bar. Compared to the compatible epoxies, the cone is more than the double in volume. The case of toughened epoxy used, resembles to the anchor-bolt failure when embedded in concrete (EN1992-4 2017). This interaction between concrete and NSM can be beneficial to the overall performance of the element.

In the case of the corroded steel reinforcement, the fracture is related to the cone breakout size. The corrosion simulated in the lab corresponds to mild rates which means that the cracking pattern in the mass of the concrete is limited ($w \approx 0.3\text{mm}$) reaches yet the surface and the pit in which the NSM is placed (Figure 6d). For the toughened epoxy, the cone created is much larger than the compatible ones, the corrosion cracking didn't affect the overall response. On the contrary, after the peak point, the load was distributed in the cracked concrete mass and the response was quite stable.

4 CONCLUSIONS

- The modified double-lap testing configuration is suitable also for testing NSM bonding solutions. The wedge modification at the grip plates restrains the slip of the composites, increasing accuracy in shear measurements.
- The bond behavior of NSM is characterized by linear elastic branch up to the peak point followed by a softening transition branch. The softening stage occurs gradually by crack opening propagating from the epoxy layer up to the limit slip point and final pull out of the mounted NSM.

Figure 5. Failure modes (a), (b), (d), (e) for compatible adhesives, (c), (f) for toughened adhesives.

Figure 6. Failure modes: breakout cone (a), (b) for compatible adhesives, (c), (d) for toughened adhesives.

- The corrosion of the substrates affected mainly the conventional epoxies schemes that is Sikadur[®]-30 and Sikadur[®]-330. These adhesives are characterized by lower strain capacity and mainly high Elastic modulus, especially Sikadur[®]-30 having the highest Elastic modulus. The influence of the toughened epoxy Sikadur[®]-370 was practically negligible.
- In the analysis of the failure modes clear differences on the breakout cones denote that the toughened epoxy Sikadur[®]-370 depict a significantly better distribution of the pull load along a larger bonding depth. The breakout cone's volume is more than the double for this epoxy.
- NSM mounted using the toughened epoxy Sikadur[®]-370 absorbs the similar or higher energy ratio if compared with the other two compatible ones. The adhesive is being designed mainly to bear dynamic stresses and to be applied on steel substrates. The application on concrete substrate for structural strengthening especially for NSM systems seems to be effective, especially for structures with high corrosion risk (e.g. bridges decks). The fact that the substrate's corrosion does not affect the system which still deforms and continues to absorb energy can be beneficial to structural applications.

ACKNOWLEDGEMENTS

This study has received funding from the European Union H2020-Marie Skłodowska-Curie Research Grants Scheme MSCA-IF-2018 (grant agreement no 845549: BRIFACE-Novel assessment of bridge retrofitting measures through Interface Efficiency Indices (InterFeis) using a Guided Wave-based monitoring method). Sika AG, as one of the industrial partners of the project, has essentially contributed to the realization of the experimental program. Special thanks to the Democritus University of Thrace and the laboratory of Reinforced Concrete and Seismic Design of Structures for collaborating on the experimental campaign.

ABSTRACT: Grooving methods (GM) have remarkably shown higher efficiency than externally bonded reinforcement (EBR) in anchoring the fiber-reinforced polymers (FRP) used for retrofitting concrete structures. The behavior of the EBR and GM installation methods were evaluated in many studies, however the behavior of grooving methods under fatigue loading has not been assessed yet, and the present study is the first attempt to achieve the above aim. Accordingly, three concrete slabs with the dimension of $650 \times 650 \times 200$ mm³ were strengthened using carbon FRP (CFRP) sheets bonded via the EBR and grooving methods and then tested by a single lap-shear setup. Furthermore, the bond behavior of CFRP strips-to-concrete substrate was investigated in this research in terms of the load capacity, slip, and debonding mechanism. The results showed that the grooving method improved the bond properties of CFRP-to-concrete joints under fatigue loading. By using this alternative technique, the number of cycles until failure (fatigue life) increases incredibly under the same fatigue cycle loading and the service life of strengthened members could be improved under fatigue loading.

1 INTRODUCTION

In recent years, fiber-reinforced polymers (FRPs) have emerged as a trustworthy option for the repair and rehabilitation of concrete structures. The attentions of researchers have been attracted because of their advantageous properties such as low weight, high tensile strength, ease of transport, easier application in confined spaces, minimizing disruption of occupancy, and high durability under harsh environmental conditions (ACI440.2R, 2017, Fib-Bulletin-90, 2019). Despite all the advantages, FRP materials also have some disadvantages. Debonding of FRP composites from concrete substrate is a major concern in retrofitting of reinforced concrete structures. In fact, the efficiency of the retrofitting system relies on the perfect bond between FRP and substrate, and thus, loss of bond would diminish the full capacity of FRP reinforcement system (Smith and Teng, 2002). In order to postpone FRP debonding and instead of using the conventionally externally bonded reinforcement (EBR) method or near surface mounted method (NSM), Mostofinejad and Mahmoudabadi studied externally bonded reinforcement on groove (EBROG) technique (Figure 1) in 2010 (Mostofinejad & Mahmoudabadi, 2010). The promising results of their research paved the road for further studies and developing the method comprehensively. EBROG technique is based on cutting grooves in concrete cover, filling them with proper adhesive, and attaching FRP composites on the surface, without any other surface preparation prior to FRP installation (Mostofinejad and Mahmoudabadi, 2010). So far, several studies implemented grooving method (Sanginabadi et al., 2022b, Sanginabadi et al., 2022a, Mohammadi Ghahsareh & Mostofinejad, 2021). CFRP-to-concrete bonded joints in CFRP

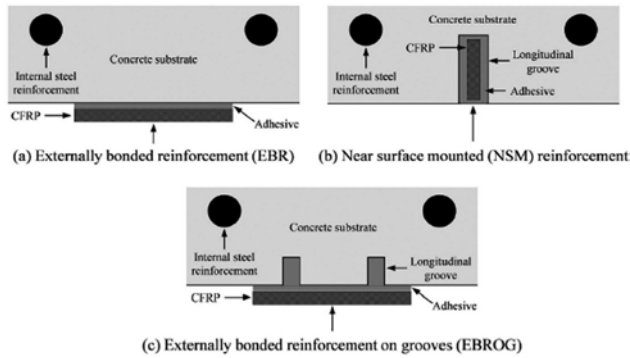

Figure 1. Schematic drawing of different bonding techniques (Moshiri et al., 2020).

strengthened structures may also be subjected to fatigue cyclic loading. Potential performance degradation of the bonded joints due to fatigue cyclic loading may affect the performance of the structure. Research has shown that bond degradation due to fatigue cyclic loading could redistribute stresses to the internal reinforcement resulting a lower fatigue life of the structure (Quatlebaum et al., 2005) and reduce their ductility (Harries et al., 2006).

Therefore, it is important to develop a sound understanding of the behavior of CFRP-to-concrete bonded joints under fatigue cyclic loading. Fatigue response of FRP-strengthened members depends on the maximum applied load in a load cycle (Kim and Heffernan, 2008). If the maximum load in a load cycle, P_{max} is less than 50% of the quasi-static failure load, the test is said to be performed under high-cycle fatigue conditions. On the other hand, if the maximum load P_{max} is greater than 50% of the quasi-static failure load, the test is said to be performed under low-cycle fatigue conditions (Carloni et al., 2012). Against this background, this research presents an experimental study investigating the behavior of CFRP-to-concrete bonded joints using EBROG method under fatigue cyclic loading that has not been studied before.

2 EXPERIMENTAL PROGRAM

2.1 Specimens details

Three concrete slabs with dimensions of $650 \times 650 \times 200$ mm³ (width \times length \times thickness) were cast. According to the width of the specimen, it is possible to install four FRP strips on each face. Also, choosing such dimensions makes the samples more similar to each other.

2.2 Strengthening techniques

The EBR and EBROG methods were used to bond the CFRP strip to the concrete surface. In the EBR, conventional surface preparation was conducted by grinding the surface to remove the weak outer layer of concrete and to expose the aggregates (Figure 2a). In the EBROG method, three longitudinal grooves (Figure 2b), each having cross-section of 5×5 mm² (width \times depth) and a clear spacing of 10 mm were cut in the concrete. The grooves were cleaned with compressed air and filled with epoxy resin, and the CFRP strip was attached to the grooves by applying a thin layer of epoxy resin.

2.3 Material properties

The average compressive strength of concrete cubes at the time of testing was 35.7 MPa. Unidirectional CFRP strips of type Sika wrap-300C (Sika, 2017) a width and thickness of 50 and 0.17 mm, respectively. The elastic modulus of the strips was 230 GPa. The CFRP ultimate tensile strength and ultimate tensile strain were 4000 MPa and 1.7%, respectively. A two-component epoxy adhesive labeled as Sikadur 330 (Sika, 2019) with an elastic modulus of 4.5 GPa, an ultimate tensile strength of 30 MPa, and an ultimate tensile strain of 0.9% was used.

Figure 2. Surface preparation; (a) EBR method, (b) EBROG method.

2.4 Test layout

The test layout is presented in Table 1. Two slabs were strengthened with CFRP strips using EBR method, two specimens were retrofitted with CFRP strips by EBROG method. Labels are arranged like EBR-M or F-n and EBROG- $b_g \times h_g$ -M or F-n. Herein, symbols b_g and h_g denote the groove width and depth, respectively. The capital letters “M” and “F” indicate loading scheme with monotonic procedure and fatigue cyclic procedure, respectively. Icon n represents order of repetitive similar tests (1, 2 or 3).

Table 1. Test layout.

No.	Specimen label	f_{cu} (MPa)	CFRP strip width, (mm)	CFRP bond length (mm)	Strengthen- ing method	Loading scheme	Groove dimensions	
							Width, b_g (mm)	Depth, h_g (mm)
1	EBR-M-1	35.7	50	200	EBR	Monotonic	-	-
2	EBR-M-2							
3	EBR-F-1	35.7	50	200	EBR	Fatigue	-	-
4	EBR-F-2					Cyclic		
5	EBR-F-3							
6	EBROG-5×5-M-1	35.7	50	200	EBROG	Monotonic	5	5
7	EBROG-5×5-M-2							
8	EBROG-5×5-F-1	35.7	50	200	EBROG	Fatigue	5	5
9	EBROG-5×5-F-2					Cyclic		
10	EBROG-5×5-F-3							

2.5 Loading procedure

The testing procedure is carried out in several steps (Figure 3). First, the loading is applied monotonically at a rate of 0.05 mm/min to a predetermined force value. Subsequently, unloading is carried out till a force value equal to the mean one of the foreseen. Finally, cyclic loading is applied at a rate of 4 Hz until failure. While applying the cyclic loading, the displacement of FRP strip at the loaded end is monitored by two LVDT's. The tested sample is also visually checked for any possible fracture during the fatigue cyclic loading.

2.6 Test setup

An apparatus specifically designed for the assessment bond behavior of CFRP-to-concrete joints was used to carry out single lap-shear tests, equipped with a 100 kN hydraulic jack. A load cell was used to accurately measure the tensile force applied to the specimen. An illustration of the test setup is shown in Figure 4.

Figure 3. Loading scheme (Zhou et al., 2021).

Figure 4. Test setup.

3 EXPERIMENTAL RESULTS AND DISCUSSIONS

3.1 Failure mode

As shown in Figure 5, by applying monotonic load, the EBR tested specimens failed due to debonding of FRP sheets off the concrete substrate (Figure 5a). On the other hand, for EBROG specimens, the failure mode involved deep debonding of FRP strips with a layer of concrete under static loading scheme (Figure 5b). In fatigue cyclic tests, all specimens (EBR and EBROG) failed by debonding of FRP strips off the substrate concrete. It is worth noticing that a concrete cone zone was accidentally observed at the end of FRP strip in EBROG specimens under fatigue loading (Figure 5d).

3.2 Static bond strengths of EBR and EBROG specimens

The results showed that the EBROG method improved the bond resistance of FRP-to-concrete joints. EBROG specimens achieved an average load of 28 kN and 100% higher than EBR specimens.

3.3 Fatigue life of EBR and EBROG specimens

Result showed the number of cycles until failure (the fatigue life) increased in EBROG joints under the same cycle amplitude as EBR joints. The maximum fatigue life achieved 2,416,750 and 109,947 cycles for EBROG and EBR specimens, respectively. A summary of fatigue life of specimens are presented in Table 3. It is worth noticing that under fatigue load, the strain distribution along the FRP strip consists mainly of three lengths, namely, the early rapid development length (the first length near loaded end, I-region) that FRP is separated from concrete surface in this region and expanded over time. In fact, debonding propagated towards from the loaded end to far end. The second length (II-region) is development length that moves to end of

Figure 5. Failure modes, (a) EBR-M, (b) EBROG-M, (c) EBR-F, (d) EBROG-F.

Table 2. Bond strength of specimens at monotonic loading.

No.	Specimen label	f'_c (MPa)	Peak load (kN)	P_m (kN)	CFRP bond length (mm)
1	EBR-M-1	35.7	13.9	14	200
2	EBR-M-2		14.2

4 THEORETICAL ANALYSIS

4.1 Evaluation of bond strength of EBR and EBROG in static conditions

A wide array of empirical and numerical models has been developed for predicting the bond strength of EBR installation method. Among these, the well-known bond strength model due to Chen and Teng (Chen & Teng, 2001) according to Equation (1) described here was used for comparisons to evaluate the bond strength in the present study.

Table 3. Fatigue life of specimens at cyclic loading.

No.	Specimen label	Fatigue upper limit, P_{\min} (kN)	Fatigue lower limit, P_{\max} (kN)	Fatigue life, N_f (cycles)	Time until failure, t_f (hours)
3	EBR-F-1	2.8	9.1	109947	7.6
4	EBR-F-2			55382	3.8
5	EBR-F-3			88124	6.1
8	EBROG-5×5-F-1	2.8	9.1	1259104	87.4
9	EBROG-5×5-F-2			2416750	167.8
10	EBROG-5×5-F-3			2129335	147.9

$$P_{Cheng\&Teng} = 0.427 \beta_p \beta_L b_f L_e \sqrt{f_c} \quad (1)$$

where L_e = effective bond length presented by Equation (2); and β_L =reduction factor to predict the bond strength of FRP–concrete joint calculated by Equation (3). The coefficient β_p in Equation (4) considers the width ratio of the bonded FRP sheets to the concrete member b_f/b_c . It is worth mentioning that ACI 440.2R (ACI 2017) is based on the model proposed in Chen and Teng (2001).

$$L_e = \sqrt{\frac{E_f t_f}{\sqrt{f_c}}} \quad (2)$$

$$\beta_L = \begin{cases} 1 & \text{if } L \geq L_e \\ \sin \frac{\pi L}{2L_e} & \text{if } L < L_e \end{cases} \quad (3)$$

$$\beta_p = \sqrt{\frac{2 - b_f/b_c}{1 + b_f/b_c}} \quad (4)$$

In Equation (4), b_f and b_c are the width of the bonded FRP strip to the concrete member width, respectively. For predicting maximum load of EBROG joints, Mostofinejad and Moghaddas (Moghaddas & Mostofinejad, 2019) proposed a novel equation as a modified version of Equation (1) which a novel term called groove coefficient (β_g) had been introduced. The modified model may be expressed in the form of Equations (5) and (6):

$$P_{M\&M} = \beta_g P_{Chen\&Teng} \quad (5)$$

$$\beta_g = f'_{t_c}{}^{-0.33} (E_f t_f)^{-0.08} (8.1 - 0.006 h_g^2 + 0.1 h_g + 0.04 b_g) \quad (6)$$

where b_g and h_g are groove width and depth, respectively. Zamani and Mostofinejad (Zamani Ghaleh & Mostofinejad, 2022) proposed a relation for the failure strain of externally bonded reinforcement on groove (EBROG) joints derived through regression analysis according to Equations (7) and (8):

$$P_{Z\&M} = E_f t_f b_f \varepsilon_{eff} \quad (7)$$

$$\varepsilon_{eff} = 1.474 (f'_c)^{0.162} (b_f)^{-0.2885} (E_f t_f)^{-0.5} \times (b_g)^{0.16} (d_g)^{0.0755} \quad (8)$$

Table 4. Bond strength prediction of specimens at monotonic loading.

No.	Specimen label	P_{exp} (kN)	$P_{exp,avg}$ (kN)	$P_{Cheng\&Teng}$ (kN)	$P_{M\&M}$ (kN)	$P_{Z\&M}$ (kN)
1	EBR-M-1	13.9	14	12.5	-	-
2	EBR-M-2	14.2				
6	EBROG-5×5-M-1	26.7	28	-	21	23.5
7	EBROG-5×5-M-2	29.4				

In general, results show that the relation proposed by Zamani and Mostofinejad (2022) outperforms the model proposed in Moghaddas and Mostofinejad (2019) in terms of estimating EBROG joint bond capacity.

4.2 Evaluation of fatigue life of specimens

Demers (Demers, 1998) studied the tensile fatigue behavior of several glass fiber and carbon composite reinforcements. According to his research, Equation (9) was proposed corresponds to the lifetime of CFRP. Zhu et al. (Zhu et al., 2016) studied the fatigue behavior of CFRP-concrete interfaces on beam specimens. The experimental campaign allowed them to develop a model (Equation (10)) in which the fatigue life of the interface depends mainly on the loading amplitude (T) and concrete compressive strength (f_c). Additionally, new relationship was presented by Chalot et al. (Chalot et al., 2019) that uses Wohler curve to predict the fatigue life according to Equation (11).

$$\text{Log}(N) = \frac{1}{0.0519} (0.8227 - \frac{P_{\max}}{P_u}) \quad (9)$$

$$\ln(N) = -31.646(T - 0.8386)(0.0021f_c' + 0.8724), \quad T = \frac{P_{\max} - P_{\min}}{P_u} \quad (10)$$

$$\text{Log}(N) = \frac{1}{0.051} (0.925 - \frac{P_{\max}}{P_u}) \quad (11)$$

Table 5 compares the fatigue life of different methods. As it can be seen in Table 5, the differences among different methods are high and needs a new approach to calculate fatigue life of CFRP-to-concrete bonded joints especially for EBROG installation methods.

Table 5. Fatigue life prediction of CFRP bonded joints at cyclic loading.

10	EBROG-5×5-F-3	2129335			

5 CONCLUSIONS

The innovative aspect of the current study consists in an evaluation of number of cycles until failure for EBR and EBROG specimens under fatigue loading. For the purposes of such study, 10 single lap-shear tests were designed and conducted to compare the EBR and EBROG bond strengths on the basis of different loading scheme such as monotonic loading and fatigue cyclic loading. The following conclusions may be drawn from the obtained results.

1. All EBR specimens under static loading underwent FRP debonding failure through the adhesive layer, while the failure mode of the EBROG joints were debonding of the FRP strips through the concrete layer. For fatigue cyclic loading, the FRP debonding with end concrete cone was observed in EBROG loading. However, for EBR specimen under fatigue cyclic loading, just FRP debonding was observed until end of loading.
2. Compared with the conventional surface preparation (EBR method), three grooves with dimension of 5x5 mm² cut beneath the FRP sheet was observed to increase bond strength by an average of 100%.
3. The Chen and Teng bond strength model is found to underestimate the specimens' failure load strengthened using the EBROG method. Furthermore, by using the models of Moghaddas and Mostofinejad or Zamani and Mostofinejad, the goodness of fit was confirmed.

4. EBROG method could significantly increase the number of cycles of CFRP-to-concrete joints comparing to EBR method at same loading range. In fact, the service life of FRP strengthened members under fatigue loading could be improved by EBROG method.

ACKNOWLEDGEMENTS

The tests were carried out at Material Testing Laboratory of Milan Polytechnic, which is thanked for the financial support. Authors would like to express their gratitude to Daniele Spinelli for his support in carrying-out the experimental activities. During the visiting research period of the first author at Polytechnic of Milan, financial support was offered by the Iranian Ministry of Science, Research and Technology (MSRT), which is admirably acknowledged.

Externally applied textile reinforced systems on RC members: Innovative and sustainable materials and techniques

F. Bencardino & R. Curto

Department of Civil Engineering, University of Calabria, Rende, Cosenza, Italy

ABSTRACT: To hinder overbuilding and find sustainable solutions in the construction sector, recent scientific researches consider the strengthening and repair of existing reinforced concrete (RC) structures using innovative materials and techniques. The Textile Reinforced (TR) system applied according to the traditional Externally Bonded (EB) technique is considered a suitable strengthening method due to the use of inorganic matrix. Using a matrix with sustainable environmental aspects, a mortar added with fibres from waste materials, that is also a corrosion inhibitor of the steel rebars, the EB technique can be replaced by the Inhibiting-Repairing-Strengthening (IRS) technique. The IRS technique is an eco-friendly strengthening method because it reduces the number of manufacturing steps and amount of chemical products used; this means less time and environmental pollution. This work shows the experimental behaviour of RC beams strengthened by IRS technique compared with the EB technique and discusses about the intermediate/end debonding strain helpful to design.

1 INTRODUCTION

Safeguarding and recovering existing building stock is becoming a major issue for several countries around the world. The common and recurring problems related to the durability of the existing reinforced concrete (RC) structures concern the corrosion of the steel rebars and the cracking of the concrete until the achievement of the spalling (expulsion of the concrete cover). In fact, these problems greatly reduce the geometric and mechanical properties of RC elements with negative effects that can affect only a part or even the entire structure. The RC degradation phenomena can have several causes: physical, chemical, mechanical, structural and biological.

In the past, different solutions have been proposed in order to solve the problems of existing RC structures. Among the effective and innovative strengthening and repair interventions of recent years is the Textile Reinforced (TR) system (Rossi et al., 2022). This method is now the most common recovery tool in engineering practice and it is considered a suitable strengthening method thanks to the use of an inorganic matrix (reinforced with dry or coated fibres in the form of an open mesh textile) that exhibits significant heat resistance, allows vapour permeability, and can be applied at low temperatures or on wet surfaces. In addition, this system has other advantages such as: lightness and handle, long-term durability, ease and speed of installation, high resistance against sulphates, and can be removed without harming the original structure. For these reasons, this system can be considered as an evolution of the previous Fibre Reinforced Polymer (FRP) system.

The TR system is known in the literature with different names, based on the types of matrix, fibres and substrate to be strengthened. The most common names are: Fabric-Reinforced Cementitious Matrix (FRCM); Textile Reinforced Mortar (TRM); Fibre Reinforced Mortar (FRM); Mineral Based Composites (MBC); Textile Reinforced Concrete (TRC), though the latter is usually used in new constructions.

The mechanical effectiveness of TR system is strongly influenced by: a) tensile properties of the cementitious matrix; b) capacity of the cementitious matrix to impregnate the roving of the textile;

c) effective fibre/matrix interface bond properties; and d) bond between the cementitious matrix and the concrete substrate.

The most suitable fibres used to make textiles for strengthening and repair of RC structures are Carbon, PBO (Poly-p-phenylene BenzobisOxazole), and Steel. If the textile is made of steel strands (stainless steel or UHTSS – Ultra High Tensile Strength Steel) the system is also called SRG (Steel Reinforced Grout).

Despite the advantages listed above, the traditional technique of application of TR systems use polluting products and materials. For example, the use of corrosion inhibitors necessary for the treatment of existing rebars has a significant environmental impact. It is known that reinforcement corrosion causes cracking in the concrete surface of RC beams, decreasing their load-bearing capacity (Srivaranun et al., 2023).

Therefore, two problems must be addressed in parallel: the need to strengthening/repair existing structures using effective and structurally valid methods and the need to use innovative and sustainable solutions, materials and techniques. In this direction, the paper shows that the use of an inorganic matrix with passivating properties coupled with stainless steel (or UHTSS) strips provide a TR system that can be applied according to an innovative and most sustainable technique, the Inhibiting-Repairing-Strengthening (IRS) technique, with a satisfactory structural performance. Moreover, some relationships for the evaluation of intermediate/end debonding strain, helpful for the design of the strengthening system, are also discussed.

2 EB, NSM AND IRS TECHNIQUES

Currently, many existing RC structures and infrastructures that need to be strengthened are also deteriorated. The most popular degradations, such as aggregate expansion or corrosion of internal reinforcing bars, cause chemical reactions in concrete leading to expansive damaging phenomena. These phenomena, created by alkali-silica reaction or corrosion of steel, may induce mechanical stresses that can cause the formation of cracks. Furthermore, if the bars were poorly installed and are located close to the concrete surface in contact with the air spalling can easily occur and flat fragments of concrete are detached from the concrete mass. This process may be accelerated by carbonation that decreases alkalinity, which is essential for corrosion prevention of the internal steel bars. The deterioration of cover concrete may engender an iterative process which leads to the reduction of the resistant section (steel bars and concrete) and consequently to a loss of structural strength. The causes of the internal steel bars corrosion should be addressed and the corrosion-related deterioration should be repaired before the installation of any strengthening system.

Therefore, for strengthening of deteriorated RC members, three different procedures could be used: traditional Externally Bonded reinforcement (EB) technique, Near Surface Mounted (NSM) technique or Inhibiting-Repairing-Strengthening (IRS) technique.

The traditional EB technique shown in Figure 1 is based on steel, carbon or PBO TR systems. Typically, this technique is used for strengthening of RC elements subjected mainly to flexure and shear. To make and apply the TR system using the traditional EB reinforcement technique, it is necessary to perform specific operations listed below (*fib* Bulletin 103, 2022): remove deteriorated concrete from all damaged areas; clean and protect corroded steel bars (application of corrosion inhibitors); restore the concrete using shrinkage-free cement grouts (reconstruction of original section shape); roughen and wet the concrete surface. Then proceed with the application of a first layer (upper layer) of mortar (matrix) with a suitable average thickness and of the fabric on the first layer of wet matrix; finally apply the second layer (bottom layer) of mortar (matrix) making sure that the textile is perfectly embedded into the matrix by pressing it with a spreader or steel roller.

In the Near Surface Mounted (NSM) technique, shown in Figure 2, the TR system is made using steel fibres (UHTSS and stainless steel). This technique is based on the bonding of the TR system in pre-cut grooves in the concrete cover, in the case of undamaged concrete structures. Instead, for deteriorated structures, the TR system must be glued to the surface obtained by removing the entire damaged concrete cover.

This technique consists in the application of the following operations (*fib* Bulletin 103, 2022): removal of deteriorated concrete from all damaged areas and removal of unsound

Figure 1. EB Technique.

concrete; cleaning and protection of corroded steel bars (application of corrosion inhibitors); application of a first layer (upper layer) of mortar (matrix) with a suitable average thickness depending on the amount of damaged concrete cover; application of steel fibre sheet reinforcement over the first layer of wet matrix; application of the second layer (bottom layer) of mortar (matrix) making sure that the textile is perfectly embedded into the matrix by pressing it with a spreader or steel roller.

Inhibiting-Repairing-Strengthening (IRS) technique shown in Figure 2, consists in the installation of UHTSS or a stainless steel strip in the cover concrete, restoring this latter with an alkali-activated matrix/geopolymers which also acts as a corrosion inhibitor/protection. The steps to perform this technique are as follows: removal (variable thickness) of the cover concrete damaged due to physical, chemical, and mechanical deterioration; assessment of the internal steel bars and brushing/sandblasting of corroded bars; application of the first layer (upper layer) of inorganic matrix, which also acts as a corrosion inhibitor/protection. The thickness (10-20-30 mm) depends upon the depth of the removed deteriorated concrete (degraded, weakened and no cohesive concrete); application of UHTSS or stainless steel reinforcement over the first layer wet matrix; application of the second layer (bottom layer) of inorganic matrix (thickness 5-10 mm) making sure that the reinforcement is perfectly embedded into the matrix by pressing it with a spreader or steel roller, and also checking that it comes out between the cords to ensure optimum adhesion between the first and second layer of matrix.

The TR system, made with stainless steel strip or UHTSS sheet and inorganic matrix with passivation property, applied according to the novel IRS technique contains sustainable aspects in terms of materials and execution works. Specifically, the inorganic matrix contains slag and/or fly ash (mineral additives) and provides corrosion protection. It is not necessary to use further chemical products/compounds to the treatment of the internal steel bars. The new and sustainable application technique of the external reinforcement allows to carry out three steps in one step, reducing the costs and times of carrying out the intervention.

Figure 2. NSM or IRS Technique.

3 EXPERIMENTAL PERFORMANCE: EB/IRS TECHNIQUE

3.1 Experimental tests

In order to test the structural effectiveness of the IRS technique, an experimental programme was defined and developed.

Three groups (A, B, and C) of strengthened RC beams were tested under monotonic load. Each group includes three RC beams: one beam strengthened with IRS technique, one beam strengthened with EB technique and another un-strengthened control beam. The strengthening system consisted of a unidirectional stainless steel strip with an elastic modulus equal to 177.6 GPa and a characteristic tensile strength of 1238 N/mm² (ST4-0622) embedded into an alkali-activated mortar with a compressive strength ≥ 50 MPa and an adhesion to concrete ≥ 2 MPa (ST11-1022).

Geometric parameters and strengthening arrangements of the tested beams are shown in Figures 3, 4 and 5, and the details are given in Table 1. For each group are summarised: number of the tested specimens; length (L), width (b), and height (h) of the beams; shear span (a); length to height ratio (L/h); shear span to depth ratio (a/d), area of the tension (A_s) and compression (A'_s) longitudinal steel reinforcements; reinforcement ratio ($\rho_s = A_s/(bd)$).

To simulate a wide range of existing RC structures built during the '60s and '70s, the specimens were cast using low concrete strength, and both smooth (12 mm diameter bars) and ribbed steel bars (8 mm and 16 mm diameters). The mechanical properties of the materials are given in Table 2 (f_{cm} : concrete compressive strength; f_{cm} : concrete tensile strength; E_{cm} : Young Modulus; f_{ym} : yield strength of steel bars).

The smooth steel bars were found/taken in a disused building/demolition site.

Figure 3. Geometry of the tested beams: RC un-strengthened beam.

The beams were internally and externally instrumented and tested under four-points bending. Two vertical loads were applied symmetrically to the midspan of the beams with a constant bending moment region and a constant shear span. All the beams were simply supported and tested with a shear span to depth ratio of $a/d=4.1$. Test setup is shown in Figure 6.

Figure 4. Geometry of the tested beams: RC beam strengthened with EB-TR system.

3.2 EB/IRS strengthened RC beams: Structural behaviour

The load-midspan deflection curves and deflections under maximum load are shown in Figures 7, 8, and 9 for the beams of groups A, B and C, respectively. Both EB-TR and IRS-TR strengthening

systems improved the load carrying capacity and decreased the ultimate deflections, and then the ultimate rotations, of the corresponding RC control beam. Furthermore, the structural behaviour of the beams A-IRS and B-IRS was better, in terms of ultimate load and deflections, compared to the corresponding RC beams strengthened with traditional EB technique (A-EB, B-EB).

As regards the failure mode, all un-strengthened beams failed in conventional ductile mode with crushing of compressive concrete after yielding of internal steel bars. With reference to EB technique, the strengthened beams A-EB and B-EB failed by sudden end debonding without warnings. This phenomenon was probably due to the surface treatment. Indeed, the beam C-EB that was subject to a deeper moist sandblasting and hydraulic scouring failed by concrete crushing, without delamination. It should also be highlighted that the concrete strength was very low for the beams of group C respect to the beams of the groups A and B. With reference to IRS technique, the beam A-IRS failed by delamination at stainless steel-matrix interface, after extensive cracking, and the beams B-IRS and C-IRS failed by concrete crushing.

Figure 7. Group A: (a) load-midspan deflection curves; (b) deflections under maximum load.

Figure 8. Group B: (a) load-midspan deflection curves; (b) deflections under maximum load.

Figure 9. Group C: (a) load-midspan deflection curves; (b) deflections under maximum load.

The experimental results highlight the effectiveness of IRS solution that provided comparable or better structural performance to traditional EB technique.

Figures 10 and 11 show the cracking pattern and failure mode of the beams strengthened with EB-TR and IRS-TR systems, respectively. It should be noted (Figures 10a and b) that for the beams strengthened with EB technique delamination at concrete-TR interface without damage at concrete substrate occurred. Instead, for the beams strengthened with IRS technique (Figures 11a and b) debonding at fibre-matrix interface (group A) and concrete crushing in the midspan section (group B) was observed.

4 INTERMEDIATE/END DEBONDING STRAIN IN TR SYSTEM

According to CNR-DT 215/2018 Guidelines, the strain limit in TR system can be evaluated with reference to the conventional strain limit ($\epsilon_{lim,con}$) and the corresponding conventional

Figure 10. Cracking pattern and failure mode of EB-strengthened beams: (a) beam of group A (length 3000 mm); (b) beam of group B (length 4800 mm).

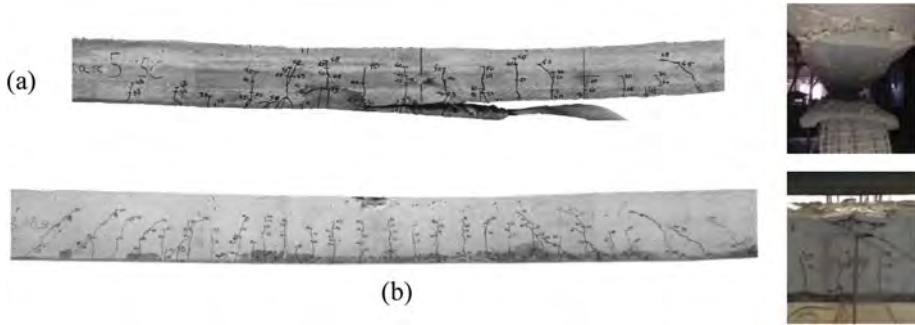

Figure 11. Cracking pattern and failure mode of IRS-strengthened beams: (a) beam of group A (length 3000 mm); (b) beam of group B (length 4800 mm).

stress limit ($\sigma_{lim,con}$). The $\varepsilon_{lim,con}$ corresponding to the end-debonding of the TR system is determined by the following formula:

$$\varepsilon_{lim,con} = \frac{\sigma_{lim,con}}{E_f}. \quad (1)$$

For the mechanical characterisation of the dry strip fibres, Direct Tensile tests were carried out. From the ultimate stress (σ_u) and the corresponding ultimate strain (ε_u), the elastic modulus of the fibre (E_f) is determined as follows:

$$E_f = \frac{\sigma_u}{\varepsilon_u}. \quad (2)$$

Instead, Direct Single-Lap Shear tests allow to determine the value of the maximum force (F_{max}), which together with the known value of the area of the fibres in the strip, allows to calculate the value of the conventional stress limit according to the formula:

$$\sigma_{lim,con} = \frac{F_{max}}{A_f}. \quad (3)$$

Note the $\varepsilon_{lim,con}$, the conventional strain limit of intermediate debonding ($\varepsilon_{lim,con}^{(a)}$) can be obtained by applying the following formula:

$$\varepsilon_{lim,con}^{(a)} = \alpha \varepsilon_{lim,con}. \quad (4)$$

The amplification coefficient α can be taken as equal to 1.5 for all the TR strengthening systems. However, there is in the literature a simpler method for determining intermediate debonding. It is possible to give the debonding predictive as a simple formula (Bencardino et al., 2018) as follows:

$$\varepsilon_{f,deb} = \alpha(n_f E_f t_f)^{-\beta}. \quad (5)$$

Where α and β are the coefficients that take into account the different mechanical characteristics of TR systems (fibres and matrix). In order to evaluate the average value of intermediate strain debonding the suitable coefficients should be: $\alpha = 2.25$ and $\beta = 0.55$.

5 CONCLUSIONS

The IRS innovative technique has proved more sustainable and effective than the traditional EB technique. Compared to the un-strengthened control beam, the data show an increase in terms of failure load of strengthened beams of 16% for the EB technique and 27% for the IRS technique in Group A; an increase of 15% for the EB and 30% for the IRS in Group B; only for the Group C the results show an inverse trend with a greater increase for the EB with 28% compared to IRS with 22%. Therefore, both techniques improved the load carrying capacity and decreased the ultimate deflections, and then the ultimate rotations, of the corresponding RC control beam. However, the behaviour of the strengthened beams with the IRS technique is interesting and effective from several points of view. By combining these important structural behaviour features with the sustainable aspects inherent the implementation of this technique, it can be concluded that the IRS technique is a viable solution to the problem of existing structures and meets the objectives of acting with more effective, sustainable and rapid methods.

The intermediate/end debonding strain, useful in designing a TR strengthening system, can be calculated according to the CNR-DT 215/2018 procedure or using the proposed simple formula. In both cases the obtained values are comparable.

Experimental investigation on strengthening of RC members with HSC overlays

N. Randl & M. Steiner

Carinthia University of Applied Sciences, Spittal/Drau, Austria

ABSTRACT: High performance concretes (HPC) with higher compressive strength are particularly suitable for subsequently generating reinforcing overlays on existing structures. The aim of the herein presented research was to experimentally demonstrate the suitability of such approach and verify an improved bond at the interface between HPC overlay and normal strength concrete (NSC) as substrate. For this purpose, small and large scale tests with different specimen geometries and setups were performed, investigating the interface shear transfer between high strength overlay and normal strength substrate. In general, the small scale tests provided consistent results with rather low scatter for same test-setups and roughness categories. The bond strength values with HPC were significantly higher than observed with normal strength overlay. While the NSC overlays showed, based on visualization of the crack pattern via digital image correlation, some slight signs of delamination in the member tests, the HPC overlays lead to a monolithic behavior of the tested composite slabs.

1 INTRODUCTION

Adding new concrete layers to an existing structure can be an effective and sustainable way for retrofitting reinforced concrete (RC) members and increasing their performance. Concretes with higher strength are particularly suitable for this purpose due to their advantageous mechanical properties such as better resistance or higher durability (Pelke et al. 2018, Orgass et al. 2018). While interface shear forces are preferably transferred via bond mechanisms between new and old concrete, perpendicular tensile forces have to be covered by adequate connectors (Randl et al. 2005) or post-installed reinforcing bars (Randl & Kunz 2014).

In the case of the herein considered concrete overlays, the focus is laid on toppings where the adhesive bond between the old and the new concrete is the key mechanism. Applications to the tensile side of an RC member would usually require connectors and depend on an adequate tensile reinforcement of the overlay, like textile fabrics which are increasingly researched in that context (Rossi et al. 2021a, b).

The aim of the research project was to experimentally demonstrate suitability and verify improved bond with HSC overlay concrete in comparison to common NSC overlay concrete. Studies such as those by Lenz (2012) at the Technical University of Munich or Júlio et al. (2006) show that rheology and specific concrete properties, as usually present in high-strength concretes in particular, can be decisive for achieving very good bond properties. Julio et al. (2006) as well as Randl et al. (2016) could show in their previous studies that higher overlay strength leads to potentially better bond. The same applies also for highest strength, i.e. ultra-high performance concrete, overlays where numerous recent studies proved the achievable excellent adhesive bonding (Javidmehr & Empelmann 2021, Ju et al. 2020, Semendary & Svecova 2020, Valikhani et al. 2020, Zhang et al. 2020).

The present research project deals with the application of HSC overlay concrete on NSC base material. The adhesive bond along such joints was investigated and characterized experimentally

in various setups. A key factor in this context was the accurate execution, description and recording of the substrate's surface roughening.

2 EXPERIMENTAL CAMPAIGN

2.1 General remarks

Several series of different small-scale bond and interface shear tests have been performed to investigate the adhesive bond resistance between NSC and subsequently applied HSC. The small-scale tests were typical specimen for the investigation of the interface shear capacity (Reinecke (2004), Randl (2013), Zanotti & Randl (2019)). For the determination of the shear strength along the interface, two different test setups were used: Shear specimens with vertical ("Push-Out") and with inclined joint ("Slant Shear").

Large scale tests involved 10 base slabs with the dimensions 3600 x 1000 x 240 mm, where a 60 mm thick layer of overlay concrete was applied. The dimensions and the layout of the reinforcement were designed on the basis of Eurocode 2 in such a way that a shear force failure with the highest possible shear stress at the interface was to be expected, while a premature flexural failure was prevented.

2.2 Materials and surface characteristics

The substrate was made of NSC - normal strength concrete C 45/55, the high-strength overlay concrete (HSC) corresponded to strength classes C 70/85 to C 80/95. For comparison purposes, also C 45/55 was also applied as overlay concrete on three slabs. The exact mean 28-day compressive cube strength values are given in Table 1. For the C 80/95 (2nd series) crushed aggregates (size 8/16 mm) were used instead of the round ones from the C70/85 (1st series).

The hardened concrete properties were determined on cubes with dimensions 150x150x150 mm, the modulus of elasticity was derived from prisms 120x120x360 mm. Furthermore, the splitting tensile strength was determined on cylindrical specimens 100x200 mm.

Table 1. Fresh and hardened concrete properties.

concrete type	slump flow [mm]	28d – compression strength [N/mm ²]	splitting tensile strength [N/mm ²]	E-Modulus [N/mm ²]
C 45/55(1 st series)	420	61,2	3,6	26400
C 45/55(2 nd series)	480	59,0	4,9	25500
C 70/85(1 st series)	460	87,9	6,5	33200
C 80/95(2 nd series)	500	101,9	6,2	36500

Before placing the HSC layer, the hardened substrate concrete was roughened with high pressure water jetting at approximately 2000 bar. The test specimens were produced and categorized with intended roughness depths of $R_t < 1.5$ mm ("smooth"), $1.5 \text{ mm} \leq R_t < 3$ mm ("rough"), and $R_t \geq 3.0$ mm ("very rough"). The surface roughness was measured directly after the surface treatment (Figure 1) by means of the sand patch method (fib (2012)).

Figure 1. Roughness measurement on HPW-jettted slab surface.

2.3 Test setup and test execution

2.3.1 Small scale tests

2.3.1.1 Push-out tests

The specimens for the Push-Out tests are shown in Figure 2. The load was introduced vertically into the mid segment very close to the interface in order to avoid significant eccentricities and in consequence load deviations. Nevertheless, due to the small eccentricity of 10 mm between load introduction and bearings, some limited bending moment transferred via the interface cannot be avoided, causing minor tensile stresses perpendicular to the interface.

Figure 2. Dimensions and front view of Push-Out Tests (units: mm).

2.3.1.2 Slant Shear tests

Slant shear tests (specimen geometry see Figure 3) represent a typical setup for the determination of the adhesive bond strength in shear along an interface. The ratio between shear force and normal force depends on the inclination of the interface (65° , 70° and 75°). By varying the joint inclination, the relationship between adhesive bond and generated frictional resistance resulting from normal stresses can be roughly identified.

Figure 3. Dimensions and front view of Slant Shear Test (units: mm).

To prevent the introduction of lateral forces, plain steel plates with lubricant in between were placed on top between specimens and actuator and a spherical bearing was used at the bottom (see also Randl et al. (2020)).

2.3.1.3 Large scale tests

The test program includes 10 large scale tests with different overlay and roughness configurations, as listed in Table 2. The 100 mm wide and 240 mm thick base slabs were provided with a strong longitudinal bending reinforcement (10 \varnothing 26 mm) to avoid premature bending failure in

the four-point bending test. The aim was to achieve finally a shear failure and thus produce maximum shear stresses along the joint. The flexural capacity of the slabs was designed to be about a factor of 2 higher than the shear resistance. All test specimens were designed without shear reinforcement. An important boundary condition, especially when determining the exact geometry, was to maintain a shear slenderness $a/d \geq 3$ (a = distance load introduction - support, d = effective depth) in order to avoid direct load transfer via inclined compression struts into the supports. The detailed geometry and the overall setup are displayed in Figure 4 (see also Randl & Steiner (2020)).

Figure 4. Geometry and setup of slab specimen.

Displacement transducers were applied to record the deflection as well as potential openings or lateral displacements at the interface. Strain gauges were applied to the bending tensile reinforcement and on various locations at the top surface of the concrete overlay. Such measurements allow for back-calculating the local shear stresses along the interface. The formation of the crack pattern and the development of crack widths were recorded by a photogrammetric system.

Two slabs were subjected to some cyclic loading during the overlay concrete placement and the overlay hardening phase in order to simulate vibrations caused by traffic on a parallel lane.

3 TEST RESULTS

3.1 Small scale tests

3.1.1 Push-out tests

All Push-out tests ended up with a clear rupture along one or sometimes both interfaces, i.e. adhesive bond failure along the interface. The main shear load was superimposed by a small moment due to the eccentricities between interface axis and load introductions/supports. Bond failure took always place very abruptly at only small displacements below 0.10 mm. Figure 5 shows the overall test results from the 1st and 2nd series graphically. The reason for the comparatively higher adhesive bond τ_{bond} in the 2nd series can be found in the modified concrete mix design: The crushed aggregates and the higher concrete strength favor the shear bond and also the interlocking between the substrate and the overlay compared to, for example, the use of round gravel. Furthermore, the increase of the adhesive bond strength can be attributed to the lower viscosity, larger

Figure 5. Results of Push-Out tests.

slump flow and better workability of the 2nd mix. As can be seen in Figure 5, no further increase of the bond strength was observed at a mean roughness larger than about 2 mm.

3.1.2 Slant shear tests

The Slant Shear tests ended up with a brittle failure, depicting different failure modes: A larger proportion (61%) of the tests failed along the interface as foreseen, with the fracture surface partially propagating into the lower strength concrete. Some tests showed a mixed kind of failure, i.e. the fracture surface followed partly the interface, ending up however with compression failure in the substrate concrete. Pure compression failure of the substrate concrete was partly observed especially with high roughness and more evident in the 2nd series where higher bond strength was measured. The results of the test series are in general consistent, with no pronounced outliers upwards or downwards.

As the shear force is superimposed by a normal force perpendicular to the interface, the identification of the pure adhesive bond strength τ_{bond} requires the definition of a failure criterion. A simple but still sufficiently accurate and widely used approach to describe the shear resistance along an interface provided by bond and frictional forces is the Mohr Coulomb hypothesis (Randl 2013). Based on this failure criterion, taking into account the measured failure loads and the dimensions of the specimens, the adhesive bond-strength values τ_{bond} of the joints can be calculated. Thereby, representative values for the friction coefficient can be chosen on the basis of the mean values presented in Randl (2013): 1.2 for $R_t < 1.5$ mm (“smooth”), 1.4 for $1.5 \text{ mm} \leq R_t < 3 \text{ mm}$ (“rough”), and 1.5 for $R_t \geq 3.0$ mm (“very rough”). Figure 6 shows the calculated adhesive bond values τ_{bond} , resulting on the basis of the before mentioned coefficients of friction. These coefficients were also checked by means of regression analyses and turned out as the best fitting approach for the relevant roughness category. Similar to the Push-Out tests, also in the Slant Shear tests no further increase in bond strength was recorded for higher roughness values. Even some single lower values were observed at high roughness, which is partly attributed to premature compression failure, but such test results still provide meaningful lower bound values.

Figure 6. Results of slant shear tests.

3.2 Large scale tests

All test slabs failed primarily in shear. With the exception of slab 6, a further load increase and the formation of a 2nd load maximum (“LM”) was observed after a 1st LM with an associated load drop; in 3 cases, even a 3rd LM was formed under increasingly large deflections. The frequently observed multiple load peaks can be attributed to the fact that after formation of the 1st shear crack, due to the strong bending tensile reinforcement, there was usually no total collapse, but together with further opening of the first shear crack and increasing deflection a shear crack formation on the other side of the slab could be observed until the final collapse.

For the evaluation of the load-bearing behavior, the results of the 1st LM are of main importance (see Table 2). These were consistent throughout and no outliers were observed. A comparison of the ultimate loads achieved (1st LM in each case) showed a certain influence of the applied overlay concrete: The mean values of the 1st LM were 919.7 kN with NSC overlay, 952.4 kN with HSC overlay (thus 3.6% higher), and lowest with HSC overlay under cyclic preloading at 898.6

kN. The highest loads at the first maximum were measured in all three overlay concrete configurations (NSC, HSC, and HSC cyclically preloaded) at the lowest interface roughness of 0.8-0.9 mm in each case. Since in all cases primarily a shear failure of the slabs and not a failure of the interface was decisive, it cannot be concluded that a lower roughness depth leads to better bond effects; however, the trend from the small scale tests (no significant increase of the bond strengths at higher surface roughness) is also reflected in the large scale tests.

Table 2. Failure loads (1st LM) observed in slab tests.

Slab No.	roughness R_t [mm] ²⁾ S / R / VR	overlay concrete NSC / HSC	1 st LM [kN]	interface damage
1	1,6	NSC	902,4	Yes
2	3,0	HSC	951,3	No
3	3,0	NSC	914,1	Yes
4	0,8	NSC	942,6	Yes
5	1,5	HSC	951,9	No
6	1,7	HSC	896,7	No
7	0,8	HSC	1014,9	Yes
8	0,8	HSC	947,2	No
9 ¹⁾	0,9	HSC	860,9	Yes
10 ¹⁾	1,5	HSC	936,2	Yes

1) Slabs vibrated during overlay casting

2) S...smooth, R...rough, VR...very rough

The influence of the type of overlay concrete on the achieved failure loads (Figure 7; 1st LM) was however less significant than in the small scale tests, which is to be expected because local bond damage in slabs can be better compensated by load redistributions (Randl et al. (2008)).

Figure 7. Load deflection curves of the slab tests.

4 DISCUSSION OF THE TEST RESULTS

4.1 Small scale tests

The results of the bond strength tests show an increase of the values with increasing overlay concrete quality (HSC), at the same substrate quality, in the order of about 35% on average compared to NSC in the Slant shear tests. Thus, overall, a decisive influence of the concrete parameters and concrete quality on the bond strength could be verified. In general, a very rough interface ($R_t \geq 3$ mm) produced no significant increase in shear bond strength compared to a rough interface (in the tests: $R_t \approx 2$ mm).

It also became apparent that the different test setups do not provide the same adhesive bond strength: in the Push-Out test, the values for rough interface were approx. 3 N/mm² in the 1st series (4 N/mm² in the 2nd series), whereas the values of the adhesive bond strengths were significantly

higher in the Slant Shear test with approx. 7-8 N/mm² in the 1st series (8-9 N/mm² in the 2nd series). Thus, even if the frictional component is eliminated via the Mohr-Coulomb failure hypothesis, the Slant Shear test setup has a clear favorable effect on the recorded bond strength due to the compressive stress state in comparison to pure interface shear loading with the Push-Out setup.

4.2 Large scale tests

The shear cracks developed, as expected, between the support and the load introduction. By means of the photogrammetric DIC (Digital Image Correlation) measuring system, the initiation and development of the cracks and the crack pattern were precisely recorded at each load level. After evaluation of all 10 test slabs, three different failure patterns reflecting the influence of the interface bond quality could be identified (see also Table 2): All tests with NSC overlay (slabs no. 1, 3 and 4) showed local damage in the interface zone: In two cases (slabs no. 1 and 3) the shear crack followed partly the interface. In the case of slab 4, local small area detachments of the overlay in the edge area were detected during the subsequent inspection of the fracture surfaces. In the case of the slabs with HSC overlays (slabs no. 2, 5, 6, 7 and 8), the shear crack crossed the interface diagonally without any signs of deviation due to the crossing interface (see Figure 8). Only in the case of slab 7, the slab with the highest first load maximum, a crack offset near the load application zone and a localized detachment of a small overlay concrete fragment in the edge area were observed. The bond in slabs 9 and 10, on the other hand, was obviously significantly weakened due to the cyclic preloading during the pouring of the concrete; as a result, the shear crack followed partly the interface over a longer distance. In these areas, clear delamination of the overlay also occurred in the further course of failure.

Figure 8. Crack pattern of slab no. 6 at 1st load maximum.

The back-calculated interface shear stresses were partly in the range of the interface bond strength recorded in the Push-Out tests. In the case of slab 7 with the highest bond stress (3,8 MPa) where some slight cracking along the interface was observed, the bond stress was at the level of the strength measured in the Push-Out tests (Figure 5).

5 CONCLUSION

The bond strength between HSC overlay and NSC substrate was studied in small scale and large scale tests. It was clearly shown that significantly higher bond strengths were observed with HSC concretes than achievable with NSC.

The combination of small scale and large scale tests provided a full picture of the load bearing behavior and the adhesive bond mechanism. The influence of the investigated parameters such as variation of roughness depth emerges more pronounced in the small scale tests. The numerical analysis of the large scale tests is backed up by calibrating the interface parameters from the small scale tests. Based on the presented tests, with HSC overlays bond values are about 20-30% higher than usually achieved with NSC overlays. Taking this into account in the design, the degree of roughening could be reduced e.g. from the category “very rough” to “rough” (fib (2012)), still providing the same interface shear resistance like with NSC concrete. In addition to the good bonding properties, HSC also offers other advantages, such as higher resistance to mechanical abrasion or better durability.

Innovative shear strengthening with post-installed undercut anchors

N. Randl & P. Harsányi

Carinthia University of Applied Sciences, Spittal/Drau, Austria

J. Kunz

Hilti Corporation, Schaan, Liechtenstein

ABSTRACT: Shear strengthening of existing structures is a rather difficult task with respect to the short available anchorage length in the structural member and the target of reasonable activation of the strengthening element before the rather brittle shear failure takes place. In order to overcome such technical requirements, an innovative undercut anchor was developed. The anchors are set into predrilled holes from the soffit of a structure and, via application of a torque moment, slightly pre-tensioned. The undercut solution provides a very short and effective anchorage inside the concrete, and applying a torque moment already activates the system during installation. Large-scale tests on 5.4 m long T-beams designed for shear failure have been performed to verify the functioning of such strengthening solution. All tests ended up in shear failure, with nearly full utilization of the post-installed anchors and load gains around 40% with four and 90% with seven rods.

1 INTRODUCTION

1.1 *General*

The task of retrofitting existing buildings and infrastructure is strongly gaining importance with respect to ever-increasing traffic loads and the target to reduce the environmental impact by increasing the lifespan of a structure instead of demolishing and rebuilding it. Strengthening in shear may be not just a stand-alone task, but become an additional necessity when such structure is undergoing global strengthening and rehabilitation measures. This is also due to the fact that new, refined prediction formulae for shear resistance of RC members are meanwhile available, which increasingly enter codes of practice.

Local strengthening in shear requires usually a very efficient anchorage of the strengthening solution, in order to introduce tensile forces over short distances into the strengthening elements. Otherwise, it would be very difficult to activate the subsequently applied strengthening elements and make use of their tensile properties. This is due to the rather brittle shear failure mode and its specific typology and failure pattern (Störzel et al. 2015).

Another frequent requirement is coming from the infrastructure operators, who request to avoid significant interruptions of the traffic flow during the strengthening process. Unfortunately, shear strengthening techniques require quite often also construction works on the top side of a structure.

1.2 *Traditional methods*

Traditional methods of shear strengthening are based on the following basic principles (Figure 1):

- a) Attaching or, if possible, wrapping around CFRP/textile/steel sheets or straps
- b) Clamping with steel rods/tendons passing aside or crossing the member in a vertical direction
- c) Applying reinforced shotcrete or cast additional concrete layers (Randl et al. 2005)

If the CFRP sheets cannot be fully wrapped around, which is usually the case, appropriate end anchorages are required in order to prevent premature delamination of the sheets from the concrete substrate (Kalfat et al. 2013). Such anchorage should be designed to transfer the tensile load directly to the RC member's compressive zone (Täljsten 2003, Randl & Harsanyi 2018). In general, high-bond two-component adhesives are used to glue the sheets to the clean and preferably slightly roughened existing concrete surface. Steel rods passing through the cross-section in a vertical direction are quite easy to handle and install, however, require construction works also on the top side of the structure (Breveglieri et al. 2014).

Figure 1. Overview of some traditional shear strengthening techniques.

1.3 *Post-installed reinforcement*

Post-installed reinforcement is used successfully in various situations of structural applications. A core purpose of the technique is to connect new and old parts of reinforced concrete structures, ensuring the full transfer of forces. The post-installed reinforcing bars are inserted into pre-drilled holes and glued in with an appropriate high-bond mortar. A key requirement in that context is the assurance of sufficient anchorage to the old concrete. While the basic anchorage length is in-line with according specifications in codes of practice for the anchorage of cast-in reinforcement, sophisticated approaches allow for reduced embedment depths (Randl & Kunz 2014).

Such types of post-installed reinforcing bars can also be successfully used for structural strengthening of a RC member. Former tests performed by Randl & Kunz (2009) and Kunz et al. (2013) show that the subsequent insertion of inclined reinforcing bars is an effective method to enhance the shear resistance of existing concrete members significantly. The results of these investigations have been translated into a design concept based on fib Model Code 2010 (Muttoni & Fernandez 2013). With respect to the required bond length, an inclination of the bars of preferably 45° is recommended to achieve sufficient end anchorage in the concrete compression zone (Figure 2).

Figure 2. Setup of post-installed reinforcement for strengthening in shear.

Marti et al. (2016) have investigated shear strengthening with vertical post installed shear reinforcement and provided recommendations to the Swiss Federal Roads Office (Bundesamt für Strassen 2016).

2 STRUCTURAL TESTS WITH INNOVATIVE UNDERCUT SLEEVE ANCHORS

2.1 Method and anchor installation

While standard shear reinforcement with stirrups or double headed studs have clearly defined, local anchorage zones, post-installed straight bonded bars have the drawback that their anchorage zone extends over a certain bond stretch. Figure 3 shows the principal stresses activated in the concrete by the two types of anchorage.

Figure 3. Principal stress from headed anchorage (left) and bonded anchor (right).

In close cooperation with the Hilti Corp., an innovative anchor element has been developed which allows for quick installation and immediate activation due to pre-tensioning via an applied torque moment. The steel anchor consists of a rod with a cone-shaped undercut at the end, providing a clearly defined local anchorage, and is embedded in a tubular sleeve. Before installation, a hole has to be drilled to provide sufficient embedment depth. After injection with an appropriate high-bond mortar, the anchor is set into the hole. Due to the undercut element at the end of the rod and the free length within the steel sleeve, it can be immediately torqued. After hardening of the mortar, higher loads can be applied as the bond between the sleeve and the borehole allows for additional utilization of the tensile resistance of the steel sleeve (see Figure 4).

Such anchors for strengthening in shear provide various advantages compared to other traditional methods:

- Allowance for installation from the soffit, thus avoiding/minimizing traffic interruptions
- Activation already at serviceability load level, i.e. when the installation torque is applied

Figure 4. Working principle of undercut sleeve anchors.

2.2 Testing program

A number of six 5.4 m long T-beams was designed in a way that shear failure was to be expected, even in the case of an enhanced shear load-bearing capacity due to applied strengthening. For that purpose, a strong longitudinal reinforcement consisting of four 30 mm and two 25 mm diameter bars as longitudinal tensile reinforcement situated at the bottom of the beam were foreseen. As top reinforcement, only four 14 mm diameter bars and two 10 mm diameter bars were placed in order to create a stable reinforcement cage.

The T-cross section had a height of 600 mm and an overall flange width of 700 mm, while the width of the web was 200 mm. Such a shape should simulate a typical representative cross-section with practical relevance. Considering the distance of 1.585 m between load introduction and support in the chosen 3-point load setup, the shear span-to-depth ratio a/d was 3.24 (with an effective depth d of 489 mm).

No stirrup reinforcement was provided in the beam sections between load introduction and closest support where the subsequent strengthening was to be applied.

Figure 5 displays the test setup. While the reference test had no stirrup reinforcement at all, the other beams were designed with stirrups outside the strengthening zone to avoid premature shear failure in the non-strengthened zones. Apart from those sections, along the remaining length 12 mm diameter stirrups at a 190 mm spacing were cast-in to enforce shear failure at the critical shear span and avoid premature failure in bending.

Figure 5. Test setup with reinforcement layout and strengthening variants (units in mm).

The number of installed anchors varied between 4 and 7, with a spacing of 380 mm with 4 and 190 mm with 7 anchors. In order to simulate a practical approach, the anchors were installed in the lab from underneath the beams, which were placed on supports at a height of about 1 m. The overall testing program is summarized in Table 1. Here, the abbreviation PUAnc stands for Post-installed Undercut Anchors, followed by the number of subsequently installed anchors and the test number.

Table 1. Overview of testing program and results.

Test	No. of elements	Spacing [mm]	F_{\max} [kN]	V_{\max} [kN]	$F_{\max}/F_{\max,ref}$
Reference	0	-	370.9	240.3	1.00
PUAnc_4_1	4	380	612.0	396.4	1.65
PUAnc_4_2	4	380	515.0	333.0	1.39
PUAnc_4_3	4	380	499.4	323.5	1.35
PUAnc_7_1	7	190	681.7	441.6	1.84
PUAnc_7_2	7	190	714.5	462.8	1.93

2.3 Material data

The beam specimens were made of normal-strength concrete C30/37. The mean concrete strength measured on 150 mm cubes on the day of testing was 43.5 N/mm².

The longitudinal reinforcing bars provided at the bottom of the beams consisted of high-grade steel S670/800, in order to ensure maximum flexural resistance with a still reasonable reinforcement degree. The nominal yield strength was 670 N/mm² with an average value of 725 N/mm². All other types of used reinforcement, i.e. longitudinal top bars and stirrups, were

made of Austrian standard steel B550 B with a nominal yield strength of 550 N/mm² and an average yield strength close to 600 N/mm².

Concerning the anchor element itself, the internal threaded rod had a steel strength grade 8.8 according to EN ISO 898-1, with a metric screw thread size M12. In combination with the steel sleeve, the outer diameter of the whole strengthening element was around 17 mm, with a free anchorage length of around 500 mm. The strengthening elements were installed in diameter 22mm hammer-drilled holes.

3 FATIGUE TESTING OF UNDERCUT ANCHOR SOLUTIONS

In order to test the load-bearing behavior of the prototypes under fatigue loading, single cyclic tests with three beams and varying load amplitude were carried out. The load was applied in a force-controlled manner using a hydraulic cylinder with a maximum dynamic capacity of 500 kN at frequencies between 3 Hz and 4 Hz. The performed tests aimed at identifying possible weak points for further development and improvement of the prototypes at a later stage. An overview of the test program and its results (maximum number of endured cycles) can be found in Table 2.

Table 2. Setup and results of shear tests subject to cyclic loading.

Test	Spacing [mm]	Min force [kN]	Max force [kN]	Max shear force [kN]	ΔV_{cyclic} [kN]	No. of cycles
PUAnc_7_3	380	32.5	305	236,6	204,02	34.460
PUAnc_7_4	380	27.1	235	184,8	161,12	590.000 ^{1}
PUAnc_7_5	380	27.1	280	218,1	189,96	38.670

{1} First anchor failure; as even after 1.5 million load cycles the beam did not fail, the test was stopped

4 TEST RESULTS

4.1 Failure modes

All tested beams showed a typical shear failure mode: The first single and slightly inclined shear cracks with an inclination of roughly 60°-70° to the horizontal axis appeared at the reference beam at a load level of about 130 to 140 kN, and at the strengthened beams such cracks showed up consistently at a significantly higher load level of around 200 to 250 kN in between the strengthening elements.

Figure 6. Force deflection curves of the tested beams.

At a load level of 300 to 350 kN, i.e. close to the failure load of the unreinforced reference beam (see load-deflection curves in Figure 6), the inclination of the propagating shear cracks started to decline to an angle between 30° and 45° to the horizontal axis. At the reference beam this was followed quickly by the formation of a continuous critical shear crack and, having passed through the flanged section, soon led to final failure. At the same load level, the strengthened beams showed no significant loss in stiffness as the strengthening elements were increasingly activated at that stage: pronounced shear cracks started to form in between the elements and the formation of a typical truss mechanism was initiated.

The load transfer via the truss mechanism was more and more identifiable and clearly developed above a load level of about 400 to 450 kN. Before the total failure of the beams, an increasing number of less inclined cracks appeared (around 25° to the horizontal axis), partly unifying and crossing the strengthening elements while showing an increasing crack width. Finally, one or two main cracks started to propagate through the whole cross-section (see Figure 7).

The failure took then place in such a way that a first inner rod of an undercut anchor broke and in most cases fell out of the sleeve. However, this first rupture of one single rod never led to a total loss: after a sudden limited drop in the load, again some recovery of the load was observed until another rod broke. Such behavior can be attributed to a redistribution of the load to other, still fully working anchors. Final failure was usually reached with the rupture of the second or even another third rod. The bonded sleeves remained intact in the structure, thereby preventing a sudden total breakthrough of the concrete beam. Additional information on observed failure modes is provided in Randl & Harsanyi (2018).

Figure 7. Photograph of representative failure mode after ultimate failure (strengthened with 7 anchors).

4.2 Achieved load gain

All strengthened beam specimens exhibited a significant load increase due to the applied strengthening elements. Despite the rather small cross-section of each rod, impressive loads were achieved with the strengthened beams. In comparison to the reference beam, the shear capacity was nearly doubled (enhancement factor 1.88) with the application of seven post-installed anchors, while a number of four rods still led to an average increasing factor of 1.46. Obviously, the increase in the number of anchors from 4 to 7, corresponding to a reduction of the spacing from 380 to 190 mm, did not lead to a proportional increase in the shear load-bearing capacity. This is due to the fact that with respect to the kinematics of the shear failure mode and the mechanical properties of the used steel not all anchor rods can be fully activated at the same time.

Apart from the mere absolute values of the achieved load enhancements, another meaningful approach to judge the efficiency is based on a very simple model used also by other researchers (see e.g. Belarbi et al. 2012): The maximum tensile strength $A_{si} \cdot f_{um}$ of all strengthening elements crossed by the assumed inclined shear crack is summed up and related to the ultimate shear load observed in the test: $k = \sum A_{si} \cdot f_{um} / V_{ult}$. Thereby, with 4 undercut anchors, an efficiency factor k of more than 80% turns out, which can be rated as very high. Note that this consideration is only a rough approach as additional effects providing a contribution to shear resistance, such as dowel action of the longitudinal reinforcement or exact kinematics of shear crack formation, are not taken into account.

4.3 Fatigue test results

All three beam specimens failed in a similar manner (see Table 3). Depending on the applied load amplitude, a different number of cycles was achieved. PUAnc_7_3 with a maximum applied cyclic shear force of 236.6 kN failed after 34.460 cycles due to a fatigue failure of the inner undercut anchor along the threaded rod. Despite the comparatively high force-controlled load application, the remaining steel sleeve was able to ensure ductile failure over another 30 load cycles. With a maximum shear force of 184.8 kN, it was possible to achieve a number of 590.000 cycles in the case of PUAnc_7_4 until the first inner threaded rod failed in a similar manner. Nevertheless and in contrast to the previous test, it was possible to maintain a sufficient loadbearing capacity due to the still intact sleeve tube, however at increased deformation and crack opening, and proceed with the fatigue test. The test was finally terminated after 1.5 million load cycles as there was no indication of any forthcoming total failure of the beam. In the third cyclic test PUAnc_7_5, a maximum shear force of 218.1 kN was applied. The beam showed the same failure behavior as PUAnc_7_3 and PUAnc_7_4 before and a first anchor, i.e. the inner threaded rod, failed after 38670 cycles. Hereafter, the beam underwent another 2000 additional cycles until it finally collapsed.

Table 3. Overview of the fatigue failure modes.

Test	Description of failure mode
PUAnc_7_3	Rupture of the second anchor (from support) after 34.460 cycles, followed by beam collapse after an additional 30 cycles
PUAnc_7_4	Failure of the third anchor (from support) after 590.000 cycles, followed by increasing deflections, test was aborted after 1.5 million cycles
PUAnc_7_5	Failure of the second anchor (from support) after 38.670 cycles, followed by beam collapse after an additional 2.000 cycles

Compared to the static load tests, the behavior differed on one side due to the load-controlled test procedure. On the other side, it could be observed that the failure due to fatigue loading was not identical to the static failure mode. After the failure of the first inner threaded rod, the deformation of the beams increased significantly. This led in consequence to a pronounced and progressive crack propagation parallel to the compressive struts, entering the compressed flanges of the T-shaped cross section. Finally extensive spalling of the concrete in the bending tensile zone was observed in the surroundings of failed anchors (Figure 8).

Figure 8. Photograph of fatigue failure of tested beam.

5 CONCLUSIONS

Strengthening in shear by means of newly developed sleeved undercut anchors is an effective way to achieve significant load enhancements without the requirement of large interventions in the existing structure. As such kind of anchorage can be set from the bottom side of an RC member, the traffic flow is not affected by the construction works. Due to the concentrated

load introduction at the anchor's head, this type of sleeved undercut anchor can be set in the vertical direction.

In the different shear tests performed with a varying number of anchors, a load increase between around 40% with 4 anchors and 90% with 7 anchors was achieved.

The undercut anchors succeed with their concentrated load introduction which enables prompt loading and in addition some pre-stressing effect when applying the torque moment. This allows for immediate activation and is helpful also for serviceability limit state considerations (e.g. crack control).

The cyclic load tests performed, allowed the identification of a possible optimization potential of the prototypes and showed that significant force transmission via the bonded steel sleeve is possible, even in case of failure of the inner threaded rod. By adapting the prototype, it should also be possible to optimize the intended reinforcement method for dynamic load scenarios.

Even though in the present tests an injection mortar was used, the undercut anchors would also work without the bond between the sleeve and the surface of the borehole (however, the contribution of the sleeve would in that case have to be canceled).

ACKNOWLEDGEMENT

The project was funded by the Austrian FFG (Grant no. 840549), together with the Austrian Infrastructure Operators for Motorways (ASFINAG) and Railways (ÖBB) which is greatly acknowledged.

Evolution of seismic fragility of reinforced concrete columns subjected to corrosion

Y. Liu, W.P. Zhang & X.L. Gu

Department Civil Engineering, Guanxi University, Nanning, PR China

ABSTRACT: This paper presents a stochastic methodology to investigate the evolution of seismic fragility for reinforced concrete (RC) columns subjected to corrosion. On account of the increasing variability of mechanical properties of corroded reinforcement, a finite element (FE) model is proposed by incorporating a stochastic constitutive model of corroded rebars. The developed fiber-based FE model is calibrated using a set of experimental data and then extended to conduct pushover analyses and nonlinear time history analyses of RC columns with different corrosion degrees. The results of damage limit states (DLSs) determined by stochastic pushover curves indicate that DLSs for deteriorating columns are corrosion-dependent and follow lognormal distributions. Based on incremental dynamic analyses (IDAs), the fragility analyses results show that reinforcement corrosion has adverse effects on life-cycle seismic performance of RC columns. Comparisons are made between the proposed methodology and traditional approaches to developing seismic fragility curves for corroded RC columns. Considerable underestimations of seismic fragility across different DLSs were found using the traditional approach compared to the stochastic methodology.

1 INTRODUCTION

In the past few decades, reinforcement corrosion in RC structures has gradually received extensive attention. RC columns or piers located in environmentally aggressive areas such as chloride-laden environments inevitably suffer from the effect of chloride-induced corrosion during their lifetime. Corrosion leads to the reduction of the load-carrying capacity of reinforcement (Zhang et al. 2014a) and cracking or spalling of concrete cover (Chen et al. 2020). Many coastal regions are tectonically active areas, and deterioration of the seismic performance of marine structures will generally increase the risk of economic loss and casualties caused by earthquake events (Sharma et al. 2016). As a consequence, it is of great significance to investigate the evolution of life-cycle performance of RC structures subjected to seismic hazard.

More recently, several experimental studies have focused on the effect of corrosion on the structural performance of RC columns under cyclic loading (Meda et al. 2014, Zhang et al. 2023). The outcomes of these studies show that the load-carrying capacity, stiffness, and ductility of the columns gradually deteriorate with the increase of corrosion degree. Meanwhile, as an important part of performance-based seismic design, seismic fragility has become a research hotspot in the field of earthquake engineering. Results in previous studies pointed out that with the increase in service time, the seismic fragility of the corroded structure increases, resulting in an increase in the failure probability of the structures (Xu et al. 2021). However, in most current studies, the damage limit states implemented in the development of fragility curves for corroded RC structures were those recommended for pristine structures, ignoring the time-dependence of the damage limit state. As a matter of fact, the corrosion-independent damage limit states might lead to an unrealistic estimation of the failure probability for corroded structures. Recent studies (Dizaj et al. 2018) have confirmed that damage limit states used for fragility assessment of deteriorated structures should be considered as corrosion-dependent parameters. Nevertheless, the limitation in current

literature lies in the perspective of deterministic analysis without accounting for the increasing variability in mechanical properties of corroded rebars. Few previous researchers (Ghosh & Sood 2016) have proposed probability distributions for corrosion-dependent damage limit states by incorporating a stochastic process model of corroded rebars. Hence, an important missing link for evaluating the life-cycle seismic fragility of deteriorating RC columns consists of putting forward a stochastic method that contains the randomness in reinforcement corrosion.

In this study, a fiber-based FE model including the impact of corrosion on reinforcement and concrete is proposed. The corrosion-dependent damage limit states distributions of corroded RC columns are obtained via a huge number of pushover analyses. An approach to developing seismic fragility curves for uncorroded and corroded RC columns considering stochastic evolution of mechanical properties of corroded rebars is presented.

2 PROBABILISTIC CORROSION DETERIORATION MODELING

2.1 Stochastic constitutive model for corroded rebars

One of the major concerns in practical engineering is the residual capacity and service life of aging RC structures. Due to the variability of the environmental action and the non-uniformity of concrete materials, concrete carbonization, chloride penetration, and reinforcement corrosion are all stochastic processes. Accordingly, the variability of mechanical properties of rebars varies with the initiation and propagation of corrosion. That is, the degradation of mechanical properties of corroded rebars is also a stochastic process (Zhang et al. 2021). It is obvious that a deterministic analysis method may result in extremely conservative structural reliability assessment, causing potential structural safety problems. Tensile tests (Zhang et al. 2012) of corroded rebars indicated that the nominal yield strength, the nominal ultimate strength, and the ultimate strain decreased, and the yield plateau shortened and even disappeared with the propagation of corrosion. Based on tests results, a deterministic model of stress-strain relationship was proposed by Zhang et al. (2014b) as shown in Figure 1 and Equations 1–2.

Figure 1. Stress-strain curves of corroded rebars.

$$\sigma_{sc} = \begin{cases} E_{sc}(\eta_s)\varepsilon_{sc}, & \varepsilon_{sc} \leq f_{yc}(\eta_s)/E_{sc}(\eta_s) \\ f_{yc}(\eta_s), & \varepsilon_{shc}(\eta_s) \geq \varepsilon_{sc} > f_{yc}(\eta_s)/E_{sc}(\eta_s) \\ f_{yc}(\eta_s) + E_{shc}[\varepsilon_{sc} - \varepsilon_{shc}(\eta_s)], & \varepsilon_{suc}(\eta_s) \geq \varepsilon_{sc} > \varepsilon_{shc}(\eta_s) \end{cases} \quad (1)$$

$$f_{yc} = \frac{\alpha_{yc}}{1 - \eta_s} f_{y0} \quad ; \quad f_{uc} = \frac{\alpha_{uc}}{1 - \eta_s} f_{u0} \quad (2)$$

where η_s is corrosion degree based on the average loss of cross-sectional area; σ_{sc} and ε_{sc} is nominal stress and strain of corroded rebars, respectively; f_{yc} and f_{uc} are the nominal yield and ultimate strengths of corroded rebars, respectively; ε_{yc} , ε_{shc} and ε_{suc} are the yield strain, hardening strain and ultimate strain, respectively; E_{sc} and E_{shc} are the elastic modulus and hardening modulus, respectively; f_{y0} and f_{u0} are the yield and ultimate strengths of uncorroded rebars, respectively; α_{yc} and α_{uc} are the yield and ultimate load ratios, respectively. More details about the definition of the model parameters are available in Zhang et al. (2014b). It is noted that mechanical properties of both uncorroded and corroded rebars are normally distributed, while the coefficient of variation

risers with the increase of corrosion degree. Consequently, the probability distribution models of mechanical properties for uncorroded steel bars and the stochastic process models for mechanical properties of corroded rebars were established by Zhang et al. (2014b):

$$f(x) = \frac{1}{\sqrt{2\pi}\delta\mu} \cdot \exp\left[-\frac{(x-\mu)^2}{2(\delta\mu)^2}\right] \quad (3)$$

$$f[x(\eta_s)] = \frac{1}{\sqrt{2\pi}\delta(\eta_s) \cdot \mu(\eta_s)} \cdot \exp\left[-\frac{[x(\eta_s) - \mu(\eta_s)]^2}{2[\delta(\eta_s) \cdot \mu(\eta_s)]^2}\right] \quad (4)$$

where x and $x(\eta_s)$ are the elastic modulus, yield load ratios, ultimate load ratios and ultimate strain for uncorroded and corroded rebars, respectively; μ and δ are corresponding mean and coefficient of variation. The relationships between $\mu(\eta_s)/\delta(\eta_s)$ and η_s are summarized in Table 1.

Table 1. Relationships between $\mu(\eta_s)/\delta(\eta_s)$ and η_s .

Stochastic process	$\mu(\eta_s)$	$\delta(\eta_s)$
E_{sc}	2.047	$\delta(\eta_s) = 0.303\eta_s + 0.079$
α_{yc}	$\mu(\eta_s) = -1.092\eta_s + 1$	$\delta(\eta_s) = 0.479\eta_s + 0.034$
α_{uc}	$\mu(\eta_s) = -1.152\eta_s + 1$	$\delta(\eta_s) = 0.559\eta_s + 0.028$
ε_{suc}	$\mu(\eta_s) = -1.092\eta_s + 1$	$\delta(\eta_s) = 0.677\eta_s + 0.216$

2.2 Impact of reinforcement corrosion on contribution of concrete

The impact of corrosion is not limited to steel bars only. The volumetric expansion actions of corrosion products induce internal tensile stresses in the concrete around the rebar, which leads to unexpected concrete cracking and spalling along the longitudinal direction of the rebar (Chen et al. 2020). In order to account for the effects of reinforcement corrosion on the contribution of concrete cover, the simplified equivalent method proposed by Coronelli (2004) is adopted:

$$\lambda = \frac{1}{1 + K\varepsilon_1/\varepsilon_{c0}} \quad (5)$$

where λ is a reduction factor for compressive strength of concrete cover; K is the steel bar roughness and diameter which can be taken as 0.1; ε_{c0} is concrete strain corresponding to the peak compressive stress; and ε_1 is average tensile strain in cracked concrete. More details about the parameters are available in Coronelli (2004). However, the stirrups corrosion inevitably causes reduction in both cross-sectional areas and mechanical properties, decreasing the confinement effects and strength improvement of core concrete, which can be considered by the reduction of the stirrup ratio and yield strength of the corroded stirrups. According to the Kent-Scott-Park model (Scott et al. 1982), compressive strength of core concrete and its corresponding strain are increased by factor of K_c , which is calculated as follows:

$$K_c = 1 + \frac{\rho_s f_{yh}}{f_c} \quad (6)$$

where f_{yh} is yield strength of stirrups; ρ_s is the stirrups ratio; f_c is the compressive strength of the sound concrete. As stirrup corrosion increases, the value of K_c inevitably decreases.

3 FINITE ELEMENT MODEL OF RC COLUMNS

3.1 FE model using non-linear fiber beam-column element

In this section, a fiber-based finite element model via *OpenSees* is presented. As shown in Figure 2, the whole length of the column incorporated with the fiber section is divided into six displacement-based elements with three Gauss integration points. The fiber section includes three

parts: longitudinal reinforcement fiber, core concrete fiber and cover concrete fiber. The fiber of each part is given the aforementioned constitutive model in Section 2, in which the concrete and reinforcement adopt *Concrete02* material model and *Hysteretic* material model, respectively. A set of uncorroded and corroded RC columns were designed according to Chinese code. The cross-sectional details of the proposed columns are shown in Figure 3. Each column was reinforced with 12 longitudinal rebars and stirrups with a spacing of 100 mm. Deformed rebars with a diameter of 16 mm were used as longitudinal rebars, and plain rebars with a diameter of 8 mm were used as stirrups. The cubic compressive strength of sound concrete was 30 MPa.

Figure 2. Overview of proposed FE model.

Figure 3. Column cross section.

Figure 4. Validation of proposed FE model.

Figure 5. Deterministic pushover analyses.

3.2 Model validation

The cyclic loading tests of uncorroded and corroded RC columns in the literature (Zhang et al. 2022; Lu et al. 2012; Gong et al. 2004) were compared with the calculation results of the proposed FE model. Column C1-1 in Zhang et al. (2022) and Corner Column A in Lu et al. (2012) were selected to validate for uncorroded specimens, while Column C3-1 with the corrosion degree of 0.166 in Zhang et al. (2022) and Z-4 with the corrosion degree of 0.09 in Gong et al. (2004) were selected for corroded one. As shown in Figure 4, the calculation results are basically consistent with the test results, which indicates that the model can be used to simulate the response of RC columns under earthquakes.

4 STOCHASTIC PUSHOVER ANALYSIS

4.1 Influence of corrosion on damage limit states

The purpose of pushover analysis is to determine the damage limit states (DLS) of components or structures. In the process of determination, according to FEMA (2003), the curvature ductility ratio (Equation 7) of the column is selected as the engineering demand parameter for pushover analysis.

$$\mu_\phi = \frac{\phi}{\phi_y} \quad (7)$$

where μ_ϕ is the curvature ductility ratio (CDR) for a curvature ϕ experienced by the RC column during the pushover analysis; ϕ_y is the idealized yield curvature.

Four different DLSs are defined by the value of critical cross-sectional curvature, including slight damage (DLS₁), moderate damage (DLS₂), severe damage (DLS₃) and complete damage (DLS₄). As the outermost tensile reinforcement yields with the onset of visible concrete cracking, the column is considered to be in the slight damage state (DLS₁) with the curvature $\phi_S = \phi_y$. Thus, for the DLS₁, the curvature ductility ratio following Equation (7) equals 1. For the curvature ϕ_M , when the concrete strain at the critical cross-section reaches a value of 0.002, the column is assumed to be in the moderate damage state (DLS₂). The curvature ϕ_C is recommended as the complete damage state (DLS₄) when the compressive strain in the extreme concrete fiber attains a value of ε_{cu} at which stirrups start to fracture. This fracture strain can be calculated as:

$$\varepsilon_{cu} = 0.004 + 1.4 \frac{\rho_s f_{yh} \varepsilon_{uh}}{f_{cc}} \quad (8)$$

where ε_{uh} is the tensile strain of stirrups corresponding to the ultimate stress and f_{cc} is the compressive strength of core concrete. Referring to Ghosh & Sood (2016), this study takes geometric mean of the DLS₂ and DLS₄ as the curvature for severe damage state (DLS₃).

In order to investigate the impact of reinforcement corrosion on damage limit states (DLS), different degrees of corrosion ($\eta_s = 0, 0.05, 0.1, 0.15, 0.2$) are considered and a series of non-linear pushover analyses are conducted. Figure 5 illustrates the results of deterministic pushover analyses. Corrosion-dependent damage limit states for RC columns are obtained and summarized in Table 2. It is shown that with the increase of corrosion degree, the load-carrying capacity gradually degrades, and each damage limit state decreases in varying degrees.

Table 2. Corrosion-dependent DLS.

η_s	0	0.05	0.10	0.15	0.20
DLS ₁	1.00	1.00	1.00	1.00	1.00
DLS ₂	3.04	2.91	2.83	2.77	2.67
DLS ₃	4.68	4.56	4.46	4.36	4.22
DLS ₄	7.21	7.10	6.98	6.86	6.72

4.2 Stochastic pushover curves and distributions of corrosion-dependent DLSs

Before stochastic pushover analysis, it is essential to sample four of the parameters based on the abovementioned stochastic constitutive model of corroded rebars in Section 2. Latin hypercube sampling method was used to conduct 100-time sampling campaign for four parameters (E_{sc} , α_{yc} , α_{uc} , and ε_{suc}) under four corrosion degrees (0.05, 0.1, 0.15 and 0.2). For all the reinforcements in the same column obtained by Latin hypercube sampling, the same constitutive relationship was adopted, while the constitutive relationship between different columns is different. Pushover analysis was carried out on 400 random RC columns under four corrosion degrees, and the stochastic pushover curves were obtained as depicted in Figure 6. It is found that the dispersion of pushover curve gradually increases with the increase of corrosion degree.

The distribution characteristics of each DLS were obtained by statistical analysis of stochastic pushover curves. A complete list of fitted distribution types for the DLSs are presented in Table 3. Consistent with previous studies on corroded columns (Ghosh & Sood 2016), the DLSs are found to follow lognormal distributions. It is noted that following Equation 7, the mean value corresponding to the slight damage state always equal to 1, and the logarithmic standard deviation is 0.035 based on the consideration of epistemic uncertainty. As shown in Table 3, the mean value of the DLS decreases with the increase of the corrosion degree of the RC column. However, the standard deviation is increasing, which indicates that the corrosion of the reinforcement increases the dispersion of the DLS. Additionally, when the corrosion degree is constant, the standard deviation increases with the increase of the damage degree.

5 SEISMIC FRAGILITY ANALYSIS BASED ON IDA

5.1 Ground motion selection

The IDA depends on nonlinear time history analyses of scaled ground motion records. Specifically, a ground motion record is applied to the structure and scaled up and down until reaching the imminent collapse. Usually, 8-to-12 scaling points should be enough to reach the desired performance and prevent excessive scaling which could affect ground motion features. In this study, a suite of 16 ground motion records are selected from Ground Motion Database of the Pacific Earthquake Engineering Research Center (PEER 2003). Figure 7 illustrates the elastic response spectra with damping equal to 5% of all un-scaled ground motions.

5.2 Deterministic and stochastic IDA results

First, a deterministic incremental dynamic analysis is performed. In this study, the peak ground acceleration (PGA) was adopted as intensity measure (IM) parameter. The IDA curve under a single ground motion was obtained by connecting the structural response points corresponding to the PGA of each record subjected to 20-time amplitude modulations, as shown in Figure 8a~e. The IDA curve cluster was obtained by summarizing 16 IDA curves, and then the median value of each IDA curve can be calculated. Finally, summarize the median value of IDA curve under each degree of corrosion to Figure 8f. It is found that with the increase of corrosion degree, the response of the RC columns increases gradually when the PGA keeps unchanged.

Afterwards, the stochastic IDA is conducted based on the Latin hypercube sampling. Under each amplitude modulated PGA, nonlinear time history analysis of 16 records is completed for 100 randomly generated corroded columns. In other words, $20 \times 16 \times 100 = 32000$ times of nonlinear time history analysis is required for a corrosion degree. The maximum curvature of each dynamic time history analysis and the corresponding PGA points are summarized to obtain the distribution of IDA as shown in Figure 9. It is demonstrated that with the gradual increase of the PGA, the dispersion of the maximum curvature gradually increases. In addition, With the increase of corrosion degree, the dispersion of maximum curvature increases gradually.

5.3 Seismic fragility curves

Seismic fragility curves are classical tools to evaluate the seismic vulnerability of structures. Fragility is defined as the probability that demand exceeds capacity conditional on a specified hazard intensity. To plot the fragility curves, first using IDA results, the corresponding curvature ductility ratio (CDR) of a given IM are calculated for different ground motion records. Then, using the following fragility function the probability of exceeding a given DLS is calculated:

$$P_f[\text{CDR} \geq \text{DLS}_i | IM = x] = 1 - \Phi\left(\frac{\ln(\text{DLS}_i) - \mu_{\ln}}{\sigma_{\ln}}\right) \quad (9)$$

where P_f is the probability that CDR exceeds i th DLS given that $IM = x$; Φ is the normal distribution function with a logarithmic mean of μ_{\ln} and logarithmic standard deviation of σ_{\ln} .

Figure 8. Deterministic IDA curves.

Figure 9. Distribution of stochastic IDA.

Similarly, based on the results of the maximum curvature obtained from the aforementioned stochastic IDA, the seismic fragility curve considering the variability of mechanical properties for reinforcement is calculated and displayed in Figure 10. It can be derived from Figure 10 that the consideration of the variability of mechanical properties for reinforcement defensibly increases the seismic fragility of RC columns, which may later lead to a raise in failure probability of structures under earthquake action. The causes of this phenomenon would be analyzed from the perspective of statistics. The increase of the randomness of the mechanical properties of the structure leads to the increase of the randomness of the seismic response. As a consequence, the standard deviation in the fragility function will increase, which causes the seismic fragility curve to move up. The comparison between fragility curves using the traditional deterministic approach and the

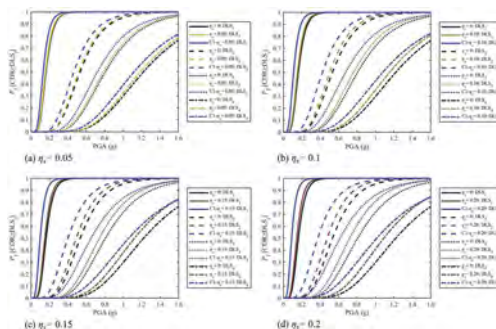

Figure 10. Seismic fragility curve considering stochastics.

proposed stochastic method illustrates that an obvious underestimation is drawn without the consideration of the increasing variability of mechanical properties for corroded rebar.

6 CONCLUSIONS

This paper provides a novel stochastic method to evaluate the seismic performance of corroded RC columns. The distribution of corrosion-dependent DLS and the seismic fragility curves obtained using deterministic and stochastic approaches is obtained through a number of push-over analyses and IDAs. The following conclusions were drawn:

- The corrosion-dependent DLSs all follow lognormal distributions. The mean value of damage limit state decreases and the standard deviation increases with the increase of corrosion degree.
- The traditional deterministic analysis method has the problem of underestimating the failure probability of deteriorated RC columns. The seismic fragility analysis method proposed in this paper can be closer to the actual circumstances.
- The limitation of the proposed method is the corrosion-dependence of DLS. The distribution of corrosion-dependent DLS will be developed into the distribution of time-dependent DLS in the further investigation.

Experimental study on water absorption in unsaturated concrete

J. Fang, C. Jiang & X.L. Gu

Key Laboratory of Performance Evolution and Control of Engineering Structures (Ministry of Education), Tongji University, Shanghai, P.R. China

ABSTRACT: The water absorption behavior plays an important role in assessing the durability performance of concrete structures. The oven drying at high temperature is a common pretreatment for concrete to reach dry state before absorption tests, whereas the concrete of existing structures remain at saturated or partially saturated states. This paper studies the effects of initial water content on the water absorption behavior of concrete. And the different water contents were achieved by drying concrete under atmospheric environment with different relative humidity at 23 °C. The result shows that the absorption rate increases with the initial water content of concrete decreasing. Finally, a transport model is established to predict the water absorption amount of concrete with different initial contents.

1 INTRODUCTION

The deterioration processes of concrete structures, including aggressive ions penetration and carbonation, are all influenced by the water transport in concrete. Aggressive ions need liquid water as carrier to penetrate into concrete, while the carbonation reaction process of concrete also takes place in the water. Therefore, it is essential to study water transport performance in concrete for durability assessment of concrete structures.

Water absorption capacity is one of the important indexes to evaluate the water transport performance of concrete. There are numerous studies that have been conducted to investigate the effects of different factors on the water absorption into concrete. These affecting factors include water to cement ratio (Zhang et al., 2020), admixture (Zhao et al., 2021), static loads (Wang and Li, 2014) and frost damage (Alyousif et al., 2016). However, the oven drying at high temperature is a common pretreatment for concrete to reach dry state before absorption tests in previous studies while the concrete of existing concrete structures remain at saturated or partially saturated states.

In this paper, the effect of initial water content of concrete on water absorption was studied using the experimental method. Moreover, a predictive model based on Lucas–Washburn equation was established to calculate the mass of water absorption.

2 EXPERIMENTS

2.1 *Materials and mix proportion*

The mixture proportion of concrete is listed in the Table 1. Ordinary Portland cement (PO 42.5) and deionized water were used to make the mixture. The ISO standard sand and crushed stone with the size of 5-16 mm were used as fine aggregates and coarse aggregates, respectively. After casting, the specimen was cured at 20 ± 2 °C, with the relative humidity set at 95% for 150 days.

Table 1. Mix proportion of concrete.

	Water	Cement	Sand	Coarse aggregate
W/C	(kg/m ³)	(kg/m ³)	(kg/m ³)	(kg/m ³)
0.53	190	359	717	1076

2.2 Sample preparation

One prism concrete specimen with water-cement ratio of 0.53 was casted in this study, and the dimensions were 300 mm × 100 mm × 100 mm. Four pieces (100 mm × 100 mm × 50 mm) used for absorption test were cut from the middle part of cured specimen, as illustrated in Figure 1. All sides of the test pieces were sealed with epoxy resin, leaving two surfaces with dimensions of 100 mm × 100 mm exposed. Then all the pieces were immersed in the deionized water for 35 days to reach the saturated states. To reach unsaturated states with different initial water content, three saturated pieces (C-1~3) were stored in 3 sealed containers with constant relative humidity. According to the previous research (Zhang et al., 2016), the maximum and minimum month-average relative humidity of the sites on the west coast of the Yellow Sea were 86.1% and 62.5%, respectively. Refer to above records, the relative humidity controlled by saturated salt in container were set as 86% (KCl), 79% (NaCl) and 67% (NaBr), respectively. The another one (C-4) was oven-dried at 50 °C to reach a dry state. All the pieces were took out of container or oven until reaching a constant weight (relative change < 0.1%/7 d).

Figure 1. The cutting method for concrete specimen C-1~C-4 (Unit: mm).

2.3 Water absorption test

Four unsaturated specimens with different initial water content (initial internal relative humidity) were used to study capillary water absorption behavior of concrete. The non-cutting surface was immersed into liquid deionized water of 3-5 mm, and the top cutting surface was covered with a loose plastic sheet. The specimens were weighed on a balance with accuracy of 0.01 g and a damped towel was used to blot off surface water as the specimen was removed from the water. The mass of specimens was measured at 5 min, 15 min, 30 min, 1 h, 2 h, 4 h and 6 h, respectively.

3 RESULTS AND DISCUSSION

3.1 Water absorption results

The water absorption I is calculated as:

$$I = \frac{m_t}{\rho_w A} \quad (1)$$

where I = the water absorption per unit area (mm); m_t = the cumulative water absorption mass (g); ρ_w =liquid water density (g/mm³); A = the exposed area of specimen (mm²).

The relationship between water absorption I and time square root $t^{1/2}$ are shown in Figure 2. Consistent with the other previous studies (Hall, 1989), the water absorption of concrete with different initial water content increase linearly with time square root during the absorption process, which can be expressed as:

$$I = St^{1/2} \quad (2)$$

where S = the sorptivity of concrete (Hall, 1989) .

And it is obvious that the water absorption rate increases with the initial water content degree (initial internal relative humidity) decreasing, e.g., the sorptivity of oven-dried concrete is 8.5, 5.9 and 4.8 times that of concrete dried in atmospheric environment with relative humidity of 86%, 79% and 67%, respectively. The external water spreads into pore in concrete induced by the capillary force. As the internal relative humidity decrease, the condensed water in the pores with large radius gradually evaporates (Jiang et al., 2019), which means there are more empty pore for concrete with lower internal relative humidity to absorb water and induce a large sorpsivity.

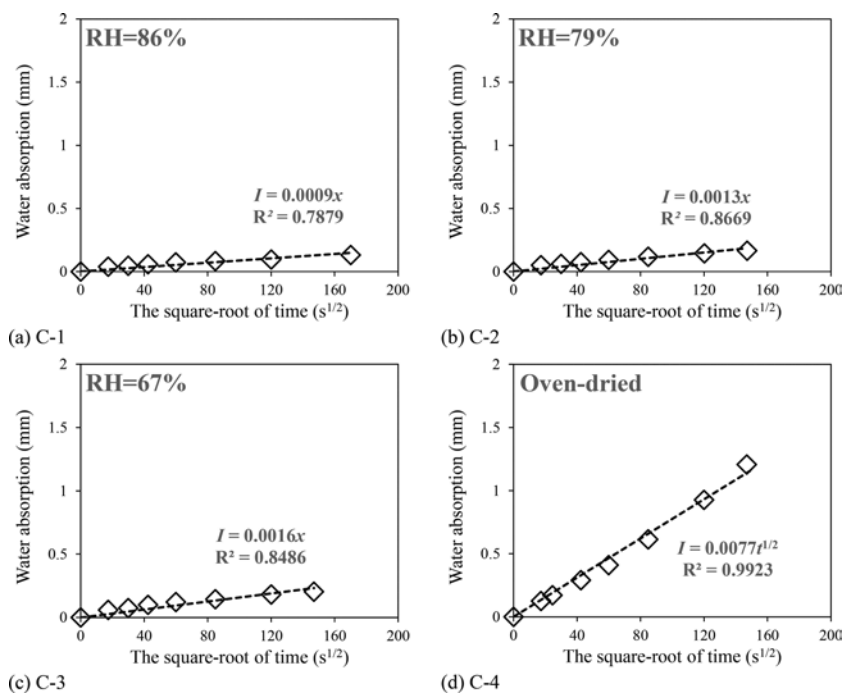

Figure 2. Cumulative water absorption of concrete with different initial water content.

3.2 Predictive model of water absorption

The process water absorption into concrete is controlled by the gravity and the surface tension of the liquid water. Because of the low water absorption height during the tests, the gravity can be neglected and then the Lucas–Washburn equation can be used to evaluate the capillary water absorption process in a cylindrical pore (Zhang et al., 2020):

$$h = \sqrt{\frac{r\gamma\cos\theta}{2\mu}t} \quad (3)$$

where h =height of water absorption (m); r = the radius of the cylindrical pore (m); γ =surface tension of liquid water (N/m), which is related to the absolute temperature T (Ishida et al., 2007):

$$\gamma = 2.66 \times 10^{-4}T^2 + 3.17 \times 10^{-3}T + 94.6 \quad (4)$$

θ =contact angle between the water and pore wall, which can be set as 0 for cementitious materials; μ = viscosity of liquid water (Pa·S) and also depend on the temperature (Ishida et al., 2007):

$$\mu = 3.88 \times 10^{-8}T^4 - 4.63 \times 10^{-5}T^3 + 2.37 \times 10^{-2}T^2 + 5.45T + 470 \quad (5)$$

Assuming that the pores in concrete are cylindrical tubes with different radius and well connected, the water absorption for concrete can be calculated based on Lucas–Washburn and pore size distribution, which is expressed as:

$$I(t) = \frac{1}{\rho_w A} \int_{r_c}^{r_{max}} \varphi \pi r^2 \rho_w \sqrt{\frac{r\gamma\cos\theta}{2\mu}} t p_d(r) dr \quad (6)$$

where φ =the porosity of concrete, which can be determined by:

$$\varphi = \varphi_{cp}(1 - V_a) \quad (7)$$

where φ_{cp} =the porosity of hardened cement paste, which can be obtain by (Zheng and Zhou, 2008):

$$\varphi_{cp} = \frac{\frac{w}{c} - 0.17\alpha}{\frac{w}{c} + 0.32} \quad (8)$$

where α =hydration degree, which is calculated by:

$$\alpha = 0.217 \ln\left(\frac{w}{c}\right) + 0.06 \ln(t_c) + 0.618 \quad (9)$$

where t_c =curing age in days; and $p_d(r)$ = probability density function of the pores, which can be determined by BJH method based on the water vapor sorption isotherms (WVSI) (Xi et al., 1994):

$$W(\text{RH}) = \frac{CkV_m\text{RH}}{(1 - k\text{RH})[1 + (C - 1)k\text{RH}]} \quad (10)$$

where RH=the relative humidity; C , k , V_m =parameter related to material types, and the method to determine these parameter can refer to the reference (Xi et al., 1994); r = radius of pores (m); r_{max} = the maximum radius of empty pore for absorption in concrete (m); r_c = the

critical radius, the evaporation of liquid water would take place when the radius of pore is larger than critical radius (m), which can be expressed as:

$$r_c = -\frac{2\gamma M}{\rho_w RT \ln(\text{RH})} + t_a \quad (11)$$

where M =the mass of water molecular (kg/mol); R = the gas constant (J/K/mol); RH =the relative humidity; t_a =the thickness of adsorbed water (Jiang et al., 2019):

$$t_a = t_0 \ln\left(\frac{-E_{ad} C^{1/3}}{RT \ln(\text{RH})}\right) \text{ (nm)} \quad (12)$$

where $t_0 = 0.191$ nm; E_{ad} = activation energy for adsorption ($E_{ad}=5900$ J/mol); R = gas constant (J/K/mol); T = the absolute temperature (K).

The pores corresponding to the equation (3) are assumed as cylindrical and straight, while the real pores in concrete are tortuous. The tortuosity factor of hardened cement paste can be set as $\pi^2/4$ (Huang et al., 2015). The transport performance of aggregate is much lower than that of cement paste, thus the existing of aggregate in concrete increases the path length of water transport and thus slows down the water absorption rate. The tortuosity factor induced by aggregate is linked to the volume of aggregate, which is proposed as (Shafikhani and Chidiac, 2020):

$$\tau_{\text{agg}} = \frac{3 - V_a}{3(1 - V_a)} \quad (13)$$

where V_a = the total volume fraction of aggregates.

Considering the total tortuosity of concrete, equation (6) is modified as:

$$I(t) = \frac{1}{\rho_w A} \int_{r_{\min}}^{r_{\max}} \frac{\pi r^2 \rho_w}{\tau} \sqrt{\frac{r\gamma \cos\theta}{2\mu}} t p_d(r) dr \quad (14)$$

where $\tau = \tau_{\text{cp}} \cdot \tau_{\text{agg}}$

Furthermore, the connectivity of pores in concrete is complex, e.g., the pore with larger radius may connect to the smaller pores. And the liquid water in large pores in concrete would be entrapped by the connected pores with smaller radius even the relative humidity of concrete decreases to the critical value for evaporation of liquid water in large pore, which is known as the ink bottle effect. The volume fraction of empty pore for water absorption may reduce due to the ink bottle effect, and the probability for large pore occupied by entrapped liquid water can be obtained as (Maekawa, 2008):

$$f_d(r) = \frac{\int_{r_{\min}}^{r_c} p_d(r) dr}{\int_{r_{\min}}^r p_d(r) dr} \quad (15)$$

where r_{\min} =the minimum radius of empty pore for absorption in concrete (m).

Considering the entrapped liquid water in large pore, equation (14) is modified as:

$$I(t) = \frac{1}{\rho_w A} \int_{r_{\min}}^{r_{\max}} [1 - f_d(r)] \frac{\pi r^2 \rho_w}{\tau} \sqrt{\frac{r\gamma \cos\theta}{2\mu}} t p_d(r) dr \quad (16)$$

The comparisons of the mass of water absorption test and calculated method are plotted in Figure 3. It can be found that the predicted water absorption is higher than experimental one with the initial relative humidity of 67%, which might be induced by the randomness of

concrete. But overall, the predicted mass absorption for concrete with different initial water content are close to the experimental results, demonstrating the acceptable accuracy of model predictions.

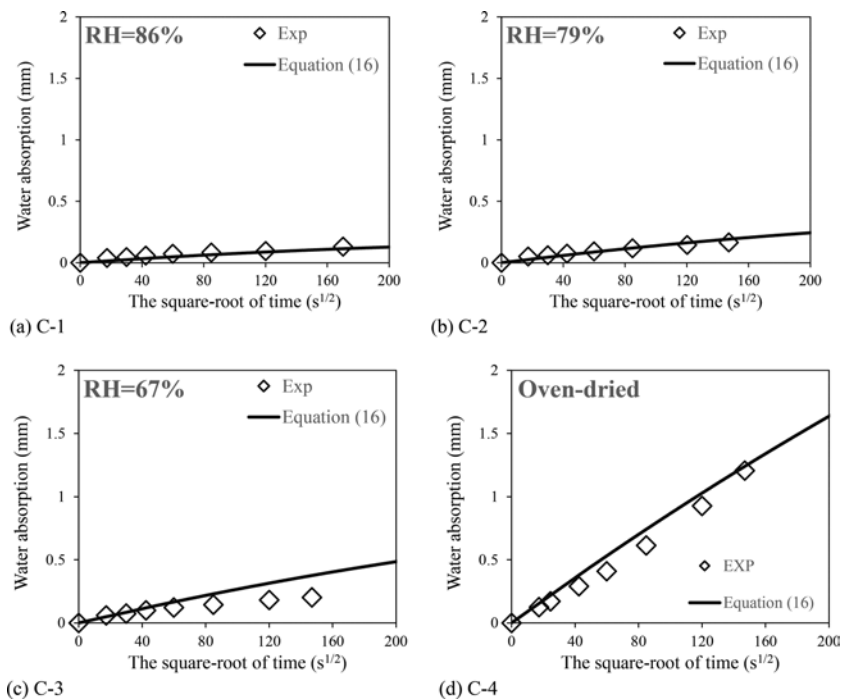

Figure 3. Comparison between calculated and experimental results of water absorption.

4 CONCLUSIONS

In this paper, the effects of initial water contents (initial internal relative humidity) on the water absorption behavior of concrete were studied experimentally and a transport model was established to predict the mass of water absorption. The main conclusions are as following:

The rate of water absorption increases with the initial water content (initial internal relative humidity) decrease. And the sorptivity of oven-dried concrete is 8.5, 5.9 and 4.8 times that of concrete dried in atmospheric environment with relative humidity of 86%, 79% and 67%, respectively.

The predictive model for water absorption was established based on Lucas–Washburn equation, which also considered the tortuosity and ink bottle effect of pores. The tortuosity factor of concrete was defined based on porosity and volume fraction of aggregate, while the ink bottle effect was determined from pore size distribution. And it was found that the predicted absorption masses were in acceptable agreement with experimental results.

Monitoring electrochemical chloride extraction process by testing chloride ion contents in electrolyte

C. Song, C. Jiang & X.L. Gu

Key Laboratory of Performance Evolution and Control for Engineering Structures (Ministry of Education), Tongji University, Shanghai, PR China

ABSTRACT: The monitoring of Electrochemical Chloride Extraction (ECE) of RC structures is crucial for both theoretical study and engineering practice, but the detection process is usually difficult to achieve. In this study, the ECE test was carried out and a method of synchronous monitoring ECE was explored. During the tests, the electrolyte of the ECE system was collected every day for daily chloride extraction monitoring. The outcomes show that the daily extraction content of chloride was high at the beginning (0 – 3 days) but declined and tended to be stable toward the end (after 3 days). The accumulated contents of chloride ions found in the electrolyte are compatible with the differences of total chloride ion contents measured before and after ECE (with a deviation of less than 4.7%), which proved the feasibility of the present method.

1 INSTRUCTION

The popularity of reinforced concrete (RC) constructions has expanded along with the growth of the construction industry. At the same time, long-term service of RC structures will be facing an important issue of durability degradation. When the performance of a structure starts to degrade, it will take the cost of maintenance and repair leading to significant financial losses (Zhang et al. 2018, Zhou et al. 2018). Hence, it is crucial to take action to stop RC structures from corroding and degrading.

An existing RC structures in marine atmospheric environment has a high risk of corrosion and durability degradation caused by chloride ion invasion (Chen et al. 2018, Gu et al. 2020). In order to alleviate the corrosion of steel bars, Electrochemical Chloride Extraction (ECE), which imposes electric fields in concrete cover and hence can effectively discharge chloride ions out of concrete, is a potential strategy to postpone the corrosion initiation.

In ECE process, understanding the chloride extracting progress is crucial for both theoretical study and engineering practice. In a theoretical study, monitoring the ECE progress can help to validate the model and solve the daily chloride discharge (Toumi et al. 2008). In engineering practice, an excessively lengthy power supply will increase the financial cost while an insufficiently short power supply will not remove the chloride completely as intended. In order to balance the rewards of time and cost, the chloride extraction process is suggested to be closely monitored (Song et al. 2022, Castellote et al. 2000).

However, due to the destructive nature of concrete chloride ion testing, it is often not possible to obtain real-time progress of chloride extraction by testing concrete. In this paper, a method for tracking ECE processes is proposed based on monitoring the content of chloride ions in the electrolyte, and the feasibility of the method is verified through experiments.

2 EXPERIMENT

2.1 Materials

The testing objects were cut from concrete blocks exposed to the actual marine atmospheric environment for 9 years in a coastal site in Qingdao of China (36°3' N, 120°25' E) (Zhang et al. 2016). The mix design of concrete is listed in Table 1. Ordinary Portland cement and deionized water were used and water-cement ratio was set as 0.53. ISO standard sand was used as fine aggregates. Figure 1 shows the exposure site and its location. Three concrete blocks (numbered Q32, Q36 and Q50) were selected from the concrete frame as test objects. In order to diversify the distribution of chloride ions in the tests, three blocks with different exposure positions were selected (Q32 – 2nd story with one-sided exposure, Q36 – 2nd story with three-sided exposure, Q50 – 3rd story with three-sided exposure).

Figure 1. Exposure site of a natural marine atmospheric environment in Qingdao of China.

Table 1. Concrete mix proportion.

Cement type	W/C	Cement	Water	Coarse Aggregates	Fine Aggregate
		kg/m ³	kg/m ³	kg/m ³	kg/m ³
P.O 42.5	0.53	368	195	1103	735

The concrete processing method is shown in Figure 2. Only the central area of the windward side (the cube surrounded by red dashed lines) was used for the ECE test. It is considered that the chloride ion in this area (the depth is 50 mm) is a one-dimensional transmission, i.e., the chloride ion content in the same depth is consistent across different points at the windward side.

2.2 ECE process

Figure 3 shows the diagram of electrolytic cell. The specimen is sealed in a plastic pipe to isolate the cathode and anode solution. To achieve complete separation of the cathode and anode electrolyte, epoxy resin was used to fill the space between the pipe and the specimen. Titanium mesh is used as a cathode and anode plate. The system is angled at a 25-degree to the horizontal to avoid ion accumulation in the local area and influence boundary conditions. The sodium hydroxide solution of 0.10 mol/L was used as an electrolyte. A current regulator with a range of 30 V and an accuracy of 0.001 A was utilized to supply a constant current density of 1 A/m² (area of cathode surface).

Figure 2. Concrete processing method.

Figure 3. Electrochemical Chloride Extraction system.

For chloride content monitoring, the electrolytes (both anode and cathode) were renewed every day and the volume of the cathode/anode solution remained constant during daily replacement. When renewing the solution, the electricity was disconnected temporarily. Then, the solution was well stirred with a stirring rod and 100 ml of the solution was taken as a sample. After sampling, replace the previous electrolyte with the new solution and turn on the power once more. The daily discharge of chloride ions from the collected samples will be measured by potentiometric titration.

According to the daily collected chloride ion content samples, the electrochemical chloride extraction process can be terminated at the specified time according to the test intent.

2.3 Chloride profiling

The initial and the after ECE chloride contents inside concrete, as well as the chloride ion contents of the electrolyte samples, were tested by the potentiometric titration method. ZDJ-4B Potentiometric Titrator was used for measurement.

For profiling the chloride distribution of concrete, concrete powder samples were first collected using a milling machine. The mass of the powder at each interval was guaranteed to be at least 25.0 g. Following sampling, the amounts of free and total chlorides in all sources were extracted by water-soluble (distilled water) and acid-soluble (1 mol/L HNO_3) methods, respectively. The chloride ion content was given as a percentage of the mass of the concrete.

The electrolyte samples were directly titrated after acidification treatment, and all chloride titration processes presented in this work followed the guidelines of JGJ/T 322-2013 in China.

3 RESULTS AND DISCUSSION

The daily extracted chloride content of the entire ECE process is shown in Figure 4

The figure shows that even while the specimen's water-cement ratio is constant, under the same current density, the chloride ion extraction rate varies due to different locations on the frame structure. The three samples all displayed a tendency for high discharge rates during the early stages (0 – 3 days), and gradually declining rates during the latter stages (after 3 days).

Figure 4. Daily chloride extraction content (electrolyte).

For model validation, the three ECE processes were all stopped when chloride was not entirely removed. When the daily chloride extracted content was observed to have a significant decrease (After 10 days), the current was cut off. Specimen Q50 was ended after 11 days of power on, specimens Q32 and Q36 were terminated after 16 days of power on.

Figure 5 shows the chloride ion distribution of the three specimens before and after ECE process. Following the ECE process, the free and total chloride ion contents of the three specimens decreased, while the peak of a chloride ion distribution curve showed no visible change. Based on the daily tracking of electrolytes, the goal of monitoring the ECE process has been achieved. Effective monitoring of ECE process can avoid energy waste caused by the prolonged power supply.

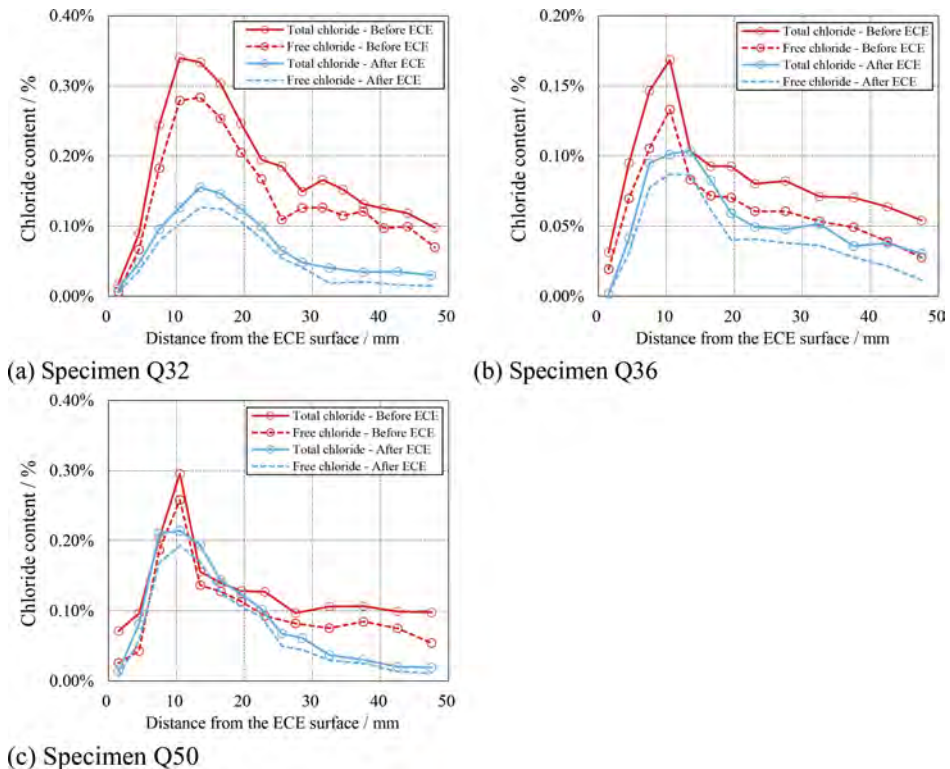

Figure 5. Chloride distribution in concrete before and after ECE.

Figure 6 illustrates the comparison of the chloride remaining content after the ECE process with chloride titrated in the electrolyte. The total chloride ion contents in the electrolyte of the three specimens were closer to the sum of total chloride ion discharge, with deviations of 4.0%, 4.7%, and -1.0%, respectively. Compared with free chloride ions, the discrepancies were -15.5%, -15.6%, and -22.8%, respectively. Overall, the electrolyte's accumulated chloride ion content and the reduction content of total chloride ion in concrete have good consistency. The electrolyte monitoring method can effectively estimate the residual total chloride ion content in concrete.

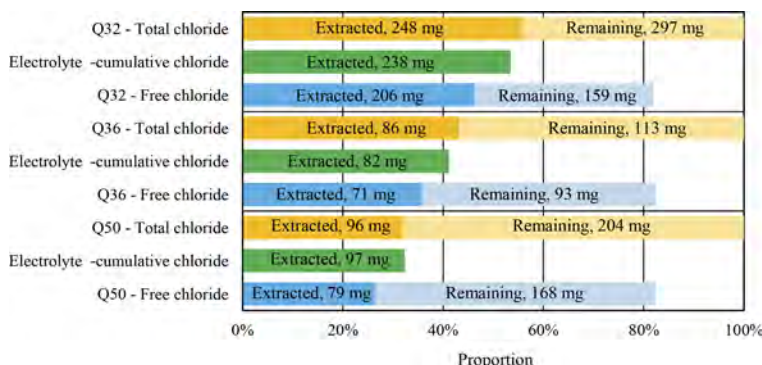

Figure 6. Comparison of chloride extracted in concrete and electrolyte.

4 CONCLUSIONS

In the ECE process of concrete with natural chloride ion intrusion, the daily extraction amount of chloride ions is at its highest during the first 3 days and it decreases after those 3 days.

The error between the total amount of chloride ions extracted from the electrolyte and the actual total amount of chloride ions extracted from the concrete is less than 4.7%, demonstrating that the ECE process tracking method by monitoring the electrolyte works is good.

ABSTRACT: Shape memory alloy (SMA) has shown great promise in retrofitting of aged infrastructure because it could be employed to conveniently apply prestress. However, the stress recovery behavior of iron-based SMA (Fe-SMA) has not been fully understood. This study presents an experimental study on Fe-SMA subjected to multi-activation. Eight specimens were prepared and loaded by two million cyclic loading simultaneously with thermal scenarios. Afterward, they were re-activated up to four times. Lost recovery stress due to fatigue was pronouncedly retrieved by reactivation. In addition, the Fe-SMA samples after fatigue loading could be reused to provide prestress for other applications but the count for reusability was limited. This study explores functional-fatigue behavior of the material and provides some useful suggestions for the strengthening technique.

1 INTRODUCTION

Shape memory alloy (SMA) is an alloy that can be deformed when cold but returns to its pre-deformed (“remembered”) shape when heated, which is called shape memory effect (SME). In addition, it is also recognized as superelastic, which means an alloy can return to its initial state after unloading even if the deformation is very large. Initially widely explored and adopted in aerospace engineering (Hartl & Lagoudas 2007, Barbarino et al. 2014) and medical devices (Song 2010, Morgan 2004), SMA materials nowadays are attracting more attention in the community of civil engineering. They are employed in fields of self-centering and energy dissipation as well as prestress strengthening (Jani et al. 2014, Huang et al. 2020, Czaderski et al. 2014, Rojob & El-Hacha 2018, Izadi et al. 2018). They could be employed to conveniently apply prestress and the recovery stress indicates the stress generated in SMA after the activation process. In comparison with nickel-titanium (NiTi-SMA), iron-based SMA (Fe-SMA) is relatively new and less understood. It has a lower price and wider temperature hysteresis (Cladera et al. 2014).

Lee et al. (2013) conducted a series of fatigue tests on Fe-SMA samples and found that major decline in recovery stress was witnessed in the first cycle. When subjected to cyclic loading with a strain range of 0.070%, the initial 2×10^2 cycles resulted in 11% reduction in the recovery stress, nevertheless only 5% further decrease was witnessed in the followed 2×10^4 cycles (Hosseini et al. 2018, Ghafoori et al. 2017). Loss of the recovery stress due to fatigue was retrieved by a second activation (Hosseini et al. 2018). In addition to fatigue loading, it was demonstrated that thermal loading also showed detrimental effect on the recovery stress. The recovery stress was dramatically declined from 350 to 156 MPa when temperature was increased from -20 to 60 °C in Lee et al. (2013).

This paper presents an experimental study on the stress recovery behavior of Fe-SMA subjected to multi-activation. Fe-SMA samples were under fatigue (strain ranges of 0.035% and 0.070%, two million cycles) and thermal loading (room temperature (RT), $-20\text{ }^{\circ}\text{C}$, $60\text{ }^{\circ}\text{C}$, -20 to $60\text{ }^{\circ}\text{C}$) followed by multi-activation up to four times. Eventually, the strips were monotonically loaded to failure to monitor variation in the machinal properties.

2 EXPERIMENTAL PROGRAM

Eight dog-bone shaped specimens were prepared and tested under fatigue followed by multi-activation. The experimental work was conducted at the Key Laboratory of Performance Evolution and Control for Engineering Structures (Tongji University).

2.1 Materials and specimens

The Fe-SMA strips were provided in rolls by the refer-AG in Switzerland. Tensile coupon test samples were prepared according to AS 1391 (2007) and are illustrated in Figure 1. Two holes were made at both ends of the specimen for connection to the actuator with the extension rods in the environmental chamber.

Figure 1. Specimen geometry and dimensions (unit in mm, not to dimension).

2.2 Test set-up

The SMA samples were first activated according to the strategy explored by the authors in the preliminary study (Gu et al. 2021), i.e., pre-strain of 8%, activation temperature of $350\text{ }^{\circ}\text{C}$ and preload of 50 MPa. The corresponding recovery stress ranged from 413 to 436 MPa. Afterward, fatigue and thermal loading were first applied to the SMA samples before multi-activation. The tests were conducted using a servo-hydraulic uniaxial testing machine (maximum loading capacity of 100 kN). Additionally, a Mechanical Testing & Simulation (MTS) furnace (Figure 2a) was employed to carry out the test at $60\text{ }^{\circ}\text{C}$, and an MTS environment chamber (Figure 2b) was selected to perform the test at $-20\text{ }^{\circ}\text{C}$ and cyclic temperature (-20 to $60\text{ }^{\circ}\text{C}$).

All the specimens after cyclic loading were reactivated by multiple times to explore the functional fatigue of the Fe-SMA and consequently potential reuse of the material. It has been reported that the prestress generated by Fe-SMAs declines as a result of creep/relaxation under fatigue (Hosseini et al. 2018, Ghafoori et al. 2017). Therefore, the second activation (the first activation referred to the original one before fatigue) was conducted in the present study to investigate retrievability of the lost prestress. In addition, considering the sustainable development, it is worthwhile to investigate whether the Fe-SMA could be recycled and reused, i.e., the functional fatigue of the material (Eggeler et al. 2004). Hence, after the second activation, the specimens were unloaded and then pre-tensioned again for the following activations. Preliminary tests with an initial preload of 50 MPa were conducted and the stress declined continuously to 0 MPa during the heating process and increased to ~ 50 MPa in the cooling

Figure 2. Test set-up.

process, indicating no SME but only thermal expansion and contraction (Gu et al. 2021). In order to promote SME of the Fe-SMA, a higher level of preload of 150 MPa was adopted. When the stress declined to 0 MPa, the test was halted to avoid compression in the test apparatus. With a larger preload, a higher heating temperature could be reached, which may activate SME. This step was repeated several times to find the upper limit of the reusing times. If the increased stress after heating and cooling was lower than 50 MPa, the re-activation test was stopped.

After the multiple activation tests, the specimens were monotonically loaded to failure at 1 mm/min. The initial elastic modulus, 0.2% yield strength, ultimate strength, and elongation at break were recorded.

3 RESULTS AND DISCUSSION

3.1 Multi-activation of the Fe-SMA

Table 1 summarizes the program and results of multiple activation tests. The specimen nomenclature is as follows: 0.035 and 0.070 represent two cyclic strain ranges (0.035% and 0.070%) adopted in the experimental program; the final letters R, L, H and C denote the four scenarios of thermal loading, i.e., room temperature, low temperature of $-20\text{ }^{\circ}\text{C}$, high temperature of $60\text{ }^{\circ}\text{C}$, cyclic temperature from -20 to $60\text{ }^{\circ}\text{C}$.

The cyclic strain ranges are commonly used in fatigue tests of retrofitted steel structures (Hosseini et al. 2017, Yu et al. 2013, Aljabar et al. 2017). Because the maximum frequency of strain-control fatigue for the test equipment could only reach 2 Hz, which was much lower than the expected test frequency (20 Hz), equivalent stress-control fatigue loading was applied to each specimen for two million cycles. The stress ranges corresponding to strain ranges of 0.035% and 0.070% were 57 MPa and 114 MPa, respectively, according to the initial elastic modulus of 162 GPa of the SMA strip. In the cases with constant temperatures, the loading frequency was set as 20 Hz. In the case with cyclic temperature, a loading frequency of 12 Hz was adopted to match the temperature variation (Chen et al. 2023).

In Table 1, the 1st activation indicates the original one before fatigue. The 2nd to 4th activations were adopted to investigate the recoverability of the lost prestress due to fatigue. By comparing the recovery stress after the 1st activation and the initial preload before the 2nd activation, it was found the recovery stress slightly decreased after fatigue and thermal loading, with the reduction percentage ranging from 1.4 to 27.8%. The higher fatigue loading histories exhibited a more detrimental effect.

Table 1. Program and results of multiple activation tests.

Specimen	Fatigue loading range (MPa)	Test temperature (°C)	The 1 st activation			The 2 nd activation			The 3 rd activation			The 4 th activation		
			Initial preload (MPa)	Maximum heating temperature (°C)	Recovery stress (MPa)	Initial preload (MPa)	Maximum heating temperature (°C)	Final stress (MPa)	Initial preload (MPa)	Maximum heating temperature (°C)	Final stress (MPa)	Initial preload (MPa)	Maximum heating temperature (°C)	Final stress (MPa)
F-0.035-R	57	RT	56	362	413	365	388	393	150	143	220	151	103	149
F-0.035-L	57	-20	54	353	423	470	463	470	148	150	252	151	93	170
F-0.035-H	57	60	51	356	436	341	381	402	150	174	247	150	114	168
F-0.035-C	57	-20 ~ 60	53	353	421	368	439	452	150	153	259	150	102	185
F-0.070-R	114	RT	54	353	417	327	413	414	150	144	233	149	103	168
F-0.070-L	114	-20	51	353	427	421	466	473	150	159	249	150	106	157
F-0.070-H	114	60	53	352	428	309	288	352	150	117	200	149	112	194
F-0.070-C	114	-20 ~ 60	53	354	427	329	421	438	149	155	238	151	97	164

During the 2nd activation, the stress first declined remarkably with the increase of temperature due to thermal expansion. As temperature increased, ϵ -martensite was gradually transformed to γ -austenite, leading to the SME effect. When the stress decreased to 10 MPa, the heating process was halted in case of compression. The corresponding temperature was recorded as the maximum heating temperature (Table 1). When the temperature returned to RT, the stress gradually increased regardless of the loading histories. The recovery stress lost due to creep/relaxation was noticeably retrieved. Four specimens were witnessed a higher recovery stress in comparison with that after the original activation, among which the specimen F-0.070-L displayed a maximum improvement of 11%. However, a second recovery stress of 352 MPa, which was 17% lower than its original level, was achieved in the specimen F-0.07-H.

More activation procedures were tried to explore the functional fatigue and potential reuse of the Fe-SMA. Figure 3 plots the stress recovery behavior during the 3rd and 4th activation procedures. In Figures 3a and 3b, the curves first declined and then became less steep due to SME. However, in Figures 3c and 3d, the decreased rates of all the curves seemed to be stable. When the temperature cooled to RT, stress of the specimens reached to 200–260 MPa in the 3rd activation (Table 1) while that in the 4th activation attained 150–200 MPa (Table 1). It was, therefore, believed that slight SME existed in the 4th activation. Based on the limited test results, the functional fatigue of Fe-SMA investigated in the present study was restricted to three times.

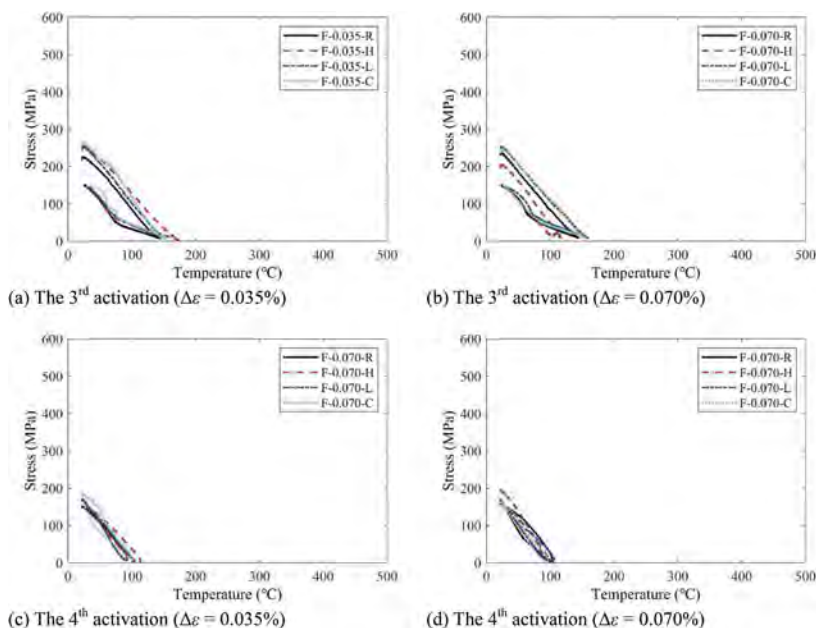

Figure 3. Stress recovery behavior after multiple activation.

3.2 Tensile behavior after multi-activation

After fatigue and thermal loading, as well as multi-activation, tensile behavior of the samples was tested and is compared with that of the as-received Fe-SMA in Figure 4. Regardless of temperature variation and fatigue strain ranges, all the specimens with loading histories exhibited similar mechanical properties (i.e., initial elastic modulus, 0.2% yield strength and ultimate strength). At the elastic stage, all the curves seemed to follow the same path. When reaching into the plastic phase, the specimens after fatigue and multi-activation presented a higher stress level than the as-received Fe-SMA. The averaged 0.2% yield strength and ultimate strength of the specimens after fatigue and multi-activation are 522 MPa and 961 MPa, which are both 6.3% higher than the corresponding values tested at RT, respectively.

The slight enhanced mechanical property may be relevant to the 4th activation, where no SME was observed, and therefore more stress-induced ϵ -martensite existed in the samples. In comparison with γ -austenite, ϵ -martensite led to a more pronounced strain hardening and higher tensile strength (Frommeyer et al. 2003). Therefore, the stronger mechanical properties were witnessed in the samples after fatigue and multi-activation. In terms of the elongation at break, the average value of the specimens after fatigue and multi-activation was 36.8%, slightly higher than that tested at RT. Hoessini et al. (2018) also tested the mechanical property of Fe-SMA after multi-activation, where the Fe-SMA experienced first activation, first cyclic loading, second activation and second cyclic loading. The ultimate tensile strength and elongation were similar to the as-received specimen and therefore, indicating no damage induced to the Fe-SMA in the activation or cyclic loading. However, in the present study, a higher mechanical property was witnessed in the specimens after multi-activation. The different findings may be resulted from the times of activation. Since no SME existed in the 4th activation, larger amount of stress-induced ϵ -martensite left in the sample and led to better mechanical properties.

Figure 4. Tensile behavior of as-received Fe-SMA and those after fatigue and multi-activation.

4 CONCLUSIONS

This study presents an experimental study on Fe-SMA subjected to multi-activation. Fatigue and thermal loading applied to Fe-SMA samples led to reduction in recovery stress of 1.4 – 27.8%. Loss in the recovery stress was pronouncedly retrieved by reactivation, which demonstrated promise in life-cycle maintenance of infrastructure. The Fe-SMA samples after service loading could be reused to provide prestress for other applications but the count for reusability was limited. The machinal properties of the Fe-SMA after fatigue and thermal loading, as well as multi-activation remained approximately the same.

ACKNOWLEDGEMENTS

This study was supported by the National Natural Science Foundation of China (Project No. 52222803). We also thank re-fer AG in Switzerland for providing Fe-SMA materials.

SMFL-based probability distribution of minimum cross-sectional areas of corroded steel bars

J.L. Qiu, W.P. Zhang & Q.Q. Yu
Tongji University, Shanghai, China

Z.P. Chen
Guangxi University, Nanning, China

ABSTRACT: In this study, a non-destructive quantitative characterization method for the probability distribution of minimum cross-sectional areas of corroded steel bars was proposed based on the dynamic linkage mechanism of the induced magnetic and self-magnetic flux leakage fields variation of steel bars. The experiment data of 28 corroded steel bars were employed to verify this method. The results indicate that the quantitative self-magnetic flux leakage variation ratio dH had a linear correlation with the cross-sectional area unevenness degree dS_n with a ratio of about 1. Based on the index dS_n and cross-sectional area ratio K that obey the Weibull distribution and Gamma distribution, respectively, the probability distribution of minimum cross-sectional area S_{\min} in a certain segment of corroded steel bars can be confirmed.

1 INTRODUCTION

Suffering from an aggressive environment, the steel bars of reinforced concrete (RC) structures inevitably corroded, resulting in a substantial reliability reduction (Bojórquez, Ponce, Ruiz, et al, 2021). Some structural reliability assessment method of corroded RC structures is well-established, such as the out-crossing rate method (Veneziano, Cornell, & Grigoriu, 1977), the first-order reliability method (Frangopol, Lin, & Estes, 1997), the time-series method (Kaminski, 2013), the probability density function method (Akiyama, Frangopol, & Ishibashi, 2020; Li, & Chen, 2009), and the equivalent limit performance function-based method (Guo, Dong, Gardoni, & Gu, 2021). However, these reliability assessment methods still have difficulties in establishing and solving mathematical models.

To avoid complex math problems, the Monte Carlo simulation (MCS) method is widely employed (Stewart, & Al-Harthy, 2008; Zhang, Song, Lim, Akiyama, & Frangopol, 2019). The calculation accuracy of the MCS method relies on the accurate probability distributions of the corroded rebar's cross-sectional area, which can be characterized by the cross-sectional area spatial heterogeneity factor R well (Bojórquez, Ponce, Ruiz, Bojórquez, Reyes-Salazar, Barraza, ... & Baca, 2021; Zhang, Zhou, Gu, & Dai, 2014; Gu, Guo, Zhou, Zhang, & Jiang 2018). However, factor R may not be suitable for a specific in-service RC structure. Corrosion of steel bars will cause self-magnetic flux leakage (SMFL) field variation that is linearly related to the corrosion degree, which is an effective method to characterize the exact corrosion characteristics of steel bars non-destructively (Zhang, Li, Zhou, Tong, & Xia, 2023; Huang, Dong, Fu, Qiu, Liu, Li, & Che, 2022; Qiu, Zhang, Zhou, & Zhang, 2021). Furthermore, the SMFL-based steel corrosion assessment is independent of stochastic corrosion processes (Qiu, Zhou, Zhao, Zhang, & Liao, 2020), and thus the enormous statistical work for the probability distributions of R could be avoided.

In this study, the linear correlation between the corrosion unevenness degree and the SMFL field variation ratio of the corroded rebars was revealed. Then, the SMFL-based probability distribution of minimum cross-sectional areas of corroded steel bars was established.

2 THEORETICAL BASIS

The corrosion-induced SMFL field variation can be theoretically analyzed based on the magnetic dipole theory (Shi & Zheng, 2016; Dutta, Ghorbel, & Stanley, 2009). In general, steel bars are uniformly magnetized in the longitudinal direction (X-direction), that is, $M_x = \text{constant}$, $M_y = 0$, and $M_z = 0$ (Qiu, Zhang, Zhou, & Zhang, 2021), as shown in Figure 1. Based on the minimum magnetic free energy principle, the longitudinally magnetized steel bar with a V-shaped corrosion defect has magnetic charges uniformly distributed on the circular ridge-lines, as shown in Figure 1. The linear distribution densities of magnetic charges are:

$$\rho_{s1'} = \frac{r}{2} M_x, \quad \rho_{s2'} = -\frac{d}{2} M_x, \quad \rho_{s3'} = \frac{d}{2} M_x, \quad \rho_{s4'} = -\frac{r}{2} M_x \quad (1)$$

According to Coulomb's law of magnetism and Figure 1, the x , y , and z components of SMFL field \mathbf{H}_S and induced magnetic field \mathbf{H}_I could be obtained. For example, the x component of \mathbf{H}_S and \mathbf{H}_I are:

$$\begin{cases} H_{Sx} = \frac{dM_x}{8\pi\mu_0} f_1(x, y, z, w, r) \\ H_{Ix} = \frac{M_x}{8\pi\mu_0} f_2(x, y, z, l, r) \end{cases} \quad (2)$$

where $f_1(x, y, z, w, r)$ is a function of x, y, z, w, r , and $f_2(x, y, z, l, r)$ is a function of x, y, z, l, r .

Based on the H_{Sx} and H_{Ix} components, a quantitative index I for the cross-sectional corrosion degree that is not affected by M_x can be constructed:

$$I = \frac{T_1(H_{Sx})}{T_2(H_{Ix})} = d \frac{T_1[f_1(x, y, z, w, r)]}{T_2[f_2(x, y, z, l, r)]} = d \cdot f_3(x, y, z, w, l, r) \quad (3)$$

where $T_1(-)$ and $T_2(-)$ are two primary factors extracted from the H_{Sx} and H_{Ix} curves, and $f_3(x, y, z, w, l, r)$ is a function of x, y, z, w, l, r .

3 THE EXPERIMENT DETAILS

3.1 The corroded steel bar specimens

As shown in Figure 2(a), the corroded rebar specimens were taken from a longitudinal girder of a wharf bridge that naturally corroded in the marine environment for 26 years. The marine-atmosphere zone steel bars at the top of the girder are barely corroded, while the tidal zone steel bars at the bottom of the girder are severely corroded. Both the top and bottom longitudinal steel bars of the girder were taken out and cut into 1000 mm long short specimens. The

original naturally corroded steel bar specimens were numbered S-NC-1 - S-NC-22, and the loose corrosion products on their surface were cleaned with a plastic brush and clean water. The middle 750 mm regions of 6 original uncorroded steel bar specimens numbered S-AC-1 - S-AC-6 were corroded by the applied-current method (Li, Dong, He, Fu, & Jin, 2022) with random corrosion duration to obtain uneven corrosion morphologies.

3.2 The 3D structural light scanning of the corrosion morphology

As shown in Figure 2(b), the accurate corrosion morphologies of all specimens were obtained using 3D structured light scanning with an accuracy as high as 0.02 mm. First, the structured light projector continuously projects several specific blue fringe patterns onto the corroded steel bar, which are distorted by the uneven corrosion morphology and then captured by the camera. According to the camera geometry model and the triangulation principle, the partial surface point cloud of the steel bar containing some mark points can be obtained based on these distorted blue fringe patterns. Finally, by identifying the mark points, the multiple surface region point clouds can be accurately merged into a complete surface point cloud, based on which the surface and solid models of the corroded steel bar can be obtained.

3.3 The SMFL field scanning

As shown in Figure 2(c), the TSC-7M-16 micro-magnetic scanner with an accuracy of 0.1 A/m was used to scan the SMFL field of all specimens. The scanning trolley equipped with a displacement pedometer moves along the longitudinal scanning path directly above the corroded steel bar, while the micro-magnetic sensors on the trolley detect the SMFL field variation. With a displacement interval of 1 mm, the displacement and the corresponding SMFL field data were recorded by the host. The vertical distance between the micro-magnetic sensors and the upper surface of the corroded steel bar is defined as the lift-off height (LFH). The value of LFH was taken as 5, 10, 30, 50, and 100 mm in this study, where 30 mm equals the concrete cover thickness of the common RC structure.

4 RESULTS AND DISCUSSION

4.1 The cross-sectional area and SMFL field variation of the corroded rebars

The experimental results of the cross-sectional area S and SMFL field components H_x and H_z of a typical naturally corroded specimen S-NC-8 are shown in Figure 3(a). The sharp peaks and fluctuations of the S curve indicate the position of the stirrups and the uneven corrosion morphology, respectively. The fluctuations of the H_x and H_z curves indicate the SMFL field variation induced by the uneven corrosion morphology. However, H_x and H_z curves only reveal limited information about uneven corrosion.

To further explore the relationship between SMFL field variation and uneven corrosion, the simulated quantitative SMFL variation degree $N-\Delta H_{SA}$ in Figure 3(b) is defined according to the definition of index I in Equation (3):

$$N-\Delta H_{SA} = \frac{\Delta H_{SA}}{H} = \frac{[H_x]_{SG} - [H_x]_{AAV}}{\sqrt{H_x^2 + H_z^2}}, \quad i \in [0, H] \quad (4)$$

where $[H_x]_{SG}$ and $[H_x]_{AAV}$ are the SG smoothing ($n = 2$ and $m = 5$) (Savitzky, & Golay, 1964) and the AAV smoothing ($m = 50$) (Simonoff, 2012) results of the H_x component, respectively.

As shown in Figure 3(b), the $N-\Delta H_{SA}$ curves reflect the uneven corrosion-induced SMFL field variation better compared with the original SMFL field curve. In addition, the SMFL fields' total strength H and the component H_z can also be used to calculate $N-\Delta H_{SA}$. To establish a more intuitive quantitative relationship between SMFL field variation and uneven corrosion, the SMFL field variation ratio dH , the corrosion unevenness degree dS_n , and the cross-sectional area ratio K are defined as shown in Figure 3(b). Using the $N-\Delta H_{SA}$ and S curves of each specimen, several dH and the corresponding dS_n and K can be obtained, which satisfies the:

$$S_{\min} = \left[1 - \frac{dS_n}{K + 1} \right] \cdot S_{\text{ave}} \quad (5)$$

where S_{\min} is the minimum cross-sectional area of a certain segment of the corroded steel bar.

Figure 3. (a) The cross-sectional area S and experimental SMFL field components H_x and H_z of specimens S-EC-8, and (b) the geometric factors used to define indices dH , dS_n , and K .

4.2 The probability distributions of indices dS_n and K

According to Equations (4)-(5) and the data of S and total SMFL field strength H of all the specimens, dH and its corresponding dS_n and K were obtained. For brevity, only data of LFH = 30 mm are given as an example, as shown in Figure 4. The experimental result shows a clear linear correlation between dS_n and dH , which indicates the corrosion-induced cross-sectional area reduction leads to the proportional SMFL. In addition, this correlation is not affected by differences in SMFL field strength, cross-sectional area, and corrosion degree. Both the

experimental and simulated K are distributed in the interval $[0.25, 4.0]$, and most of the data points are concentrated around 1.0.

Figure 4. The experimental and simulated results of dS_n and K with LFH = 30 mm.

Probability distribution statistics and analysis of dS_n and K are further implemented based on the nonparametric kernel density estimation (KDE) method (Zhang, Yu, Liu, Dong, Li, Zang, & Xu, 2022). KDE is based on the sample points in Figure 4, and the Gaussian kernel function and the default optimal window width are used.

First, the probability density of dS_n is estimated. The range of the experimental dH is divided into 11 intervals, and then the probability density of dS_n of each dH interval is estimated using the KDE method one by one. Then, the complete probability distribution of dS_n is obtained by combing these KDE results, as shown in Figure 5(a). The Kolmogorov-Smirnov method is used to test the distribution type of dS_n in each dH interval, and the test results show that at the 95% confidence level, dS_n of all dH intervals obey the Weibull distribution:

$$f(x; \lambda, k) = \begin{cases} \frac{k}{\lambda} \left(\frac{x}{\lambda}\right)^{k-1} \exp\left(-\left(\frac{x}{\lambda}\right)^k\right), & x > 0 \\ 0, & x < 0 \end{cases} \quad (6)$$

where λ and k are two parameters of Weibull distribution.

As shown in Figure 5, the distribution parameters λ and k of dS_n of each dH are approximately linearly and inversely proportional correlated with dH , respectively, and thus λ and k are fitted. Then, the fitting results of λ and k are substituted into Equation (5) to acquire the fitted Weibull distribution of dS_n as shown in Figure 5(b). The fitted Weibull distribution is similar to the KDE result, which indicates the potential of the Weibull distribution to determine the probability density distribution of dS_n .

Second, the probability density of K is estimated. According to trial calculation, it is found that the probability distribution estimation of $(K - 0.25)$ is more feasible than that of K . The probability distribution estimation of $(K - 0.25)$ is the same as that of dS_n . As shown in Figure 6(a), the change of LFH has no significant influence on the form and magnitude of the probability distribution of $(K - 0.25)$. However, as shown in Figure 6(b), the probability distribution of $(K - 0.25)$ shows a local mutation that includes 90.1% of the data volume with the increase of dH . Therefore, the influence of dH on the probability distribution of $(K - 0.25)$ needs to be considered. The complete KDE probability distribution of $(K - 0.25)$ is shown in Figure 6(c). The Kolmogorov-Smirnov method is also used to test the distribution type of $(K - 0.25)$, and the test results show that at the 95% confidence level, $(K - 0.25)$ of all intervals obey the Gamma distribution:

$$f(x; \alpha, \beta) = \begin{cases} \frac{1}{\beta^\alpha \Gamma(\alpha)} x^{\alpha-1} \exp\left(-\frac{x}{\beta}\right), & x > 0 \\ 0, & x < 0 \end{cases} \quad (7)$$

where α and β are two parameters of Gamma distribution.

As shown in Figure 6(d), the fitted probability density distribution of $(K - 0.25)$ is similar to the KDE result, which indicates that it is appropriate to use the Gamma distribution to

Figure 5. The (a) KDE result and (b) fitted Weibull distribution of dS_n with LFH = 30 mm.

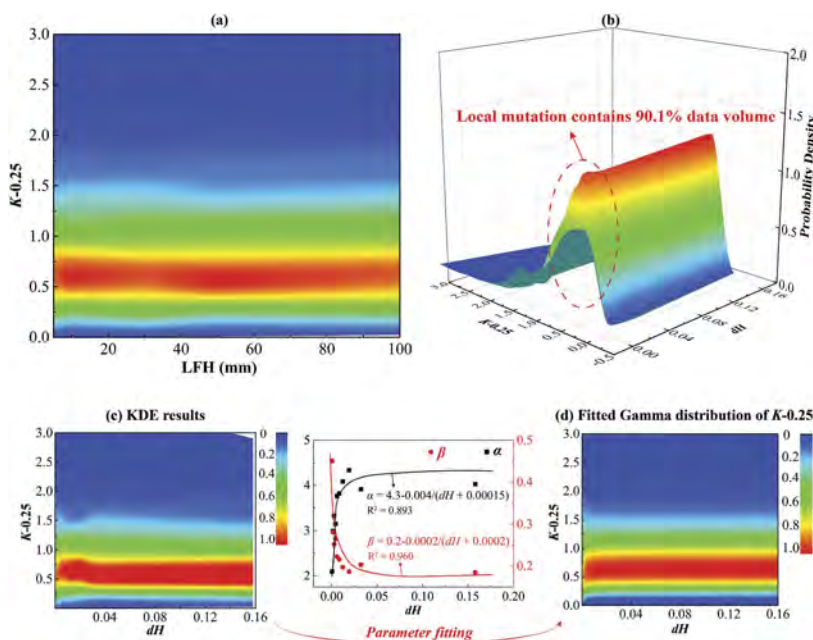

Figure 6. The effects of (a) LFH and (b) dH on $(K - 0.25)$, the (c) KDE result, and (d) fitted Weibull distribution of $(K - 0.25)$ with LFH = 30 mm.

determine the probability density distribution of $(K - 0.25)$. According to Equation (5), Figures 5 and 6, the probability density distribution of S_{min} can be determined.

5 CONCLUSIONS

The corrosion unevenness degree dS_n and cross-sectional area ratio K of the corroded rebar obey the Weibull distribution and the Gamma distribution at the 95% confidence level, respectively, based on which the probability density distribution of the minimum cross-sectional area S_{min} of the corroded steel bar can be established.

Reliability analysis considering epistemic uncertainties with small initial sample and successive updating data

Yi-hua Fei, You-bao Jiang, Yu Leng & Lei Wang

School of Civil Engineering, Changsha University of Science and Technology, Changsha, China

Zheng Chen

School of Civil Engineering and Architecture, Guangxi University, Nanning, China

ABSTRACT: In structural engineering, the epistemic uncertainties of random variables, including distribution parameters and distribution type uncertainties, usually exist due to initial data scarcity. Moreover, the data will be updated over time, which causes the structural reliability updating. In this paper, for the initial data scarcity and successive data updating cases, a random variable model is developed to quantify the uncertainties of distribution parameter and distribution type based on the Bootstrap method, Akaike information criterion and Bayes update method. Considering the epistemic uncertainties, the reliability index of structure becomes a random variable and its probability density function (PDF) is presented. The numerical results show that the variability of the distribution parameters gradually decrease as the data update, and so does the variability of the reliability index. The PDF of the reliability index with the uncertainties of both distribution parameters and distribution type is largely different from that with only the uncertainty of distribution parameters.

1 INTRODUCTION

There are many uncertainties in engineering structures (Enright & Frangopol 1998, Li et al. 2015). And these uncertainties can be divided into aleatory uncertainties and epistemic uncertainties (Kiureghian & Ditlevsen 2007, Wang & Roger 2021, Jiang et al. 2020). The former is objective and its uncertainty cannot be reduced, and the latter is due to incomplete knowledge and data scarcity and so on and its uncertainty can be reduced with the deepening of cognition (Kiureghian & Ditlevsen 2007).

The aleatory uncertainty has been intensively and extensively studied in the past few decades, however the studies regarding the epistemic uncertainty are relatively less. In engineering, aleatory uncertainty is usually described by a deterministic probability distribution function. While for epistemic uncertainty, it can usually be characterized and quantified by using fuzzy models (Moens & Vandepitte 2002) and non-probabilistic methods such as interval analysis and convex set theory (Ben-Haim 1994, Elishakoff & Elisseff 1994). Many probabilistic methods have also been developed in recent years to quantify epistemic uncertainty. For example, an engineering design parameter usually has the distribution parameters and distribution type uncertainty due to data scarcity. In view of this, Most et al. (Most & KNABE 2010) employed the Bootstrap method to model the variability of the mean and standard deviation of soil shear strength parameters and their influences on the reliability of foundation bearing capacity. Sankararaman et al. (Sankararaman & Mahadevan 2013) used the likelihood method to model the distribution parameters as random variables, and pointed out that the distribution type also has uncertainty due to data scarcity. From the above, the uncertainty of distribution parameters and distribution type usually exist with small samples, but it is considered less in the data updating for the current reliability methods.

In this paper, the epistemic uncertainty is unified in the probabilistic framework with the aleatory uncertainty. For the cases of small initial sample size and subsequent data updates, a model is developed to quantify the uncertainties of distribution parameter and distribution type based on the Bootstrap method, Akaike information criterion (AIC) and Bayes update method. First, the initial

samples are sampled by the Bootstrap method to obtain the prior distribution of the distribution parameters, and then the prior distribution of the distribution type is obtained with the aid of AIC. Then the posterior distribution after the data updates is obtained by the Bayes update method. Herein the distribution parameters are considered as continuous random variables and the distribution type is considered as discrete random variables. Next, a reliability analysis was performed to investigate the effects of uncertainty in the distribution parameters and distribution types on the conditional reliability index (Based on Bayesian statistical theory, the traditional reliability index are defined as conditional reliability index (CRI) (Kiureghian 1989)). Finally, the practicality and validity of the proposed method is demonstrated by example analysis.

2 EPISTEMIC UNCERTAINTY QUANTIFICATION METHODS

2.1 Bootstrap method

The Bootstrap method (EFRON 1979) is usually applied for random sampling with put-back of the initial test data to obtain information on the epistemic uncertainty of the distribution parameters. The method can obtain a large amount of new data with the characteristics of the original test data by sampling when the actual test data are relatively sparse. So it is an effective way to quantify epistemic uncertainty under small sample conditions.

2.2 Akaike information criterion

For the distribution types, the AIC (Akaike information criterion) (AKAIKE 1974) is often used in engineering to identify the optimal distribution type by comparing the AIC values corresponding to each distribution type. The distribution type corresponding to the smallest AIC value is considered to be the optimal distribution type.

In this section we can identify the optimal distribution type by comparing the AIC values corresponding to each distribution type calculated for each Bootstrap subsample, with each subsample corresponding to an optimal distribution type. And the uncertainty of the distribution type can be characterized by this method by calculating the number of times that different distribution types are identified as the optimal distribution among 10,000 Bootstrap subsamples. And then we divide the number of times by 10,000 as a priori probability of distribution type.

2.3 Bayes update method

For the distribution parameters, let D_1 and D_2 denote the initial data and the updating data of the random variable Θ , respectively. Also, the probability density function obtained by statistical inference from D_1 is $p_{\Theta}^{(1)}(\theta|\zeta_1)$, where ζ_1 is the distribution parameter obtained from the statistical analysis of the data D_1 . If there is epistemic uncertainty in this analysis process, i.e., ζ_1 is inherently uncertain. In general, the prior distribution $p_{\zeta}(\zeta)$ of ζ_1 is artificially assumed. But in this paper, this prior distribution is given based on the Bootstrap method. The posterior distribution of the distribution parameters is obtained by the Bayes update method when the additional updating samples D_2 are introduced:

$$p_{\zeta}(\zeta|D_2) = \frac{L(D_2|\zeta)}{\int L(D_2|\zeta)p_{\zeta}(\zeta)d\zeta} \cdot p_{\zeta}(\zeta) \quad (1)$$

where $L(\cdot)$ is the maximum likelihood function, with.

$$L(D_2|\zeta) = \prod_{i=1}^{n_2} p_{\Theta}^{(1)}(\theta_i|\zeta) \quad (2)$$

where, n_2 denotes the number of new updated data.

And for the distribution type, the Bayes formula for discrete random variables should be considered, i.e:

$$P(A_i|D_2) = \frac{P(A_i) \cdot P(D_2|A_i)}{\sum_{i=1}^n P(A_i) \cdot P(D_2|A_i)} \quad (3)$$

where A_i is the distribution type, A_1 is normal distribution, A_2 is lognormal distribution and A_3 is extreme value distribution, $P(A_i)$ is the prior probability of each distribution type given by the Bootstrap method combined with AIC, $P(D_2|A_i)$ is the conditional probability its calculation formula is:

$$P(D_2|A_i) = \prod_{j=1}^n p(\theta_j|A_i, \zeta) \quad (4)$$

where $p(\theta_j|A_i, \zeta)$ is the value of the probability density function of the distribution type corresponding to A_i at the data point θ_j , and n is the number of samples. The posterior probability of each distribution type can be determined by Equation (5).

In this paper, the M-H algorithm in the Markov Chain Monte Carlo (MCMC) method (Chib & Greenberg 1995) is used to solve the posterior distribution of the distribution parameters.

Based on the above basic theory, the steps of epistemic uncertainty characterization under a small initial samples and continuous update conditions are as follows:

- 1) Based on the initial data, the prior distribution of the distribution parameters is given based on the Bootstrap method. And the prior probability of the distribution type is then given by Bootstrap combined with the AIC.
- 2) Calculate the likelihood function and conditional probability by Equation (2) and Equation (4) based on the updating data, then solve Equation (1) to obtain the posterior distribution of the distribution parameters after the updating using the MCMC method. And solve Equation (3) to obtain the posterior distribution of the distribution type.
- 3) Repeat the step 2 according to the continuous updating data, and use the previous posterior distribution as the prior distribution of this update, Then perform multiple updates to obtain the final posterior distribution of the parameter distribution type and distribution parameters.

2.4 Reliability analysis under epistemic uncertainty

The probability of structural failure under epistemic uncertainty can be expressed as:

$$P_f(\Theta) = \int_{G(\mathbf{X}, \Theta) \leq 0} f_{\mathbf{X}, \Theta}(x, \theta) dx \quad (5)$$

where $P_f(\Theta)$ is the failure probability, \mathbf{X} denotes the random uncertainty variables, Θ denotes the epistemic uncertainty variables, $G(\mathbf{X}, \Theta)$ denotes the performance function, and $f_{\mathbf{X}, \Theta}(x, \theta)$ is the joint probability density function of \mathbf{X} and Θ . Since the distribution parameters and distribution type of the variable Θ are uncertain, the failure probability $P_f(\Theta)$ is also uncertain. The corresponding reliability index is also uncertain, and defined as:

$$\beta(\Theta) = \Phi^{-1}[1 - P_f(\Theta)] \quad (6)$$

where Φ^{-1} denotes the inverse function of the standard normal cumulative distribution function.

For the calculation of the CRI, we adopted a two-loop approach and used the Monte Carlo simulation (MCS). That is, the CRI is calculated in two loops. The first loop being the determination of the distribution parameters and the distribution type by random sampling of its probability distribution. The second loop is to compute the CRI of the distribution parameter and distribution type from the first loop repeatedly. In this paper, the number of loops is 10,000, which means that we can obtain 10,000 CRI samples. And we can obtain the PDF of CRI through these samples. Then we can evaluate the mean and coefficient of variation of CRI, too.

3 NUMERICAL EXAMPLES AND INVESTIGATIONS

Consider the stability analysis model of the retaining wall in slip damage mode (Li et al. 2015), as shown in Figure 1.

In the case that the bearing capacity is satisfied, its corresponding performance function is:

$$g = \frac{c_{\text{int}}(a + b) + (W_1 + W_2) \tan \phi_{\text{int}}}{P_a} - 1 \quad (7)$$

Figure 1. Stability analysis model of retaining wall.

where: $c_{int} = 1/3 \cdot c_b$ and $\varphi_{int} = 2/3 \cdot \varphi_b$ are the cohesion and friction angle of interface shear strength. Respectively, and c_b and φ_b are the cohesion and friction angle at the corresponding foundation soil, P_a is the active earth pressure, whose expressions are:

$$P_a = \frac{1}{2} \gamma_s H^2 K_a - 2cH \sqrt{K_a} + \frac{2c^2}{\gamma_s} \quad (8)$$

where K_a is the coefficient of active earth pressure, given by Rankine's theory:

$$K_a = \tan^2(\pi/4 - \phi/2) \quad (9)$$

The other parameters are defined and their values are shown in Table 1.

Table 1. Stability analysis model parameters of retaining wall.

Parameters	Value	Physical meaning
a/m	0.5	Retaining wall geometry parameters
b/m	2.5	Retaining wall geometry parameters
H/m	10	Retaining wall geometry parameters
$\gamma_s /(\text{kN/m}^3)$	18	Unit weight of backfill
$\gamma_w /(\text{kN/m}^3)$	24	Unit weight of retaining wall
$\gamma_b /(\text{kN/m}^3)$	18	Unit weight of foundation
W_1	$0.5bH\gamma_w$	Unit retaining wall gravity
W_2	$aH\gamma_w$	Unit compartment gravity
c_b /kPa	300	Cohesion of foundation soil
$\varphi_b /(^{\circ})$	30	Friction angle of foundation soil

The actual engineering test data of consolidated-drained triaxial compression shear strength parameters (c and φ) are limited, and the literature (Li et al. 2015) provides 63 sets of test data of shear strength parameters. This example examines the effect of epistemic uncertainty of parameters on the stability analysis of retaining walls using the shear strength test data.

Case 1: Consider only the distribution parameters uncertainty

We first study the uncertainty of the distribution parameters for these 63 sets of data. And we divide the 63 groups of data into two groups. Next, we use the first 30 groups of data to construct the prior distribution of the distribution parameters by the Bootstrap method. The literature (Wang & Cao 2015) shows that the mean and standard deviation samples obtained by the Bootstrap method sampling fit better with the normal distribution. So in this paper, the prior distribution is taken as normal distribution. And the posterior distribution of the distribution parameters is then obtained by the MCMC method using the latter 33 sets of data as the updated data. It is known that the posterior distribution is also normal from the theory of conjugate distribution (Bolstad 2007). It can be seen from Table 2 that the posterior distribution has less variability compared to the prior distribution, i.e., it can narrow the range of the distribution parameters and reduce the epistemic uncertainty after updating the data.

To further considered the effect of continuous updating of the samples of the distribution parameters uncertainty. It is assumed that there are 4 sets of data and each with 100 samples form random

sampling. The additional 100 samples of each updating are form random sampling of the sampling PDF (normal distribution). The mean and standard deviation of the sampling PDF is determined by the first 63 sets of data. And the scatter plot of the the additional 100 samples of each updating is shown in Figure 2. The distribution parameters are updated using these 4 sets of data, and the posterior distribution of the distribution parameters is also shown in Table 2. As can be seen from Table 2, with continuous updating of the sample, the variability of the distribution parameters keeps decreasing and the epistemic uncertainty also decreases.

Figure 2. Scatter plot of the additional 100 samples in each updating (case 1).

Table 2. Uncertainty of distribution parameters.

Distribution parameters	Priori distribution	Posterior distribution	1 st updating	2 nd updating	3 rd updating	4 th updating
Sample size	30	63	163	263	363	463
μ_c	$N^*(66.56, 3.27)$	$N(65.97, 2.26)$	$N(66.07, 1.55)$	$N(65.73, 1.25)$	$N(65.08, 1.07)$	$N(65.47, 0.95)$
σ_c	$N(17.84, 2.44)$	$N(21.19, 1.61)$	$N(21.17, 1.08)$	$N(21.47, 0.86)$	$N(21.75, 0.74)$	$N(21.72, 0.66)$
μ_ϕ	$N(21.82, 0.41)$	$N(22.65, 0.28)$	$N(22.76, 0.19)$	$N(22.88, 0.15)$	$N(22.85, 0.13)$	$N(22.74, 0.12)$
σ_ϕ	$N(2.22, 0.28)$	$N(2.61, 0.19)$	$N(2.59, 0.13)$	$N(2.61, 0.1)$	$N(2.61, 0.09)$	$N(2.63, 0.08)$

* where $N(\mu, \sigma)$ denotes a normal distribution with mean μ and standard deviation σ .

In the following, we use the proposed method to calculate the CRI. The PDF of CRI determined by the probability distribution of some of the distribution parameters in Table 3 is shown in Figure 3, and the statistical parameters of CRI determined by each updating are shown in Table 4. It can be seen that the CRI also has a larger range of variation when the epistemic uncertainty is large. When the distribution parameters are updated to reduce the epistemic uncertainty, the range of uncertainty of the CRI becomes narrower. Also it can be seen through Figure 3 and Table 3 that the coefficient of variation of both the distribution parameter and the CRI decreases with the continuous updating of the samples.

Case 2: Considering both distribution parameters and distribution type uncertainty

In this case, we further investigate the effect of distribution type uncertainty of shear strength parameters on the reliability of retaining wall stability. Firstly, we discuss the distribution type uncertainty by 63 sets of data in the literature (Li et al. 2015), and the data are grouped as in case 1. Then the prior and posterior probability are obtained by the proposed quantification method of distribution type uncertainty, as shown in Table 4.

We next consider the uncertainty of the distribution types under the condition of continuous updating of the samples. Similar to case 1, it is assumed that there are 4 sets of data and each with 100 samples form random sampling. The additional 100 samples in 1st updating and 3rd updating are form random sampling of the sampling PDF(lognormal distribution). The additional

100 samples in 2nd updating and 4th updating are form random sampling of the sampling PDF (extreme value distribution). The mean and standard deviation of the sampling PDF is determined by the first 63 samples. The scatter plot of additional 100 samples in each updating is shown in Figure 4. And the posterior distribution of the distribution types of the shear strength parameters obtained by the Bayes update method is shown in Table 5. From Table 5, it can be seen that the posterior probabilities of the distribution type will tilt toward a certain distribution type under the condition of continuous update of the samples generated by the different distribution types.

Figure 3. PDF of conditional reliability index in case 1.

Table 3. Statistical parameters of CRI in case 1.

Statistical parameters	Priori distribution	Posterior distribution	1 st updating	2 nd updating	3 rd updating	4 th updating
Sample size	30	63	163	263	363	463
Mean	2.552	2.168	2.162	2.138	2.130	2.127
Standard deviation	0.333	0.144	0.106	0.075	0.063	0.058
Coefficient of variation	0.130	0.067	0.049	0.035	0.030	0.027

Table 4. Prior and posterior probability of the distribution type.

Distribution Type	Priori probability		Posterior probability	
	c	φ	c	φ
Normal distribution	0.9844	0.9865	0.9990	0.8756
Lognormal distribution	0.0132	0.0129	0.0008	0.1095
Extreme value Distribution	0.0024	0.0006	0.0002	0.0149

Based on this, we use the proposed method to calculate the CRI. The statistical parameters of CRI (case 1 and case 2) after each update are shown in Table 6. And The PDF of the CRI corresponding to the partially updated batch is shown in Figure 5. From Table 6 and Figure 5, it can be seen that the mean value of CRI and the variability increase in some cases when both distribution parameter and distribution type uncertainties are considered, and the shape of the PDF may also change. This is because the uncertainty of distribution type is considered in the reliability analysis, while the traditional method only adopts a fixed distribution type of shear strength parameter in the reliability analysis. These results prove the importance of considering the uncertainty of the distribution type of the shear strength parameters in the reliability analysis.

Table 5. Posterior distribution of distribution types.

(a) Friction angle φ				
Distribution Type	1 st updating	2 nd updating	3 rd updating	4 th updating
Normal distribution	0.5609	0.0275	0.0056	0.0003

Table 6. Statistical parameters of CRI in case 2.

Statistical parameters	Posterior distribution	1 st updating	2 nd updating	3 rd updating	4 th updating
Sample size	63	163	263	363	463
Mean(Case 1)	2.168	2.162	2.138	2.130	2.127
Mean(Case 2)	2.726	2.618	2.128	2.123	2.108
Coefficient of variation(Case 1)	0.067	0.049	0.035	0.030	0.027
Coefficient of variation(Case 2)	0.085	0.095	0.036	0.031	0.026

4 CONCLUSION

In this paper, a method is developed to quantify the epistemic uncertainties of random variable, including the uncertainties of distribution parameter and distribution type, which unifies the epistemic uncertainty in the probabilistic framework with the aleatory uncertainty. Then, the reliability analysis is performed to obtain the PDF of the CRI, and the influences of these uncertainties on the CRI are investigated.

The main conclusions are drawn as follows:

- (1) The uncertainties of distribution parameter and distribution type can be quantified well by the AIC combined with the Bootstrap method in case of data scarcity.
- (2) The variability of the distribution parameters gradually decreases as the data successively updates with Bayes update method, and the variability of CRI continuously decreases, too.
- (3) The PDF of CRI with the uncertainties of both distribution parameters and distribution type is largely different from that with only the uncertainty of distribution parameters.

ABSTRACT: Concrete is subject to the alternate action of positive and negative temperatures of the environment frequently in cold regions. The freeze-thaw cycle causes the spalling of concrete surface. In view of this, the investigation of the changes of fluid migration and icing in concrete during the temperature change process were carried on, the critical pore radius of frozen pore at different temperatures was determined based on the thermodynamic law. Then, considering the thermal deformation of all constituents, the deformation induced by the micro-cryosuction process and the deformation caused by the phase change of water-ice during the freeze-thaw cycle, the internal pore stress of a representative volume element is analyzed. Finally, considering the effect of the phase change of water ice, a numerical model of concrete freeze-thaw failure under the coupling of thermal-water-mechanical field is established. It is found that, influenced by the temperature, the concrete will shrink first and then expand under the freeze-thaw effect. The stress during freezing process of the concrete surface is higher than that of thawing process and the concrete will be more prone to spalling damage.

1 INTRODUCTION

The repeated freeze-thaw cycle will cause damage and destruction of concrete structures or components in cold regions, such as concrete pavement, retaining wall, bridge deck and railing, which is a major reason for the huge expenditure to repair and replace concrete structures. As one of the three main factors of concrete damage, freeze-thaw action plays an important role in the field of concrete durability research and has received extensive attentions (Mehta, 1991). With the service life of concrete structural components increasing, the safety of concrete structures is facing the challenge of freezing and thawing in many countries (Asphaug et al., 2020).

A range of achievements have been made in the study of freeze-thaw damage mechanism at present (Gong et al., 2015), among which the hydrostatic pressure theory and osmotic pressure theory (Powers and Helmuth, 1953) proposed by Powers have the highest recognition. The biggest difference between the osmotic pressure theory and the hydrostatic pressure theory lies in the migration direction of the solution in the unfrozen pores. According to the theory of hydrostatic pressure, pore solutions leave ice crystals and migrate from large pores to small ones. Furthermore, osmotic pressure theory suggests that pore solution migrates from pores to ice crystals. In general, when the water cement ratio of concrete is large, the strength is low, the age is early and the hydration degree is small, the hydrostatic pressure will lead to the freeze-thaw damage of concrete; For the concrete frozen in the environment with small water cement ratio, high strength and large salt content, the osmotic pressure will lead to the freezing and thawing damage of concrete. However, hydrostatic pressure and osmotic pressure can neither be measured by test, nor can they be accurately calculated by the formula of physical chemistry, which makes many scholars unable to reach an agreement on which of hydrostatic pressure and osmotic pressure is the main factor of

freeze-thaw damage. Although Powers himself later preferred the osmotic pressure hypothesis (Powers and Helmuth, 1953), the research results of Fagerlund (ouml and Ran, 2004), Pigeon (Pigeon and Lachance, 1981) and others supported the hydrostatic pressure hypothesis from different aspects.

The freeze-thaw damage of concrete involves complex physical changes. Although there are many researches on the freeze-thaw damage mechanism of concrete, most scholars believe that the freeze-thaw damage mechanism of concrete is closely related to its pore structural members. Since Powers put forward the theories of hydrostatic pressure and seepage pressure, there has been no more outstanding progress in the research on the mechanism of concrete freeze-thaw damage, and no unified theory has been formed. In the past twenty or thirty years, some scholars have made further quantitative research on the micro dynamic development, internal stress and strain state of concrete during icing based on the theory of Powers. However, more scholars started from the material test level to study the influence of the properties of concrete and its components and the external environment on concrete freezing and thawing, such as cooling rate, water saturation, self-healing effect, environmental humidity and minimum freezing and thawing temperature (Lee et al., 1994). Therefore, the research on the freeze-thaw damage mechanism needs to be further deepened, so as to obtain a consistent freeze-thaw damage mechanism.

Numerical simulation, as an effective research method, can obviously shorten the research cycle, save the cost and avoid the shortcomings of dispersion. Nowadays, some achievements have been made in the numerical model research on the freezing and thawing damage layer (Olsen, 1984). Among them, Olsen (Olsen, 1984) established a two-dimensional finite element calculation model that can simulate the freezing process of saturated concrete based on the differential equation of humidity and temperature, the relationship between the amount of ice and temperature, and the calculation of pore pressure; Bazant et al. (Bazant et al., 1988) proposed a mathematical model that can predict the frost resistance durability of concrete, and theoretically determined the stress and strain of freeze-thaw damaged concrete. Zuber et al. (Zuber and Marchand, 2004) proposed a two-dimensional analysis model that can predict the expansion of freeze-thaw damaged concrete. Ueda et al. (Ueda et al., 2009) established the micro constitutive model of freeze-thaw concrete based on the two-dimensional rigid body spring model, and carried out numerical analysis on the mechanical properties of freeze-thaw damaged concrete. Numerical simulation is an effect method to predict the freeze-thaw damage of concrete. Stress caused by freezing of pore liquid is the main reason of freeze-thaw damage, however, these researches paid less attention to the relationship between freeze-thaw expansion force and damage.

Based on the pore structure of concrete in cold regions, this study establishes the relationship between the saturation of pore structure and the internal expansion force of concrete during freezing and thawing. The multi-factor coupling effect is then considered to establish the multi-factor coupling numerical model of concrete under freezing and thawing. Finally, the numerical model is used to predict the stress and strain evolution of various parts of concrete under freeze-thaw cycles.

2 PORE STRUCTURE AND FREEZING

2.1 *Pore structure and pore size distribution*

As a multiphase material, concrete has complicated porosity, which depends on the material composition and the hydration of cement. Due to the change of cementitious hydration time, the total porosity of concrete can be calculated by Equation (1) (Clifton et al., 1994)

$$\phi_t = f_c \frac{w/b - 0.17\alpha}{w/b + 0.32} \quad (1)$$

where ϕ_t = total porosity of concrete, f_c = volume fraction of binder in concrete, w/b = water-to-binder ratio of concrete, α = hydration degree of cement. The hydration degree of cement is related to the w/b and hydration time.

The pore size distribution of concrete is continuous, including nano scale gel pores to millimeter scale macropores. Duan(Duan, 2009) analyzed several groups of samples in the experiment, and obtained the pore distribution function close to the actual test results through fitting:

$$\phi(r) = \frac{1 - \phi_r}{1 + \left(\frac{\log r}{2.0783}\right)^{3.8059}} \quad (2)$$

where ϕ_r = function of pore size distribution, r = pore size, nm. The pore size distribution of concrete can be obtained by combining Equations (1) and (2).

2.2 Freezing and ice saturation

The concrete is unsaturated in most cold regions, and it is difficult to achieve full saturation even if the concrete is immersed in frozen water for a long time (Liu et al., 2021a). The unsaturated concrete element in the freezing process is taken as the research object, it can be assumed that there are only three kinds of substances in its pores: ice crystal, liquid and gas. It can be considered that in the pores of a certain temperature state, these three-phase substances in concrete have the following relationships:

$$\phi = \phi_C + \phi_L + \phi_G \quad (3)$$

$$S_C + S_L + S_G = 1 \quad (4)$$

where, ϕ = porosity, ϕ_C = porosity of ice crystal, ϕ_L = porosity of liquid, ϕ_G = porosity of gas, S_C = saturation of ice crystal, S_L = saturation of liquid, S_G = saturation of gas.

The freezing of water in concrete is related to the pore size. Due to the complexity of the pore structure of cement-based materials, the process of water freezing in the pores is different from that of large volume water in nature. When ice crystals are generated, there is a certain balance in the pores, as shown in the Figure 2:

Figure 1. Ideal pore freezing at the microscopic level.

When the liquid water and ice crystals in the pores are in steady state, the ice crystal pressure p_C and liquid pressure p_L satisfies Young-Laplace equation:

$$p_C - p_L = \frac{2\gamma_{CL}}{\varrho} = \frac{2\gamma_{CL} \cos \theta}{r} \quad (5)$$

where p_C = ice crystal pressure, MPa, p_L = liquid pressure, MPa, γ_{CL} = interface energy of crystal and liquid, MPa/m, ϱ = curvature radius of ice crystal, m, r = pore radius of the cylindrical pore, m, θ = contact angle of crystal and liquid. According to the thermodynamic theory of phase transition of water in pores, the thermodynamic equilibrium of ice crystal coexisting with liquid water requires that their chemical potentials be equal (Gibbs, 1878). Restricting to the terms of higher order of magnitude, this condition implies (see for instance (Coussy, 2005))

$$p_C - p_L = \sum_m (T_m - T) \quad (6)$$

where T_m = melting temperature, K, Σ_m = melting entropy, MPa/K. As for water, $T_m \cong 273.15$ K, $\Sigma_m = 1.2$ MPa/K at 273.15 K (Petrenko and Whitworth, 2002).

Combining Equations (5) and (6), we can get the famous Gibbs-Thomson equation:

$$r = \frac{2\gamma_{CL} \cos \theta}{\Sigma_m(T_m - T)} \quad (7)$$

Generally, the ice crystal does not directly contact the hole wall, there is a layer of water film around the edge of solid matrix, with a thickness of δ . It is generally 1.0~1.2 nm. The manifestation of water ice phase transition at molecular scale is regular redistribution of water molecules. However, it is difficult to verify through experiments and simulations. It is difficult to observe the icing process in the nanoscale pores of cement-based materials even at absolute zero (Matsumoto et al., 2002). For cement-based materials, Liu et al. and Xu (Liu et al., 2021b) found through molecular dynamics that the mobility of water molecules within 0.7 nm from the wall of C-S-H gel is lower than that far away, indicating that water molecules are adsorbed by the wall of C-S-H in this range. The adsorption of water molecules on the near wall surface of C-S-H gel will affect the redistribution of water molecules. Therefore, it is assumed that the thickness of the unfrozen liquid film is consistent with the thickness of the water adsorption zone near the wall surface of the pores of cement-based materials. For cement paste, assuming that the contact angle between ice crystal and hole wall is equal to 180° , Equation (7) is:

$$r_c = \frac{2\gamma_{CL}}{\Sigma_m(T_m - T)} + \delta \quad (8)$$

where $\delta = 0.7$ nm.

According to Equation (8), the corresponding relationship between the critical pore radius and temperature can be obtained.

When the temperature drops to the freezing point, the water in the large pores freezes first. With the temperature decreasing, the ice crystals gradually grow into the small pores. For the pore size distribution curve of concrete, the corresponding frozen and unfrozen pores can be determined. The relationship between ice crystal saturation and temperature can be calculated by Equation (9):

$$S_C = \phi(r_c)/\phi_t \quad (9)$$

When the pore is completely saturated, it can be considered that the gas phase saturation is zero, then the liquid saturation can be calculated by Equation (10):

$$S_L = 1 - \phi(r_c)/\phi_t \quad (10)$$

In unsaturated concrete, the gas phase saturation of each pore is the same value, the pore phase saturation can be calculated according to Equations (4), (9) and (10).

3 VOLUME DEFORMATION AND PORE PRESSURE DURING FREEZING AND THAWING

3.1 Volume deformation

During the freezing process, the deformation and mechanical behavior of concrete are complex, including the deformation caused by temperature change, the volume deformation caused by water migration, and the volume expansion caused by water ice phase change. Poromechanics is one of the effective methods to study the mechanical behavior of cement-based materials during freezing. Select representative volume element (RVE) from porous media as Figure 2. Applying the first and second laws of thermodynamics to RVE, Clausius-Duhem equality without considering the energy dissipation of cement skeleton is obtained. When there is no external stress, the strain of RVE can be obtained as follow (Coussy and Monteiro, 2007):

$$\begin{aligned} \epsilon = & \frac{bp_L + (b_c \Sigma_m - 3\alpha_s K)\Delta T}{K} = -3 \left[\alpha_s + \frac{\phi Mb}{K + b^2 M} (S_C \alpha_C + S_L \alpha_L - \alpha_s) \Delta T \right] \\ & + \frac{M}{K + b^2 M} \left(\frac{b_c}{K_L} - \frac{b_L}{K_C} \right) \Sigma_m \Delta T + \frac{\phi Mb}{K + b^2 M} S_C \left(1 - \frac{\rho_C^0}{\rho_L^0} \right) \end{aligned} \quad (11)$$

Equation (11) contains the strain of thermal deformation of all constituents, the deformation induced by the micro-cryosuction process and the deformation caused by the phase change of water-ice during the freeze-thaw cycle.

3.2 Pore pressure

It is assumed that the cross section of pore is circular. Then the pore cross section is taken as the research object as shown in Figure 2.

Figure 2. Stress of pore structure cross section.

For the pore structure in Figure 2, its pore diameter is r , and there may be one or two of the three substances of crystal, liquid and gas in the pore. It is assumed that the pore wall is only affected by the pressure of one substance p_j . Hydrostatic pressure and crystallization pressure of the pore can be calculated according to Equation (11):

$$\omega_S = \begin{cases} p_C = \frac{K\epsilon + b_L \Sigma_m \Delta T + 3\alpha_s K \Delta T}{b} \\ p_L = \frac{K\epsilon - b_c \Sigma_m \Delta T + 3\alpha_s K \Delta T}{b} \end{cases} \quad (12)$$

Equation (12) is the pressure on the pore wall with pore diameter r , combined with the pore diameter distribution equation (Equation (2)), and the saturation distribution of the corresponding pores (Equations (9) and (10)). The load received by the concrete during freezing and thawing can be obtained through integration:

$$p^* = \int_{r_{min}}^{r_{max}} \omega_S \frac{d\phi(r)}{dr} dr \quad (13)$$

where p^* = average pressure, r_{min} = minimum pore radius, r_{max} = maximum pore radius.

4 FREEZE-THAW DAMAGE DETERIORATION

In cold region, freeze-thaw damage of concrete is the result of the coupling of stress, thermal and humidity field.

4.1 Thermal field

A certain amount of energy is absorbed by the transformation of water ice in concrete, which is a phase change process. The Fourier quantification considering the latent heat of water ice phase change can be calculated as follows:

$$\rho C_p \frac{dT}{dt} = \nabla \cdot (\lambda \nabla T) - L \frac{dS_L}{dt} \quad (14)$$

$$\lambda = \frac{nS_L\lambda_L + nS_C\lambda_C + \lambda_s}{nS_L + nS_C + 1} \quad (15)$$

$$C_p = \frac{nS_L C_{pL} + nS_C C_{pC} + C_{ps}}{nS_L + nS_C + 1} \quad (16)$$

where C_p = specific heat capacity, λ = thermal conductivity coefficient, L = latent heat of liquid and crystal, 333.3 kJ/kg. C_p and λ can be calculated by homogenization method.

4.2 Stress field

For the volume force inside the porous medium, the equation can be written as:

$$\begin{cases} \frac{\partial \sigma'_x}{\partial x} + \frac{\partial \tau_{xy}}{\partial y} + \frac{\partial \tau_{xz}}{\partial z} - b \frac{\partial p^*}{\partial x} = 0 \\ \frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \sigma'_y}{\partial y} + \frac{\partial \tau_{zy}}{\partial z} - b \frac{\partial p^*}{\partial y} = 0 \\ \frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} + \frac{\partial \sigma'_z}{\partial z} - b \frac{\partial p^*}{\partial z} = 0 \end{cases} \quad (17)$$

4.3 Humid field

Saturation degree is one of the humidity formation in concrete, and the governing equation of saturation degree is represented by Fick's second law(Liu et al., 2021a):

$$\frac{\partial S}{\partial t} = \nabla(D_0 e^{nS} k_T \nabla S) \quad (18)$$

where $S = S_l + S_c$, D_0 = reference humid transport coefficient, m^2/s n = coefficient, and usually $n = 6$, k_T = temperature correction coefficient of humid transport coefficient which follows Arrhenius equation $k_T = \exp(U(1/T_{ref} - 1/T)/R_g)$. U = activation energy of liquid transport, kJ/mol, R_g = relative gas constant J/mol/K, T_{ref} = reference temperature, K.

4.4 Modelling

The size of concrete specimen used for simulation is 40 mm×40 mm×160 mm, one eighth of the overall structure is selected in this model. Three adjacent surfaces are set as the boundary of contact with the environment, and the other three surfaces are symmetric boundaries. Finally, the deformation and damage of the overall structure are reconstructed in a symmetrical form. The geometric model and boundary conditions of this numerical model are shown as Figure 3.

Figure 3. Geometric model and boundary conditions.

Taking a certain environment in northern China as an example, it is assumed that the daily temperature change of concrete in the cold region is -6 ~ 6 °C, which satisfies the cosine function relationship.

$$T_b(t) = \frac{T_{max} - T_{min}}{2} \cos\left(\frac{2\pi t}{t_{cycle}}\right) + \frac{T_{max} + T_{min}}{2} \quad (19)$$

where $T_b(t)$ = temperature in cold region, 267.15 K, T_{max} = maximum temperature in cold region, 299.15 K, T_{min} = minimum temperature in cold region, K, t_{cycle} = time period of a freeze-thaw cycle, 1 d.

4.5 Results of model

According to the equations in Section 3, when the ambient temperature changes, the saturation of and pore pressure of concrete change with time. Figure 4 shows the relationship between time and pore saturation at the center of the largest concrete surface and the center of concrete:

Figure 4. Pore saturation evolution.

Figure 4 shows the distribution of pore water saturation in concrete with a water-cement ratio of 0.26 in cold regions. The initial pore liquid saturation S_{l0} is 0.4, and the liquid saturation at the boundary is 1.0. Therefore, there is no gas saturation at the boundary, only the change of liquid saturation and crystal saturation occurs at the boundary. However, the obvious difference is that with the migration of moisture to the center of the concrete, the liquid saturation in the center of concrete gradually increases (as shown by the dotted line in Figure 4), and the ice crystal saturation of concrete also gradually increases under the influence of freezing and thawing. In the first cycle, the first cover of water transfer has not yet reached the center of the concrete, but in the second freeze-thaw cycle, the pore water saturation and crystal saturation in the concrete have increased. The contribution of crystallization pressure to pore pressure is greater than that of hydrostatic pressure, crystallization of the liquid in pores is the main factor of freeze-thaw damage. The same result is also reflected in the deformation of concrete as shown in Figure 6.

Figure 5. Evolution of strain.

Figure 5 shows that the contribution of micro-cryosuction, crystal expansion and thermal contribution to the strain of RVE is quite different. The second is the leading factor causing the volume deformation of RVE, and the thermal contribution dominates the shrinkage of concrete. Before freezing, the following interesting phenomena can be observed: the shrinkage of concrete occurs when the temperature is reduced, and the water invades the unsaturated concrete at the

same time, resulting in a certain humidity expansion of concrete. Within a short time after the temperature reaches below zero, the concrete still shrinks, which is caused by the contribution of micro-cryosuction. With the increase of the crystal saturation in the pores, the concrete gradually expands, which occurs during the whole process of the temperature below the freezing temperature. After thawing, the water in the concrete pores did not thaw at the first time due to the phase change effect of water to ice. Different concrete saturation has certain influence on the freeze-thaw strain of concrete. The freeze-thaw peak value of concrete with lower initial water saturation should greatly, due to the lower the initial water saturation, the faster the water absorption, the more obvious the frost heaving of surface concrete, and the lower the initial saturation, the later the peak value of concrete strain appears.

Figure 6. Stress and spalling damage.

The surface stress of the concrete is shown in Figure 6(a). There is shrinkage stress during the cooling process. With the occurrence of freezing, the stress of the concrete increases sharply, and there is another peak stress during thawing. With the continuous increase of freeze-thaw cycles, the peak stress of concrete freezing decreases and gradually equals the peak stress generated by thawing. When the concrete stress exceeds its tensile strength, it can be considered that spalling damage occurs at this part of concrete. With the increase of concrete strength, the loss of concrete freeze-thaw quality can be greatly reduced.

5 CONCLUSION

In this paper, a multi-factor coupling numerical simulation method is used to reveal how the damage of concrete occurs in cold regions. The investigation of the changes of fluid migration and icing in concrete during the temperature change process was carried on, and a numerical model of concrete freeze-thaw failure under the coupling of thermal-water-mechanical field is established. The following results can be concluded:

- (1) The ice crystal saturation of concrete is directly related to the temperature and pore size. The lower the temperature, the greater the ice content of the pores, making the pore size smaller, and the more difficult it is for the concrete to freeze.
- (2) The transport of water in unsaturated concrete will affect the frost resistance of concrete. When the initial saturation of the pore structure is low, the transport of water in the concrete will become easier. Meanwhile, the water transfer rate of concrete will be so large that a large freezing strain will form in concrete.
- (3) The stress during freezing process of the concrete surface is higher than that of thawing process and the concrete will be more prone to spalling damage. Increasing the strength of the matrix can intuitively reduce the spalling damage of the concrete.

ABSTRACT: A 1-D CNN regression model is designed for autonomously monitoring stress in concrete specimens utilizing the raw impedance signatures of smart aggregate (SA) sensors. The fundamental theory of the impedance measurement model of SA is presented. Next, the compression experiment on SA-embedded concrete cylinders is carried out, and the impedance signals of the cylinders are recorded under different stress levels. The 1-D CNN regression model learned the impedance signals for predicting the concrete stress is constructed. Then, the average performance of the proposed model is verified via the 10-fold cross-validation method. Consequently, the feasibility of the developed model is investigated under the effect of noises in signals and reduction of the input training data.

1 INTRODUCTION

Recently, the convolutional neural network (CNN)-based deep learning techniques have been considered as an efficient approach for assessing damage conditions of civil infrastructures (Yuan et al. 2020, Abdeljaber et al. 2018, Wang et al. 2021, Abdeljaber et al. 2017, Ta et al. 2022, Azimi & Pekcan 2019, Ta & Kim 2020, Huynh 2021, Ta et al. 2022, Huynh et al. 2019). In comparison with traditional multi-step damage detection methods (Yuan et al. 2020), CNN-based approaches can extract damage sensitivity and predict damage occurrence in one procedure (Abdeljaber et al. 2018, Wang et al. 2021); besides, the CNN has the ability to learn damage features from raw signals, which considerably decreases initial processing workload (Abdeljaber et al. 2017).

Several studies have shown the effectiveness of CNN for impedance response-based damage assessment. For example, Oliveira et al. 2018 applied a CNN based deep learning algorithm to detect damage in an aluminum plate based on changes in impedance responses. The algorithm was able to accurately detect and locate damage in the plate. Nguyen et al. 2021 proposed a 1-D CNN model learnt impedance signatures for classifying different damage conditions of a smart PZT interface. In the following year, Nguyen et al. 2022 developed a novel 1-D CNN-based autonomous feature extraction model for impedance-based PS force prediction. Their experimental verification indicates that the proposed model significantly outperforms the traditional approach using manual feature extraction. Also, the applications of CNN models learned impedance signals for damage identification have been extensively studied in various structures (Zheng et al. 2022, Li et al. 2023, Ai & Cheng 2023, Rezende et al. 2020). However, the applicability of the 1-D CNN regression model for stress monitoring inside concrete specimens using smart aggregate (SA) has not been investigated.

In this study, a 1-D CNN regression model is developed for autonomously predicting stress in concrete structures utilizing the raw impedance signatures of SA sensors. The fundamental theory of the impedance measurement model of SA is presented. The compression experiment on SA-embedded concrete cylinders is carried out, and the impedance signals of the cylinders are recorded

under different stress levels. A 1-D CNN regression model learned the impedance signals for evaluating the concrete stress is constructed. The feasibility of the developed model for predicting stress under the effect of noises in signals and reduction of the input training data is also investigated.

2 SMART AGGREGATE-BASED IMPEDANCE MEASUREMENT

Figure 1 shows a model of SA-based impedance monitoring for concrete structures. The SA is fabricated by embedding a protected PZT sensor in a small concrete block, and it is installed in an inspected structure to obtain impedance signals via the interaction between the SA and the structure (see Figure 1a). The coupling motions of the coated layer, the concrete block, and the monitored structure could be demonstrated as a 3-degrees of freedom (3-DOF) impedance model (Huynh et al. 2020, Pham et al. 2021) (see Figure 1b). The electromechanical impedance $Z(\omega)$ is computed using the SM impedance of the PZT sensor and that of the SA-host structure:

$$Z(\omega) = \left\{ j\omega A_p \left[\hat{\epsilon}_{33}^T - \frac{1}{Z_p(\omega)/Z_s(\omega) + 1} d_{31}^2 \hat{Y}_{11}^E \right] \right\}^{-1} \quad (1)$$

where A_p is the geometric constants of the PZT patch; $\hat{\epsilon}_{33}^T$ is the complex dielectric constant of at zero stress; $Z_p(\omega)$ is the structural-mechanical (SM) impedance of the PZT; $Z_s(\omega)$ is the SM impedance of the protective layer, concrete block, and host structure; d_{31} is piezoelectric constant in one-direction at zero stress; \hat{Y}_{11}^E denotes complex Young's modulus of the PZT at zero electric field.

As shown in Equation (1), the real impedance $Z(\omega)$ is the function of the SM impedance of the PZT patch, the SA, and the host structure. Once the PZT patch has no changes in its characteristics, thus, any structural changes can lead to a change in the measured impedance signatures.

Figure 1. Model of SA-based impedance monitoring for concrete structure.

3 COMPRESSION EXPERIMENT ON SA-EMBEDDED CONCRETE CYLINDER

3.1 Fabrication of SA

Figure 2 shows the fabrication of the SA. A PZT 5A patch soldered with electric wires was protected by an epoxy layer (see Figure 2a). Then, the coated PZT was embedded in the center of a PVC mold during concrete casting to form a SA sensor (see Figure 2b). The concrete mixture used for the monitored structures (without coarse aggregates), was employed for the SA's construction (see Table 1). The SA samples are shown in Figure 2c. The compressive strength of concrete after 28 days was 25.3 MPa, which was achieved via uniaxial compressive tests.

3.2 Fabrication of SA-embedded concrete cylinder

Figure 3 shows the fabrication of a concrete cylinder embedded with the SA sensor. The SA was localized at the center of a standard cylinder mold having a size of 100×200 mm (see Figure 3a). The distance between the center of the SA and the top and bottom surfaces of the mold was

Figure 2. SA's fabrication (dimension in mm).

Table 1. Concrete mixture for SA sensor*.

Material for 1 m ³	Mass (kg)
Sand	710
Coarse aggregate (D _{max} 25)**	948
Cement	425
Water (liter)	170

* Concrete mixture was used for concrete cylinder specimens in next section.

** SA sensor was constructed without coarse aggregate.

about 100 mm. Figure 3b shows the casting process for the concrete cylinder. The concrete mixture was selected as listed in Table 1. After 28 days of the curing process, three concrete cylinders (Cylinders 1-3) embedded with three SAs (SAs 1-3), respectively, were used for the impedance test.

Figure 3. Fabrication of SA-embedded concrete cylinder (dimension in mm).

3.3 Experimental setup for impedance measurement under compression

Figure 4a shows an impedance testing setup of the concrete cylinders (i.e., Cylinders 1-3) embedded with SAs 1-3, respectively, under compression forces. As shown in the figure, the concrete samples were placed inside a load frame of an MTS system. A load cell with a capacity of 500 kN was used to monitor the real compression force. In the experiment, a wired impedance analyzer HIOKI 3532 was used to obtain impedance responses from the SA sensors corresponding to each loading case. The laboratory temperature was also monitored via Kyowa EDX-100A.

Figure 4b shows twelve loading cases, $S_1 = 0$ MPa to $S_{12} = 22.32$ MPa with an interval of 2.03 MPa, which were applied on the cylinders. The applied stresses were gradually increased in an automatic loading procedure with a loading speed of $0.0113 \text{ MPa.s}^{-1}$. The amplitude of a harmonic excitation was set at 1 V to obtain impedance signatures from the SAs (i.e., SAs 1-3). The impedance responses were swept in the frequency range from 100 kHz to 600 kHz with 501 points. Four ensembles of the signals were recorded in each loading. The monitored temperature varied around a variation of 1°C.

3.4 Impedance signals of SAs

Figure 5 shows impedance signals (in the range of 100 - 600 kHz) of SAs 1-3, respectively, under twelve loading cases (i.e., S_1 to S_{12}). Three resonant peaks, Peaks 1-3, were observed. Peak 1 is

Figure 4. Testing setup for impedance measuring from SA-embedded cylinder under compression.

about 200 kHz, Peak 2 is about 270 kHz, and Peak 3 is around 500 kHz. The signals of SAs 1-3 were slightly changed with respect to each increasing applied stress, but variations were slight.

Figure 5. Impedance signals of SAs 1-3 under twelve applied stresses.

4 IMPEDANCE-BASED STRESS MONITORING USING 1-D CNN DEEP LEARNING

4.1 1-D CNN model

As shown in Figure 6, the schematic of 1-D CNN deep learning consists of two phases: 1) data acquisition and preparation and 2) 1-D CNN training and evaluation. In the first phase, a K-fold cross-validation is adopted to classify the stored datasets into training and validation datasets. In the second phase, a series of deep learning stages are performed to identify the 1-D CNN regression model. The impedance datasets and their corresponding stress levels are utilized for training the 1-D CNN model. For a stress level trained in the 1-D CNN model, the validation datasets are used to evaluate the accuracy of stress prediction.

Figure 6. Schematic of 1-D CNN deep learning.

Figure 7 illustrates a typical 1-D CNN architecture with three counterparts called input, output, and hidden layers. The 1-D CNN regression model takes 1 x 501 series raw signal as input, then returns output, which can be used for evaluating and predicting stress in concrete structures.

4.2 Stress monitoring of SA-embedded concrete cylinder by 1-D CNN model

4.2.1 Data preparation for SA sensors in concrete cylinders

This study uses a specific K-Fold Cross Validation technique called stratified shuffle-split to divide data from dataset. Of the twelve impedance signals (four ensembles per SA sensor)

Figure 7. Designed architecture of 1-D CNN using raw impedance signals of smart aggregate.

measured at each compressive stress stage, 75 % were randomly assigned to the training fold data set, and the remaining 25 % were assigned to the evaluation fold data set. Repeat this procedure K(10) times and create K(10) fold data sets. In summary, there are 144 signals in the impedance data set, of which 108 and 36 signals are used for 1-D CNN training and validation, respectively.

4.2.2 Training and evaluation of 1-D CNN regression model

Figure 8 shows the typical training process of 1-D CNN regression model using the training fold data sets as input. The loss and root-mean-square error (RMSE) values of training and validation for fold 4 were plotted because this fold produced the best predictive model. In general, the loss and RMSE values show that the proposed 1-D CNN regression model has a good performance. Figure 9 shows the performance of the 1-D CNN regression model trained with three presentative fold datasets. The smaller the RMSE index value, the higher the prediction accuracy. Figure 10 shows the average performance of the trained 1-D CNN regression model. Figure 10a presents the RMSE values of 10 test folds ranging from 0.85 to 2.14, with an average of 1.38 MPa. Figure 10b emphasizes the relative between the average predicted stresses and actual stresses. Note that the average predicted stress results in each stress level were quite consistent with the actual ones. Compared to the stress prediction result of the 1-D CNN model trained with each single-fold dataset, the average stress prediction result of 10 folds was more accurate.

Figure 8. Loss and RMSE values of 1-D CNN regression model after 100 epochs.

Figure 9. Evaluation results of 1-D CNN regression model.

Figure 10. Average performance of trained 1-D CNN regression model.

5 CONCRETE STRESS PREDICTION USING 1D CNN REGRESSION MODEL

5.1 Databank and training 1-D CNN regression model

5.1.1 Noise-contaminated databank

The whole impedance signals of SA 2 under twelve stress levels were used to build a databank for training and testing the proposed model. These signals were injected with noises to simulate realistic circumstances. Four ensembles of signals were repeatedly measured for each stress level. First three impedance signals were randomly noised by adding a standard deviation of 0%, 1%, 2%, 3%, 4%, and 5% of the signal amplitude. A total of 216 signals were used to train the 1-D CNN model. Remaining ones were injected with different levels of noise ranging from 1% to 16% (interval of 1%). A total of 1932 signals were used for testing the model. Adding such noises to signals could help to test the reliability of 1-D CNN model on unseen test data. Examples of impedance signals with and without noise injections at the stress level S_1 are shown in Figure 11.

Figure 11. Adding noises to impedance signals for data argumentation (stress level S_1).

5.1.2 Training 1-D CNN model with noise-injected datasets

Figure 12 shows loss and RMSE values after 100 epochs of the 1-D CNN regression model using the training dataset. Generally, the training loss and training RMSE were reduced, while validation loss and validation RMSE fluctuated during 100 epochs.

Figure 12. Loss and RMSE values of 1-D CNN regression model after 100 epochs.

5.2 Prediction for untrained levels of noises

Figure 13 shows three typical results of investigating the effects of noises on the accuracy of the model. It can be observed that the accuracy of the model in predicting stress decreased as the levels of noise increased. The relationship between the RMSE index and noise levels is illustrated in Figure 14. Note that the RMSE values increased with increased percentages of noise.

Figure 13. Effect of noise on the accuracy of 1-D CNN regression model.

Figure 14. Relation between RMSE and noise levels.

5.3 Prediction for untrained stresses in concrete cylinder

5.3.1 Untrained-stresses databank

The robustness of the 1-D CNN regression model was investigated for stress monitoring using limited impedance data. The 1-D CNN regression model was trained by using the untrained-stress databank. The untrained-stress databank was generated by excluding impedance datasets corresponding to a few stress levels. Then the performance of the 1-D CNN model was evaluated for the untrained stress levels. The 216 impedance signals were utilized to build a training dataset. One untrained-stress dataset was designed. The untrained-stress dataset (198 signals) excluded stress level S4 from the 216 impedance signals. The testing dataset (untrained-stress datasets) was 216 impedance signals measured, completing all stress levels.

5.3.2 Train 1-D CNN regression model using untrained-stress databank

Figure 15 shows the training process of the 1-D CNN regression model using the designed dataset. It is observed that the training loss and training RMSE gradually converged, while validation and RMSE loss fluctuated during the whole training process (100th epoch).

Figure 15. Training 1-D CNN regression model using training dataset 1 (excluded S4).

5.3.3 Prediction results for untrained concrete stresses

Figure 16 plots the results of predicted stresses versus actual stresses. It is observed that there was only a small variation in RMSE values between the cases of the excluded and included stress levels. The results demonstrated that the retrained model was capable of predicting stress values even when a stress level was not trained.

Figure 16. Stress prediction on the training dataset 1 (Std: 0-5%).

6 CONCLUSION

In this study, the 1-D CNN regression model was developed for autonomously predicting stress in concrete structures utilizing the raw impedance signals of SA sensors. The fundamental theory of the impedance measurement model of SA was presented. The compression experiment on SA-embedded concrete cylinders was carried out, and impedance signals of cylinders were recorded under different stress levels. The 1-D CNN regression model learned impedance signals for evaluating the concrete stress was constructed. The feasibility of developed model for predicting stress under the effect of noises in signals and reduction of the input training data was also investigated.

ABSTRACT: Several buildings and infrastructures, located in urban areas, are identified as strategic in the case of an earthquake event. This is the case of a water treatment plant which is currently built in Genoa, Italy, and which has been assessed for the scope of this research. Since the structure has been designed following the seismic design prescriptions, this work aims to provide a preliminary assessment of how the degradation mechanisms do affect its earthquake response. To this purpose, both chloride attack and carbonation are taken into account as main degradation mechanisms. Moreover, due to the importance of the water treatment plant, to develop a realistic Life Cycle Assessment (LCA) analysis, the earthquake resistance of the structure and its evolution over time as a function of the aforesaid degradation mechanisms, have been accounted as Serviceability Limit State to estimate the frequency of the maintenance activities needed in a timeframe of 100 years.

1 INTRODUCTION

Nowadays, the large use of concrete within the construction sector outlines the need to investigate in deep the degradation phenomena that occur over the time in which a structure, an infrastructure or, simply, a structural element is designed to ensure an adequate serviceability. This, also in view of the environmental, economic and social consequences associated to the production of cement-based materials in general when not characterized by an appropriate durability. As an example, not only the production of all concrete components, including Portland Cement (PC) that is responsible for 2 billion tons/year of CO₂ (Szabo et al., 2006) (Turner & Collins, 2013)(Ouellet-Plamondon & Habert, 2015)(McLellan et al., 2011), must be taken into consideration, but also the maintenance activities that could contribute to 55% of the CO₂ emissions generated from the construction phase until the dismissal of a structure (Kumanayake & Luo, 2018). These data, when referred to the worldwide total production of concrete per year, clearly highlight the magnitude of the overall sustainability issue that, as stated by Huntzinger and Eatmon (2008) can be at local, global or regional scale. To overcome the latter, some studies focused their attention, in the recent past, on the development of advanced cement based materials such as the self-healing ones, able to restore their integrity in the case of a crack creation (Shields et al., 2021)(di Summa et al., 2022)(Van den heede et al., 2018)(Cappellesso et al., 2023). Moreover, the behaviour of concrete when exposed to aggressive environmental scenarios (e.g. carbonation or chlorides penetration) generated an increasing interest also because of the market awareness regarding the need of having long durability, reduced maintenance costs and adequate environmental performance. In this framework, the scope of this investigation is to address the effects that certain aggressive

degradation phenomena have on the structural performance of a construction in the event of an earthquake. More specifically, the largest water treatment plant within Northern Europe, identified as a strategic structure, has been assessed. Moreover, the moment when a specific damage affects the structural performance is taken into consideration as serviceability limit state in correspondence of which the maintenance activities have to be carried out to restore the normal functionality. Thus, the Life Cycle Assessment (LCA) methodology has been employed to assess the environmental performance within the defined service life (SL). In line with other researches (Kannikachalam et al., 2022)(di Summa et al., 2022)(Al-Obaidi et al., 2021)(Al-Obaidi et al.2022), the idea is to propose an approach that can help the decision process of the designers, accounting for, a priori, the overall sustainability performance due to the interaction of the material with the surrounding environment. Such approach could be then replicated, in the future, for strategic structures similar to the one here assessed.

2 DESCRIPTION OF THE CASE STUDY AND DEGRADATION MECHANISMS

2.1 Description of the case study

The water treatment structure is located in Genoa, northern Italy, within the port area and aimed at serving a population of 250,000 inhabitants. It has been identified as a strategic structure in the case of an earthquake event, reason why a SL equal to 100 years has been taken into consideration for the following analysis. A frame structure, with beams which are sometimes eccentric in relation to the corresponding pillars, characterizes the ground level. The beams have a cross section equal to 0.70m x 0.70m or 0.70m x 1.00m, the pillars of 0.70m x 0.70m while the walls of the basins at the first floor have a thickness varying between 0.30m and 0.25m. Figure 1 gives an overview of the layout of the entire structure. To have a complete knowledge of the structure, the behaviour in the event of an earthquake has been assessed prior to estimating the durability of the construction within the SL. This was possible by carrying out a modal analysis in which the vibration response has been identified for each element of the structure. Figure 1 also details a vibration example in which it is possible to highlight how the overall behaviour is not uniform. The analysis hereinafter presented is focused on the 26 pillars of the structure. The pillars are characterized by 24 Φ 24 steel reinforcement bars equally located along the 4 sides. They are subjected to a biaxial compression and bending with an average axial force of 2,300 kN and the highest value of the acting bending moment (M_{Ed}) is equal to 1200 kNm. Figure 2 details the cross section of the pillars besides the M-N interaction diagrams due to the eccentric axial force. The structure being located at the seaside and being characterized by an XS1 exposure class, both the carbonation and the chlorides penetration phenomena have been taken into consideration. With regard to the concrete, the structure has been realized by employing ordinary reinforced concrete (ORC) and ORC containing crystalline admixture (1% by mass of cement). The latter was added to enhance not only the self-healing properties but also to reduce the permeability of the concrete, avoiding the ingress of harmful substances. Even though the pillars have been realized without the addition of the crystalline admixture (CA), hereinafter two cases are assessed. The first one, corresponding to the reality, with the pillars made with ORC (referred as P_ORC) and the second one, purely hypothetical, in which they are made with the addition of the crystalline admixture (referred as P_CA).

2.2 Carbonation

To estimate the carbonation penetration, 12 cube specimens (150mm x 150mm) have been cast during the structure casting phases (March 2022). Half of the specimens were realized with the mix design of P_ORC while the remaining ones with the one of P_CA. With regard to the carbonation tests, after being exposed to open air within the worksite for 3, 6 and 9 months, as shown in Figure 3 each specimen was split into two halves and each half was then divided in two equal parts to have two perpendicular areas on which phenolphthalein was then sprayed. Table 1 indicates the average penetration depth achieved after 3 months and 6 months respectively and it is also possible to observe an overall better performance of P_CA at both ages.

Figure 1. Layout of the structure (left) and the vibration response (right) in which the color red represents the parts more vulnerable to vibration.

Figure 2. Cross section of the pillars (left) and biaxial interaction diagram due to an eccentric axial force.

Figure 3. Example of the division of the specimen to spray the phenolphthalein.

Table 1. Carbonation depth (mm), Average and standard deviation after 3, 6 and 9 months.

	Average	SD
P_ORC (3 months)	3.8	0.60
P_CA (3 months)	1.72	0.35
P_ORC (6 months)	3.92	0.33
P_CA (6 months)	2.54	0.53
P_ORC (9 months)	4.3	0.75
P_CA (9 months)	3.03	0.25

The values presented in Table 1 have been then employed to predict the evolution of the carbonation over the SL of the structure through Equation 1 where x_c represents the depth of the carbonation, t the time expressed in years, $W(t)$ a weather function used to consider the time in which the concrete is wet and k is the carbonation coefficient measured in $\text{mm}/(\text{years})^{0.5}$. The latter depends

on several factors such as water to cement ratio, relative humidity and CO₂ concentration. While $W(t)$ has been assumed as equal to 1 due to the fact that the pillars are inside a prefabricated structure and, then, they are not wet, k has been determined by employing a non-linear regression analysis for Equation 1 and using the values reported in Table 1. The values obtained were 6.23 mm/(years)^{0.5} for P_ORC and 3.53 mm/(years)^{0.5} for P_CA. Thus, it was then possible to calculate the time needed for the carbonation process to reach the reinforcement bar surfaces located at a depth of 0.40mm according to the standards prescriptions for structures exposed to a XS1 environment. This corresponded to 41.3 years for P_ORC and 128.1 years for P_CA.

$$x_c = W(t)k\sqrt{t} \quad (1)$$

The result of P_CA being even higher than the accounted SL, the reduction of the diameter of the steel reinforcement bars have been estimated only for P_ORC by employing Equation 2 in which ϕ_0 represents the initial diameter of the reinforcement (mm), t the time (years), t_n is the time that the carbonation needs to reach the steel bars surface. Moreover, j is a constant equal to 0.0116 for the case of the steel and i_{corr} represents the power intensity in $\mu\text{A}/\text{cm}^2$ assumed as equal to 0.5 $\mu\text{A}/\text{cm}^2$ for the scope of this analysis according to (Bertolini & Pedferri, 1996).

$$\phi(t) = \phi_0 - 2i_{corr}j(t - t_n) \quad (2)$$

By employing Equation 2 it has been possible to estimate for P_ORC, a reduction of the cross section of each bar equal to 5.60% at the time of 100 years. These results are reported in Figure 3 which also contains the behaviour that the bars would have had in the case of P_CA. Then, following the model proposed by Maaddawy (El Maaddawy & Soudky, 2006) the time needed to form the first cracks because of the expansion products of the corrosion has been calculated. Such phenomenon is dictated by the thickness of the concrete cover, the diameter and the expansion volume of the steel bars, the elastic modulus of concrete and the thickness of the porous layer between concrete and steel. It was then estimated that the complete detachment of the concrete cover happens 11 years after the corrosion onset, in correspondence of the obtainment of 1 mm cracks, meaning after 52 years in total for P_ORC. Nevertheless, it must be specified that these results have to be considered as optimistic predictions since they are referring to a non-cracked state which is practically never achievable in the reality.

Figure 4. Loss of the cross section of the reinforcement bars in percentage (left) and decrease of steel tensile strength (F_{yk}).

2.3 Chlorides induced corrosion

As for the carbonation tests, 12 cubic specimens (150 mm x 150 mm) were realized during the casting procedures and were then split along two perpendicular areas to spray the 0.1-N AgNO₃ solution and check the chlorides penetration after 3 and 6 months of exposure to open air. Also in this case the results have shown a better performance for the case of the mix design of P_CA. Table 2 reports the value observed for the chloride penetration.

Table 2. Chlorides depth (mm), Average and standard deviation after 3, 6 and 9 months.

	Average	SD
P_ORC (3 months)	1.24	0.45
P_CA (3 months)	0.97	0.34
P_ORC (6 months)	2.10	0.81
P_CA (6 months)	1.13	0.22
P_ORC (9 months)	3.03	0.57
P_CA (9 months)	2.10	0.64

The values presented in Table 2 have then been used to calculate the apparent chloride diffusion coefficient (D_{app}) which, as already highlighted in other works (di Summa et al., 2022) (Cappellesso et al., 2023) (Kannikachalam et al., 2023) is a key parameter to predict the penetration of the chlorides within a certain time. Thus, considering a critical chloride content equal to 0.11% by weight of concrete as in (Stipanovic Oslakovic et. al, 2008), it has been possible to calculate a value of $9 \times 10^{-13} \text{ m}^2/\text{s}$ and $3.4 \times 10^{-13} \text{ m}^2/\text{s}$ for P_ORC and P_CA respectively by employing the second Fick's law. Figure 5 provides an overview of the chloride content for both P_ORC and P_CA at the age of 20, 40, 60, 100, 140 and 180 years for which both Cs and D_{app} have been assumed as constant over the time for the scope of these calculations. As it is possible to observe, the latter is reached, in correspondence of the reinforcement bars surface (namely 40 mm as the designed concrete cover) after 137 years for P_ORC and after more than 300 years for the case of P_CA. These years correspond to the corrosion initiation time. Moreover, considering that these values are based on the results obtained from the experimental campaign conducted on the uncracked state the influence of the cracks on the D_{app} value has also been checked. More specifically, considering a crack opening equal to 0.2 mm as suggested for the assumed environmental condition in the Eurocode and employing the model suggested by Wang et al., (Wang et al., 2022) an initiation time equal to 82 years for P_ORC and 135 years for P_CA was then calculated. Both periods are much higher than the ones previously estimated for the carbonation.

2.4 Structural performances of the case study subjected to the degradation phenomena

According to what has been stated in sections 2.2 and 2.3, P_ORC has a worse durability performance for both carbonation and chlorides penetration. Therefore, also its structural performance has been checked within the SL. More specifically, since carbonation is the degradation phenomenon which first leads to the reduction of the reinforcement cross section in the columns, it is the one hereinafter taken into account. Thus, the following timeframes have been assessed for the scope of the structural analysis: i) from 0 to 41 years, during when the cross section of the column doesn't show any variation; ii) from 42 to 51 years, when the corrosion starts to occur with the consequent cracks creation; iii) from 52 to 100 years, when, if no maintenance activities are going to be carried out, the concrete cross section is reduced because of the detachment of the concrete cover and the reduction of reinforcement area further continues. It has been calculated that, due to the corrosion consequences, the cross section design resistant moment M_{Rd} reduces from 1,216 kNm to 902 kNm in the M-N interaction diagrams which anyway keep their symmetry within the time. Then, the dynamic behaviour of the structure has been further assessed, hypothesizing the worst scenario in which all the pillars are subject to isotropic degradation. This represents the most dangerous scheme since in the reality there are sides of the pillars that could be more protected against the deterioration, simply because of their location and the cladding in the actual structure,. In general, it can be commented that a redistribution of the actions and a top column deflection not higher than 7.17 mm have been calculated. The latter is anyway within the limits allowed by the current codes which correspond, for a structure like the one here assessed, to a maximum value of 25.7 mm. Moreover, also a non-linear pushover analysis has

Figure 5. Calculated chlorides content at different ages for different depths for P_ORC (A) and P_CA (B).

been carried out with the consequent observation that plastic hinges form in correspondence of the edge of the pillars instead of along the beams. This is due to the design of the structure as a non-dissipative one. Nevertheless, the analysis demonstrated that the reduction of the cross section of the pillars doesn't cause any relevant changes in terms of structural resistance.

3 LIFE CYCLE ASSESSMENT AND LIFE CYCLE COST

3.1 *The system boundary of the analysis*

A cradle to grave system boundary has been employed to develop the LCA taking into consideration a SL of 100 years in total and supposing the need of one maintenance activity at 52 years only for the case of P_ORC. This is due to the carbonation that, based on the results of experiments, turned out to be the most severe degradation phenomenon for the case here assessed. The hypothesized maintenance activities consisted in the removal of the damaged concrete cover and reinforcement bars with the substitution of the latter and the casting of a new layer for the concrete cover after having applied a primer to favor its adhesion to the substrate. Ten impact indicators have been employed in total to describe the outcomes of the analysis according to the 10 CML IA impact method which aims to describe the overall consequences on a local, regional and global scale. More in detail, the following impact categories have been accounted for the scope of this analysis: global warming (GWP); acidification (AP); ozone depletion (ODP); photochemical oxidation (POCP); eutrophication (EP); abiotic depletion potential (ADP); human toxicity potential (HTP); freshwater aquatic ecotoxicity potential (FAETP); marine aquatic ecotoxicity (MAETP) and terrestrial ecotoxicity potential (TETP).

3.2 LCA and LCC outcomes

The LCA analysis highlighted a relevant reduction of the impacts of P_CA compared to P_ORC up to 40% as for HTP, FAETP and TETP. This is mainly due to the complete absence of the maintenance activities within the predefined SL for the case of P_CA. In this regard it must also be highlighted that all the steel scraps generated because of the maintenance activities of P_ORC are accounted as recycled, representing an environmental benefit, and for this reason are numerically counted with a negative value. If that were not the case, the reduction of the impacts of P_CA in comparison to P_ORC would have been even higher. In general, cement has a relevant contribution to some impact indicators as 45 % for GWP for both P_ORC and P_CA. Such percentage value is even higher in the case of MAETP impacts of reinforcement, with a value equal to 98% for P_ORC. Moreover, the effect of reinforcement on the overall impacts is smaller in the case of P_CA due to the fact that no replacement of the steel bars is supposed for the latter. Figure 6 presents some results in this regard.

Figure 6. Impacts reduction of P_CA relative to P_ORC (left) and indication of the incidence of the main components on the overall impacts for P_ORC.

4 CONCLUSIONS

This research aimed to quantify the sustainability of a structure defined as strategic for the urban metropolitan area, comparing an ordinary technological solution to a self-healing one. To this purpose, the seismic resistance has also been checked after the appearance of a consistent degradation at the age of 52 years, because of the carbonation, for P_ORC. One of the first observations that can be made is that the use of CA for P_CA results in better durability parameters and hence longer predicted SL. In addition to this, the structural analysis demonstrated that the degradation mechanisms may affect the structural response but, for the case studied here, having been basically designed as non-dissipative, there is no significant problem though a reduction of the safety factor does actually occur. Moreover, the LCA outcomes, showing the consistent advantages of P_CA in comparison to P_ORC, highlight their importance as a decision making tool. They allow to make an “a priori” evaluation of the potential sustainability already starting from the design phase, to improve, in the future, the economic and environmental efficiency of the case study.

ACKNOWLEDGEMENTS

This project has received funding from the European Union’s Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 860006.

The authors thank Penetron Italia and the construction management team, responsible for the works execution of “Nuovo Impianto di Depurazione Area Centrale di Genova D.A.C”, for allowing us access to the construction site besides giving us the opportunity to cast the samples necessary for the laboratory tests.

The influence of the expansive site of delayed ettringite formation on the anisotropy of expansion evaluated by mesoscale discrete model

M. Fujishima, T. Miura & H. Nakamura

Department of Civil Engineering, Nagoya University, Nagoya, Japan

ABSTRACT: In this study, the effect of the expansive site ratio on the anisotropy of expansion due to delayed ettringite formation (DEF) was numerically evaluated considering creep. In this analysis, aggregates and mortar were separately modeled using 3D-Rigid Body Spring Model. The expansion strain was applied to the expansive site for 200 days. Each analysis was conducted under stress-free and restraint conditions. As a result of the 1 % expansive site, the expansion under restraint condition was smaller than that under stress-free condition. In the case of a higher expansive site ratio, the expansion under restraint condition was larger, and the larger compressive stress was generated in the restraint direction. The reason why the expansion under restraint condition was smaller for the 1 % expansive site case is the less accumulated compressive stress due to the localization of expansion origin. Consequently, the expansion origin may be scattered in the actual phenomenon.

1 INTRODUCTION

When concrete materials undergo the high-temperature history at 70 °C and over at the early hydration stage, delayed ettringite formation (DEF) occurs and expansion cracks are possibly induced. The DEF mechanism was suggested by Taylor et al. 2001 as follows. When concrete is applied to the high temperature at the early hydration stage, ettringite is decomposed, and sulfate ions are absorbed in calcium silicate hydrate (C-S-H). In the curing stage, sulfate ions are gradually released, and ettringite is secondary precipitated. The crystal growth pressure of secondarily produced ettringite possibly causes expansion cracks inside the concrete. The expansion due to DEF reaches up to 2 %, which is larger than the alkali-silica reaction (ASR) which is one of the internal swelling reactions.

The cracking at the concrete surface due to ASR and DEF shows a similar crack distribution. However, the cracks inside the concrete shows different trend, because the origin of the expansion is different. The origins of ASR and DEF expansion are aggregates and cement paste, respectively. The internal cracks due to DEF are formed at the interfacial transition zone (ITZ). The crack propagation process due to DEF was proposed as follows (Sanchez et al. 2018). At the first stage of expansion, the bond between aggregates and cement paste is weakened. Then, the width and length of the cracks at the aggregates interface become larger, and they propagate to the mortar phase and are connected to adjacent aggregates. On one hand, for the internal cracks due to ASR, the cracks are generated from the inside aggregates and propagate to mortar.

For ASR and DEF expansion under restraint condition, the cracks show the directionality, which is parallel to the restraint direction, and the anisotropic expansion can be observed (Liaudat et al. 2018, Hansen et al. 2021, Anca et al. 2021, Kawabata et al. 2021). In the case of ASR under uniaxial restraint condition, the transversal expansion without any restraint is larger than that under stress-free condition, which is called expansion transfer (Multon et al. 2006, Gautam et al. 2017, Liaudat et al. 2018). By contrast, in the case of DEF under uniaxial restraint condition, because the transversal expansion is smaller than that under stress-free condition, the volumetric strain decreases approximately by 20 % (Bouzabata et al. 2012, Kawabata et al. 2021).

Comparing ASR and DEF expansion, the internal cracking and the anisotropy of expansion indicate different trends, and it may be attributed to the difference in expansion origins.

Currently, the numerical analysis for DEF expansion has been developed by some researchers. Roubin et al. 2014 modeled DEF expansion using FEM, and confirmed that the crack pattern at the interface of aggregates was consistent with the experimental observations. Wang et al. 2019 directly modeled spherical aggregates and simulated ASR and DEF expansion using 3D-RBSM (rigid body spring model) to reproduce the crack patterns and the change in compressive properties. Miura et al. 2020 evaluated the effect of the expansion origins of DEF on the expansion behaviors using 3D-RBSM. The result indicated that the expansive site ratio has a large influence on the anisotropy of expansion under restraint condition. However, creep behavior was not considered in the expansion model used in the simulation.

In this study, the anisotropy of expansion under the uniaxial restraint condition was numerically evaluated to discuss the influence of the expansion origins of DEF and the time-dependent behavior. In the analysis, coarse aggregates and mortar were separately modeled using 3D-RBSM as well as the previous modeling Miura et al. 2020. The creep model was applied to the mortar phase to consider the time-dependent behavior of concrete. To reproduce DEF expansion, the expansive site was randomly selected from mortar elements with various expansive site ratio, and the expansion strain was applied to the expansive site for 200 days. DEF expansion under stress-free and restraint conditions was numerically simulated. From the results, the effect of the expansion origin on the expansion behaviors under different expansion conditions was discussed.

2 OVERVIEW OF NUMERICAL ANALYSIS

2.1 3D-RBSM

RBSM can directly evaluate discrete behavior such as cracks. The elements are the rigid body, and the mechanical springs are placed at the boundary surface between rigid body elements. To reduce the element size dependency (Thomure et al. 2001), the rigid body element is described by random voronoi particle. Figure 1 shows voronoi elements and mechanical springs. Mesoscale material constitutive law is applied to mechanical springs to reproduce the macroscopic mechanical behaviors of concrete. Mechanical springs are composed of one normal spring and two shear springs, and the three springs are placed at integral points of the boundary surface.

Figure 2 Shows the mesoscale constitutive laws. Normal spring behaves based on the tensile and compressive constitutive laws and does not indicate a yielding due to compression so material failure is attributed to only tensile and/or shear failure. Shear spring behaves based on the shear constitutive law and is related to the compressive stress of normal spring to consider the stress dependency of normal spring. The mesoscale parameters for mesoscale constitutive law are calculated based on compressive strength as shown in Table 1. The other analytical parameters were described in reference (Miura et al. 2022).

* indicates macroscopic mechanical properties.

2.2 Expansion model for DEF

The course aggregates and mortar are separately modeled as shown in Figure 3(a). The analytical concrete model is cubic shaped with 75x75x75 mm. The coarse aggregate size is uniformly 10 mm in diameter, and the number of course aggregates is 200. The aggregate diameter used in this analysis was selected as representative diameter which is the greatest number of aggregates in the grain size distribution. The average element size of the coarse aggregate phase and mortar phase is 1.3 and 3.0 mm, respectively. The mortar elements around the aggregate were smaller than 1.0 mm so at least two mortar elements exist between the adjacent aggregates to describe the cracking of the mortar phase. The material properties of mortar and aggregate are shown in Table 2.

The creep model was applied to mortar elements to consider the time-dependent behavior during expansion. The creep model of the JSCE model (JSCE 2017) was modified as shown in Equation 1 to apply to the mesoscale discrete analysis.

$$\varepsilon_{i,t} = \alpha \sum_{t_j=0}^t \Delta\sigma_{i,t_j} \cdot \frac{4W(1 - RH) + 350}{12 + f'_c} \cdot \log(t - t_j + 1) \cdot 10^{-6} \quad (1)$$

where, $\varepsilon_{i,t}$: total creep strain, α : mesoscale coefficient, $\Delta\sigma_{i,t_j}$: increment stress from t_{j-1} to t_j , W : water content per unit (kg/m^3), RH : relative humidity, f'_c : compressive strength (MPa), respectively.

When the JSCE model is directly applied to the mesoscale discrete analysis, the effect of creep is much larger. Thus, the mesoscale coefficient α was induced to reduce the creep effect. The mesoscale coefficient α was determined by sensitivity analysis to fit the deformation of concrete without expansion under restraint stress. The creep model was applied to a normal spring, and creep strain was calculated by a step-by-step method. Although in mesoscale discrete analysis, different creep models between normal and shear springs or between concrete, mortar, and cement paste should be applied, the simple creep model was used in this analysis.

To reproduce DEF expansion, the expansive site was randomly selected from all mortar elements corresponding to the expansive site ratio. The expansive site ratio was 1, 5, 10, and 100 % as a parameter to discuss the effect of expansive site on the anisotropy of DEF expansion. Figure 3 shows each expansive site as gray elements. The expansion strain of 100 μ /day had been applied to normal springs of expansive sites for 200 days.

The expansion under free and uniaxial restraint conditions was analyzed to evaluate the expansion behavior of DEF under restraint condition. In the case of expansion under restraint condition, top and bottom surfaces in y direction were restrained by steel plates. To consider only the expansion behavior of DEF, the friction between restraint plate and concrete was not taken into account.

2.3 Definition of macroscopic expansion strain

The expansion strain was defined by the points on the concrete surface of x and z directions. The points were placed on elements 10 mm inside from each side. The strains were obtained from the change in length of 55 mm. The number of obtained strains was 4 in each x and z direction and 8 in the y direction, they were averaged and the expansion in each direction was obtained. One of the

Figure 3. Expansion models.

Table 2. Material properties for mortar and aggregate.

Scale	Material	f_c (MPa)	E (GPa)	f_t (MPa)	c (MPa)	G_f (Nm)
Macro	Aggregate ^{*1}	100.0	50.0	11.00	-	-
	Mortar ^{*2}	35.0	29.5	2.46	-	0.0559
Meso	Aggregate ^{*3}	150.0	70.0	8.80	14.0	0.0005 ^{*4}
	Mortar ^{*3}	52.5	41.3	1.97	4.9	0.0280
	ITZ ^{*5}	26.25	20.65	0.98	2.45	0.0140

*1 Material properties for aggregate were based on (Roubin et al. 2014) and (JSCE 2017). f_c for the aggregate was assumed as 100 MPa.

*2 The compressive strength of the mortar was set to 35 MPa and the other material properties of the mortar were calculated based on the formulation from the JSCE (JSCE 2017).

*3 The fracture energy is unknown. In this analysis, it was applied using a small value as the aggregate cannot represent softening after cracking.

*4 The properties of the ITZ are unknown. This analysis halved the mortar properties, similar to Wang's approach in (Roubin et al. 2014, Giorla et al. 2015).

purposes of this study is to understand the anisotropy of expansion under uniaxial restraint condition. Thus, average expansion and transversal expansion were calculated as follows under stress-free and restraint conditions, respectively. The average expansion was defined as the average expansion of the x, y, and z directions in the stress-free expansion case, and the transversal expansion was defined as the average expansion of the x and z directions in the restraint case.

3 NUMERICAL RESULTS

3.1 Expansion evolution

Figure 4 shows the expansion evolutions under stress-free and restraint conditions for all expansive site ratios. In the case of stress-free expansion, the expansion increased with time, and the expansion rose with an exponential trend for the lower expansive site ratio while it linearly increased for the higher expansive site ratio. The maximum expansion is also strongly influenced by the expansive site ratio. It is approximately 2 % for a 100 % expansive site ratio and similar to the experimental trend (Bouzabata et al. 2012, Kawabata et al. 2021). In this analysis, the imposed strain was fixed for all analytical parameters, and the maximum expansion and its evolution are directly influenced by the imposed strain. Therefore, it is difficult to conclude that the analytical result of the 100 % expansive site ratio is coincident with the actual phenomena from only the stress-free expansion trend. In the cases of 1, 5, and 10 % expansive sites, the expansion in each direction indicated variation. By contrast, in the case of the 100 % expansive site, the isotropic expansion evolution was observed. The variations would be attributed to the distribution and ratio of randomly selected expansive sites as shown in Figure 3. In the case of restraint condition,

Figure 4. Expansion evolution under stress-free and restraint conditions.

the expansion in the restraint direction is almost zero. This is because the restraint plates at the top and bottom of the concrete were fixed in this analysis. The transversal expansion indicates the remarkable difference between the 1 % expansive site ratio and others. The transversal expansion under restraint condition for the 1% expansive site ratio is smaller than that under stress-free expansion while it is higher for a higher expansive site ratio. The anisotropic expansion for the 1 % expansive site ratio is similar to the experimental trend (Bouzabata et al. 2012, Kawabata et al. 2021). The expansive site ratio would be one of the dominant factors to explain the inherent phenomena of DEF expansion such as the expansion evolution and the anisotropic of expansion.

3.2 Deformation

Figure 5 shows the deformation diagrams after 200 days. For the stress-free expansion, the expansion cracks were randomly distributed, and the number of cracks increased with the increase in the expansive site ratio. In the case of the 100 % expansive site, the expansion cracks were generated on the entire surface of mortar elements without any localized cracks. As the expansive site ratio decreases, the expansion cracks were gradually localized and the width of the crack was wider than that of the 100 % expansive site ratio. This map cracking is the unique crack behavior generated by DEF expansion. Regarding the restraint condition, the expansion cracks were generated in parallel to the restraint direction. Therefore, the directionality of crack can be clearly observed. This trend is consistent with the previous experimental results (Kawabata et al. 2021).

3.3 Internal crack distribution

Figure 6 shows the internal crack distributions under stress-free and restraint conditions at the center of the cross section at 25, 50, 100 and 200 days. From this figure, the crack propagation process due to DEF was confirmed as follows. Firstly, the cracks at the interface of aggregates, which is the unique internal cracking due to DEF, are generated. Then, the width of the cracks at the interface of aggregates becomes larger and it propagates to the mortar with time. This crack propagation process is consistent with the previous experiments (Sanchez et al. 2018, Diamond 1998). For the larger expansive site ratio cases, the cracks propagated earlier and more cracks were generated in mortar independent of the restraint conditions. However, the case of the 100 % expansive site under stress-free condition showed a different trend that no-cracked mortar area existed in spots although the cracks at the interface of aggregates were generated.

Figure 5. Deformation diagrams after 200 days under stress-free and restraint conditions.

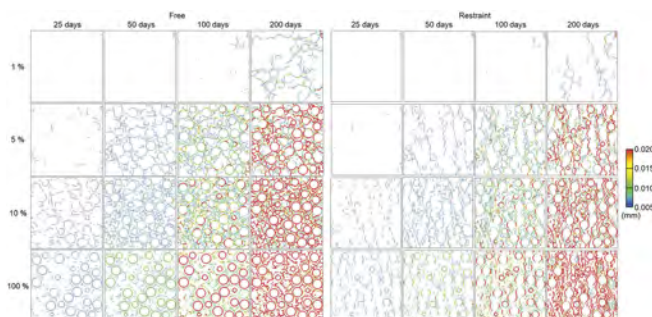

Figure 6. Crack distributions at the center of cross section under stress-free and restraint conditions.

Regarding the restraint condition, the expansion cracks were generated at only the interface of aggregates in the restraint direction, while the entire interface of aggregate was cracked in the stress-free expansion. In addition, the vertical cracks at the mortar phase can be observed. This trend is coincident with the surface crack distribution as shown in Figure 5.

4 DISCUSSION

According to the analytical results of DEF expansion under stress-free and restraint conditions, the transversal expansion under restraint condition was smaller than the average expansion under the stress-free condition in the 1 % expansive site case. This trend is similar to the experimental evidence (Bouzabata et al. 2012, Kawabata et al. 2021). Probably, the mechanisms of the expansion and crack generation process for the 1% expansive site ratio would be different from that for the higher expansive site ratio. In this chapter, the reason why the less expansive site ratio can reproduce the anisotropy of DEF expansion is discussed.

First, in order to assess the characteristic expansion behavior, the changes in the expansion rate of one expansive site for each expansive site ratio were calculated. The normalized expansion rate was defined as the increment of macroscopic expansion in a day divided by the expansive site ratio as shown in Equation 2 to compare the expansion rate between different expansive site ratio cases.

$$R_{macro,t} = \frac{\partial \varepsilon_{ave}}{\partial t} / S_{ex} \quad (2)$$

where, $R_{macro,t}$: normalized expansion rate (%/day), ε_{ave} : average expansion (%), S_{ex} : expansive site ratio, respectively. ε_{ave} under restraint condition is the averaged transversal expansion in the x and z directions. This index indicates the contribution of one expansive site to macroscopic expansion.

Figure 7 shows the change in the normalized expansion rate. In terms of stress-free expansion, the normalized expansion rate of the 100 % expansive site ratio is very low, while that of the 1 % expansive site ratio is the highest and indicates a different trend. This trend means that one expansive site largely contributes to macroscopic expansion in smaller expansive site cases. Regarding restraint condition, the trend is similar to the stress-free expansion case. The normalized expansion rate under restraint condition is higher than that of stress-free expansion, while the trend of the 1 % expansive site ratio is the opposite. In the case of the 1 % expansive site ratio, the normalized expansion rate under restraint condition is smaller than that of stress-free expansion within 100 to 175 days. Therefore, the contribution of one expansive site to macroscopic expansion under the restraint condition was smaller.

Figure 8 shows the stress distributions in the y-direction at the center of the cross-section under stress-free and restraint conditions at 25, 50, 100 and 200 days. For the stress-free condition, compressive and tensile stresses were locally generated in the cases of 1, 5 and 10 % expansive site. Tensile stress was released with the development of cracking and, subsequently, compressive stress was gradually decreased. By contrast, in the case of the 100 % expansive site under stress-free condition, compressive stress was generated at the entire cross-section while it was relatively lower than the others. Based on the stress distribution, the no-cracked mortar area in spots as shown in Figure 6 is probably attributed to that compressive stress was accumulated at entire mortar elements and, therefore, cracks cannot be generated at some parts so that internal stresses are balanced. For the restraint condition, compressive stress in the direction parallel to the restraint was increased with time. For the larger expansive site ratio cases, larger compressive stress was promptly accumulated in comparison to the stress-free condition.

Considering the expansion behavior as shown in Figures 7 and 8, the process of expansion evolution is described as follows. At the initial expansion stage, the expansion did not increase so much. This would be attributed to the internal constraint effect of the cross-section against the internal expansion pressure. After cracking, the internal constraint effect would be decreased, and then, the expansion rate increases. After that, the normalized expansion rate of 5 and 10 % expansive site ratio is in a plateau. These trends can be explained by the crack development process and internal stress accumulation. As many expansion cracks are generated in the cross-section, the internal stresses cannot be accumulated so much because the resistance force against the imposed strain is

Figure 7. Expansion rate evolution.

Figure 8. Stress distributions in the y-direction at the center of cross section.

decreased due to the existence of cracks. Therefore, the expansion trend of the 100 % of the expansive site ratio can be explained by a much faster cracking process and dissipation of internal stress corresponding to imposed strain. With the same concept, the expansion trend of the 1 % expansive site ratio can be also explained by the slow cracking process due to the small expansive site.

In the case of the 1 % expansive site ratio, the expansion rate increased around 100 days (Figure 7). This is because compressive stress against the internal expansion pressure was small before 100 days and, then, the accumulated compressive stress became larger. After that, expansion cracks were generated and the expansion subsequently developed. In other cases, for the stress-free condition, the locally accumulated compressive stress was not largely changed corresponding to the expansive site ratio. By contrast, for the restraint condition, larger compressive stress accumulated in the higher expansive site ratio cases. When larger compressive stress accumulates in the y-direction, larger deformation in the lateral direction occurs. This is attributed to the deformation due to the Poisson effect during compressive loading. Thus, in the higher expansive site ratio cases, the transversal expansion under restraint condition was larger than the average expansion under stress-free condition. As a result of the 1 % expansive site ratio, the less accumulated compressive stress resulted in the anisotropy of DEF expansion. Consequently, the compressive stress accumulated in the restraint direction possibly effects on the expansion behavior.

Generally, expansion cracks due to DEF with small width are distributed at the first stage of expansion and, then, the width of cracks locally becomes large. Kchakech (2015) investigated the relationship between the expansion due to DEF and the crack propagation of concrete surface. The result indicated that the crack length increased after the expansion was developed. Especially, even if the expansion plateaued, the crack length increased. Based on the analytical results, although such inherent trends were not confirmed, the expansive site may be scattered in the actual DEF expansion such as in the case of the 1 % expansive site. Furthermore, the unique crack propagation process may involve a complicated expansion process, such as the time-dependent change in the expansive site distribution or ratio.

5 CONCLUSIONS

In this study, considering creep behavior, the effect of the expansive site ratio on the anisotropy of expansion due to DEF was numerically evaluated. To reproduce DEF expansion

under stress-free and restraint conditions, coarse aggregates and mortar were separately modeled using 3D-RBSM, and the expansive site was randomly selected from mortar elements.

- 1) In the 1 % expansive site case, the expansion under restraint condition was smaller than that under stress-free condition, which is consistent with previous experiments. This may be attributed to less accumulated compressive stress due to scattered expansive sites.
- 2) In the 1 % expansive site case, the expansion rate significantly increased after the crack generation. This indicates that the crack generation and propagation involve in the increase in the expansion rate of DEF.
- 3) Based on the deformation diagrams, map cracking was observed on the concrete surface under stress-free condition, which is the characteristic cracking due to DEF expansion. For the cases under restraint condition, cracks indicated the orientation parallel to the restraint direction. This trend is consistent with the previous experimental results
- 4) Based on the crack distribution, cracks at the interface of aggregates were generated at first. Then, the width of the cracks at the interface of aggregates became larger and it propagated to mortar. This crack propagation process is consistent with the previous experiments.

ABSTRACT: Integrated chemo-physics and mechanistic modeling is presented with regard to the multi-scale referential volume for behavioral simulation of reinforced concrete in service. The timescale of application ranges from nano-second for explosive events to years or century for life cycle of building and infrastructures. The developed simulation platform is being applied to the performance assessment of both new-designed and existing reinforced concrete on the scheme of performance-based design.

1 INSTRUCTIONS

Structural safety performances and durability of reinforced concrete (RC) are closely associated with chemo-physics and mechanistic events developing inside the microscopic spaces like pores which is thermodynamically equilibrated with surrounding environments. At the same time, the chemo-physics is mutually influenced by macroscopic structural damages and deformation like cracking, which plays a substantial role as high-speed path of substances such as water, carbon dioxide, chloride. Thus, the integration of structural kinetics and material mechanics shall be performed to meet the challenge of infrastructure design and maintenance.

This paper presents an integrated chemo-physics and mechanistic modeling with regard to the multi-scale referential volume. The timescale of simulation in cyber spaces ranges from micro-seconds for explosive events to years or century for life cycle of building and infrastructures. The developed simulation platform is being applied to the safety and durability performance examination of newly constructed RC and life-cycle assessment of existing RC on the scheme of performance-based design and maintenance.

2 INTEGRATED SCHEME OF CHEMO-PHYSICS AND MECHANICS

The microstructure modeling of concrete composite with micro-pores and the macroscopic structural concrete constitutive modeling are integrated as shown in Figure 1. The microstructure of porous media consists of capillary, gel and interlayer pores which is stochastically described by the pore size distribution function (Maekawa et al. 2008). The moisture state is identified by solving the thermodynamic equilibrium under the paths of wet and drying cycles. Here, the motion of liquid and vapor through the connected micro-pore network is idealized so that the mass balance is satisfied. The solids of hardened cement are consequently built according to the cement hydration, which is formulated by the multi-mineral hydration

model. The kinetics of substances solved in pore water is formulated together with the mutual equilibrium of multi-ions (Cl^- , Mg^{2+} , Ca^{2+} , OH^- , SO_4^{2-} , Na^+ , K^+ , Fe^{2+}) and the solved O_2 and CO_2 (Ishida et al. 2004, Maekawa et al. 2004, Elakneswaran and Ishida 2014, Wang et al. 2022). The macroscopic modeling of structural concrete with cracking was presented by integrating shear transfer along crack, transversal tension stiffening and softening and compression-tension along crack. This has been practically applied for static and dynamic behavioral simulation of RC structures (Maekawa et al. 2004).

These sub-frameworks are combined through the meso-scale modeling for crack kinetics as shown in Figure 1. Liquid water, compressive gas, frozen ice, corrosion rust and ASR gels are allowed to stay and flow in spaces surrounded by crack planes whose volume may dynamically vary. Then, the wide range of time-dependency of RC and constituent materials can be covered systematically. Figure 1 shows the governing equations of crack substances by poromechanical scheme (Biot et al. 1973). Here, the driving force of pore substance's motion denoted by " ω " is the gradient of pore pressure indicated by " p " in Figure 1. The poromechanical scheme can be multi-overlaid to handle the mixed system of several pore substances (Gong et al. 2019).

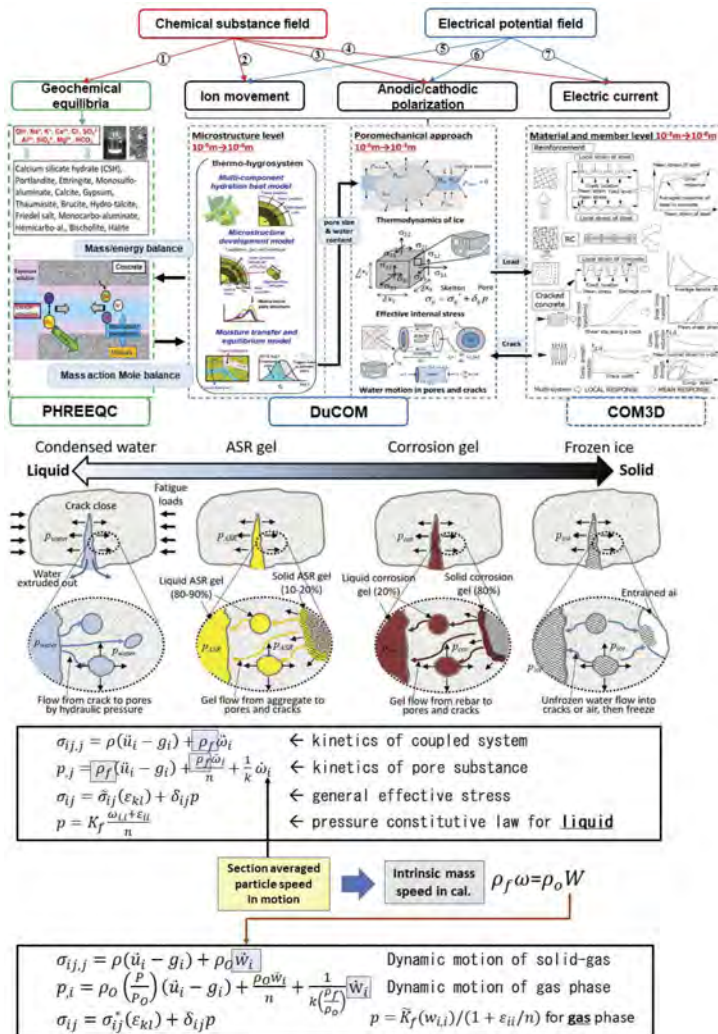

Figure 1. Integrated scheme of micro, meso and macroscopic modeling and the governing equations of kinetics of substances inside mores and crack spaces.

3 EXTENDED POROMECHANICS OF COMPRESSIVE MEDIA - MICRO-SECOND

As shown in Figure 1, the formulae of poro-mechanical kinetics can be applied to compressive gas by defining the mass rate of pore substance instead of the original particle in motion. Here, the constitutive model of gaseous pore-substance becomes highly nonlinear unlike the uncompressive liquid phase, which has been applied to consolidation and liquefaction of foundation. Figure 2 shows the numerical solution of dynamics inflation of gas (micro-second) at the gravity center of RC slab for verification of the extended gaseous poro-mechanics. The gas pressure develops inside crack spaces and spread out in a circle accompanying progressive cracking. We have a similar event of corrosion cracking which the corrosion gel introduces the cracking and at the same time it migrates into the crack spaces. Thus, the meso-scale model may build the multi-phase functionality with different timescale.

Figure 2. Verification of the computational scheme for extended poro-mechanics of compressive idealized gas substance associated with crack propagation of reinforced concrete – nano and micro-second event.

4 CHEMICAL REACTION, DECOMPOSITION AND RE-HYDRATION – HOUR SCALE

Hardened cement binder of concrete may be deteriorated owing to chemical reactions in the micro-scale volume under high temperature, which also causes the meso-scale cracking. The former chemical event results in the varying micro-pore structures and released crystal water inflates inside concrete and introduce the explosive mechanical damages of meso and macro-scales. The fire performance assessment requires the integrated modeling of chemo-physics and mechanics.

Figure 3 shows the chemical reaction formula under high temperature and consequent reform of the micro-pore structures (Iwama et al. 2022). Through the meso-scale modeling of compressive strength of concrete composites, digital data of microscopic events are linked with the macroscopic behavioral simulation of structural concrete via meso-scale modeling as shown in Figure 4. The experimental validation of the predictive platform was conducted in use of the weight change of extremely heated concrete cylinders as well as RC beams whose ductility was upgraded by the high temperature history over 1,000°C. It is computationally confirmed that the structural behaviors after exposure to fire are governed by the microscopic reform of crystals and macroscopic damage caused by thermal stress and explosion provoked by the rising vapor pressure.

5 LONG-TERM PERFORMANCE ASSESSMENT – NON-POROMECHANICS

Moisture migration and thermodynamic equilibrium may cause volumetric change related to the self-equilibrated time-dependent stresses which lead to structural performances. If no

cracking is introduced, moisture migrates through the micro-pores. Figure 5 shows the long-term excessive deflection of hollow-type long span PC viaducts over a half century (Ohno et al. 2012), and the chemo-physics and mechanics modeling can capture the long-term serviceability, and this has been included in the code specification of JSCE. Since the moisture kinetics is highly size-dependent, macroscopic mechanistic behaviors do follow the size-effect as shown in Figure 5. The impact of moisture migration arises appears slowly for structures with large-sized members like nuclear power plants compared to the normal RC building (Kurihara et al. 2017). When cracks are introduced, moisture migration is accelerated since cracks are the path of substances. The multi-scale modeling may capture the timeline of structural concrete.

6 POROMECHANICS OF INCOMPRESSIVE MEDIA

6.1 Assessment of fatigue life of RC bridge deck – condensed water in pores

The meso-scale plays a critical role on the coupling problems of liquid water and cracked reinforced concrete under repeated actions as shown in Figure 6. The cyclic crack open & closure may create the pressure rise of pore substances owing to its viscosity and incompressibility. Thus, this impact may reach the micro-pore structures and consequent erosion. This microscopic action in seconds is similar to concrete damage by freeze-thaw cycles in days. This scheme successfully reproduces the shortened life of RC decks under wheel-type moving load with stagnant water in cyber space (Maekawa and Fujiyama 2013) and was validated by comparing the simulation with the real bridge deck lifetime over a half century (Takahashi et al. 2022) as shown in Figure 6.

Crack is one of critical factors, since it offers the pore-pressure rises caused by external loading to structures. At the same time, cracking brings about large-sized continuous paths of pore substances which may reduce the pore pressure. In some cases, ASR induced cracks may prolong the fatigue life of RC decks even under the condensed water which can escape through cracks.

6.2 Coupled chemical reaction and solid formation

Figure 7a shows the coupling of ASR gel formation driven by alkalinity of pore-solution and cracking of concrete. For computing the rate of reaction, the migration and equilibrium of sodium and potassium ions are computed (Takahashi et al. 2016) by solving the mass balance requirement. Since the ASR gel is formed inside aggregates, the micro pore structure is assumed not to be changed but it can absorb the gels inside the pore spaces including the space of aggregates. Here, it should be noted that ASR expansion of macroscopic concrete composite is apparently size dependent, because produced silica gel is hardly in motion when

the concrete composite is large and kept longer inside the composite with sustained pore pressure. It means that ASR expansion is not a material characteristics but the macroscopic structural behavior.

The ASR gels are known to be solidified in years after the creation. Thus, crack spaces are filled by the solidified gels and the mechanical properties of concrete may change (Takahashi et al. 2016, 2018). The impact of cracking is taken into account in the RC constitutive modeling in accordance with the field of strains as for the macroscopic indicator. The integrated scheme can handle these coupling of micro and macroscopic events to meet the challenge of simulating overall structural concrete subjected to forces and ambient conditions (Figure 5).

Figure 8 shows the simulation of cracking around a single reinforcing bar embedded in concrete. If the sequence of actions to cause cracking (corrosion of steel, ASR and freeze-thaw cycle: FTC) would be changed, damage profiles are predicted to be different (Gong and Maekawa 2019). The authors assume that each substance is driven by the gradient of its concentration with mutual interaction among them (see Figure 8). These attribute to the nonlinearity of each chemo-physical and mechanistic events. Here, the authors hope to be validated experimentally and by some site-inspection of real infrastructures under natural climates.

Recently, the chemo-physics and mechanical scheme for structural concrete and cementitious composites was applied to the design and construction of underground LNG storage tanks as shown in Figure 9 (Takahashi et al. 2019). The construction processes including the excavation of foundation and settlement of retaining walls were traced. The curing of fresh concrete was also re-produced inside the cyber space according to the specification of constructions. In each stage, the path-dependent parameters were taken over from the previous one. After overall 23 stages of construction, the maintenance stage begun in a long timeline till 100 years. During the period of maintenance, the safety check was conducted under statics as well as dynamics as for assessing earthquake resistance, because the seismic resistance and deformability would vary in time as shown in Figure 5.

7 CONCLUSIONS

Integration of modeling for chemo-physics of cement composites and structural concrete mechanics with cracking was presented in multi-scale spaces and time domains from micro-seconds to hundred years as follows.

- (1) Kinematic modeling for substances in crack spaces may integrate the micro chemo-physics and macro mechanical modeling by poro-mechanical scheme.
- (2) The framework of poro-mechanics can be extended to compressive gaseous media which may migrate and accompany the progressive cracking similar to the corrosion and freeze-thaw actions.
- (3) The grand system is applied to the design and construction of real infrastructures on the scheme of performance-based design.

ABSTRACT: Structural build-up describes the stability and early-age strength development of fresh mortar used in 3D printing. It is influenced by several factors, i.e. the composition of the printable material, the printing regime, and the ambient conditions. The existing modelling approaches for structural build-up usually define the model parameters for a specific material composition without considering the influence of the ambient conditions. The goal of this contribution is to explicitly include the temperature dependency in the modelling approach. Temperature changes have significant impact on the structural build-up process: an increase of the temperature leads to a faster dissolution of cement phases and accelerates hydration. The proposed extended model includes temperature dependency using the Arrhenius theory. The new model parameters are successfully calibrated based on Viskomat measurement data using Bayesian inference. Furthermore, a higher impact of the temperature in the re-flocculation as in the structuration stage is observed.

1 INTRODUCTION

For extrusion-based 3D concrete printing, the early age of printable mortars is of great importance, which is affected by various time dependent phenomena like structural build-up, plasticity as well as viscosity. Structural build-up is the time dependent structuration of cementitious material at rest due to thixotropy and early hydration processes. It influences the printability, buildability, and open time of printing processes (Reiter et al., 2018, Mohan et al., 2021). For a deeper introduction it is referred to (Roussel et al., 2012). Generally, the structural build-up is influenced by several factors from the raw material constituents to external conditions such as temperature as discussed in detail in (Jiao et al., 2021).

There are several approaches to model the structural build-up of cementitious materials. Most phenomenological models are based on a time-dependent internal structural parameter describing the flocculation state, which is assumed to be zero after mixing and increases with time (Roussel, 2006). The approaches differ in the definition of the time dependency (linear, exponential, bi-linear). In the most often used model proposed by (Roussel, 2006), the static yield stress at rest increases linearly in time with the constant structuration rate A_{thix} from an initial value τ_{y0} :

$$\tau_y(t) = \tau_{y0} + A_{thix} t. \quad (1)$$

Covering the speed-up of the structural build-up after a certain time due to an onset of the acceleration period of hydration, an exponential dependency is proposed in (Perrot et al., 2015). The static yield stress following this exponential model is given as:

$$\tau_y(t) = A_{thix} t_c \left(e^{\frac{t}{t_c}} - 1 \right) + \tau_{y0}, \quad (2)$$

with an additional parameter of the characteristic time t_c . Recently, (Kruger et al., 2019) developed a bi-linear approach considering two stages of the structural build-up development with different rates: re-flocculation and structuration. By differentiating between those stages a higher precision of the first rapid re-flocculation stage dominated by physical processes is possible. The structuration stage is mainly governed by chemical reactions. The static yield stress according to the Kruger model is then given by two equations:

$$\tau_y(t) = \begin{cases} \tau_{y0} + R_{thix}t & \text{if } t < t_{rf} \\ \tau_y(t_{rf}) + A_{thix}(t - t_{rf}) & \text{if } t > t_{rf} \end{cases} \quad (3)$$

In the latter, the re-flocculation time t_{rf} defines the time period between the first stage with the re-flocculation rate R_{thix} and the second structuration stage (A_{thix}). The ratio between both rates depends on the material mixture composition (Kruger et al., 2019). In (Ivanova et al., 2022) the bilinear model is applied in the context of constant rotational velocity tests of printable mortar and concrete and for several characterization methods of 3D printable cementitious mortars in (Bos et al., 2021).

Usually, the model parameters are defined for a specific material composition without considering the influence of ambient conditions. Nevertheless, ambient conditions such as temperature and humidity will change in real life printing processes due to weather conditions, summer, winter, day, night as well as the printing process itself (pumping process changes the temperature due to pressure changes (Strangfeld, 2022)). In the discussion of eight implemented 3D concrete printing projects from around the world by (Bos et al., 2022), the challenges of the ambient temperatures' influence were also pointed out. Printings were stopped or shifted to the night by increased ambient temperature or a continuous measurement of the system temperature were applied. The temperature has a particularly significant influence on the structural build-up process because an increase of the temperature leads to a faster dissolution of cement phases and accelerates hydration. Nevertheless, there are only limited studies available to date. (Bos et al., 2019) investigated the influence of material temperature and they have shown that warm water accelerates the structural build-up rate but reduces the bonding strength between layers. (Huang et al., 2019) have shown that the increase of the temperature in a constant shear rate test of cement pastes results in an increase of the structural build-up rate. The temperature sensitivity is studied by calculating the activation energy by Arrhenius theory. They extend their studies by measuring the storage modulus by small amplitude oscillatory shear test (SAOS) in (Huang et al., 2022). It was pointed out that a rise of the temperature leads to a faster storage modulus development for cement paste samples with the same hydration degree. However, (Bogner et al., 2020) using SAOS tests at 10, 20, 25 and 30°C, found out that regardless of the ambient temperature, all investigated samples demonstrated a similar evolution of the complex shear modulus during the first 1.4 h of hydration. After that, a significant temperature influence on the modulus was observed. The discrepancy between those results could also be related to the different material compositions, methods, and time scales. The authors themselves observed a significant temperature influence on the storage moduli for cement pastes measured by SAOS with a bi-linear increase over the resting time (Mezhov et al., 2022).

The goal of this contribution is to develop a temperature dependent structural build-up model. Therefore, the bi-linear Kruger model (Equation 3) is extended by temperature dependent parameters modelled based on the Arrhenius theory. The new model parameters are estimated using Bayesian inference. Therefore, static yield stress data measured via Viskomat at four different temperature levels are used.

2 MATERIALS AND METHODS

2.1 Mixture composition and measurement set-up

Mortar samples were prepared according to the mixture composition given in Table 1. First cement CEM I 42.5 R, silica fume, sand, fly ash and superplasticizer were mixed with a spoon

around 30 sec in a 600 ml cup. The water was added within 15 sec during the second mixing at 200 rpm for 1 min by IKA STARVISC 200–2.5 mixer. After a pause and hand mixing for 30 sec, the mortar samples were mixed at 400 rpm for 2 min.

Table 1. Mixture composition.

Components	Amount [kg/m ³]
Cement (CEM I 42.5 R)	650
Sand (0.1/0.5)	980
Fly ash	190
Silica fume	90
Superplasticizer powder	4.3
Water	260
Spread by DIN EN 1015-3:1999-04	190 mm
Water cement ratio	0.4
Temperature after mixing	27°C

The structural build-up measurements were performed using a Schleibinger Viskomat NT with a double gab basket cell. The used device can measure torque from 0 to 500 Nmm. Note, the mixture composition was designed in such a way that the maximum torque does not exceed those range for all investigated temperature levels. Ten points with a rotational velocity of 0.1 rpm within 30 min were measured. The test protocol is summarized in Figure 1. Three tests for every temperature were carried out using a waterbed temperature control system with constant temperatures 17, 22, 27, 32 and 42°C. The initial temperature of the mortar after mixing was always 27°C.

Figure 1. Test protocol for Viskomat NL measurements.

2.2 Temperature dependent structural build-up model

The bi-linear model of (Kruger et al., 2019) given in Equation 3 is extended to model the temperature influence on the early age behavior of the static yield stress τ_y . Therefore, the model parameters re-flocculation rate, structuration rate, re-flocculation time and initial static yield stress are introduced as temperature (T) dependent functions. So that the temperature dependent bi-linear model reads:

$$\tau_y(t, T) = \begin{cases} \tau_{y0}(T) + R_{thix}(T)t & \text{if } t < t_{rf}(T) \\ \tau_y(t_{rf}(T), T) + A_{thix}(T)(t - t_{rf}) & \text{if } t > t_{rf}(T) \end{cases} \quad (4)$$

Where the temperature dependent parameter functions are defined as:

$$\gamma(T) = \alpha_\gamma \exp\left(\beta_\gamma \left(\frac{1}{T} - \frac{1}{T_{ref}}\right)\right) \quad (5)$$

for $\gamma \in [\tau_{y0}, R_{thix}, A_{thix}, t_{rf}]$. This exponential functionality of a reaction rate of chemical as well as physical processes is known as Arrhenius equation. In the Arrhenius equation, the pre-factor β_γ in Equation 5 is defined by the negative ratio of a specific activation energy E_a and the gas constant R . Among other things, the Arrhenius theory is usually applied to model and characterize the temperature dependency of the cement hydration, see e.g. (Poole et al., 2007, Carette and Staquet, 2016). The unknown activation energy is thereby usually determined by calorimetry. Here, the Arrhenius equation is used to consider the temperature dependency of the structural build-up rates (re-flocculation rate and structuration rate) as well as for the re-flocculation time and the initial yield stress. The extended temperature dependent bi-linear model in Equation 4 and 5 has in total nine new unknown model parameters: the four α 's and β 's and the reference temperature T_{ref} . Those are to be defined via measurement data at different ambient temperatures for each mixture composition.

2.3 Bayesian model parameter estimation

In general, the estimation of unknown model parameters based on measured data is an inverse problem. The aim is to find appropriate values for a set of unknown model parameters θ (here the model parameters in Equation 4 and 5) minimizing the error between a given set of measurement data y and the corresponding model output values $g(\theta)$ (here Equation 4). In deterministic methods, the best parameter set is found by minimizing this difference by optimization approaches e.g. least-squares, L_p norm or weighted least square ansatz (see e.g. (Mohammad-Djafari, 1998)). The solution is a single set of the parameters' estimates and carry no information about how reliable or likely they are. In contrast, probabilistic methods provide a probabilistic description of information and beliefs, allowing the consideration of various uncertainties. In those approaches, the posterior probability distribution is computed using the Bayes' rule via

$$P(\Theta|y) = \frac{P(y|\Theta)P(\Theta)}{\int P(y|\Theta)p(\Theta)d\Theta}. \quad (6)$$

In the latter, the unknown parameter vector $\Theta = (\theta, \sigma)$ includes beside the model parameters θ additional noise parameters σ (describing e.g. the standard deviation of a Gaussian distributed additive noise $e \sim \mathcal{N}(0, \sigma^2)$). The prior probability density function $P(\Theta)$ reflects the prior knowledge on the parameters, while the likelihood $P(y|\Theta)$ defines the probability that the model has generated the data under the given model parameters. The normalization term in the denominator describes the evidence for the data considering the model. More details on the mathematical background can be found e.g. in (Watanabe, 2018).

The computation of the posteriori (Equation 6) is cumbersome, especially with increasing dimensionality of the parameter space. For that reason, sampling-based methods (Lye et al., 2020) are usually applied to evaluate Equation 6. In this paper, the well-known Markov Chain Monte Carlo (MCMC) sampling (Metropolis et al., 1953) is used. The parameter estimation is conducted via the open-source Python package *probeye* (<https://pypi.org/project/probeye/>).

3 RESULTS AND DISCUSSION

The measured temperature effect on the static yield stress evaluation in the first 30 minutes is given in Figure 2. The mean and standard deviation of the static yield stress based on three tests (stars) for all investigated temperature levels are given over the time as solid line and bars, respectively. The static yield stress is computed from the measured torque multiplied by the conversion factor for the specific cell. Two aspects are shown. First, a significant temperature effect in the yield stress evaluation is observed. With increasing ambient temperature, the rate of the static yield stress evolution increases confirming the need of a temperature dependent modelling approach. Second, the evaluation is split into two stages: a re-flocculation stage followed by

Figure 2. Mean and standard deviation of static yield stress measurements over time for five different temperatures. Separation into re-flocculation and structuration stage demonstrated for the data at 27 °C.

a structuration stage which is additionally demonstrated using the data at 27°C on the right side of Figure 2. The change between the two stages, the re-flocculation time, happens around 15 min. Independent of the ambient temperature, the first (re-flocculation) rate is usually higher than the second (structuration) rate. The rate's ratio depends on the temperature.

In a Bayesian parameter estimation, the model parameters of the proposed temperature dependent model were inferred using the measured data at temperature 17, 22, 27 and 42°C (the data at $T = 32^\circ\text{C}$ is used for the verification). Therefore, a MCMC solver with 10^6 steps in 20 chains and 5000 initial steps were running using the open-source Python module *probeye*. The prior distribution for the nine model parameters were chosen as:

$$\begin{aligned} \alpha_{\tau_{y0}} &\sim N(20, 6^2) \text{ [Pa]}, \alpha_{R_{thix}} \sim N(6, 2^2) \text{ [Pa/min]}, \alpha_{A_{thix}} \sim N(4, 1^2) \text{ [Pa/min]}, \alpha_{t_{rf}} \sim N(10, 3^2) \text{ [min]} \\ \beta_{\tau_{y0}} &\sim N(-30, 9^2) \text{ [1/K]}, \beta_{R_{thix}} \sim N(-30, 9^2) \text{ [1/K]}, \beta_{A_{thix}} \sim N(-10, 3^2) \text{ [1/K]}, \beta_{t_{rf}} \sim N(0, 3^2) \text{ [1/K]} \\ \sigma &\sim U(1, 30) \text{ [Pa]}. \end{aligned}$$

For the reference temperature, the sample's temperature after mixing was used: $T_{ref} = 27^\circ\text{C}$.

The resulting predictive posterior probability is plotted in Figure 3 as a pair plot. Here, the advantage of using a probabilistic approach can be seen. Instead of one parameter set (like the result of a deterministic approach), the deviation and correlation of the model parameters are estimated. Especially, the parameter $\alpha_{R_{thix}}$ (in the figure α_2) and $\alpha_{\tau_{y0}}$ (α_1) as well as $\beta_{\tau_{y0}}$ (β_2) and $\beta_{R_{thix}}$ (β_1) are clearly correlated, showing the ill-posedness of the inverse problem. Note, the results are also influenced by the here chosen prior distributions. Furthermore, a close to zero mean of $\beta_{t_{rf}}$ (β_4) indicates a neglectable temperature dependency of the re-flocculation time. An averaged ratio between $\beta_{R_{thix}}$ (β_2) and $\beta_{A_{thix}}$ (β_3) of around two suggests a significant higher activation energy of the re-flocculation stage compared to the structuration stage.

The inferred temperature dependency of the primary parameters: initial yield stress τ_{y0} , re-flocculation rate R_{thix} , structuration rate A_{thix} and re-flocculation time t_{rf} , modelled by the functionality given in Equation 5 is evaluated in Figure 4. The solid line represents the mean values, whereas the bars give the first standard deviation based on the MCMC samples. The plot visualizes the significant temperature dependency in the rates. But the structuration rate is less temperature dependent as the re-flocculation rate. The physical processes in the re-flocculation stage seems to have a higher temperature sensitivity, where rising temperatures increase the Brownian motion between the particles. Additionally, the shape of the temperature dependency of the two rates differs. The re-flocculation rate increases nearly linear, where

Figure 3. Pair plot of the posterior distribution with the abbreviations 1 : τ_{y0} , 2 : R_{thix} , 3 : A_{thix} , 4 : t_{rf} .

the structuration rate temperature function seems to be logarithmic. Furthermore, the initial static yield stress increases like the re-flocculation rate since both parameters describe the re-flocculation stage. In contrast, the re-flocculation time is approximately independent of the temperature with an aver-aged value of around 15 min. The measurement noise was assumed to be temperature independent, and its mean is estimated as 12 Pa.

As verification of the proposed temperature dependent structural build-up model in Equation 4 and 5 the model is reevaluated for the training temperature values 17, 22, 27 and 42°C using the estimated parameter distribution as well as newly evaluated at temperature 32°C and compared to the corresponding measured data. That comparison is shown in Figure 5 given the mean model

Figure 4. Inferred temperature dependency computed with Equation 6.

response as well as its first standard deviation for each temperature value and the measured data. A very good agreement for all investigated temperature values is reached even for those which were not included in the calibration part. In this way, the proposed model seems promising in predicting the temperature influence on the structural build-up of fresh mortar.

Figure 5. Inferred temperature dependency (mean as solid line and first standard deviation as dashed line of the static yield stress according to Equation 5 compared to the measured data (stars).

4 CONCLUSION

The present paper presents experimental results of the constant shear rate test indicating the influence of different ambient temperatures on the structural build-up evolution of mortar. The measured yield stress data show a presence of two stages: a re-flocculation period and a structuration stage. The temperature influence is more pronounced in the first re-flocculation stage dominated by physical processes. A new temperature dependent model approach is derived by extending the bi-linear Kruger model capturing this temperature sensitivity of the structural build-up for fresh cementitious materials. The model assumes temperature dependent functions based on the Arrhenius equation for the rates (re-flocculation and structuration rate) as well as for the initial yield stress and re-flocculation time parameters. In a Bayesian parameter estimation, the proposed model parameters are estimated for the investigated mortar composition. The analysis identifies a nearly linear temperature dependency in the re-flocculation rate, whereas the re-flocculation time is nearly temperature independent. Furthermore, a lower temperature sensitivity of the structuration rate with a logarithm shape over temperature is detected. The identified model shows very good agreement with the measured data, even for those not included in the parameter estimation process. Therefore, the proposed model could be used predicting the temperature sensitivity of structural build-up of cementitious materials. Of course, for more general conclusions further verification studies are required based on additional experimental data e.g. varying the cement type, the water content as well as using different admixtures and additions.

ABSTRACT: Compressive strength and elastic modulus are important mechanical properties of concrete, which are closely related to curing age, temperature, humidity and other conditions. The cube compressive strength, prism axial compressive strength, stress-strain relationship and elastic modulus of C50 concrete were tested under winter construction and curing condition. The effects of curing age, curing temperature and humidity on the development of mechanical properties were analyzed. The results show that with the increase of curing age, the compressive strength and elastic modulus of concrete increased rapidly in the early stage and slowly in the later stage. The compressive strength and elastic modulus of concrete cured under the natural conditions were lower than those of standard curing. The curing method had a great influence on the mechanical properties of short age specimens. Finally, according to the test results, the curing suggestions of concrete in winter construction were put forward, which provides reference for speeding up the project progress and ensuring the quality of the project.

1 INTRODUCTION

Concrete curing conditions, especially environmental temperature and environmental humidity, have a great influence on the mechanical properties of concrete. The lower environmental temperature and humidity values in the winter in northern China resulted in a large difference between the mechanical property growth of concrete and that under standard indoor curing. In recent years, to meet the development needs of transportation facilities, there are many bridges, especially assembled bridges, using winter construction methods, which brings challenges to the project schedule control (Freyermuth, 1999). Early strength and elastic modulus growth of concrete is particularly important under winter construction conditions. On the one hand, the reasonable connection between processes is a strong guarantee to speed up the project progress. If the early strength and elastic modulus values of concrete do not meet the construction requirements, it will seriously delay the project progress and reduce the project quality (Chen, & Duan, 2014). On the other hand, the early strength of concrete develops more rapidly than the elastic modulus, and concrete beams with small values of elastic modulus will lead to increased creep in the later stages of the beam after prestressing tendons are tensioned. Large-span continuous rigid frame bridge and continuous beam bridge will produce large deformation and deflection after several years of use, which will seriously affect the safety and durability of the bridges (Yan & Xie 2017; Xie & Cui 2019). Therefore, in the construction of bridge superstructures, dual parameter control of concrete strength and elastic modulus is usually required. Mechanical property parameters such as compressive strength and elastic modulus of concrete are influenced by a variety of conditions such as material composition, curing age and curing method, and have obvious regional and climatic characteristics (Xie & Li 2014). Among the existing research (Xie & Yan 2018), there are more studies on the mechanical properties of concrete at 28 days, while there is a relative lack of

research on the effects of winter construction and curing conditions on the developmental changes of concrete mechanical properties.

In this paper, cube compressive strength, prismatic axial compressive strength, stress-strain relationship during compression and elastic modulus of concrete were tested under winter construction and curing conditions, and the effects of curing age, curing temperature and curing humidity on the development of mechanical properties were analyzed, which can provide a reference to ensure the safety, suitability and durability of the project.

2 EXPERIMENTAL PROGRAM

2.1 Specimen fabrication and maintenance

2.1.1 Fabrication

Cube specimens with size of 100 mm×100 mm×100 mm were used for cubic compressive strength test, 3 pieces in each group. Prismatic specimens with size of 100 mm×100 mm×300 mm were used for axial compressive strength and elastic modulus test. 6 pieces of each group were used, 3 pieces for axial compressive strength test and the other 3 pieces for elastic modulus test. When testing the axial compressive strength of prisms, the stress-strain relationship during compression is also tested. The specimens are formed by mechanical mixing and artificial vibrating.

2.1.2 Maintenance

The maintenance methods are divided into two types of standard curing and natural curing. The environmental temperature for standard curing is 20±1 °C, and the environmental humidity is >95 %rh. The process of natural curing is as follows: the specimens were left in the natural environment with temperature 6~9 °C and humidity about 40% rh for 3 hours after the specimens were poured, and then the specimens were steam cured by steam curtain(steam curing temperature 30~35 °C, humidity>85 %rh), and the steam curtain was withdrawn after 7 hours of steam curing, and the specimens were placed in the natural environment to continue curing.

The cube compressive strength of 1 day, 6 days, 7 days, 28 days and 60 days and the axial compressive strength and elastic modulus of 7 days, 10 days and 60 days were tested. Take the specimens of different curing methods under the same age for testing, one curing method corresponds to a group of specimens.

2.2 Material properties

The cement was P·O 42.5 grade cement, and the physical and mechanical properties are shown in Table 1. The sand was natural river sand, and the indicators are shown in Table 2. The coarse aggregate was continuous graded aggregates from 5 to 25 mm, and the performance indexes are shown in Table 3. The indicators of fly ash are shown in Table 4. The external additive was high performance water reducing agent, which meets the requirements of Chinese standard GB 50119-2013 (2013) Mixing water was daily drinking water. The concrete was C50 pea gravel concrete with water-cement ratio of 0.37 and slump of 210 mm, as shown in Table 5.

2.3 Test method

The tests of concrete cubic compressive strength, axial compressive strength and elastic modulus were carried out according to Chinese standard GB/T 50081-2019 (2019). The stress-strain relationship of the concrete during compression was tested as follows: after wiping and grinding the surface of the prismatic specimen, four strain gauges were symmetrically pasted at the center of the four sides of the specimen, as shown in Figures 1(a)-(b). The test setup was YA-3000C automatic pressure machine with accuracy level 1, as shown in Figure 1(c). The strain was collected by the static strain test and analysis system, and the stress was calculated by Equation (1).

$$\sigma = \frac{F}{A} \quad (1)$$

Where σ is the specimen stress (MPa); F is the value of the loading force (N); A is the cross-sectional area of the specimen (mm²).

Figure 1. Strain gauge arrangement and test setup: (a) 3D view, (b) Photo, and (c) Test setup.

2.4 Test results

The cubic compressive strength, axial compressive strength and elastic modulus data of the same group of specimens were averaged and the results were summarized in Tables 6 and 7.

Table 6. Test results of the cube compressive strength.

60	59.3	53.3	46.6	43.4

3 EFFECT OF CURING AGE ON THE MECHANICAL PROPERTIES OF CONCRETE

3.1 Cube compressive strength

The variation of the cube compressive strength of concrete under standard curing with the curing age is shown in Figure 2. From Figure 2, the cube compressive strength grew monotonically with the curing age, but the growth rate slowed down and tended to converge. The cube compressive strength of the specimens with ages of 1 day, 6 days, 7 days and 60 days were 50.95 %, 73.35 %, 74.52 % and 105.56 % of the cube compressive strength of the specimens with ages of 28 days, respectively. Compared with the standard value of cube compressive strength of 50 MPa for C50 concrete, the percentage increase in cube compressive strength of the specimens with age of 1 day, 6 days, 7 days, 28 days and 60 days were -30.4 %, 0.2 %, 1.8 %, 36.6 % and 44.2 %, respectively. The data show that the cube compressive strength of this batch of specimens grew faster in the early stage and slowed down in the later stage, with early strength characteristics.

Figure 2. Variation curve of cube compressive strength with curing age.

Figure 3. Variation curve of axial compressive strength with curing age.

3.2 Axial compressive strength

The variation of axial compressive strength of concrete with the curing age for different curing methods is shown in Figure 3. From Figure 3, the variation pattern of axial compressive strength with the curing age tended to be the same for different curing methods, all of which showed a fast growth of strength in the early stage and a slow growth of strength in the later stage. At the age of 7 days, the axial compressive strength of standard curing and natural curing reached 72.51% and 73.55% of the 60-day strength, respectively. At the age of 10 days, the axial compressive strength of standard curing and natural curing reached 77.07% and 77.67% of the 60-day strength, respectively.

3.3 Elastic modulus

The elastic modulus is an important mechanical parameter of concrete, which reflects the relationship between force and deformation. The factors affecting the value of the elastic modulus of concrete include external factors and internal factors. The external factors are specimen age, specimen size, load holding time, curing temperature and curing humidity, etc. The internal factors are mainly concrete raw materials and mix ratio. The variation of the elastic modulus of concrete with the curing age for different curing methods is shown in Figure 4.

Figure 4. Variation curve of elastic modulus with curing age.

As can be seen from Figure 4, the variation of elastic modulus of concrete with the curing age was similar for different curing methods. At the age of 7 days, the elastic modulus of standard curing and natural curing were 67.38% and 66.13% of the 60-day elastic modulus, respectively. At the age of 10 days, the elastic modulus of standard curing and natural curing were 74.46% and 69.59% of the 60-day elastic modulus, respectively.

3.4 Elastic modulus

The stress-strain relationship of concrete is an important basis for studying the strength, deformation and crack development of specimens. The shape of the stress-strain curve reflects the elastic, plastic and fracture processes occurring in the material under the action of external forces, which is important for analyzing the force behavior of the specimen. The stress-strain curves of concrete under different curing methods are shown in Figure 5, where the strain is positive in compression.

Figure 5 (a) shows that: i) at the initial stage of loading, the strains of the specimens at different ages varied approximately linearly. ii) The slope of the stress-strain curve at the initial stage of loading was progressively larger for the specimens at 7, 10 and 60 days of age, indicating that the degree of concrete hardening gradually increased for the specimens at 7, 10 and 60 days of age. This also reflected the increase of the elastic modulus value with the increase of the curing age. iii) Loaded to failure, the stresses in the specimens at 7, 10 and 60 days of age were approximately 40 MPa, 50 MPa and 65 MPa, respectively, indicating that the compressive strength of concrete gradually increased with the growth of the curing age. iv) The stress-strain curves of the specimens at 7 and 10 days of age grew more stable, without obvious turning points, and with lower elastic modulus values. There was an obvious turning point (stress value approximately 20 MPa, strain value approximately $375 \mu\epsilon$) in the growth process of the stress-strain curve for the specimens aged 60 days, after which the slope of the curve decreased, indicating the rapid development of microcracks inside the specimens, resulting in a decrease in the ability of the specimens to resist deformation.

Figure 5 (b) shows that: i) the development of stress-strain curves for specimens at 10 and 60 days of age were closer at the initial stage of loading. ii) The specimens with an age of 7 days had larger strain values at the initial stage of loading and larger strain growth in the middle and late stages, indicating that the resistance to deformation of the specimens under

Figure 5. Stress-strain relationship of concrete under different curing methods: (a) Standard curing and (b) Natural curing.

natural curing was poor. iii) With the growth of the curing age, the compressive strength and elastic modulus of concrete also gradually increased.

4 EFFECT OF CURING METHOD ON THE MECHANICAL PROPERTIES OF CONCRETE

4.1 Axial compressive strength

According to the Chinese standard GB 50010-2010 (2010), the standard value of axial compressive strength of C50 concrete is 32.4 MPa, and the percentage increase of axial compressive strength under different curing methods was calculated using this value as the strength base value, as shown in Figure 6. From Figure 6, the percent increase of axial compressive strength under standard curing was approximately 15 % higher than that under natural curing for the specimens at 7, 10 and 60 days of age. This is because the higher environmental temperature and environmental humidity of standard curing make the cementitious material hydrate faster and therefore the axial compressive strength is higher.

4.2 Elastic modulus

According to the Chinese standard GB 50010-2010, the standard value of elastic modulus of C50 concrete is 34.5 GPa, and using this value as the base value of elastic modulus, the percentage increase of elastic modulus under different curing methods was calculated, as shown in Figure 7.

Figure 6. Variation curve of the percentage growth of axial compressive strength with the curing age.

Figure 7. Variation curve of the percentage growth of elastic modulus with the curing age.

As can be seen from Figure 7, the percentage increase of the elastic modulus under standard curing was approximately 10% higher than that under natural curing for the specimens at 7, 10 and 60 days of age, which is consistent with the law of development of axial compressive strength of concrete, where the value of elastic modulus under standard curing was higher.

4.3 Stress-strain relationship

The stress-strain curves of concrete at different ages of specimens under standard curing and natural curing are shown in Figure 8. Figure 8 shows that: i) the specimens with an age of 7 days, especially under natural curing, had larger strain values at the initial stage of loading and larger strain growth at the middle and late stages, indicating that the resistance to deformation of the specimens under natural curing was poorer than under standard curing. ii) At the early stage of loading, partial overlap was observed at the initial section of the stress-strain curves for the 10-day and 60-day age specimens under different curing methods, while it did not occur for the 7-day age specimens (Figure 8 (a)). This may be because the short-age specimens under natural curing were more sensitive to environmental temperature and environmental humidity, resulting in inadequate hydration reaction of cement, which in turn caused poor resistance to deformation of the specimens, indicating that the curing method had a greater effect on the mechanical properties of the short-age specimens than the long-age specimens. iii) The slope of the concrete stress-strain curves began to differ for specimens at 7, 10 and 60 days of age under different curing methods in the middle and late stages of loading. The slope of the curve under natural curing was smaller and gradually flattened, while the slope of the curve under standard curing varied more than that of natural curing, which indicated that the compressive strength of concrete under standard curing was higher than that under natural curing.

Figure 8. Stress-strain relationship of concrete at different ages: (a) 7 days of age, (b) 10 days of age, and (c) 60 days of age.

5 CONCRETE MAINTENANCE RECOMMENDATIONS UNDER WINTERCONSTRUCTION

Under winter construction conditions, the growth of early strength and elastic modulus of concrete is particularly important (Xie & Zhao 2018). For concrete beams with prestressed tendons, if the early elastic modulus value does not meet the design requirements, the later deformation and prestress loss of the beam after tensioning of prestressed tendons increases, thus reducing the safety and durability of the structure. For the project with time limit, only the early strength and elastic modulus value of concrete reach the construction requirements, so that the next process can be carried out as scheduled or ahead of schedule, thus speeding up the project progress and improving the quality of the project.

The early strength and elastic modulus values of concrete depend on the rate of hydration reaction of cement. The higher the external temperature, the faster the hydration process of the cement. The higher the external humidity and the longer the time, the slower the relative humidity inside the specimen decreases and the more complete the cement hydration reaction is (Gao & Shi 2021; Chen & Zhou 2021).

To guarantee the quality of winter concrete maintenance, the following recommendations are proposed in this paper combined with the test results: i) increase the curing temperature and curing humidity, and extend the period of steam curing, to approach or reach the standard curing conditions is better. ii) Under the premise of not affecting the progress of the project, properly extend the specimen curing age. iii) Age as a variable, increase the number of specimen groups, and increase the frequency of compressive strength and elastic modulus tests to grasp the development of mechanical properties of concrete in real time. iv) The specimens under natural curing are cured for at least 10 days before the subsequent processes are carried out.

6 CONCLUSIONS

By testing the mechanical properties of concrete under winter construction and winter curing conditions, the following main conclusions were obtained.

- (1) Under standard curing, the cube compressive strength of C50 concrete grew monotonically with the gradual increase of curing age, but the growth rate was decreasing. The cube compressive strength of concrete exhibited early strength characteristics.
- (2) With the increase of the curing age, the axial compressive strength and elastic modulus of concrete developed similarly, both showing the law of fast growth of early strength and slow growth of late strength.
- (3) The compressive strength and elastic modulus values of concrete under natural curing were lower than those of standard curing. The resistance of concrete to deformation under natural curing was worse than standard curing.
- (4) The curing method had a greater effect on the mechanical properties of the short-age specimens than the long-age specimens.
- (5) The paper proposed recommendations for winter concrete maintenance, which accumulates experience for speeding up the project progress and guaranteeing the project quality.

Hygro-thermo-chemo-mechanical coupled discrete model for the self-healing in Ultra High Performance Concrete

A. Cibelli, L. Ferrara & G. Di Luzio

Department of Civil and Environmental Engineering, Politecnico di Milano, Milan, Italy

ABSTRACT: Reliable durability predictions and design for advanced cement-based materials cannot disregard the modelling of their inherent self-healing capability. A discrete meso-scale model to simulate the recovery in water tightness, stiffness and strength induced by the (stimulated) autogenous healing of cracks for Ultra High Performance Concrete is presented. In this paper the model is implemented into the numerical framework of the Multiphysics-Lattice Discrete Particle Model (M-LDPM), resulting from the coupling of the Hygro-Thermo-Chemical (HTC) model and Lattice Discrete Particle Model (LDPM). Consistently with experimental evidence, the development of the self-repairing process is modelled as consisting of two independent stages: (a) the healing of matrix cracks, affecting both moisture permeability and fracture strength in the cracked state, and (b) the recovery in terms of fibre bridging action, relying on the adhesion between the healing products and the walls of the tunnel cracks which form during the fibre debonding process. This research activity is framed into the Horizon 2020 project ReSHEALience (GA 760824).

1 INTRODUCTION

Concrete cracks, even in service conditions, represent a predisposing factor for several degradation phenomena. As a consequence, in the last decades the comprehension of the processes affecting the concrete long-term performance has gathered an increasing interest among concrete professionals and researchers. Reliable durability predictions and design for either ordinary and/or advanced cementitious materials cannot disregard a proper modelling of their inherent self-healing capability. As demonstrated in a number of experimental works (e.g. Snoeck and De Belie 2015; Ferrara et al. 2018), the latter might lead to a significant recovery of physical and, in some cases, mechanical properties in the cracked state.

In structural concrete research, the term self-healing refers to the material capacity of repairing the damage in cracked state autonomously. Three major categories of concrete self-healing can be identified: (i) autogenous when the mixture composition only includes regular concrete constituents, (ii) stimulated autogenous when tailored constituents of akin chemical nature are employed to facilitate the process, and (iii) autonomic/engineered when the inclusion of specific additions, not normally employed as such, is used with the explicit purpose of favouring/activating the healing reactions.

From an accurate literature survey it stands out that, over the years, researchers have placed much more effort on the experimental investigation of the self-healing process, rather than on the modelling issues. As a matter of fact, only few models have been developed to simulate how mechanical performance of concrete are affected by the healing of cracks (Barbero et al. 2005, Voyiadjis et al. 2011, Aliko-Benítez et al. 2015, Hilloulin et al. 2016, Davies and Jefferson 2017, Oucif et al. 2018, Di Luzio et al. 2018, Jefferson et al. 2018, Yang et al. 2020, Chen et al. 2021). To the best of the authors' knowledge, none of them addresses the issue concerning the reduction of moisture permeability due to the autonomous cracks clogging. Furthermore, the majority of the published models relies on continuum-based

approaches, and consider the healing-induced effects on the mechanical properties as a smeared contribution in terms of stiffness and strength recovery in the cracked state. With this approach, they miss in simulating the local nature of the phenomena.

In this paper a discrete model to simulate the recovery in water tightness, stiffness and strength induced by the (stimulated) autogenous healing of cracks for Ultra High Performance Concrete is presented. The model is implemented into the numerical framework of the Multi-physics-Lattice Discrete Particle Model (M-LDPM) (Alnagar et al. 2017), resulting from the coupling of the Hygro-Thermo-Chemical (HTC) model (Di Luzio and Cusatis 2009, Pathirage et al. 2019) with the Lattice Discrete Particle Model (LDPM) (Cusatis et al. 2011) and its extension to fibre-reinforced concrete (LDPM-F) (Schauffert and Cusatis 2012). Consistently with experimental evidence, the development of the self-repairing process is modelled as consisting of two independent stages: (a) the healing of matrix cracks, affecting both moisture permeability and fracture strength in the cracked state, and (b) the recovery in terms of fibre bridging action, relying on the friction between the healing products and the walls of the tunnel cracks which form during the fibre debonding process.

This research activity was framed into the Horizon 2020 project ReSHEALience, which was terminated in March 2022 and delivered two valuable results: (i) the concept of Ultra High Durability Concrete, articulated into a sound approach to tailor the mix design depending on the environmental conditions to face (Lo Monte and Ferrara 2020, Lo Monte and Ferrara 2021), and (ii) a Durability Assessment-based Design strategy, validated against laboratory evidences and on-site monitoring data (Al-Obaidi et al. 2021).

2 MODELLING APPROACH

The modelling approach herein presented can be classified as a multi-scale model, in which two different scales of damage phenomena are considered: (i) matrix cracks at the mesoscale, and (ii) fibre-matrix interface cracks, which are governed by mechanisms occurring at the microscale (Figure 1). In the following, the latter are also referred to as *tunnel* cracks.

Figure 1. (a) matrix cracks at the mesoscale; (b) fibre-matrix interface cracks at the microscale.

The modelling approach relies on the idea for which the self-healing of matrix and tunnel cracks affect the material mechanical behaviour differently. For this reason, the autogenous repairing of the matrix cracks is implemented within the constitutive fracture law at the meso-scale, whereas the effect of healing on the fibres response is taken into account within the calculation of the bridging force carried by the discrete fibre reinforcement.

In the proposed model, the moisture permeability is assumed to be affected only by the matrix cracks, then only their closure contributes to the recovery in water-tightness that healed material might experience. The healing of the tunnel cracks has been considered to play a role exclusively on the mechanical behaviour.

3 NUMERICAL IMPLEMENTATION IN M-LDPM

3.1 Evolution of the healing process

The healing kinetic law formulated for plain cementitious materials (Di Luzio et al. 2018) can be employed for fibre-reinforced composites as well. Since the damage in the mechanical model evolves a two different scales (i.e. meso- and microscale), the implementation in the HTC module within the M-LDPM framework is performed by following the same conceptual

differentiation between matrix and tunnel cracks. This yields a two-fold advantage: (i) the possibility of having two separate internal variables describing the damage healing phenomena (i.e. λ_{sh}^m for matrix cracks and λ_{sh}^f for tunnel cracks) feeding the mechanical model at two different levels, and (ii) the chance of capturing the effect that the self-sealing of the matrix cracks has on the moisture permeability in the cracked state. In the following the formulation emphasising this differentiation is reported, with no theoretical differences with respect to the original one (Di Luzio et al. 2018).

Hereinafter the superscript k can be either m or f depending on which scale of damage is of interest. When $k = m$ formulas and parameters refer to the matrix cracks at the mesoscale, whereas with $k = f$ they refer to tunnel cracks at the microscale.

The kinetic laws reads

$$\dot{\lambda}_{sh}^k = \tilde{A}_{sh}^k (1 - \lambda_{sh}^k) \quad (1)$$

in which \tilde{A}_{sh}^k , inversely proportional to the reaction characteristic times, is calculated as

$$\tilde{A}_{sh}^k = \tilde{A}_{sh0}^k \cdot f_h(h) \cdot f_w^k(w_c) \cdot \exp\left[-\frac{E_{sh}^k}{R} \left(\frac{1}{T} - \frac{1}{T_{ref}}\right)\right] \quad (2)$$

where $\tilde{A}_{sh,0}^k$, namely the inverse of the reaction characteristic times in standard conditions (RH=100%, $T = T_{ref}$, $w_c = 0$), values

$$\tilde{A}_{sh0}^k = \tilde{A}_{sh1}^k (1 - \alpha_c^{sh0}) c + \tilde{A}_{sh2}^k \cdot ad \quad (3)$$

where c and ad are the cement and healing-promoting admixture content, respectively. The material parameters E_{sh}^k , \tilde{A}_{sh1}^k , and \tilde{A}_{sh2}^k are calibrated against experimental data, allowing to capture the key aspects of phenomena occurring at two different scales (Cibelli et al. 2022). In Eq. 2 the relative humidity, h , and temperature, T , fields are provided by the HTC model.

It is worth highlighting that the coefficient $f_w^k(w_c)$ provides the possibility of calibrating the effect of crack width on the process kinetic differently for matrix and tunnel cracks. Such double degree of freedom allows to trigger the healing model (i) at the mesoscale for cracks larger than the material macroporosity ($\approx 10 \div 20 \mu\text{m}$), and (ii) at the microscale for crack openings one order of magnitude smaller, as the debonding stage is typically characterised by narrower cracks.

The coefficient $f_h(h)$ accounts for relative humidity and simulates the relevant role played by the moisture supply, making the process proceed or stop whether the healing water-driven reactions are fed or not.

3.2 Moisture permeability in the healed material

The healing process has a significant effect on the moisture diffusion in presence of cracks due to the crack closure effect. This phenomenon is taken into account straightforwardly in the factor governing the crack size dependence of water permeability $f_D(w_c)$, whose formulation reads

$$f_D(w_c) = \frac{D_h^{cracked}(h, T, w_c)}{D_h^{uncracked}(h, T)} = 1 + \frac{999e^{n_c} \xi}{1 - (1 - e^{n_c}) \xi} \quad (4)$$

in which $\xi = \min[\max(w_c - w_{c0}; 0) / w_{c1} - w_{c0}; 1]$, by replacing the crack opening w_c with $w_c \cdot (1 - \lambda_{sh}^{(m)})$. It means that the actual damage affecting the moisture permeability is reduced proportionally to the evolution of the self-healing process up to completion, i.e. $w_c \cdot (1 - \lambda_{sh}^{(m)}) = 0$ for $\lambda_{sh}^{(m)} = 1$. It is worth emphasising that $\lambda_{sh}^{(m)}$ assumes the meaning of matrix crack closure degree. w_{c0} and w_{c1} express two threshold values. When $w_{c0} \leq w_c \leq w_{c1}$, D_h and moisture transport phenomena undergo a sudden and steep increment, due to a material permeability up to 1000 times larger. For $w_c \geq w_{c1}$, instead, the moisture flux stops growing even though cracks continue widening.

3.3 Self-healing of matrix cracks in LDPM

The matrix cracks (Figure 1a) are induced by the loads, either mechanical or environmental, and are responsible of the fibres mechanical activation: as long as no cracks intersect a fibre, the latter does not contribute to the structural response.

For matrix cracks, the healing effect is modelled by enforcing a homothetic expansion of the LDPM boundary limit curve $\sigma_{bt}(\varepsilon, \omega) = \sigma_0(\omega) \exp[-H_0(\omega) \langle \varepsilon_{max} - \varepsilon_0 \rangle / \sigma_0(\omega)]$, as more pronounced as more the repairing process has developed. Experimental evidences have confirmed that even plain concrete specimens, once loaded, fractured and unloaded, might show a recovery in strength and stiffness if re-loaded after a curing period in a moist environment. This is mainly due to two water-driven phenomena occurring in the cracks: delayed hydration and calcium carbonation precipitation. The healing products partially restore the material continuity, lowering, at least locally, the material bulk permeability and limiting the ingress of aggressive agents. The effect on the mechanical response, instead, depends on: (i) the chemical bounds between the filling products and the crack walls, and (ii) the nature, strength and stiffness of the healing products. Because of this, it is not granted that the crack sealing results in an actual concrete healing.

In this work, the modelling strategy adopted relies on the homothetic expansion of the boundary curve $\sigma_{bt}(\varepsilon, \omega)$ (Figure 2a) proportional to the healing degree λ_{sh}^m . Then, it allows to capture the recovery in strength, without varying the crack width within the numerical framework. Therefore, the healed material must be allowed to have a fracture strength exceeding that of the same material with the same level of damage with no healing occurred.

In LDPM, the healing implementation affects the strength limit calculation, thus, on turn, the limit curve. The updated version of the healing dependent-constitutive law relevant to the fracture behaviour reads

$$\sigma_0(\omega, \lambda_{sh}^m) = \sigma_0(\omega) (1 + c_{sh} \cdot \lambda_{sh}^m) \quad (5a)$$

$$\sigma_{bt}(\varepsilon, \omega, \lambda_{sh}^m) = \sigma_0(\omega, \lambda_{sh}^m) \exp \left[-H_0(\omega) \frac{\langle \varepsilon_{max} - \varepsilon_0 \rangle}{\sigma_0(\omega, \lambda_{sh}^m)} \right] \quad (5b)$$

In Eq. 5a, c_{sh} is an empirical coefficient steering the impact of crack closure on mechanical strength. It is defined as *healing mechanical impact coefficient*. The parameter c_{sh} depends on several aspects, e.g. curing conditions and mixture composition, therefore, it has to be calibrated experimentally. Looking at the updated equation of the boundary curve (Eq. 5b), it is important to notice that the healing, through the product $c_{sh} \cdot \lambda_{sh}^m$, governs the shape of the softening branch and sets the stress limit for the earlier stage of the constitutive law, namely when the maximum strain does not exceed the elastic limit. However, though the modelling strategy involves both linear and post-peak behavior, the former is never imposed at the mesoscale, being the limit curve expanded exclusively on those facets which experience cracking and healing.

3.4 Self-healing of tunnel cracks in LDPM-F

The fibre-matrix interface cracks (Figure 1b) develop during the interface debonding. Experimental evidences, collected through single-fibre pull-out tests, stopped after the first load drop and resumed up to rupture upon curing featuring different duration and exposure conditions (Qiu et al. 2019), confirmed that the healing of the interface cracks does affect the pull-out strength. As a matter of fact, whenever the healing process happens, delayed hydration products and CaCO_3 crystals fulfill the tunnel between the fibre and the surrounding mortar. This results in a recovery of the interface frictional bond. The phenomenon is implemented in LDPM-F by updating the value of the fibre bridging force $P(v)$ with a coefficient proportional to λ_{sh}^f . The updated constitutive law for the fibre load reads

$$P(v, \lambda_{sh}^f) = (1 + \gamma_{sh} \cdot \lambda_{sh}^f) P(v) \leq \alpha \cdot P_0 \quad (6)$$

Referring to a single-fibre pull-out test, in Figure 2b the effect of the tunnel crack self-healing on the mechanical response is qualitatively shown. After the loading and unloading stages (branches L and U), the specimen is exposed to given environmental conditions for a time span long enough to permit the self-healing process to develop. The cured specimen is then reloaded (branch R) up to rupture. Due to the recovered frictional bond, the specimen might experience a recovery in stiffness and strength, to an extent proportional to the degree of completion of the healing process. By means of the device in Eq. 6, LDPM-F is updated to be capable of capturing this experimental evidence. In Figure 2b the updated constitutive law is plotted with reference to increasing self-healing degrees, in the hypothesis of $\gamma_{sh} = 1.00$.

Figure 2. Healing model: (a) matrix cracks; (b) fibre-matrix interface (or tunnel) cracks.

The coefficient γ_{sh} has a physical meaning similar to c_{sh} . It governs the impact that the healing of the tunnel cracks has on the fibres contribution to the mechanical equilibrium. With $\gamma_{sh} = 0$ it is possible to capture the crack sealing, whereas if $\gamma_{sh} \geq 0$ the load carried by the fibre is enhanced thanks to the increased friction along the crack walls. The latter has an upper bound ($\alpha \cdot P_0$) in which the bridging force at full debonding P_0 is either amplified or reduced by the coefficient α . Both γ_{sh} and α are material parameters to calibrate against experimental data. Depending on the composition of the cementitious composites, the technique adopted to engineer the process, the type of the fibres (i.e. material, geometry), the curing conditions and the loading regimes, the healing might allow to recover either partially or entirely the fibre load bearing capacity. The parameter α sets the maximum achievable level of recovery. Once calibrated experimentally, γ_{sh} must comply with the condition for which, in case of full fulfilment of the tunnel crack:

$$\text{if } \lambda_{sh}^f = 1.00 \Rightarrow \gamma_{sh} \leq \frac{\alpha \cdot P_0}{P(v)} - 1 \quad (7)$$

4 VALIDATION OF THE IMPLEMENTED MODEL

4.1 Matrix cracks

The model implementation is expected to affect the mechanical response of the material in tension and shear. In order to investigate the reliability of the implemented model, the numerical simulations of how two ordinary plain concrete (OPC) specimens behave after being damaged in tension and brought to collapse, after curing, either in pure tension or shear have been executed. The material adopted has been an ordinary plain concrete whose mix composition included: (i) cement (300 kg/m³), (ii) water (190 kg/m³), and (iii) aggregates 5.5 ÷ 16 mm (1950 kg/m³).

The behaviour in tension has been investigated for a dogbone (DB) specimen, as usual for pure tensile tests, having the dimensions reported in Figure 3a and thickness of 20 mm. The dimensions have been chosen in order to localise the damage in the narrowest part of the sample, namely the mid-span cross-section. The other geometrical characteristics have been set accordingly. For the shear behaviour, instead, a double edge notched prismatic (DENP) specimen has been used (Figure 3b), having dimensions 100×70×20 mm³, and the notches 2 mm wide and 25 mm deep. It has been necessary to avoid a slender sample, as the dog-bone specimen presented above is. As a matter of fact, a stocky element presents a larger proneness

to shear failure. For both specimens it has been necessary (i) to shape the sample in order to have all the mechanical energy channelled into the growth of the fracture at the mid-span, with no dispersion due to multi-cracking scenarios, and (ii) to have the smallest dimension larger than the maximum aggregate size of the simulated material.

Once the samples geometry has been generated, both specimens have been damaged by means of an increasing tensile loading, up showing a single crack roughly $350\mu\text{m}$ wide (Figures 3c,d). Afterwards, the dog-bone sample has been brought to failure in tension, whereas the one in shear. This second stage has been repeated after having imposed an increasing value of the normalised healing degree, λ_{sh}^m , ranging from 0.00 to 1.00, and in the hypothesis of having unit healing mechanical impact coefficient, c_{sh} . Then, in Figures 3e,f, the model ability of catching the healing-induced recovery in tensile and shear strength is shown plotting the (e) tensile load vs. displacement and (f) shear load vs. slip curves.

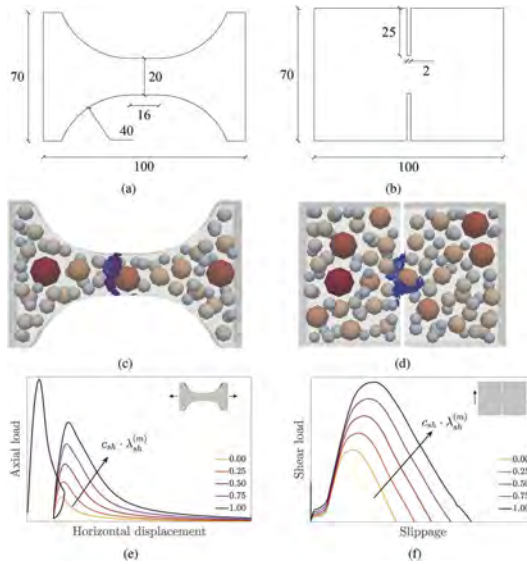

Figure 3. (a,b) DB and DENP dimensions in mm; (c,d) DB and DENP specimens: aggregate particles and cracks; (e,f) DB and DENP specimens: pure tension for pre- and re-cracking.

4.2 Tunnel cracks

The dogbone specimen in Figure 3a has been used also for testing the implementation of the tunnel cracks healing, by generating a FRC-based mesh with the same geometry. The concrete composition included: (i) cement (600 kg/m^3), (ii) water (200 kg/m^3), (iii) aggregates ranging between $3 \div 6 \text{ mm}$ (1518 kg/m^3), and (iv) steel fibres with diameter and length equals to 0.22 mm and 20 mm , respectively (0.50% by volume).

As for matrix cracks, the purpose of investigating if the healing implementation affects the fibre load-slip constitutive law as expected is achieved through a simple set of numerical simulations. The dogbone specimen has been loaded in uniaxial tension up to feature a single prominent crack ($w_c \approx 60 \mu\text{m}$). Then, it has been completely unloaded; afterwards, the sample has been reloaded up to failure. The reloading stage has been performed by assuming for λ_{sh}^f increasing fixed values: 0.00, 0.25, 0.50, 0.75, and 1.00. The numerical simulations have been carried out in two different scenarios: with no matrix cracks healing, $\lambda_{sh}^m = 0.00$, and in the hypothesis of matrix and tunnel cracks healing evolving identically, $\lambda_{sh}^m = \lambda_{sh}^f$.

Firstly, it is important to assess how the model performs at the single fibre-facet intersection. The comparison between the fibre load vs. slip curves on one of the most damaged LDPM facets obtained with λ_{sh}^f equals to 0.00 and 1.00 are shown in Figure 4b. The effect of healing acts as expected, though the re-loading in presence of healing stops before reaching

the ultimate slip (Figure 4b). As it stands out from Figure 4c, the numerical model is able to capture what has been experimentally observed in (19), where the authors detected a recovery in load-bearing capacity at macroscale with a negligible matrix crack healing. Finally, in Figure 4d, the model captures the coupled effect also on the fracturing behaviour induced by the simultaneous autogenous repairing of both matrix and tunnel cracks.

Figure 4. (a) DB FRC specimen: aggregate particles, fibres and cracks; (b) fibre load vs. slip curve experienced along one of the most damaged facets; (c) only tunnel cracks healing; (d) both matrix and tunnel cracks healing.

5 CONCLUSIONS

The model presented in this work has proved to have the potential for capturing phenomenological trends and mechanics standing out from the experimental investigations available in the literature.

The proposed numerical model presents a framework allowing to simulate the self-healing capacity of fibre reinforced cementitious composites, as affected by both the matrix crack sealing (i.e. reconstruction of material through crack continuity) and fiber-matrix interface crack healing, also called tunnel cracks, resulting into a recovery of the fibre-matrix bond capacity.

The validation against laboratory results, currently matter of study, might help in further improving the proposed approach.

ABSTRACT: The need of sustainable resilient structures and infrastructures push towards the use of cementitious materials able to heal micro-cracks and defects. For real structural application under service loading the time-dependent behavior is of the utmost importance, especially in presence of cracks which can lead to a nonlinear creep behavior that might cause the structural failure. Now the new challenge is to study and quantify the effect of crack-healing on the nonlinear creep behavior. This study aims at the following goals: 1) to characterize with experimental investigations the effect of the healing in tests in which the specimens, along the exposure time and under controlled environmental conditions, are under sustained load, the expected service load, determined as a fraction of the pre-cracking load; 2) develop a comprehensive numerical framework for the interpretation and simulation of the experimentally observed results. To this purpose an experimental investigation is currently ongoing at Politecnico di Milano with reference to an Ultra High-Performance Concrete developed in the framework of the H2020 ReSHEALience project for exposure to extremely aggressive environments. The numerical framework is based on the recent developments of the multiphysics lattice particle model.

1 INTRODUCTION

Creep and shrinkage of concrete are time-dependent deformations that influence primarily the serviceability, and in some cases also the safety, of reinforced concrete structures with and without prestressing, and of composite concrete and steel structures. Shrinkage is mainly due to the changes in the moisture content/status dictated by both self desiccation and drying if exposed to lower humidity environments.

Shrinkage alone may cause damage and early age cracking of concrete with a huge impact on the durability of the structure. In addition and in combination to that, the large and widely unrecoverable creep deformations of concrete can cause significant modifications of action effects in structures in terms of internal stress distributions, excessive deflections and loss of prestressing forces, and produce large cracks.

All these effects affect the serviceability and the durability of structures, and may impact on their structural safety as well. In tall structures, absolute and differential shortening and deviations from verticality due to creep and shrinkage of concrete may be a matter of concern requiring serviceability and safety checks and proper remedial actions (Khan et al. 1997; Jirásek & Bažant 2002; Bažant & Jirásek 2018).

For long-term prediction and design the inherent self-healing capability of either ordinary and/or advanced cementitious materials cannot be disregard. The term self-healing refers to the material capacity of repairing the damage in cracked state autonomously.

However, time-dependent behavior of concrete must be contextualized in a more wide comprehensive framework since it is a result of interplay between multiple chemical, physical, and mechanical processes that are functions of the material composition and its curing as well as the surrounding environmental and loading conditions. Chemical processes include the

continued reactions of cementitious materials, aging, healing in the cracks, in addition to a variety of deleterious reactions, such as Alkali-Silica Reaction (ASR), Sulphate Attack, Physical Salt Attack, and others. Physical changes are typically related to thermal and hygral changes. As the hygro-thermal environmental conditions surrounding concrete vary, moisture and heat diffusion processes take place within the material and result in volumetric deformations, such as during thermal shocking, exposure to fire, repeated freeze and thawing, temperature rise in early-age massive structures, or moisture drying that in thick or restrained elements can be induce serious damage.

This paper reports the initial results of an ongoing activity. In the manuscript, first it is presented an experimental investigation on the effect of the crack healing in tests in which the specimens, along the exposure time and under controlled environmental conditions, are under sustained load, close to the expected service load and determined as a fraction of the pre-cracking load. The tests are performed on an Ultra High-Performance Concrete developed in the framework of the H2020 ReSHEALience project for exposure to extremely aggressive environments. Second the mesoscale approach, which is the Multiphysics-Lattice Discrete Particle Model (M-LDPM) (Alnaggar et al. 2017; Yang et al. 2021), resulting from the coupling of the Hygro-Thermo-Chemical (HTC) model (Di Luzio & Cusatis 2009a; Di Luzio & Cusatis 2009b) with the Lattice Discrete Particle Model (LDPM) (Cusatis et al. 2011b), is here for the first time adopted the numerical simulations of the creep and healing phenomena acting simultaneously. In this framework, creep and shrinkage deformations are modeled based on a discrete version (Abdellatef et al. 2015; Alnaggar et al. 2017) of the Microprestress-Solidification theory (Bažant & Prasannan 1989; Bažant et al 1997; Bažant et al. 2004; Di Luzio & Cusatis 2013). This framework has also been recently extended for the crack healing modeling in plain cementitious materials (Cibelli et al. 2022b) and fiber reinforced concrete (Cibelli et al. 2022a), but never considering the shrinkage and creep deformations during crack healing.

2 EXPERIMENTAL INVESTIGATION

Three different UHPC mixes – two with nano-additives, alumina nano-fibres (ANF) and cellulose nano-crystals (CNC), and one as reference – were characterised with both non-destructive and destructive tests; the tests were performed on $500 \times 100 \times 30 \text{ mm}^3$ thin beams obtained cutting pre-cast slabs. The main goal of the experiments was to analyse the material behaviour under real service conditions and its evolution over time; for this purpose, both mechanical loading and environmental exposure were simultaneously applied to the specimens. The experimental campaign was carried out in three different stages, defined as follows: (i) uncracked specimens, (ii) pre-cracked specimens, and (iii) cured/healed specimens (i.e., after exposure). Material properties were first evaluated on beams in virgin conditions, then the specimens were pre-cracked by means of 4-point bending, targeting a crack opening displacement (COD) of $200 \mu\text{m}$ under load, resulting in a residual COD of $75\text{-}125 \mu\text{m}$. The properties were then investigated again through non-destructive measurements, setting the reference for the effectiveness of the self-healing process. A new setup was specifically designed to apply a constant sustained load on the beams during the environmental exposure. After the pre-cracking process, beams were coupled referring to the peak load achieved during the process itself. The couple was braced and loaded with a steel frame, as shown in Figure 1; two cylinders (pink colour) act as hinges in the mid span of the beams, while four bars (black colour) are used to hold the specimens on the sides. With the system described, it was possible to emulate the 4-point bending condition during the curing and healing process, guaranteeing the presence of a constant moment in the central region of the beams. The loading process can be described in three different stages, starting from unloaded and pre-cracked specimens; (a) two load cells (blue colour) are positioned above the second layer of steel bars and braced with the top bars, (b) the targeted load, derived from the pre-cracking process, is first applied to the cells tightening the top nuts (red colour), ensuring that the exact value will be transferred to the beams, then (c) the load is finally applied to the specimens tightening the nuts in the middle (brown colour) and simultaneously releasing the load cells, allowing to remove them. The sustained loading setup was previously tested on a couple of samples to validate the effective maintenance of a constant load over time on the braced pair, keeping the load cells in position for the whole

duration of the test; the system was able to guarantee an almost constant load, with less than 10% reduction. An extensive summary of the results has been provided in Al-Obaidi et al. (2023).

Figure 1. Sustained loading setup.

The specimens paired and braced with the sustained loading system were exposed into chloride solution (3.3% NaCl), geothermal water, and tap water as reference, to simulate the chloride and sulphate environmental attack respectively. The curing period varied between 1 and 12 months, and the specimens were tested at 1, 2, 3, 6, 9, and 12 months. The effect of healing and the crack sealing – promoted by crystalline admixture and nano-additives – were evaluated at the end of each exposure period, allowing to define the evolution of the performance that can be expected in a real structure. The material proved to be substantially resilient even under aggressive conditions such as sustained loads and different chemical attacks, maintaining constant mechanical performance over time.

3 GENERAL MULTI-PHYSICS FRAMEWORK

This section presents the numerical framework that merges the Hygro-Thermo-Chemical (HTC) model with a discrete meso-scale (LDPM) model for concrete. For time-dependent mechanical analysis, it is essential to use a multi-physics model that simulates all the relevant chemical/physical phenomena in a cement based material, such as the chemical reactions of the binder coupled with moisture transport and heat transfer in interaction with the environmental changes. Especially in the cracks chemical/physical phenomena are fundamental to characterize the healing evolution.

3.1 *Hygro-Thermo-Chemical (HTC) model*

The HTC model (Di Luzio & Cusatis 2009a; Di Luzio & Cusatis 2009b) simulates the moisture and temperature evolution in a cementitious material considering the simultaneous chemical reactions – hydration of cement and pozzolanic reactions. The reaction kinetics are formulated in terms of reaction degrees that represent the progress of a chemical reaction as the ratio between the amount of reacted material and the total initial amount of it. Similarly, if a pozzolanic material is utilized in the mixture, such as silica-fume, the rate of its reaction degree can be describe using a similar approach (Di Luzio & Cusatis 2009a).

The coupling between chemical reactions and transport processes (water and heat) is achieved by combining the water mass and enthalpy balance equations with the reaction degree kinetic equations, in which the cement hydration degree and the pozzolanic material reaction degree are assumed as an internal variables, leading to a system of partial differential equations with only two state variables, i.e. the temperature T and the pore relative humidity h . All the details of the formulation can be found in Di Luzio & Cusatis (2009a); Pathirage et al. (2019); Bousikhane et al. (2018).

3.2 *Discrete mesoscale mechanical model*

The mesoscale discrete model employed in the framework is the so-called Lattice Discrete Particle Model (LDPM) (Cusatis et al. 2011a; Cusatis et al. 2011b). It simulates the heterogeneity of concrete considering the mechanical interaction of coarse aggregates in the cementitious matrix. The

discretized concrete mesostructure creates a system of polyhedral cells interacting through triangular facets and a lattice system composed by the line segments connecting the particle centers. A rigid body kinematics is assumed to describe the deformation of the LDPM lattice/particle system. By summing up the stress contributions of all the facets and equating the total internal work with the total external work, one can obtain the discrete equilibrium equations of the LDPM formulation.

Figure 2. Equivalent rheological model based on strain additivity at the meso-scale.

The LDPM has been used successfully to simulate concrete behavior under a large variety of loading conditions (Cusatis et al. 2011a). It has been also formulated for fiber reinforced concrete (Schauffert & Cusatis 2012) and for ultra-high performance concrete (UHPC) (Smith et al. 2014). Assuming the additivity of strains at mesoscale level of each facet, one can write

$$\dot{\epsilon} = \dot{\epsilon}^* + \dot{\epsilon}^a + \dot{\epsilon}^s + \dot{\epsilon}^t + \dot{\epsilon}^v + \dot{\epsilon}^f \quad (1)$$

where $\dot{\epsilon}$ is the total strain, $\dot{\epsilon}^*$ represents the effect of instantaneous elasticity and damage, $\dot{\epsilon}^a$ represents the strain rate due to material degradation such as ASR; $\dot{\epsilon}^s$ and $\dot{\epsilon}^t$ are shrinkage and thermal strain rates, respectively; $\dot{\epsilon}^v$ is the viscoelastic strain rate and $\dot{\epsilon}^f$ is the purely viscous strain rate. The strain additivity of Eq. 1 can be represented as a rheological model of elements in series that is depicted in Figure 2.

3.2.1 Elastic, cracking, and damage behavior

In the elastic regime, the normal and shear stresses are proportional to the corresponding strains. In vectorial form, one has $\dot{\epsilon}^* = \frac{1}{E_0} \mathbf{G} \sigma$, where $\mathbf{G} = [1, 0, 0; 0, 1/\alpha, 0; 0, 0, 1/\alpha]$, E_0 = effective normal modulus, and α = shear-normal coupling parameter. It must be observed that, E_0 represents the instantaneous deformation since all creep strains, which always occurs during quasi-static loading, are included in the Kelvin chain of the rheological model. However, the Kelvin chain has a limited number of elements and, in this case, E_0 will also include the effect of very short term creep whose characteristic time is smaller than the smallest of the discrete chain. All the detail on the LDPM constitutive law can be found in Cusatis et al. (2011b).

3.2.2 Rate effect

The loading rate has a direct effect on the mechanical properties of concrete as it has been shown by many authors, among others Watstein (1953), Hughes & Gregory (1972), Reinhardt (1985). This phenomenon is explained by three main contributions: the creep of the material, the rate effect on the bond rupture in the mesoscale fracture, and the effect of inertia force on the crack propagation. For quasi-static loads, the first two mechanisms mentioned above are dominant. While increasing the strain rate loading the third contribution becomes more and more dominant. Since the fracture can be seen as the consequence of the rupture of atomic or molecular bonds dominated by a thermal activation of the bond breakages, the rate effect can be modeled by the concept of a rate dependence on the fracture process (Di Luzio & Cedolin 2005).

As proposed in Wu & Bažant (1993), the cohesive crack model can be made a time-dependent process characterized by its aforementioned activation energy. This concept has been implemented in LDPM (Smith & Cusatis 2016; Boumakis et al. 2018) by scaling the tensile stress-strain boundary by the function with the normal strain rate.

3.2.3 Solidification Theory for visco-elastic deformations

According to the Solidification Theory (Bažant & Prasanna 1989; Bažant et al 1997; Bažant et al. 2004; Di Luzio & Cusatis 2013), the visco-elastic behavior of concrete comprises the

visco-elastic strain of the aging hardened cement gel. A non-aging micro-compliance function of cement gel produces strains that reduces overtime with a function that represents the volume fraction of cement gel produced by early-age chemical reactions. This formulation is expressed in an incremental stress/strain relation using the approximation of the creep function with a Dirichlet series with the introduction of a continuous retardation spectrum based on the Post-Widder formula to calculate the parameters of the Dirichlet series (Bažant & Xi 1995; Bažant & Jirásek 2018; Di Luzio et al. 2020).

3.2.4 *Microprestress Theory for viscous deformations*

The purely viscous strain rate represents the totally unrecoverable part of the creep strain and it is associated to long-term creep, drying creep effect (also called Pickett effect), and transitional thermal creep. From the microprestress theory the purely viscous strain rate can be expressed with the dashpot in Figure 2 whose viscosity is function of the microprestress (Bažant et al 1997; Bažant et al. 2004; Di Luzio & Cusatis 2013).

Recently it has been shown that the microprestress theory arises in nanoscale numerical simulations of C-S-H in which the logarithmic creep and power-law microprestress relaxation emerge from generic deformation kinetics in such disordered systems (Masoero & Di Luzio 2020).

3.2.5 *Hygral and thermal deformation*

The variation of the relative humidity in the material pores causes free hygroscopic strain ϵ^s (swelling or shrinkage, for positive or negative relative humidity change, respectively). Similarly, temperature changes cause thermal strain rates, $\dot{\epsilon}^t$ (Abdellatef et al. 2019).

3.2.6 *Self-healing modeling*

The modelling approach consider the matrix cracks at the mesoscale, and the fibre-matrix interface cracks (*tunnel* cracks). The modelling approach relies on the idea for which the self-healing of matrix and tunnel cracks affect the material mechanical behaviour differently. For this reason, the autogenous repairing of the matrix cracks is implemented within the constitutive fracture law at the mesoscale, whereas the effect of healing on the fibres response is taken into account within the calculation of the bridging force carried by the steel reinforcement. In the proposed model, the moisture permeability is assumed to be affected only by the matrix cracks, then only their closure contributes to the recovery in water-tightness that healed material might experience.

The healing kinetic is described by an internal variable that characterized the crack close. It is formulated for plain cementitious materials can be also employed for fibre-reinforced composites as well. For all the details on the formulation an interested reader has to refer to Di Luzio et al. (2018); Cibelli et al. (2022a); Cibelli et al. (2022b).

3.2.7 *Aging*

As widely known concrete properties typically improve in course of time, especially in the early weeks after casting. This complex process is called aging and its principal source is the ongoing hydration, which depends on the mix design and the environmental boundary conditions (Cernuschka et al. 2022).

The evolution of mechanical properties are expressed as a function of an aging degree internal variable making some meso-scale parameters age-dependent that are the normal modulus, the tensile strength, the tensile characteristic length, and the shear strength ratio. For all the details on the formulation an interested reader has to refer to Di Luzio & Cusatis (2013); Wan et al. (2016).

4 MODEL APPLICATIONS

The initial results of the application of the computational framework presented in the previous Section are reported here. The proposed computational framework has been first calibrated for the aging mechanical properties of the considered material, by simulating an extensive laboratory campaign conducted at the Politecnico di Milano and looking for the best match between numerical and experimental results. As an example, in Figure 3 the comparison between numerical and experimental curves is shown for the fracture behaviour of notched specimens after three different ages from casting: 6, 28 and 180 days.

The same approach has been adopted also for the healing model, which has been calibrated and validated by using the evidences presented in Cuenca et al. (2021). In Figure 4 the model capability of capturing (i) the effect of cracks on the moisture transport phenomena and (ii) the time evolution of crack sealing due to the self-healing (Index of Crack Sealing, ICS) is shown.

Figure 3. Ageing model – Comparison between experimental and numerical results relevant to three different ages from casting: 6, 28 and 180 days.

Figure 4. Healing model – Moisture gradient and healing evolution in cracked conditions over time.

Figure 5. Shrinkage model – Comparison between experimental and numerical autogenous shrinkage in UHPC.

Finally, the proposed computational framework is being calibrated for the shrinkage and creep properties of the considered mixes. Some preliminary results are reported in Figure 5.

5 CONCLUSIONS

This study presents the initial results of an experimental/numerical research on the cross effects of the crack healing and creep in typical expected service load condition. The numerical model is based on the mesoscale Multiphysics-Lattice Discrete Particle Model (M-LDPM) for the characterization of the long- and short-term mechanical behavior with coupled thermal, shrinkage, creep deformations, and self-healing. Preliminary results are presented in this manuscript. This research allows to learn something new about the behavior of crack healing under loading condition, which is of utmost importance for practical applications.

ACKNOWLEDGMENTS

The work described in this paper has been performed in the framework of the project ReSHEALience (funded by European Commission with grant agreement No 760824), whose funding the authors gratefully acknowledge. The numerical analyses have been performed by means of MARS, distributed by ES3 Inc. (Engineering and Software System Solutions), which is gratefully acknowledged. The grant for Senior Resident research 2021/2022 to Roman Wan-Wendner from Department of Civil and Environmental Engineering is gratefully acknowledge.

Homogenized mesoscale discrete model for coupled multi-physical analysis of concrete

J. Eliáš

Faculty of Civil Engineering, Brno University of Technology, Brno, Czechia

G. Cusatis

Department of Civil and Environmental Engineering, Northwestern University, Evanston, IL, USA

ABSTRACT: The contribution develops an asymptotic expansion homogenization of a mesoscale model based on rigid-body kinematics. The model is capable of solving coupled mechanics and mass transport in concrete. Two coupling phenomena are considered: the Biot's theory and an effect of cracks on the material conductivity. The homogenization technique is used to deliver a two scale model: (i) the macroscale emerges as a homogeneous Cosserat continuum coupled with mass transport. Each integration point contains (ii) a mesoscale periodic Representative Volume Element (RVE), a submodel replacing the constitutive function. The RVE is discrete, loaded by a projection of Cosserat strain tensor and macroscopic pressure gradient. The homogenized model is compared to the full model by simulating two examples: the Terzaghi's consolidation and hydraulic fracturing of a hollow cylinder.

1 INTRODUCTION

Life-cycle assessment of concrete structures demands robust numerical models capable of solving multi-physical problems. The contribution focuses on coupled mechanics and mass transport in concrete solved by a meso-scale model based on rigid body kinematics. Each rigid particle represents a larger mineral aggregate and the surrounding matrix. Cohesive contacts between particles lump both elastic and inelastic mechanical behavior. The constitutive relations are vectorial and naturally account for crack orientation (Cusatis, Pelessone and Mencarelli, 2011; Eliáš, 2020).

The mass transport is coupled with mechanics via Biot's theory where (i) the effective stress at the contacts is composed of the stress in the solid and the pressure component and (ii) the rate of volumetric deformation is linked to the pressure. (iii) Another coupling terms account for cracking which enhances the permeability coefficient of the associated conduit elements. The importance of cracking in the transport solution resulted in special coupling scheme based on a dual lattice (Grassl, 2009; Grassl and Bolander, 2016; Fahy et al., 2017; Li et al., 2018), which is employed here as well.

This high fidelity *full* model is computationally expensive because it is formulated at the meso-scale. Eliáš and Cusatis (2022) developed a homogenization technique capable of reducing computational cost of the model. It extends work of Rezakhani and Cusatis (2016) where the mechanical discrete model was homogenized. Identical homogenization technique is applied also in Rezakhani et al. (2019, 2017) and Eliáš et al. (2022). This contribution is a brief summarization of results published in the journal paper of Eliáš and Cusatis (2022).

2 DISCRETE MODEL OF COUPLED MECHANICAL AND TRANSPORT PROBLEM

The model to be homogenized is a discrete mesoscale model of concrete mechanical behavior extended by coupling with mass transport in fully saturated medium. It is similar to the well known Lattice Discrete Particle Model (LDPM) (Cusatis, Pelessone and Mencarelli, 2011; Cusatis, Mencarelli, Pelessone and Baylot, 2011). The most recent applications of LDPM are simulations of the cyclic behavior of concrete (Zhu et al., 2022) and size effect (Pathirage

et al., 2023). The model used in this contribution has different internal geometry derived from the power tessellation on spheres representing mineral aggregates (Eliáš, 2017). The constitutive functions are adopted from Cusatis and Cedolin (2007) and slightly modified, see Eliáš and Cusatis (2022) or Eliáš (2016).

The model features two types of nodes and elements. The transport nodes P and Q bear only one degree of freedom called pressure and denoted p . The mechanical nodes I and J bear displacement vector \mathbf{u} and rotation vector $\boldsymbol{\theta}$. h and S are length and area of the transport element, l and A are length and area of the mechanical element. Vectors \mathbf{c}_I and \mathbf{c}_J connect nodes I and J with the centroid of the mechanical element facet, where the constitutive equations are defined.

The kinematic equations give the pressure gradient, g , the strain vector, $\boldsymbol{\varepsilon}$, and the curvature, χ .

$$g = \frac{p^Q - p^P}{h} \quad (1)$$

$$\varepsilon_\alpha = \frac{1}{l} (\mathbf{u}^J - \mathbf{u}^I + \boldsymbol{\varepsilon} : (\boldsymbol{\theta}^J \otimes \mathbf{c}_J - \boldsymbol{\theta}^I \otimes \mathbf{c}_I)) \cdot \mathbf{e}_\alpha \quad (2)$$

$$\chi_\alpha = \frac{1}{l} (\boldsymbol{\theta}^J - \boldsymbol{\theta}^I) \cdot \mathbf{e}_\alpha \quad (3)$$

Note that displacement and rotation vectors are transformed into the local coordinate system by multiplication by directional vectors \mathbf{e}_α , $\alpha = N, M, L$ being the normal and two tangential directions.

The constitutive equations are stated in a general form and provide the flux scalar, j , the traction vector, \mathbf{t} , and the couple traction vector, \mathbf{m}

$$j = -\lambda(p, \delta)g \quad \mathbf{t} = f_s(\varepsilon) - bp_a\mathbf{e}_N \quad \mathbf{m} = f_m(\chi) \quad (4)$$

Functions λ , f_s and f_m can be defined arbitrarily. The first constitutive equation introduces the effect of crack opening, δ , on the material permeability. The second constitutive equation brings Biot's effect of fluid pressure on the normal component of the traction (Biot, 1941; Detournay and Cheng, 1995), b is a material parameter called Biot coefficient. The pressure p_a is the weighted average pressure from control volumes surrounding the mechanical element.

The final set of equations consists of the balance of fluid mass and the balance of linear and angular momentum of particles

$$\rho_{w0} \left(3b\dot{\varepsilon}_V + \frac{\dot{p}_\lambda}{M_b} \right) + q = \sum_{Q \in W} \left[\frac{Sj}{W} - \rho_{w0}\dot{v}_c \left(1 - b + \frac{p_\lambda - p_0}{K_w} \right) - \rho_{w0}v_c \frac{\dot{p}_\lambda}{K_w} \right] \quad (5)$$

$$V\rho\ddot{\mathbf{u}}^I + \mathbf{M}_{u\theta} \cdot \ddot{\boldsymbol{\theta}}^I - V\mathbf{b} = \sum_J A t_\alpha \mathbf{e}_\alpha \quad (6)$$

$$\mathbf{M}_\theta \cdot \ddot{\boldsymbol{\theta}}^I + \mathbf{M}_{u\theta}^T \cdot \ddot{\mathbf{u}}^I = \sum_J A [\mathbf{w} + m_\alpha \mathbf{e}_\alpha] \quad (7)$$

where J runs over all neighbors of particle I and Q runs over all simplices surrounding the control volume of node P , q and \mathbf{b} are external loads, M_b is Biot's modulus, K_w is the bulk modulus of fluid, ε_V is the volumetric strain reduced by the amount of cracks, v_c is volume of cracks, ρ and ρ_{w0} are densities of solid and fluid, \mathbf{M} represents various inertia tensors, $\mathbf{w} = \boldsymbol{\varepsilon} : (\mathbf{c}_I \otimes \mathbf{t}) = t_\alpha \boldsymbol{\varepsilon} : (\mathbf{c}_I \otimes \mathbf{e}_\alpha)$ is the moment of traction with respect to the mechanical node I , and $\boldsymbol{\varepsilon}$ is the Levi-Civita permutation tensor. Further details can be found in Eliáš and Cusatis (2022).

3 SEPARATION OF SCALES

The separation of scales is employed now. The macroscopic, slow variable \mathbf{x} and the microscopic, fast variable \mathbf{y} are related via separation of scales constant $\mathbf{x} = \eta\mathbf{y}$. The model appears

continuous from the viewpoint of the reference system \mathbf{x} but discrete in the reference system \mathbf{y} . Furthermore, a unique global reference system \mathbf{X} defines positions in the continuous macroscopic space.

The primary variables p , \mathbf{u} and $\boldsymbol{\theta}$ are now asymptotically expanded into components with different powers of η

$$p(\mathbf{X}, \mathbf{y}) = \eta^{-1}p^{(-1)}(\mathbf{X}, \mathbf{y}) + p^{(0)}(\mathbf{X}, \mathbf{y}) + \eta p^{(1)}(\mathbf{X}, \mathbf{y}) + \dots \quad (8)$$

$$\mathbf{u}(\mathbf{X}, \mathbf{y}) = \mathbf{u}^{(0)}(\mathbf{X}, \mathbf{y}) + \eta \mathbf{u}^{(1)}(\mathbf{X}, \mathbf{y}) + \dots \quad (9)$$

$$\boldsymbol{\theta}(\mathbf{X}, \mathbf{y}) = \eta^{-1}\boldsymbol{\omega}^{(-1)}(\mathbf{X}, \mathbf{y}) + \boldsymbol{\omega}^{(0)}(\mathbf{X}, \mathbf{y}) + \boldsymbol{\varphi}^{(0)}(\mathbf{X}, \mathbf{y}) + \eta \boldsymbol{\varphi}^{(1)}(\mathbf{X}, \mathbf{y}) + \dots \quad (10)$$

The neighboring mechanical nodes I and J are close to each other from the viewpoint of the \mathbf{X} reference system. One can use the macroscopic gradient ∇_X at node I to approximate the mechanical field variables at node J , see Fish et al. (2007). The same is valid for pressure. The Taylor expansions of the primary fields yield

$$p(\mathbf{X}_Q, \mathbf{y}_Q) = p(\mathbf{X}_P, \mathbf{y}_Q) + \frac{\partial p(\mathbf{X}_P, \mathbf{y}_Q)}{\partial X_i} x_i^{PQ} + \frac{1}{2} \frac{\partial^2 p(\mathbf{X}_P, \mathbf{y}_Q)}{\partial X_i \partial X_j} x_i^{PQ} x_j^{PQ} + \dots \quad (11)$$

$$\mathbf{u}(\mathbf{X}_J, \mathbf{y}_J) = \mathbf{u}(\mathbf{X}_I, \mathbf{y}_J) + \frac{\partial \mathbf{u}(\mathbf{X}_I, \mathbf{y}_J)}{\partial X_j} x_j^{IJ} + \frac{1}{2} \frac{\partial^2 \mathbf{u}(\mathbf{X}_I, \mathbf{y}_J)}{\partial X_j \partial X_k} x_j^{IJ} x_k^{IJ} + \dots \quad (12)$$

$$\boldsymbol{\theta}(\mathbf{X}_J, \mathbf{y}_J) = \boldsymbol{\theta}(\mathbf{X}_I, \mathbf{y}_J) + \frac{\partial \boldsymbol{\theta}(\mathbf{X}_I, \mathbf{y}_J)}{\partial X_j} x_j^{IJ} + \frac{1}{2} \frac{\partial^2 \boldsymbol{\theta}(\mathbf{X}_I, \mathbf{y}_J)}{\partial X_j \partial X_k} x_j^{IJ} x_k^{IJ} + \dots \quad (13)$$

The asymptotic expansion along with Taylor expansion is inserted into the kinematic equations to deliver scale separation of the pressure gradient, strain and curvature. The scale separation is also applied to constitutive equation. Due to assumed complex nonlinear nature of functions $\lambda(p, \delta)$, $f_s(\boldsymbol{\varepsilon})$ and $f_m(\boldsymbol{\chi})$ which are yet unknown, the separation is delivered by Taylor expansion with respect to variables p , δ , $\boldsymbol{\varepsilon}$ and $\boldsymbol{\chi}$ (see details in Eliáš and Cusatis (2022)).

Finally, all these quantities are inserted into the balance equations. The resulting expressions contain terms at different scale, distinguished by power of η . The balance needs to be satisfied at each of these scales, one therefore needs to solve several sets of balance equations. Some of them are trivial and can be solved analytically, two of them become the *macroscale* and *mesoscale* problems that are solved numerically.

4 MACROSCOPIC LEVEL

The macroscale delivers the following balance equations

$$\rho_{w0} \left[\dot{v}_{c0} \left(1 - b + \frac{p^{(0)} - p_0}{K_w} \right) + v_{c0} \frac{\dot{p}^{(0)}}{K_w} + 3b\dot{\varepsilon}_V^{(0)} + \frac{\dot{p}^{(0)}}{M_b} \right] + q = \nabla_X \cdot \mathbf{f} \quad (14)$$

$$\nabla_X \cdot \boldsymbol{\sigma}_s - \nabla_{Xp}^{(0)} \cdot \boldsymbol{\xi} = \langle \rho \rangle \ddot{\mathbf{u}}^{(0)} - \mathbf{b} \quad (15)$$

$$\nabla_X \cdot \boldsymbol{\mu}_s - \nabla_{Xp}^{(0)} \cdot \boldsymbol{\zeta} + \boldsymbol{\varepsilon} : \sigma_s - p^{(0)} \boldsymbol{\varepsilon} : \boldsymbol{\xi} = 0 \quad (16)$$

These equations describe Cosserat continuum coupled with mass transport in saturated solids. The new tensors emerging in these equations are collected from the mesoscale solution

$$\mathbf{f} = \frac{1}{V_0} \sum_{d \in V_0} h S_j^{(0)} \mathbf{e}_\lambda \quad (17)$$

$$\boldsymbol{\sigma}_s = \frac{1}{V_0} \sum_{e \in V_0} l A s_\alpha^{(0)} \mathbf{e}_N \otimes \mathbf{e}_\alpha \quad (18)$$

$$\boldsymbol{\mu}_s = \frac{1}{V_0} \sum_{e \in V_0} l A \mathbf{e}_N \otimes \left[\eta m_\alpha^{(1)} \mathbf{e}_\alpha + s_\alpha^{(0)} \boldsymbol{\varepsilon} : (\mathbf{x}_c \otimes \mathbf{e}_\alpha) \right] \quad (19)$$

$$\boldsymbol{\xi} = \frac{1}{V_0} \sum_{e \in V_0} l A b e_N \otimes \mathbf{e}_N \quad (20)$$

$$\boldsymbol{\zeta} = \frac{1}{V_0} \sum_{e \in V_0} l A b e_N \otimes [\boldsymbol{\varepsilon} : (\mathbf{x}_c \otimes \mathbf{e}_N)] \quad (21)$$

\mathbf{f} is the flux vector, $\boldsymbol{\sigma}_s$ is the solid stress tensor, $\boldsymbol{\mu}_s$ is the solid couple stress tensor and $\boldsymbol{\xi}$ and $\boldsymbol{\zeta}$ are second order tensors describing RVE internal structure producing an effect of pressure on the macroscopic stress and couple stress.

The primary fields (unknowns) at the macroscale are pressures $p^{(0)}$, displacements $\mathbf{u}^{(0)}$ and rotations $\boldsymbol{\varphi}^{(0)}$. Several emerging coupling terms are obtained describing storage of the fluid in cracks, an effect of volumetric changes on the pressure, an effect of the pressure gradient on the linear momentum balance, and effects of the pressure gradient and the pressure on the angular momentum balance. The macroscopic equations are naturally anisotropic due to the heterogeneity and cracking at the microscale.

The macroscale problem, supplemented with boundary conditions, is solved by the finite element method. Each integration point contains an embedded RVE with subscale model derived in the next section. The macroscopic pressure gradient \mathbf{a} and the Cosserat strain tensor $\boldsymbol{\gamma}$ are computed and sent to the RVE as loads. RVE serves as a macroscopic constitutive routine; after solving it, the stress like tensors (Eqs. 17–21) are received by the macroscale. According to Rezakhani and Cusatis (2016) the Cosserat effect does not contribute in a significant way and simplification to Cauchy continuum is possible.

5 MESOSCOPIC LEVEL

The RVE problem is described by the following balance equations

$$\sum_{Q \in W} S_j^{(0)} = 0 \quad (22)$$

$$\sum_{J \in V} A s_\alpha^{(0)} \mathbf{e}_\alpha = p^{(0)} \sum_{J \in V} A b e_N \quad (23)$$

$$\sum_{J \in V} A \left(s_\alpha^{(0)} \mathbf{e}_\alpha \boldsymbol{\varepsilon} : (\mathbf{c}_I \otimes \mathbf{e}_N) + \eta m_\alpha^{(1)} \mathbf{e}_\alpha \right) = p^{(0)} \boldsymbol{\varepsilon} : \sum_{J \in V} A b c_I \otimes \mathbf{e}_N \quad (24)$$

with degrees of freedom being $\eta p^{(1)}$, $\eta \mathbf{u}^{(1)}$ and $\omega^{(0)}$, the microscopic pressure, translation and rotation, respectively.

It turns out that load is provided by the eigen-pressure gradient \hat{g} and eigen-strain $\hat{\boldsymbol{\varepsilon}}_\alpha$, which are expressed as negative projections of the macroscopic pressure gradient $\mathbf{a} = \nabla_X p^{(0)}$ and the Cosserat strain tensor $\boldsymbol{\gamma} = \nabla_X \otimes \mathbf{u}^{(0)} - \boldsymbol{\varepsilon} \cdot \boldsymbol{\varphi}^{(0)}$

$$\hat{g} = - \frac{\partial p^{(0)}}{\partial X_i} e_i^\lambda = -\mathbf{a} \cdot \mathbf{e}_\lambda \quad (25)$$

$$\hat{\epsilon}_\alpha = -e_i^\alpha \left[\frac{\partial u_i^{(0)}}{\partial X_k} - \mathcal{E}_{ijk} \varphi_j^{(0)} \right] e_k^N = -\mathbf{e}_N \cdot \boldsymbol{\gamma} \cdot \mathbf{e}_\alpha \quad (26)$$

The RVE balance equations are solved numerically by the discrete mesoscale model. The constitutive equations are the original constitutive functions of the full model, λ , f_s , and f_m . Note that unlike the macroscale the RVE problem is steady state (or static).

Since the primary field $\eta p^{(1)}$ has no effect on the mechanical behavior, the mechanical RVE is partially decoupled from the transport one, which needs crack openings and it is therefore solved after the mechanical RVE.

According to the homogenization theory, the unknown fields should be periodic. Thus, the periodic boundary conditions must be enforced for pressure, displacements and rotations. Additional boundary conditions are needed for pressure and displacements as the balance equations consider only differences in these primary fields and are therefore ill-conditioned without some additional constraint. These fields are lower scale fluctuations which are supposed to be zero on average, therefore the last boundary conditions should prescribe zero volumetric average of these fields over the RVE: $\langle \eta p^{(1)} \rangle = 0$, $\langle \eta \mathbf{u}^{(1)} \rangle = 0$ where the weighted volumetric average reads $\langle \bullet \rangle = \frac{1}{V_0} \sum_{w \in V_0} V_w \bullet$.

Figure 1. Single RVE loaded by straining in x direction and pressure gradient in z direction. Both diffused and localized cracking states are captured. One can see how cracks enhance conductivity of transport elements. The red (or blue) color indicates high (or low, respectively) values of depicted variables. a) RVE internal structure – aggregate diameters; b)+c) crack opening in the mechanical RVE; d)+e) fluxes in the transport RVE.

Example of fractured RVE is shown in Figure 1. The constitutive model features strain softening and therefore the mechanical problem suffers from strain localization. The localization phenomenon cannot be homogenized as the scale separation does not hold (Gitman et al., 2007), the RVE response becomes dependent on its size. Some researchers (Coenen, Kouznetsova, Bosco and Geers, 2012; Unger, 2013) suggested remedies to incorporate the strain localization into the homogenization scheme, but these techniques are not adopted here yet. The only way to simulate localized fracture is therefore to use RVE volumes corresponding to volumes associated to integration points in the macroscale model (Rezakhani and Cusatis, 2016). Unfortunately, the major benefit of the homogenization, that the large material volume can be macroscopically represented by a small RVE, would be lost.

6 IMPLEMENTATION, VERIFICATION AND APPLICATION

The constitutive models and material parameters are described in Eliáš and Cusatis (2022). The mechanical model is taken from Cusatis and Cedolin (2007) and simplified. However, any functions f_s and f_m can be easily used at the RVE level. The transport constitutive function λ can also be chosen arbitrarily. It is here considered as a simple linear dependency of the flux on the pressure gradient in the intact material with additional terms according to Grassl and Bolander (2016) when cracks are present. The macroscopic equations are rewritten into the weak form and implemented in an in-house software called OAS (Open Academic Solver). Computational domain is discretized into Cosserat trilinear isoparametric brick elements extended by additional pressure degrees of freedom.

The model is verified by simulating Terzaghi’s consolidation and applied to simulate hydraulic fracturing of hollow cylinder. These examples compare the *full* discrete model and the *homogenized* model. The comparison should ideally be repeated several times and statistically evaluated because of the intrinsic randomness of the mesoscale discrete model (Eliáš and Vořechovský, 2020), but only single realization is used. Also, only one computational thread was employed. There is a huge potential to speed-up the *homogenized* model further by distributing independent RVE problems over several processors.

6.1 Linear Terzaghi’s consolidation

The model is verified by simulating Terzaghi’s consolidation, a transient simulation of classical poromechanical problem. A partially sealed prism from a linear elastic material, initially under zero pressure and zero strain, is loaded by prescribed fluid pressure 1 MPa at the front end. Biot coefficient is $b = 0.5$.

The problem is analyzed using the *full* discrete model, and the *homogenized* continuous model composed of five trilinear 8-node isoparametric finite elements. Evolution of displacement and pressure along the central axis of the 3D prism is shown in Figure 2. There is also an analytical solution included in the comparison. Small differences are attributed to (i) heterogeneity and (ii) boundary layer effect (Eliáš, 2017), or wall effect, that is present in the *full* model and modify the mechanical properties in the vicinity of the boundary.

The *full* model features approx. 124,000 DoF and run for approx. 3 hours. The *homogenized* model has only 40 DoF and calculation took approximately 1 s. The speed-up factor is about four orders of magnitude thanks to the enforced linearity of the RVE response, which can be pre-computed at the simulation initialization.

Figure 2. Comparison of results of the Terzaghi’s consolidation problem: displacement profiles and fluid pressure at various times of simulation as computed by the *homogenized* model (macroscopic component only) and the *full* model.

6.2 Hydraulic fracturing of hollow cylinder

The specimen is a hollow cylinder with transport boundary conditions prescribing zero pressure at the outer cylinder shell, pressure linearly increasing in time at the inner surface and zero normal flux at the upper and bottom surfaces. Mechanical boundary conditions restrict normal movements at the upper and bottom surface and apply inward traction on the inner surface of a magnitude equal to the prescribed pressure. Three variants of Biot’s coefficient are simulated: $b = 0, 0.05$, and 1 .

The *full* model has approximately 323,000 DoF. The *homogenized* model has only 4 elements in radial direction and 10 element along circumference. In total, it has 40 element, 320 RVEs and approx. 1.3 mil. DoF (macroscale and microscale combined). This number is, however, only virtual as most of the RVEs remain linear elastic during the calculation so their response is pre-computed and their degrees of freedom are not activated. The simulation is controlled by an increasing pressure so it eventually reaches a state when a macroscopic crack runs across the whole cylinder and solver fails due to loss of convergence. Another complication arises in *homogenized* models because the macroscopic crack may develop in any direction. Standard periodic boundary conditions cannot handle such situation (Stránský and Jirásek, 2011) and advanced approach is needed (Coenen, Kouznetsova and Geers, 2012). Instead, the RVEs are rotated in this study so they are all aligned with the radial direction under which the crack is expected.

Reasonable correspondence between the *full* and *homogenized* solution is documented in Figures 3 and 4. The larger differences occurring in the later stages of the simulations are attributed to the developed strain localization, which cannot be homogenized by the standard technique.

Figure 3. Left: loading pressure vs. volumetric change of the central hole; right: inner and outer fluxes.

Figure 4. Cracks developed in the *full* and *homogenized* models at the last valid step of the simulation.

The *full* model simulations took 2970 min, 1220 min and 730 min for Biot coefficients 0, 0.5 and 1, respectively; the *homogenized* models run for 330 min, 150 min and 120 min (in the same order). The speed-up factors are approximately 9, 8.1 and 6.1, respectively.

7 CONCLUSIONS

Asymptotic expansion homogenization is developed for the discrete mesoscale models of coupled mechanics and mass transport in a fully saturated heterogeneous medium. Only brief description is given in this conference paper, detail are provided in Eliáš and Cusatis (2022).

- The macroscale problem corresponds to transient Cosserat continuum coupled with mass transport. It is solved with a help of the finite element method; the constitutive function is supplied by a subscale RVE problem. The homogenized macroscopic material exhibits natural anisotropy due to cracking at the microscale, both for the mass transport and mechanical behavior.
- The microscale problems are discrete and steady state. RVE loading is given by a projection of macroscopic strain and pressure gradient into eigen-strains and eigen-pressure gradients of the discrete elements. Summations of discrete stress-like quantities over the RVE then provide macroscopic stress, couple stress and flux.
- Reasonable correspondence between the *full* and *homogenized* solution and significant speed-up factors are achieved.
- The strain localization remains unsolved, the localized solution is dependent on RVE size. Possible remedies described in literature (Coenen, Kouznetsova, Bosco and Geers, 2012; Unger, 2013) shall be implemented in the future.

Early-age cracking in concrete slabs with FRP reinforcement

J.E. Bolander

University of Miami, Coral Gables, Florida, USA

ABSTRACT: This paper reports on a combined experimental and numerical modeling investigation of cracking of concrete slabs with FRP reinforcement. At this stage of the project, attention is given to early-age cracking driven by plastic shrinkage, preceding longer term considerations of cracking resistance over the service life of field applications. Small-scale slab specimens are subjected to controlled evaporation rates. Images of crack development are acquired periodically, from which crack width estimations are made. Comparisons are made between slabs reinforced with conventional steel and those reinforced with FRP, along with control specimens that lack reinforcement. During the period of plastic shrinkage, the time of crack initiation and subsequent crack openings do not appear to be influenced by the presence of the reinforcing bars.

The numerical modeling component of the research is based on a Voronoi-cell lattice model. The relative humidity, temperature, and displacement fields are discretized in three-dimensions, which allows for a comprehensive investigation of fracture development. For the reduced bond properties that are expected at early ages, the simulations confirm that cracking behavior is not significantly influenced by the presence of the reinforcing bars.

1 INTRODUCTION

Corrosion of reinforcing steel is a primary factor affecting the durability of structural concrete, especially for exposures to severe environments. The potential for corrosion-induced durability problems can be reduced by controlling crack formation in the concrete, particularly at early ages when the concrete is susceptible to cracking. Alternatively, non-corroding materials can be used as concrete reinforcement.

This research involves the use of fiber reinforced polymer (FRP) bars to reinforce concrete exposed to severe conditions, such as those presented by marine environments. Despite the fact that FRP bars have been successfully used for structural reinforcement in concrete members in building and bridge projects for the past 30 years, there has recently been interest in using FRP bars and meshes as secondary reinforcement for non-structural concrete members, such as plain concrete footings, concrete slabs-on-ground, and plain concrete walls, in place of conventional temperature and shrinkage steel reinforcement (Ekenel et al. 2022). Of interest is the effectiveness of such reinforcement in restricting plastic shrinkage cracking at early ages. It is known that conventional steel reinforcement does not restrict the opening of plastic shrinkage cracks. However, the nature of the bond mechanisms is potentially different and, in relative terms, the mismatch in stiffness between FRP and immature concrete is smaller.

FRP bar performance, relative to that of conventional steel reinforcement, is investigated through a combination of physical experimentation and numerical modeling. The bases for the experiments and modeling exercises are first described, after which preliminary results are presented. In particular, based on the assumption of poor bonding at early stages of matrix development, the type of reinforcement does not significantly influence time of cracking and crack opening driven by plastic shrinkage.

2 EXPERIMENTAL PROGRAM

2.1 Test set-up and procedure

Potential for plastic shrinkage cracking is assessed using a modified form of the set-up described in ASTM C1579 (ASTM 2021). The set-up involves small-scale slab specimens that incorporate metallic inserts attached to the formwork base. The insert is a 1/4 in. steel plate with 3 welded T-bars as illustrated in Figure 1. The T-bars at both ends restrain plastic shrinkage of the concrete, which fosters crack formation; the one at mid-span acts as a stress riser that influences the point of crack initiation.

Whereas ASTM C1579 pertains to the testing of fiber reinforced (or plain) concrete materials, a reinforcing bar is positioned within each of reinforced specimens, as shown in Figure 1. Along with plain concrete specimens, two types of bars were considered: glass FRP (GFRP) bars and conventional steel reinforcing bars, both having a nominal diameter of 10 mm. The main challenge is to consistently ensure the occurrence of cracking at the early stages. Therefore, an environmental chamber was designed and built to provide the critical rate of evaporation for plastic shrinkage cracking. In addition to the environmental condition considerations, several mixture designs were evaluated to maximize the plastic shrinkage. Moreover, the mixing water was heated to 50°C before addition to the mixture to increase the initial concrete temperature and rate of evaporation.

Crack initiation and development were monitored by acquiring images of the drying surface. Post-processing of the images provided data regarding time of crack initiation and the evolution of crack openings.

2.2 Experimental results

All specimens exhibited cracking within three hours after the first contact between water and cement. Images of the middle portion of the cracked specimens are presented in Figure 2. Table 1 provides crack data measured after six hours of exposure to the specified conditions of evaporation. Crack widths did not noticeably narrow in the vicinity of reinforcement, but were rather uniform over the crack lengths. The premature bond between the reinforcement and concrete during this time span results in a poor stress transfer between the concrete and reinforcement. As expected, the reinforcement is ineffective in controlling plastic shrinkage cracking.

Using the same mixture design, a companion set of pullout tests according to ASTM D7913 (ASTM 2020) was conducted to measure the bond properties of the GFRP bars at early age.

It was found that the bond strength at $t = 2\text{h}$ (the approximate time of initial cracking) is only about 0.14 MPa. For comparison, the ASTM D7957 (ASTM 2022) requires a minimum guaranteed bond strength of 7.6 MPa after 28 days of concrete hardening and the guaranteed value is the mean minus three standard deviations of the samples.

Table 1. Measured crack data at six hours after concrete casting.

Specimen ID	Reinforcement	Crack area (mm ²)	Crack length (mm)	Crack width (mm)
P-SC-1	Plain	133.5	345.4	0.39
S-3S-SC-1	Steel	246.5	353.1	0.70
S-3S-SC-2	Steel	73.5	188.0	0.39
S-3S-SC-3	Steel	129.7	342.9	0.38
G-3S-SC-1	GFRP	112.9	340.4	0.33
G-3S-SC-2	GFRP	58.1	139.7	0.42
G-3S-SC-3	GFRP	219.4	322.6	0.68

3 MODELING APPROACH

Voronoi-cell lattice models (VCLM) are used to simulate the early-age thermal and hygral fields acting in the concrete, as well as the mechanical response to those actions. Such discrete modeling approaches are particularly effective in simulating cracking and other forms of displacement discontinuity (Bolander et al. 2021). A VCLM discretization of the test specimens and plywood formwork is shown in Figure 3. The study of reinforcing bars within the concrete volume requires three-dimensional simulations.

The thermal-hygral-mechanical model employed herein utilizes the analysis framework developed by Pan et al. (2017), which has the following features:

- Cementitious materials hydration is based on the model proposed by Riding et al. (2012). The degree of cementitious materials reaction can be expressed by the amount of chemically combined water or, equivalently, by

$$\alpha(t) = \frac{H(t)}{H_u} \quad (1)$$

where $H(t)$ is the cumulative amount of heat produced by the hydration reaction (J/g); and H_u is total heat available for reaction (J/g). The total available heat depends on the composition and proportioning of the cementitious materials (Riding et al. 2012);

- The temperature field within the model domain is simulated using a lattice composed of conduit elements. A convective boundary layer models heat transfer between the exposed surface of the specimen and the environment. For field exposure conditions, heat exchange with the environment is due to convection, solar radiation, thermal radiation, evaporation and condensation. For the lab specimens considered herein, convection and evaporation will be the dominant forms of heat exchange. Convective heat exchange across exposed surfaces (including the outer surfaces of the plywood formwork) depends on the difference between the solid surface temperature T_s and that of the surrounding ambient medium T_a

$$q_{conv} = A_T(T_s - T_a) \quad (2)$$

where A_T is the coefficient of convective heat transfer, which depends on material type, wind speed and other conditions (Bentz 2000). Heat of hydration is calculated at the lattice nodes and used as a source term in the thermal analyses;

- The humidity field is simulated using a parallel set of conduit elements, based on the same set of nodal points and element connectivities. After setting of the concrete, moisture transport is assumed to be governed by a diffusion process (i.e., according to Fick's 2nd law). A convective boundary layer accounts for moisture transfer between the drying surface of the concrete and the environment. The modeling of this layer is analogous to that of the temperature field, expressed by Eq. 2, although governed by different mechanisms;
- The solution process involves a time-stepping scheme in which, for each time step, the temperature and humidity fields are solved using the Crank-Nicholson method in conjunction with a fixed-point algorithm to achieve convergence;
- The simulated thermal and hygral fields produce thermal and hygral strains, respectively, within the mechanical component of the analysis framework. These strain increments produce stress that might lead to crack formation;
- Concrete property development, including strength and stiffness, depends on the degree of cementitious materials hydration. In particular, solidification theory is used to simulate creep processes and stiffness development (di Luzio & Cusatis, 2013). The development of tensile strength is represented by

$$f(\alpha) = f(\alpha_u) \left(\frac{\alpha - \alpha_0}{\alpha_u - \alpha_0} \right)^\zeta \quad (3)$$

where $f(\alpha_u)$ is the tensile strength at the ultimate degree of hydration; α_0 is the degree of hydration associated with setting; and coefficient $\zeta = 1$ when tensile strength is being modeled (de Schutter & Taewre, 1996);

- At a given stage of strength development, concrete fracture is simulated using an energy-conserving crack band model (Berton & Bolander, 2006). The geometry of neighboring Voronoi cells define the extents of the crack band;
- Each reinforcing bar is represented by series of frame elements, which connect to the concrete nodes via special link elements (Kang et al., 2014). The link elements account for the nonlinear bond actions between the concrete and reinforcement, including FRP bars as described by Focacci et al. (2000).

The model has been modified to approximate behavior of concrete in the plastic state. In particular, the modeling of plastic shrinkage is based on the simulations of Ghourchian et al. (2019), as presented in Figure 4. Plastic settlement produces volumetric strain that begins with a vertical component. A smaller horizontal strain component appears at a later time. By studying the behavior of different concrete types, Ghourchian et al. suggest that crack initiation is governed by a limiting value of horizontal strain (e.g., $\epsilon_{h-crack} \approx 0.003$), rather than a stress measure.

Herein, volumetric strain is introduced into the lattice model from the time of horizontal strain commencement; the preceding accumulation of vertical strain is neglected. This volumetric straining continues until the end of the plastic stage, after which drying shrinkage is assumed to be caused by moisture diffusion, as described above. The rate and duration of this form of volumetric straining are model parameters. The stress-based fracture criterion, as expressed by Eq. 3, is retained.

The model has also been extended to include the effects of evaporation on concrete temperature. Heat flux due to evaporative cooling is determined by

$$q_e = -E_c h_l \quad (4)$$

Figure 4. Volumetric instability of concrete in the plastic state (adapted from Ghourchian et al., 2019).

where E_c is evaporation rate from the concrete surface ($\text{kg/m}^2/\text{s}$) and h_l is latent heat of vaporization (J/kg). The evaporation rate from the fresh concrete surface is calculated according to Uno (1998) in the following form

$$E'_c = 5(V + 4) \left[(T_c + 18)^{2.5} - r(T_a + 18)^{2.5} \right] \times 10^{-6} \quad (5)$$

in which V is wind velocity (km/h); T_c is temperature of the concrete surface ($^\circ\text{C}$); T_a is the ambient temperature ($^\circ\text{C}$); and r is relative humidity of the environment. The evaporation rate is modified to account for maturation of the concrete according to

$$E_c = E'_c \exp \left[-(t/a)^{1.5} \right] \quad (6)$$

where t is maturation time (h) and a is a time constant set equal to 3.75h for concrete (Schindler et al., 2004).

4 SIMULATION RESULTS AND DISCUSSION

4.1 Thermal analyses

As previously noted, the thermal analyses, as well as the simulation of property development, are based on a modeling of cementitious material hydration. The recorded wind speed was used to determine transfer of heat from the upper concrete surface due to convection and evaporative cooling, as described above. Specimen temperature was measured using a thermocouple device, inserted through the plywood formwork and extending into the concrete specimen. A computational node was introduced at the location of the thermocouple tip to have one-to-one correspondence with respect to the measurement location.

Figure 5 compares the measured and simulated temperature results from the time of casting for specimen S-3S-SC-1. The initial decline in temperature was typical of the results of most of the other specimens. In the numerical simulations, the decline was found to be caused mainly by evaporative cooling, rather than other environmental factors.

4.2 Cracking behavior

In agreement with experimental observations, cracks form across the midspan width of the specimen, over the central restraint (Figure 6). Although not evident in the figure, microcracking also occurs local to the peripheral restraints, which has been observed in other experimental programs (Combrinck et al., 2018).

Prior to simulating plastic shrinkage in terms of volumetric strain, as shown in Figure 4, attempts were made to simulate plastic shrinkage as a diffusion phenomenon, as done for drying shrinkage. In addition to being conceptually invalid, these attempts failed in several respects. The resulting crack widths at $t = 6$ h were much smaller than those observed in the experiments. Furthermore, significant distributed microcracking occurred over the drying surface and the resulting macrocrack (which formed over the central device) propagated from the upper surface downward. In contrast, by introducing plastic shrinkage as a volumetric strain, the central device acts as a stress riser, such that cracking initiates at the device tip and propagates upward. Ghourchian et al. (2019) observed such upward propagation of plastic shrinkage cracking from images produced by x-ray radiography.

Figure 5. Measured and simulated temperatures at the thermocouple location in specimen S-3S-SC-1.

Figure 6. Crack pattern in specimen S-3S-SC-1 at $t = 4$ h.

In Pan et al. (2021), the VCLM has been extended to simulate such hygro-mechanical behavior using the effective stress concept of Biot (1941). Transport of water in the porous media is driven by gravity and described using Darcy's Law in rate format. Work toward integrating this capability with fracture modeling, and the other relevant chemo-physical processes, is ongoing.

4.3 Effects of reinforcing bars

As noted in Section 3, each reinforcing bar is represented by a series of frame elements, which connect to concrete nodes via nonlinear link elements. The frame elements are assigned the geometric and material properties of the steel or FRP bars, as the case may be. The bond strength assigned to the link elements was determined through the aforementioned pullout tests conducted at $t = 2\text{h}$, the approximate time of plastic shrinkage crack initiation.

Figure 7 presents the simulated crack opening profile for specimen S-3S-SC-1, which contains steel bar reinforcement; similar results are obtained for GFRP bar reinforcement. From these results, it is apparent that the presence of the reinforcement (of either type) does not have an appreciable effect on the crack opening profile. Given the low bond strength at this early age, this result was foreseeable. Short distributed fibers, which supply a much larger bonded surface area, are seen as a solution.

Figure 7. Simulated crack opening profile for specimen S-3S-SC-1 at $t = 6\text{h}$ (where y represents position along the crack within width b of the specimen).

5 CONCLUSIONS

The physical testing and numerical modeling of plastic shrinkage cracking is complicated by many factors. These factors include uncertainties regarding the thermo-hydro-mechanical processes and their couplings, the roles of sustained load and plastic settlement on the fracture process, frictional effects along the specimen base, and bond properties at early ages. To help address these uncertainties, more comprehensive test and analysis efforts are needed. Nonetheless, several statements can be made based on the results presented herein.

- Consistent cracking behavior of the control specimens was obtained by optimizing the concrete mixture design, controlling the environmental boundary conditions, and raising the initial temperature of the concrete which increased the evaporation rate from the drying surface. Initial temperature was raised by heating the mixing water, before its addition to the dry materials.
- For the specimens considered herein, crack opening does not appear to be restricted in the vicinity of a bar, but rather openings are fairly uniform over the specimen width. This suggests poor bond properties between the reinforcing bars and the concrete at these early ages. In other words, the presence of the reinforcing bar of either type, GFRP or steel, does not have an appreciable effect on time of plastic shrinkage crack initiation and ensuing crack opening.
- The proposed numerical analyses elucidate the roles of the various thermo-hydro-mechanical processes that affect early-age cracking of the specimens. In particular, by modeling plastic shrinkage as a bulk material phenomenon (in the form of volumetric strain), the central device acts as a stress riser. The simulated cracking initiates from the device tip and propagates upward, as seen by others using images based on x-ray radiography.

- Concrete temperatures, and thus properties of the concrete, are influenced by the thermal properties of the formwork and related boundary conditions. The modeling of evaporative cooling was found to be essential in simulating the concrete temperatures, particularly early in the testing period where temperature decreased with time.
- The numerical analyses support the notion that, due to poor bonding properties, both the steel and GFRP bars do not significantly influence crack formation and opening. To address the potential for early-age cracking, short distributed fibers are seen as an option.

Toward distinguishing the chemical, physical, and wetting-drying sulfate attack on concrete

I.A.N. Omrani, M. Koniorczyk & D. Bednarska
Lodz University of Technology, Poland

ABSTRACT: Depending on the mode of exposure, concrete structures might experience various forms of sulfate attack during their service life. In the case of a concrete element which is partially subjected to a sulfate-contaminated solution, the immersed sections receive intense alterations in their mineralogical composition that affect their mechanical properties, known as “Chemical sulfate attack”. The upper sections of the element which experience no direct exposure to the solution are prone to face the crystallization and dissolution of various kinds of sulfated salts, known as “Physical sulfate attack”. The middle parts of the element that might receive a cyclic exposure to the sulfated solution via waves are vulnerable to the combination of the both noted phenomena, known as the “Wetting-drying sulfate attack”. A particular exposure condition has been designed in this paper to distinguish the three mentioned modes of sulfate attack in terms of the concrete’s mechanical response.

1 INTRODUCTION

Unlike the ideal laboratory regulations on the topic of “sulfate attack” under which cementitious samples face a saline solution in a constant immersed mode, concrete structures in real service environments mostly experience the external sulfate-contaminated sources through a partial exposure; i.e. foundation elements or basic columns of concrete structures in marine environments or industrial zones are partially immersed in the external saline sources.

Under such circumstances, the immersed sections of the element receive severe chemical alterations such as crystallization of secondary ettringite, gypsum, etc., and de-calcification of their portlandite and C-S-H gel (Santhanam et al. 2003). For an ordinary Portland cement paste and under the assumption that the aggressive sulfated source mainly possesses sodium and sulfate ions, ettringite crystallization as a through-solution reaction can be written as:

Where the Ca^{2+} cations are obtained from the decalcification of portlandite and C-S-H gel, the Al^{3+} cations come from the destabilization of the aluminate-containing hydrates (Afm, etc.) and/or clinker phases (C_3A , etc.), and the hydroxyl ions arise from the paste’s alkali elements (Marchand et al. 2002). Once the aluminate sources become exhausted in certain zones of the matrix, further intrusion of sulfate ions leads to the through solution generation of gypsum crystals as:

Which fully consumes the local portlandite and accordingly decrease the hydroxyl sources of the system, causing the destabilization of the remaining intact C-S-H gels (Marchand et al.

2002). The excessive precipitation of secondary ettringite and gypsum forces a crystallization pressure upon the solid matrix which results in the induction of expansive microcracks within the concrete's microstructure; Together with this, the decalcification of the C-S-H gel lessens the cementitious quality of the structure. Such typical aftermaths are known as "chemical sulfate attack" which makes the material vulnerable against other aggressive factors of the field and decreases its service-life (Zhang et al. 2019).

On the other hand, the cyclic precipitation/dissolution of sodium sulfate salts, namely, decahydrate and its anhydrous forms, induces expansive microcracks and surface scaling in case of sub-florescence in the dried sections of the concrete element (Scherer 2004), known as "physical sulfate attack". Such situation can be written as:

Where v_0 is the number of water molecules of the hydrated salt, 10 in case of decahydrate.

Distinguishing the above noted chemical and physical modes of sulfate attack on cementitious materials has been a topic of discussion for years (Neville 2004).

Recently, some attempts were carried out in order to regulate the physical sulfate attack in concrete (Hartell et al. 2011, Alyami et al. 2019, Najjar et al. 2017, Zhao et al. 2021); mass measurement, assessing the expansion and mechanical strength of the samples were the main approaches of such works; yet, since these analyses were conducted on the total scale of the material, the separate contribution of the chemical and physical modes of aggressions could not be clarified. Some of the cited studies also tended to evaluate the microstructural properties of the partially immersed concretes, however, their sampling locations were limited and again a clear distinction between the different forms of sulfate attack could not be recognized.

Consequently, to fill the current gap in the literature, this paper is a simple experimental approach toward distinguishing the contribution of different modes of sulfate attack; i.e. chemical degradation & physical damage. To do so, a novel exposure condition has been designed, detailed in the upcoming sections.

2 EXPERIMENTAL PROGRAM

2.1 Materials

Table 1 presents the mix proportions of the prepared concrete samples.

Table 1. Mix proportions of the concrete samples (kg/m³).

Cement	Water	W/C	Coarse agg*	Fine agg	Sand
390	195	0.5	558	648	594

* Aggregate

The utilized cement was Portland CEM I 42.5. Coarse and fine aggregates were obtained from a local river with the diameters of 8-16 and 2-8mm, respectively. Also, the diameter of the used sand was 0-2mm.

After homogeneous stirring for 5 minutes in a laboratory mixer, the fresh mixture was poured in rectangular prism moulds having the length of 200mm and cross-sectional height & width of 100mm. Subsequently, samples were de-moulded after 24h of resting in laboratory conditions. Next, they were immersed in water tanks for curing at 25°C until the age of 28th day. Finally, samples were ready for the sulfate exposure.

2.2 Exposure conditions

Anhydrous sodium sulfate salt and distilled water were utilized for preparing the aggressive sulfated environment having a concentration of 5%. Samples faced the prepared sulfate solutions as illustrated in Figure 1.

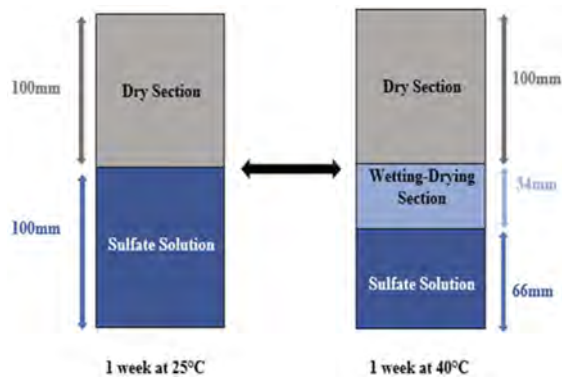

Figure 1. Schematic sulfate exposure condition.

As can be seen, samples received sulfate solution up to half of their length for 7 days at 25°C; subsequently, samples were moved to an oven drier at 40°C for 7 days where the height of the sulfate exposure was decreased to 1/3 of the sample's length. Next, samples were removed from the sulfated environment and dried at room temperature for 24h; following this, the crystallized salts of the concrete were gently removed via a brush and samples got ready for the analysis. After the analysis, samples were returned to the solutions to repeat the described cycle. Hence, sulfate solution was renewed every two weeks.

Such cyclic exposure design created three sections within the concrete; namely, the bottom 1/3 of the concrete was always immersed in the solution, denoted as the “immersed section”, the middle section which got weekly wetting-drying cycles is denoted as the “W-D section”, and the upper half of concrete that was constantly kept dry is denoted as the “dry section”.

As noted above, the employed temperature cycles are 25°C and 40°C. Such temperature ranges were chosen as realistic temperatures that might be experienced in warm zones of the planet. In addition, since the samples faced wetting-drying cycles in their middle sections, the exposure design of this study can simulate the conditions of the concrete columns which are in partial contact with a moving saline source that can produce splashing waves, i.e. marine environments.

3 RESEARCH OBJECTIVE AND METHOD

The objective of this paper is to assess and compare the mechanical properties of the immersed, W-D, and dry sections of the concrete. To do so, the conventional through transmission ultrasonic method has been employed. This method is based on the speed of the stress wave propagation through the sample which is a function of the concrete's elastic constants and density (ACI committee 228 1998). Thus, it is expected that the sulfate-induced expansive microcracks and other interruptions within the cementitious phases prolongs the stress wave's propagation speed and decreases the ultrasonic pulse velocity (UPV) of the samples.

The utilized device was Controls E48. Water was used as the coupling agent between the device's probes and concrete.

Accordingly, UPV of each section of concrete was assessed every two weeks for six months. Measurements were conducted on at least three samples to assure their reproducibility.

4 RESULTS

4.1 Visual inspection

Figure 2 illustrates the visual conditions of a typical sample at the beginning, after 3 and 6 months of the exposure.

Figure 2. Typical appearances of the samples at different ages.

As can be observed, after 3 and 6 months of exposure, it is the W-D section of the sample that received the most intense damage. In this region, surface scaling was evident and coarse aggregates which lies beneath the paste surface of the concrete began to reveal themselves. Next, it is the dry section that had received a notable surface scaling, particularly after 6 month of exposure. Finally, the appearance of the immersed section remained approx. intact after 3 month, and moderately affected after 6 month of sulfate exposure.

Based on the mentioned visual inspections, one can assume that those sections of the concrete that were prone to physical sulfate attack failed more abruptly compared with the immersed section of the material.

4.2 UPV measurements

Figure 3 shows the results of the UPV measurements on different sections of the concrete.

Figure 3. UPV changes of the samples.

According to Figure 3, the W-D section had the most abrupt drop of UPV. During the first four weeks of the exposure, the UPV of the W-D section was enhanced for approx. 2%. Such initial improvement is possibly due to the capillary suction of the sulfated solution which partially enhanced the material's density. After this enhancement, however, a sudden drop in the stress-wave propagation's speed was observed for approx. 10% until the 20th week which indicated the induction of the microstructural damages within the section. After the 20th week, the quality of the concrete's surface at the W-D section became so low that more contact between the device's probe and surface was not possible.

In the dry section of the material, the UPV retained approx. constant with partial enhancements during the first 12 weeks of the measurements. Such prolonged time of soundness stated that the dry section of the material had more resistance against the sulfate exposure compared with W-D section of the concrete. After this period, the UPV dropped suddenly for approx. 8% until the 20th week, after which the measurements were not possible due to the severe surface scaling of this section.

The immersed section of the concrete had the highest improvement in its UPV compared with the other two sections (approx. 3%). This section also revealed the longest soundness period, lasting for 14 weeks. After 14 weeks of exposure, the UPV of this section began to drop gradually until the final measurement point for only 4%. Such trends indicated that compared with the W-D and dry sections, the immersed section of concrete had the least sulfate-induced microstructural damages.

5 DISCUSSIONS

In this section, the possible mechanisms which led to the failure of the three sections of concrete are discussed.

At the beginning, it is important to note that concrete is a cementitious medium which is chemically active against sulfate ions, therefore, one cannot say that the W-D and dry sections of the material only received physical sulfate attack and chemical alterations were just limited to the immersed section of the samples. In other words, an interconnected network of chemical and physical phenomena is expected to occur in various sections of a concrete element which is partially subjected to sulfate solution and a rigid distinction between the various mechanisms of failure is not correct. However, it can be stated that some failure mechanisms are likely to play a more dominant role than others in precise sections of the concrete.

The notable initial improvement of the UPV in the immersed section of concrete is probably due to the precipitation of secondary ettringite and gypsum crystals as hinted in the section 1. At first, such crystals tend to precipitate through the microstructural gaps and free spaces of the matrix (Santhanam 2002); thus, their crystallization densifies the material and accordingly improves its mechanical properties. However, once the mentioned free gaps of the matrix became filled by the excessive formation of the sulfate-induced crystals, their continuous formation in time can lead to the generation of expansive crystallization pressure upon their surrounding solid skeleton, causing microcracks and failure of the material.

The dominant mechanism of failure in the W-D section of concrete was probably due to the cyclic dissolution/re-crystallization of decahydrate within the porous matrix of concrete. When exposed to 40°C, the previously wetted W-D section of concrete was dry as detailed in section 2.1; therefore, evaporation of saline pore solution occurred in this section, which eventually led to the supersaturation of its remaining saline pore solution and salt crystallization; the salt which crystallizes at 40°C is thenardite based on the phase diagram of $\text{Na}_2\text{SO}_4 \cdot n\text{H}_2\text{O}$ system (Steiger & Asmussen 2008). Now, once the concrete was returned under 25°C and its W-D section became immersed again, the previously crystallized thenardite became de-stable and dissolved. Under the assumption that such dissolving continued until pore solution became saturated with respect to thenardite, decahydrate could crystallize from a supersaturated solution for 1 week which probably generated expansive microcracks throughout the medium.

Higher up, in the dry section of the material, sub-florescence of the sodium sulfated crystals in the sections where the rate of evaporation exceeded the rate of capillary rise, could be the main mechanism of damage. Such destructive process was expected precisely when samples were placed at 40°C for 1 week.

6 CONCLUSION

In this paper, a novel sulfate exposure condition was designed under which concrete samples experienced chemical, wetting-drying and physical sulfate attack simultaneously under 25°C and 40°C temperature cycles. Such exposure conditions are common in concrete structures at marine environments. The objective was to distinguish the response of concrete when receiving the three mentioned modes of sulfate attack.

It was observed that the most intense damage was occurred in those sections of the material that were under wetting-drying sulfate attack. The dominant mechanism which causes failure in such sections are likely the dissolution and recrystallization of decahydrate. Following this, it was the dry section of concrete that got damaged. This section was mainly under physical mode of sulfate attack caused by salt sub-florescence. The immersed section of the concrete that was likely under dominant chemical alteration was the most resistant section that had a gradual damage.

The reports of this paper were solely focused on the mechanical response of the designed sections of concrete in terms of their ultrasonic pulse velocity. A more detailed analysis of the situation via different techniques at both macro- and microscopic scales are to be conducted by the authors in near future to develop an un-ambiguous and precise description of the contribution of different modes of sulfate attack on the failure of the partially subjected concrete samples.

Requirements for gutting and demolition cost index

H. Kesting

University of Siegen, Siegen, Germany

M. Helmus

University of Wuppertal, Wuppertal, Germany

ABSTRACT: The development of a gutting and demolition cost index is essential to determine the life cycle costs and to design recyclable buildings appropriately. Accordingly, it is important to record and analyze the dismantling phase and the existing concepts for planning recyclable buildings. In addition, the available cost indices for dismantling and demolition must be researched and analyzed with regard to their structure and information content. Taking a top-down approach into account, the essential parameters are to be worked out. Consequently, a framework was established in terms of pollutants, gutting, demolition and disposal. In addition, certain standards such as the Cradle 2 Cradle concept, the determination of the actual residual value of a building according to Madaster, the Urban Mining Index and the DGNB certificate requires a valid cost index related to the demolition. This should also meet the demand for secured dismantling costs. The integration of the cost groups according to DIN 276, the STL-Bau as well as the waste key and the statistical processing of costs on the subject of demolition is needed to be considered. By analyzing the offer documents and further discussions with experts, further factors can be worked out that influence the unit price. A database system is to be developed in a bottom-up approach, taking into account the identified requirements. Madaster and Concular and Cradle2Cradle requirements are met as digital planning and documentation are included.

1 PLANNING OF RECYCLABLE STRUCTURES

In the future, architects and planners will be asked to plan and build buildings that are capable of recycling. If one considers the entire life cycle of a building, the life cycle phase of operation must be emphasised. Between 50 % and 80 % of all costs related to the entire life cycle are incurred in the operation phase. (Litau 2015)

With the focus on the use of resources, however, the planning and execution of the building project is of particular importance. This is because the course is set during planning and execution for the later use phase, deconstruction and thus for the ecological sustainability of the building. “The EU assumes that 80% of the effects of a product can be influenced or predicted in the planning phase.” (Alt 2018, p. 28) It can also be stated that “whether a product is recyclable, what materials it is made of and what quantities of materials are to be used, is largely determined by the product design.” (Alt 2018, p. 29) However, the necessary quantitative assessment standards for dismantling are still lacking.

1.1 *Cradle 2 Cradle – A circular economy concept*

“According to the wording, circular economy means management without beginning and end. Applied to the management of materials or resources, this means that they should be managed in such a way that they do not leave the cycle, but rather remain in the cycle. At the end of

their life, they should be returned to the material cycle and thus continue to be used for other or the same product.” (Alt 2018, p. 36) A concept based on this quote for the design of circular buildings is the Cradle 2 Cradle (C2C) concept. Based on the valid regulations in the construction of buildings to comply with safety-relevant standards, we speak of C2C-inspired buildings. (C2C im Bau: Orientierung für Kommunen 2022a)

One instrument for the implementation of a C2C-inspired building is also seen in the subsequent digitisation of the building stock. (C2C im Bau: Orientierung für Kommunen 2022c)

According to the EU Commission, “85 to 95% of the buildings that exist today will probably still exist in 2050, so we should use the potential of the materials already present in them. This can be done on the basis of parameters such as year of construction, type or volume, as well as through the exchange of experience between experts.” (C2C im Bau: Orientierung für Kommunen 2022d)

The C2C project phases (C2C im Bau) are based on the life cycle of a property. In the planning project phase, reference is made to the planning of deconstruction, which addresses the main processes of the demolition life cycle phase from the life cycle of a property. (Bresser *et al.* 2020) In addition, digital planning and digital documentation of the execution and building operation of the C2C project phases is another criterion of the C2C concept. Here, attention is paid to the fact that possible material flows and material values can be mapped in the sense of urban mining. (C2C im Bau: Orientierung für Kommunen 2022d) Furthermore, the C2C concept states: “In addition, a comparison of demolition or deconstruction and the costs of a new building should be obligatory in all profitability calculations - always taking into account the ecological effects and their financial implications.” (C2C im Bau: Orientierung für Kommunen 2022b)

1.2 Urban Mining Index (UMI)

The Urban Mining Index (UMI) provides a method for assessing the circular potential of building structures. The assessment of the loop potentials of building constructions is based on the consideration of open and closed loops for materials and recyclables. For this purpose, the UMI determines a loop potential (open) and a closed loop potential (closed).

The Urban Mining Index defines “The closed-loop potential is the percentage of materials and building materials of a construction that can be kept in closed loops without loss of quality, taking into account defined criteria. Reuse and recycling are among the after-use strategies where no loss of quality occurs.” (Rosen März/2021, p. 25) Furthermore, the Urban Mining Index states that “The loop potential of a construction includes, in addition to the percentage closed-loop share, shares of materials and building materials that, taking into account defined criteria, enable material recovery with a loss of quality (reuse/downcycling). The loop potential thus represents open loops in addition to the closed loops. The closed-loop potential is thus part of the loop potential.” (Rosen März/2021, p. 25)

Furthermore, the UMI divides the life cycle of building structures into the three phases listed below:

- Pre-use phase
- Use phase
- Post-use phase.

The determination of the loop potentials is carried out separately for the pre-use and post-use phases. Thus, a closed-loop potential pre- and post-use as well as a loop potential pre- and post-use can be determined for the assessment.

Essential parameters for determining the loop and closed-loop potentials are the

- material level
- constructive level
- economic level.

Here, effects can be seen from the material via the constructive level to the economic level. These effects serve to quantify a cost value for the deconstruction or separation of materials. The UMI makes clear: “Basically, what is needed for this is a “demolition cost index”, similar to the BKI construction cost index, which provides demolition costs for both conventional and circular constructions.” (Rosen März/2021, p. 98)

1.3 DGNB certificate deconstruction

In order to close the material flows in the building industry and to establish a promotion of the building fabric in terms of value in the sense of the circular economy, the DGNB has, with a view to the planning of deconstruction measures, developed the DGNB Deconstruction Certificate (Deutsche Gesellschaft für Nachhaltiges Bauen 2022) for sustainable deconstruction. “By creating transparency with regard to the data quality underlying the calculation of the deconstruction costs as well as the remaining risks, the building owner is to be supported in the decision-making process.” (Frank, p. 49)

The certificate is issued on the basis of criteria to be evaluated. The criteria to be assessed are divided into the five subject areas of ecological quality, economic quality, socio-cultural and functional quality, technical quality and process quality. The five subject areas are equally weighted. Each weighting is included in the assessment of the DGNB certificate with a 20% share of the overall result. (Deutsche Gesellschaft für Nachhaltiges Bauen 2022)

The assessment within the DGNB certificate for building deconstruction is implemented via 12 criteria in Figure 1, which are assigned to the aforementioned five thematic fields.

This makes it clear that the topic area of “risk assessment and cost security” as well as “pure separation and recycling” and “material flow balance” were given a high priority.

Figure 1. Criteria share DGNB certificate deconstruction.

2 COST(PLANING) IN CONSTRUCTION

If one pursues the question of transparently available demolition costs, one comes to the conclusion that there is a lack of available knowledge on this topic area. With reference to new construction, for which there is commercially available literature on object-related construction cost indices, no sources for object-related demolition costs in the sense of demolition cost indices have been identified for the area of deconstruction and demolition.

The production, repair as well as the demolition and subsequent disposal of a building are constantly affected by cost shifts. Especially the disposal costs of non-recyclable construction waste will increase in the future, also due to the shortage of landfills. (Thorsten Thörner,

Sigrid Hams, Dr.-Ing. Gabriele Becker, Dr. Bärbel Birnstengel, Arno Häusler, Nadja Schütz 2014) (AU Consult GmbH, Bayerisches Landesamt für Umwelt LfU 2015) (Iswing Dehne, Florian Knappe, Rüdiger Oetjen-Dehne, Stefanie Theis 2016)

The aim is to develop a structured planning tool that makes it possible to include the end of use of a property in the life cycle cost analysis in monetary terms. Assured costs for gutting, demolition and disposal expenses are to be compiled, which will ensure transparency in the cost calculation.

2.1 Life cycle costs

The main certification systems on the German market include the BREEAM, LEED and DGNB certificates. The DGNB has the largest market share.. (Litau 2015) For the evaluation of sustainability certificates, the determination of life cycle costs is also taken into account. Of these, the DGNB certificate for the assessment of life cycle costs has a 13 % share of the total. This is the largest share within an assessment for sustainability certificates. (Kasper Guldager, Harpa Birgisdottir, Gitte Gylling, Paul Stoller, Stefan Holst, Tiffany Broyles Yost 2018)

Life cycle costs in the narrower sense include the

- Building costs
- Operating costs
- Costs for cleaning, care and maintenance
- Costs for dismantling and disposal
- or other end-of-life scenarios. (Koschlik 2022)

The basis for calculating the life cycle costs are the production costs according to DIN 276 for the cost groups 300 and 400. Selected utilisation costs according to DIN 18960 are also used. The calculated costs are related to the gross floor area (GFA) in the area unit m². (Litau 2015)

If we look at the development of the cumulative costs along the vertical axis in relation to the horizontal life cycle phases (concept, planning, construction, use and demolition), we see that the ability to influence the resulting life cycle costs is mainly concentrated on the life cycle phases concept and planning. As time progresses, the influence on the resulting life cycle costs decreases. The cost difference between conventional planning and life-cycle-optimised planning is presented as “potential savings at the end of the life cycle” in Figure 2.

Figure 2 clearly shows that the influence on life cycle costs is decisive in the early phase of a building’s life cycle.

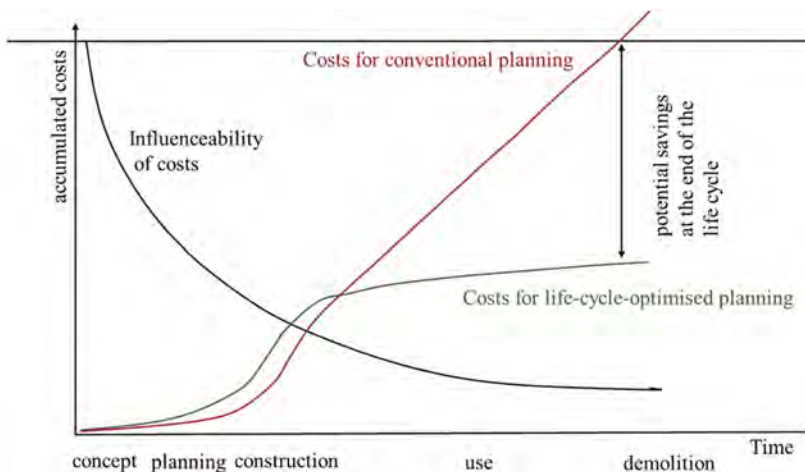

Figure 2. Influencing life cycle costs (Litau 2015, p. 24).

2.2 *Cost in construction – DIN 276*

Cost planning in construction is implemented using the standard DIN 276:2018-12 “Costs in construction” (DIN 276). DIN 276 is essentially used for cost determination and cost classification in new construction, reconstruction and modernisation of buildings and facilities. Cost planning pursues the goals of economic efficiency, cost security and cost transparency for a construction project. In addition, the cost calculations are used as a basis for financing, decision-making with regard to awarding and execution, as well as for the subsequent assessment and evaluation of construction costs incurred. The use of DIN 276 ensures that the cost calculations to be carried out are comparable. Depending on the point in time within a construction project, different cost investigations are carried out. These can be carried out once at a specific point in time or repeatedly in several steps during the course of the project. (DIN Deutsches Institut für Normung e. V. 2018)

The cost determination “cost framework” represents the beginning of the cost determination within a construction project. Based on the information available for the preparation of the “cost framework” cost calculation, the accuracy of the calculated costs is still subject to uncertainties. As the project progresses, the underlying information for the preparation of the further cost calculations becomes more detailed. At the end of each construction project, the cost determination “cost statement” is carried out. The information provided for the cost determination is based on the actual expenses incurred. (DIN Deutsches Institut für Normung e. V. 2018)

The analysis of the minimum information to be taken as a basis for the implementation of each cost calculation are the following parameters

- Service descriptions
- Quantities
- Auditable supporting documents - Evidence
- Grouping of costs to the levels of the cost groups according to DIN 276.

2.3 *Cost indices in construction*

In addition to the application of cost groups for the preparation of cost determinations, the underlying costs for the preparation of a cost determination are also required. Cost indices available on the market support this.

When conducting the market analysis according to available indices with reference to construction costs in general, the following providers could be identified:

- Building Cost Information Centre of German Chambers of Architects (BKI)
- SIRADOS construction data
- Baukosten 2020/21

The BKI construction cost database is published, among other things, in the form of reference books, which in turn are grouped into reference book series. Within the BKI reference books, statistical cost parameters for construction projects are published. The basis for the evaluation of the statistical cost parameters is formed by construction projects that have already been completed. The data is made available to the BKI by external planners or tenderers. (BKI Baukosteninformationszentrum Deutscher Architektenkammern GmbH and Baukosteninformationszentrum Deutscher Architektenkammern)

The statistical cost parameters shown in the individual reference books differ in terms of their level of detail. The level of detail is based on the cost group level of DIN 276. Here the variants

- Building
- Components
- Positions

are differentiated. The analysis of the BKI’s reference book series has shown that the reference book series “Altbau” is the only reference book series that presents cost parameters with reference to the topic of demolition and dismantling work.

The SIRADOS construction data are published, among other things, as reference books for the preparation of cost calculations according to DIN 276 and for the preparation of tenders. In addition, SIRADOS Baudaten provides several reference books as costing aids. In the reference books, construction prices are documented on the basis of price receipts of current tenders. The analysis of the SIRADOS Baudaten reference books has shown that the following reference books

- Loose-leaf work on old buildings
- SIRADOS Construction Price Manual
- SIRADOS costing atlas for shell and finishing work in old buildings

report key cost data with reference to the topic of demolition and dismantling work.

The technical book series *Baukosten 2020/21 Volume 1: Altbau - Instandsetzung, Sanierung, Modernisierung, Umnutzung* can be used to prepare cost calculations according to DIN 276. The assignment to the service areas of the STL-Bau is also given. The technical book is also dedicated to the topic of demolition and dismantling work. The content on demolition and dismantling work is very limited compared to the other products. (Schmitz *et al.* 2020)

3 REQUIREMENTS FOR A GUTTING AND DEMOLITION COST INDEX

Considering the aforementioned analyses on the planning of circular structures and cost planning in the construction industry, the first requirements for the development of a gutting and demolition cost index (EKI) can be derived from this.

3.1 *Requirements from the planning of recyclable structures*

From the analysis of the C2C concept (cf. Chap. 1.1), it can be deduced that the requirement of a disposal assignment of materials and, if applicable, the services to the waste codes and the waste designation from the “Regulation on the European Waste Catalogue - (Waste Catalogue Regulation - AVV)” must be fulfilled. At the same time, it should be possible to evaluate materials and the associated allocation to the AVV for an entire building. This would allow statements to be made about the recycling potential for buildings. Likewise, possible statements on polluted materials are possible. This in turn can lead to statements about the composition of a building in the sense of a C2C concept. Furthermore, C2C demands that digital planning and documentation are included. It can thus be deduced that a gutting and demolition cost index should serve this basis.

The Urban Mining Index (cf. Chap. 1.2) goes further in its statement and demand, and calls for a demolition cost index following the example of the BKI. Possible requirements from cost indices have been examined separately (cf. Chap. 2.3). The requirements from the Urban Mining Index can essentially be narrowed down to the parameters for determining the loop and closed-loop potentials.

The requirements from the DGNB certificate Deconstruction are based on the analysis of the catalogue of criteria to be complied with. The criterion that is highlighted most is the criterion “risk assessment and cost security”. Support for “deconstruction planning”, “separation and recycling”, “recycling and disposal”, “hazardous materials clean-up” and the “material flow balance” are further possible requirements that could be implemented with the EAKI.

3.2 *Requirements from cost planning in construction*

Possible requirements from life cycle costing (cf. Chap. 2.1) for the development and construction of an EAKI can be derived on the one hand from the provision of costs for dismantling and disposal as well as other end-of-life scenarios. Furthermore, the integration of cost groups according to DIN 276 should be considered. The preparation of the provided data of an EAKI should also meet the requirements that the data for the calculation of life cycle costs is possible in the early phases “concept” and “planning”.

The requirements from DIN 276 (cf. Chap. 2.2) refer to the fact that the data of the gutting and demolition cost index can be used for the cost determination based on DIN 276. Furthermore, the minimum information for carrying out any cost determination should be

- Service descriptions
- Quantities
- Auditable supporting documents - Evidence
- Grouping of costs to the levels of the cost groups according to DIN 276

taken into consideration. Whereas the “Verifiable Evidence - Evidence” is due to the fact that the data provided for the content of the EAKI is based on estimates of actual offers calculated by demolition companies.

The requirements from the cost indices in construction (cf. Chap. 2.3) can be summarised in connection with the aforementioned requirements on further additional points. The provision of statistical cost parameters, the integration of the STL-Bau, the allocation of the cost parameters to cost groups of DIN 276, the provision of data from external partners of already completed construction projects for the determination of statistical cost parameters, as well as the publication as a reference book and as an online version are to be mentioned here.

4 CONCLUSION

In addition to the above-mentioned requirement parameters, additional parameters for the evaluation of statistical cost parameters must be determined. Here, the documents of supporting partners are to be consulted. On the one hand, these are service specifications and additional planning and tender documents related to deconstruction and demolition. Here, the deconstruction and disposal concept as well as the deconstruction application can be named. A more in-depth analysis of the processes of the demolition life cycle phase may reveal further documents. Further expert discussions can contribute to the determination of influencing factors for the formation of the unit price of deconstruction, demolition and disposal services.

The allocation of waste code numbers to service and disposal items should also be worked out in expert discussions. In the sense of circular construction, the allocation of cost groups according to DIN 276 should not be limited to demolition and disposal. Here, an allocation should be made in the same way as for new constructions.

In order to be able to map and evaluate the complex interrelationships for a subsequent evaluation of demolition costs, coupled with the demand for digitisation, implementation in the form of a database system (DBMS) (Heuer 2018) should be preferred and developed.

Numerical determination of the wrinkling stress of steel polyurethane sandwich panels for reuse scenarios

K. Janczyk & M. Kuhnhenne

Institute of Steel Construction - Sustainable Metal Building Envelopes, RWTH Aachen University, Aachen, Germany

ABSTRACT: Sandwich panels are generally used as building envelopes in industrial and commercial buildings. They consist of two metallic face sheets and a core that provides the heat-insulating function of these components. The core material most commonly used is polyurethane (PUR) rigid foam. Due to the factory production of the sandwich panels, they can be quickly installed on the building and meet high building physics requirements. For those reasons, they are ideally suited for reuse. In addition, there is currently little to no possibility of recycling rigid polyurethane foam. Furthermore, recycling the steel is also energy-intensive and requires complex separation of the materials. The reuse of sandwich panels is therefore not only possible but also necessary from an ecological point of view. In this context, it is important to be able to assess the load-bearing behaviour of the panels after the first life-cycle in order to ensure a safe design. Generally, the material properties of the composite panels are determined by tests according to *EN 14509, 2013*. The modulus of elasticity and the shear modulus as well as the tensile, compression and shear strengths are determined in small specimen tests. The wrinkling stress of the panels is determined by component tests. Due to the size and number of test specimens, the effort to determine the wrinkling stress by tests is generally very high. To ensure that the reuse of sandwich panels remains attractive, the effort required to determine the material properties must be as low as possible. Avoiding the tests to determine the wrinkling stress could make an important contribution. This paper presents investigations to determine the wrinkling stress based on small-scale tests and numerical simulations, which represent an important step towards the reuse of sandwich panels.

1 INTRODUCTION

1.1 *Sandwich panels as building envelopes*

Sandwich panels are space-enclosing components that are commonly used as building envelopes in industrial and commercial construction. They consist of two metallic face sheets and a core, which takes over the heat-insulating function of these components. The core layer is usually made of mineral wool (MW), polyurethane (PUR) or polystyrene rigid foam (PIR). Due to the factory production and the low dead weight, sandwich panels allow a quick assembly while maintaining a high level of building physics quality. This leads to a great popularity and high demand of this construction method. In 2020, orders for sandwich panels amounted to over 17 million m² in Europe, *IFBS, 2021*. Sandwich panels are usually considered as self-supporting building components and are regulated by the corresponding standard *EN 14509, 2013*. Figure 1 shows a typical sandwich wall of an industrial building.

1.2 *End-of-life scenario and reuse*

Currently, end-of-life scenarios for sandwich panels do not consider reuse scenarios. The state of the art can be taken from the Environmental Product Declarations of *PPA-Europe, 2018*.

Figure 1. Typical wall made of sandwich panels.

These focus on the recovery of materials. First, the materials of the deconstructed sandwich panels are separated. Since the face sheets of the panels are usually made of steel, they can be easily recycled. The processes for the core material of the panels depend on the core material. Polyurethane core materials are usually used for energy recovery. The advantages of reuse compared to the usual end-of-life scenarios were clarified in the European research project PROGRESS as well as the difficulties and special requirements, *PROGRESS, 2020*. Furthermore, it was shown that sandwich panels in general meet the requirements for reuse. Those are in particular the possibility of standardisation, the durability, the maintenance of the physical properties of the building at a high level and sufficient material properties after the end of one life-cycle. In *Kuhnhenne et al., 2020*, it was shown that the mechanical properties of the sandwich panels after one life-cycle are basically at a sufficient level to be reused. Furthermore, rigid polyurethane foams retain their thermal properties permanently *IVPU, 2009*.

However, the high effort required to determine the mechanical properties and the associated uncertainty represent barriers to the reuse of sandwich panels. In general, the mechanical properties of sandwich panels are investigated experimentally in small-scale and component tests according to EN 14509, 2013. The small-scale tests usually refer to the properties of the core material and the component tests to the resistance of the entire panel.

1.3 Numerical investigations for the removal of uncertainties

The fact that component tests involve high effort and that it is questionable whether the results even meet the requirements represents a hurdle in the reuse of sandwich panels. Numerical simulations carried out as preliminary investigations can reduce the uncertainty about the outcome of the tests and thus represent an important barrier for future reuse. These simulations are performed on the basis of small-scale tests according to *EN 14509, 2013* and the measurement of geometric imperfections. Since both the small-scale tests and the measurement involve significantly less effort than component tests, especially with regard to the disassembly and transport of the panels, this method is suitable for making an initial statement about the reuse potential of sandwich panels.

In the following, this method is validated under laboratory conditions. First, a brief overview of the theory of wrinkling stress is given. Afterwards, experimental investigations on sandwich panels are presented. Both small-scale and component tests are carried out. In addition, the geometric imperfections of the face sheets are recorded with a high definition laser scanner before the bending tests are performed on the panel. The simulations are used to determine the wrinkling stress and are based on the small-scale tests and the measurement of the geometric imperfections. Subsequently, the numerical simulations are validated by comparing the numerical and experimentally determined wrinkling stress.

2 WRINKLING STRESS

Sandwich panels are characterised by a high load-bearing capacity with a simultaneously low dead weight. The so-called sandwich principle is created by the shear- and tension-resistant connection of the two extensional-stiff face layers with the shear-stiff core material. A bending moment is transferred by a pair of forces consisting of normal forces, which are divided between the two faces. In the case of a positive bending moment, a compressive stress occurs in the upper and a tensile stress in the lower face. Due to the high extensional stiffness and tensile strength of the metallic cover layers, the tensile stress can be absorbed without any problems. The upper face layer, which is subjected to pressure, is at risk of buckling. This face layer is elastically bedded by the core material. Exceeding the buckling stress leads to failure, the so-called wrinkling. In this case, a wrinkle forms across the width of the panel. The supporting core material allows compressive stresses in the face layer, which in turn allows for practical span lengths. From a mechanical point of view, the face layer can be seen as an elastically bedded plate under uniaxially acting normal stress, Figure 2. It can be seen that the elastic bedding is essentially dependent on the Young's modulus and shear modulus of the core material.

Figure 2. Wrinkling of elastic bedded steel layer.

The theoretical principles of sandwich panels have been extensively derived and presented by *Stamm & Witte 1974, Davies 2001 and Plantema 1967*, among others. The derivation takes place via the differential equation of an elastically bedded plate under uniaxial normal force loading according to Equation (1).

$$\frac{E_F \cdot t^3}{12(1 - \nu_F^2)} w(x)^{IV} + N_F w(x)'' + p(x) = 0 \quad (1)$$

where E_F = Young's modulus of the face; ν_F = Poisson's ratio of the face; w = vertical deflection of the face; $p(x)$ = function for elastic bedding.

The initial function according to Equation (2) describes the sinusoidal deformation of the cover layer.

$$w(x) = \sin\left(\frac{\pi}{a_x} x\right) \quad (2)$$

where a_x = The half wavelength.

After several transformations, the solution for the critical wrinkling stress is given by Equation (3).

$$\sigma_{w,cr} = \chi \sqrt[3]{G_C E_C E_F} \quad (3)$$

where E_F = Young's modulus of the face; G_C = Shear modulus of the core material; E_C = Young's modulus of the core material; and

$$\chi = \sqrt[3]{\frac{9(1 - \nu_C)^2}{2(1 + \nu_C)(3 - 4\nu_C)^2(1 - \nu_F^2)}} \quad (4)$$

where ν_F = Poisson’s ratio of the face; ν_C = Poisson’s ratio of the core.

Stamm & Witte 1974 also extended the approach of the critical wrinkling stress by taking imperfection into account. This should make it possible to determine the wrinkle stress under bearing load. The solution found its way into the current standard *EN 14509, 2013* and is expressed through Equation (5):

$$\sigma_w = 0.5 \sqrt[3]{G_C E_C E_F} \tag{5}$$

where E_F = Young’s modulus of the face; G_C = Shear modulus of the core material; E_C = Young’s modulus of the core material.

However, the theoretical approach underestimates the actual wrinkling stress under bearing load. In practice, this leads to manufacturers of sandwich panels resorting to the much more component tests to determine the wrinkling stress.

3 EXPERIMENTAL INVESTIGATIONS

3.1 Measurement of geometric imperfections

As described in chapter 1.3, the accuracy of the numerical analysis should be increased by taking into account the geometry of the lined surface layers on the one hand and the geometric imperfections on the other hand. To ensure the latter, a laser scanner was used to record the actual geometry of the face layer in the area of the maximum moment in the test. The accuracy of the laser is in the range of a few hundredths of a millimetre. Subsequently, the result of a scan was superimposed on the nominal geometry in the GOM-Correlate software. This makes it possible to determine the deviation of the actual geometry from the nominal geometry and thus the initial imperfections. Figure 3 shows the scanning of the surface layers on the left and the overlay of the nominal and actual geometry on the right.

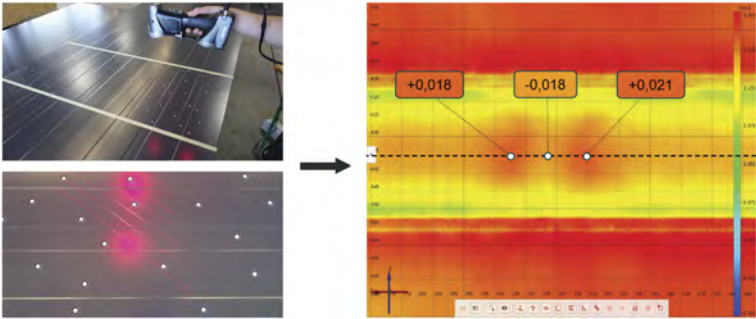

Figure 3. Determination of geometric imperfections.

The results of the measurement of the geometric imperfection are shown in Table 1. Those are the maximum deviation of the actual from the nominal geometry found in the scanned area of the respective test specimen.

Table 1. Measured geometric imperfection.

Specimen	Imperfection
-	mm
Bending test 1	0.018
Bending test 2	0.040
Bending test 3	0.029

3.2 Small-scale tests

Within the framework of the small-scale test program, tensile tests, compression tests and shear tests were carried out. Figure 4 shows the test set ups for the tensile test (left) and the compression test (centre). Both types of test were carried out in a Zwick-Roell testing machine. The test specimens had dimensions of 100 x 100 mm for both types of test. In addition, Figure 4 shows the corresponding diagram with the force-compression and force-elongation curves of individual test series.

Figure 4. Test set up of tensile test (*left*); Test set up of compression test (*centre*); load-displacement diagram (*right*).

The shear tests were carried out on a 1000 mm long beam, which was then loaded to failure in a 4-point bending test. In the evaluation, the proportion of bending deformation is subtracted from the total deformation. This results in the pure shear deformation of the test specimen, so that it is possible to determine the shear modulus of the core material. The shear strength results from the maximum load related to the beam cross-section. The test set up and the load-deflection-diagram of the shear test is shown in Figure 5.

Figure 5. Test set up of shear test (*left*); load-displacement diagram (*right*).

Table 2. Experimentally determined modules of the core material.

	Young's Modulus E_{Ct}	Shear Modulus G_C
	N/mm^2	N/mm^2
Meanvalue	6.21	4.74

3.3 Component tests

Furthermore, three component tests were carried out to determine the wrinkling stress. This was done by means of a 6-point bending test. The panels had a span length of 6000 mm in accordance with *EN 14509, 2013*. The load transfer was realised over all 4 points by means of air cushions. Compared to the commonly used cross beams, air cushions have the advantage that they transfer the load over a large area and do not concentrate on one point at the top face layer of the panel. This avoids stress concentrations and the wrinkling stress is determined realistically. The test setup is shown in Figure 6 (left). The right of Figure 6 shows the load-deflection diagram of the tests.

Figure 6. Test set up of bending test (*left*); load-displacement diagram (*right*).

The results of the bending tests are shown in the Table 3. It shows the maximum applied load, the resulting bending moment and the resulting wrinkling stress of the face sheet. Both the scatter of the results and the values determined are within a typical range for sandwich panels *Lange et al, 2020*.

4 NUMERICAL INVESTIGATIONS

4.1 Buckling analysis

The numerical simulations were carried out using the ABAQUS software. First, the top face layer and the core material were created separately from each other. The face layer consists of shell elements of the type S4R. The core material consists of volume elements of the type C3D8R. The top layer and core material are connected to each other with the “Tie” function. The model is supported in three places Figure 7 (*left*). First, the surface on the left is constrained in the plane of symmetry and displacements are only possible on this surface in the y-direction. Second, the surface at the bottom is supported flat against displacements in all directions. Third, the right-hand edge of the face layer is clamped and displacements are only possible in the Z-direction. This leads to the typical eigenform, the wrinkling of an elastic bedded plate under uni axial compression stress, Figure 7 (*right*).

Figure 7. Numerical model: Boundary conditions and load (*left*); typical 1. eigenform (*right*).

The face layer of the core material is made of steel and the material model was made with the usual Young's modulus of 210,000 N/mm² and a Poisson's ratio of 0.3. The core material consists of rigid polyurethane foam. The modulus of elasticity is entered directly in the material model in ABAQUS. The input of the shear modulus, however, is only indirect via Poisson's ratio of the material. Since Young's modulus and shear modulus often have a similar order of magnitude in rigid polyurethane foams, the Poisson's ratio becomes negative. This is actually only the case with auxetic materials, to which polyurethane does not belong. Due to the simplification, it was necessary to validate the model in different combinations of Young's modulus and shear modulus. For this purpose, the analytical results according to equation (3) were compared with the results from the buckling analysis. The limits were defined in the range of $-0.5 < \nu_C < 0.5$. Figure 8 shows on the left all combinations of shear modulus and Young's modulus in the usual orders of magnitude of polyurethane foam. On the right, Figure 7 shows the comparison of the results of the numerical simulations and the analytical solutions.

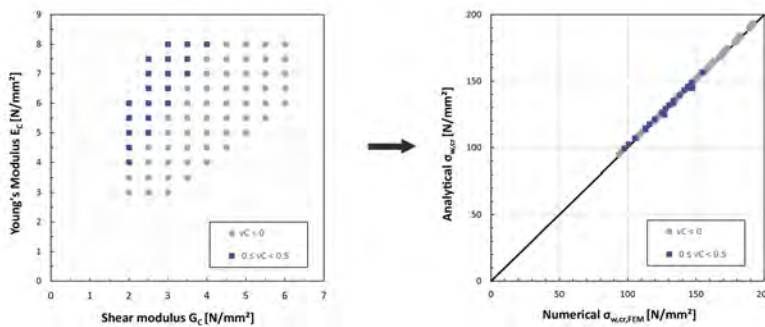

Figure 8. Results of wrinkling stresses.

It is clearly visible that the results agree very well. This applies to both the results with positive and negative Poisson's ratio. The deviation of the results is 0.94 % on average. Therefore, it can be concluded that the model is very well suited for determining the critical wrinkle stress.

4.2 Post-buckling analysis

The postbuckling analysis is done after the linear buckling analyses. Here, the eigenform from the linear buckling analysis is used to apply the imperfection. In this case, three post-buckling analyses were carried out. In each case, the maximum values of the measured imperfections from chapter 3.1 were applied. In addition, a non-linear material behaviour of the steel was assumed. Therefore, the experimental data from the manufacturer were used. Since the core material only undergoes minor deformation, the linear material behaviour from the buckling analysis was also applied here.

The evaluation of the presented method, in particular the applicability of the numerical analysis, is performed by comparing the experimentally determined wrinkle stress with the numerical. The determined wrinkling stresses are shown in Table 4. The comparison between experimental and numerical results shows a quite good agreement. In particular, the mean values of the results have only a slight deviation from 1.57%. However, it becomes clear that the dispersion of the results is much larger in the experimental investigation. This is most likely due to structural imperfections in the composite or in the core material. These could not yet be reproduced in the simulations. Nevertheless, it can be briefly summarised that the ultimate load analysis of the numerical model is capable of predicting the real ultimate load behaviour.

Table 3. Comparison between experimental and numerical wrinkling stresses.

5 CONCLUSIONS

In this paper, numerical investigations were presented that can increase the planning reliability in the reuse scenario of steel-polyurethane sandwich panels. It was shown that it is basically possible to determine the wrinkling stress of sandwich panels under bearing load with numerical simulations. The simulation was performed on the basis of small-scale tests to determine the material behaviour, as well as the measurement of the real geometric imperfections in the top face layer of the panels. The numerical simulations were able to predict the load-bearing behaviour of the component tests.

In the future, it might therefore be possible to first carry out small-scale tests on test specimens from existing panels and measure the imperfections. Here, the results of the simulations can serve as a decision-making aid. These can be considered as expected values of the results of the component tests. If the expected values meet the requirements for reuse, the component tests can be carried out with significantly less risk.

In order to show that the results are reproducible, further random tests must be carried out. Of particular interest are tests on panels that have already gone through a life cycle and could be prepared for reuse.

ABSTRACT: System scaffolds used in construction sites have the reused characteristic that members are used repeatedly without discarding it in terms of price, environment, and recycling. It is known that the performance of reused products could be decreased compared to the nominal allowable stress due to ‘reuse of members’ and ‘residual stress by manufacturing method’. Therefore, there is a possibility that there is a difference between the structural safety intended by the designer and that of the reused members to be installed. In this study, the performance test report of the scaffold vertical members of the reused scaffold stored and managed at the construction site in Korea was collected, and the strength reduction was analyzed considering the buckling curve specified in the design standard (Eurocode 3).

1 INTRODUCTION

Temporary structures are essential structures used in most construction sites, and many studies are being conducted on the structural safety of temporary structures. However, in research on temporary structures or temporary equipment constituting temporary structures, unused products have generally been considered (Lee et al. 2020). In general, temporary equipment at construction sites uses reusable products. At construction sites, the reused system scaffolding and system support, which are relatively inexpensive, have been used by rent avoiding high purchase costs for new products. Note that the temporary equipment such as system scaffolding are usually used for a short period of time, but they are susceptible to degradation like corrosion due to exposure to the surrounding environment and are likely to gradually lose the load-carrying capacity as usage history accumulates. The use of temporary equipment with reduced load-carrying capacity resulting from the repeated reuses can cause the collapse of the temporary structure even if design and construction are conducted by conventional practice (Jeong & Lee 2016).

In South Korea, it is legally required to check the structural safety of temporary structures before construction, and the design of a temporary structure follows the allowable stress design method. When designing temporary structures, it is difficult to verify the actual strength of temporary equipment in the site so that in practice, the structural safety of the temporary structure is checked by applying the nominal allowable stress of steel stipulated in the design standards. However, in general, the allowable stress for the design standards is mainly for the unused new steel members (Kim et al. 2008). Therefore, there might be a difference between the actual performance of reused temporary equipment at the site and that expected in the design process.

Therefore, there might be a difference between the actual performance of reused temporary equipment at the site and that expected in the design process. Thus, when designing temporary structures, some design experts often apply a reduced value 15-20% lower than the nominal allowable stress under consideration of the characteristics related to the repeated reuses. However, the background for the strength reduction rate is not clear; in fact, there are not many studies on the actual strength reduction effect of reused temporary equipment, which can be referred to in the design. Several studies on the pipe support as a typical type of temporary equipment were carried out to track the long-term changes in load-carrying capacity according to reuse history (Paik & Ro 2004; Paik 2005; Paik & Choi, 2006;). However, depending on the type of temporary equipment, the result of the decrease in resistance capacity of the reuse pipe support cannot be applied to other reused temporary equipment such as system scaffolding because of the difference in structural shape and load carrying system.

This study analyzes the decrease in the load-carrying capacity of the vertical member of system scaffold due to the reuse. In order to analyze the degradation in the load-carrying capacity of the reused temporary equipment, the quality test reports for the temporary equipment were collected from the construction sites, and then a comparative study considering the unused new temporary equipment was done to quantify the difference and characteristics. In addition, the ratio of the reused temporary equipment that did not satisfy the design standard was analyzed for the case when the allowable stress suggested by the design standard (Eurocode 3) was applied to the reused temporary structure design.

2 BUCKLING CURVE OF EUROCODE 3

The equation for the ultimate load of columns in Eurocode 3The buckling strength (P_{ut}) of the compression member subjected to concentric axial compression is calculated by the following equation based on the compressive class according to the diameter-thickness ratio (D/t).

The design equation for the ultimate load (P_{ut}) of the compression member subjected to concentric axial compression in Eurocode 3 is calculated by the following equation based on the compressive class (for class 1, 2, 3 sections) according to the diameter-thickness ratio (D/t).

$$P_{ut} = \chi A_g \sigma_y \quad (1)$$

where χ = buckling reduction factor; A_g = total cross section; σ_y = yield stress.

The reduction factor considering compression buckling is calculated by Equation 2 below:

$$\chi = \frac{1}{\phi + \sqrt{\phi^2 - \bar{\lambda}^2}} \leq 1 \quad (2)$$

where $\phi = 0.5(1 + \alpha(\bar{\lambda} - 0.2) + \bar{\lambda}^2)$; α = imperfection factor for the circular hollow section columns, 0.21 for the steel pipes with buckling shapes; $\bar{\lambda} = \sqrt{A\sigma_y/N_{cr}}$, non-dimensional slenderness; N_{cr} = critical buckling load according to the slenderness ratio and is calculated by Equation 3 below:

$$N_{cr} = \frac{\pi^2 EI}{(KL)^2} \quad (3)$$

3 ALLOWABLE STRENGTH OF REUSED VERTICAL MEMBERS BY QUALITY CERTIFICATION REPORTS

In South Korea, quality tests and inspections are required for quality assurance of temporary equipment at construction sites. The quality test report should be filed at the site according to the Enforcement Decree of the ‘‘Construction Technology Promotion Act’’ (Articles 91 and 93).

The quality test method and steel materials (STK400) for vertical members of system scaffolding are stipulated in the “Safety certification notice for protective devices” of the “Occupational Safety and Health Act.” A compression load test is performed as a quality test method for vertical members. In this study, the information for material (only ‘STK400’), diameter, thickness, length, and maximum test strength of the vertical member were collected from the certificate for quality test after confirming the authenticity of the quality test report filed at the construction site and the content appropriateness of the quality test. A total of 500 vertical member test result data were collected from the quality test reports. The specification is summarized as shown in Table 1. The experimentally determined buckling reduction factor (hereafter ‘Experimental buckling factor’) was calculated by dividing the collected maximum load of the quality test report by the product of cross-sectional area and tensile strength of each vertical member.

Table 1. Specifications of the collected reused vertical member test data.

Diameter	Thickness	Length	Count
mm	Mm	mm	
48.6	2.2	475	3
		950	4
		1900	4
		3800	4
	2.3	475	47
		900	54
		1900	63
		3800	63
	2.4	475	51
		900	54
		1900	69
		3800	84
Total			500

4 THE DIFFERENCE IN LOAD-CARRYING CAPACITY BETWEEN UNUSED AND REUSED VERTICAL MEMBERS

The load-carrying capacity of unused vertical member of system scaffolds against the compression load test was referenced by Jang (2020). The compression load test objects are the vertical member with 950 mm and 1900 mm length; both are frequently used structural members for the assembly at construction sites. The test was conducted according to the method specified in Korean national standard KS F 8021 (Components for tied post system scaffolding and shoring). Table 2 shows the detailed specifications of the unused system scaffolds. The material of the unused system scaffolds is STK400 steel.

Table 2. Specifications for the unused vertical members.

Diameter	Thickness	Length	Count
mm	mm	mm	
48.6	2.2	950	18
		1900	18

As seen in Table 3, the reused system scaffold group with a length of 950 mm ($\bar{\lambda}$: 0.67) has an average load-carrying capacity of 107.1 kN, which is about 7.4% smaller than the unused system scaffold group (115.7 kN). The reused system scaffold group with a length of 1900 mm ($\bar{\lambda}$: 1.33) has an average load-carrying capacity of 48.3 kN, which is about 8.7% smaller than the unused

system scaffold group (52.9 kN). In addition, the coefficient of variation (COV) of the reused system scaffold increased by 121.4% in the group with a length of 950 mm and 29.3% in the group with a length of 1900 mm respectively, compared to the unused system scaffold. In the case of reused products of the system scaffold, the average load-carrying capacity tends to decrease while the COV increases. Therefore, when designing a structure of a system scaffold using a reused product and determining the nominal allowable stress according to the design standard, there might be a high probability that the actual structural strength may be smaller than the designer’s calculation.

Table 3. Comparison of the load-carrying capacity between the reused and the unused system scaffolds.

Length		Reuse or not	Mean	Reduction ratio	COV	Increase rate
mm	Slenderness		kN	%	kN	%
950	0.67	Unused	115.7	-	0.089	-
		Reused	107.1	7.4	0.197	121.4
1900	1.33	Unused	52.9	-	0.174	-
		Reused	48.3	8.7	0.225	29.3

5 COMPARISON OF EXPERIMENTAL BUCKLING FACTOR AND BUCKLING CURVE OF EUROCODE 3

Figure 1 shows the buckling reduction factor according to the non-dimensional slenderness of the reused system scaffolds in the form of a box plot in the buckling reduction curve of Eurocode 3. Tables 4 show the average and standard deviation of the buckling reduction factor.

Excluding the reused vertical member group with a slenderness ratio of 0.67, about 75% of the remaining recycled vertical member groups are below the Eurocode 3 buckling curve. In the group of vertical members with a slenderness ratio of 2.67, all collected vertical member data are below the buckling curve of Eurocode 3. The higher the slenderness of the collected vertical members, the smaller the ratio of the experimental buckling factor to Eurocode 3, and in the case of the vertical member group with a slenderness of 2.67, it decreased to 70.6% compared to buckling curve of Eurocode 3. Therefore, considering the imperfection factor (α) of 0.21 in the buckling curve of Eurocode 3, the buckling curve of Eurocode 3 may not be suitable for the structural analysis of systems scaffolding for reused products. Even when using the highest value of 0.76 among the imperfection factor suggested by Eurocode 3, about 50% and 80% of vertical members with slenderness of 1.33 and 2.67, respectively, do not meet the criteria of Eurocode 3. When designing system scaffolding using reused products in consideration of Eurocode 3, a reasonable reduction method for the imperfection factor of the buckling curve is required.

Figure 1. Comparison of buckling reduction factor between the reused system scaffolds and Eurocode 3.

Table 4. Comparison of the buckling reduction factor between the reused system scaffolds and Eurocode 3.

Non-dimensional slenderness	0.33		0.67		1.33		2.67	
	Mean	COV	Mean	COV	Mean	COV	Mean	COV
Collected quality test report	0.95	0.13	0.77	0.19	0.34	0.22	0.09	0.22
Eurocode 3 (α : 0.21)		0.97	-	0.86	-	0.45	-	0.13
Reduction ratio (%)	93.3		88.8		76.2		70.6	

6 CONCLUSIONS

In this study, based on the test reports of the system scaffold, which is filed and managed at the construction site, the difference between the buckling reduction factor of the vertical member of the reused products and the buckling curve evaluated by the Eurocode 3 was investigated.

In the case of slender reused vertical members, it decreased to about 71% of the buckling curve of Eurocode 3. In addition, the coefficient of variation in vertical member groups of some slenderness more than doubled compared to unused vertical members. The buckling curve of Eurocode 3 may not be suitable for the structural analysis of systems scaffolding for reused products. Further studies are needed on the imperfection factor of Eurocode 3 buckling curves that may be considered for the use of reused products.
