The calculation results of the probability of failure with different autocorrelation coefficients are shown in Figure 3. The probability of girder failure increases with the exposure time due to the growth of corrosion depth. Moreover, the auto-correlation coefficients affect the girder failure significantly since the girder failure depends on many factors. These factors, such as girder geometries, loads, and corrosion depth, are interrelated at different time points in service life. As a result, the load effect is correlated in the time domain. The considerable difference in the probability of failure under different justifies the necessity of using a time-variant reliability method based on the concept of first passage probability theory. However, there is a lack of time-history statistical data for estimating the autocorrelation coefficient.

5 CONCLUSIONS

In this study, the time-dependent failure probability of steel girder was quantified. First passage probability theory was employed. A case study was provided to illustrate the proposed method. From the results of the worked example, it has been found that the probability of failure is related to the auto-correlation coefficients. Statistical data obtained from site-specific measurements and laboratory tests are recommended to establish the correlation among the parameters. The proposed method can be used for developing rehabilitation strategies for existing steel structures.

Quantification of the effect of corrosion on the compressive membrane action in restrained hollow core slabs

T. Thienpont, W. De Corte, R. Van Coile & R. Caspeepe

Department of Structural Engineering and Building Materials, Ghent University, Ghent, Belgium

ABSTRACT: Precast concrete hollow core slabs are often designed with a limited concrete cover considering the high quality control for prefabricated members. However, experiments on prestressed concrete members have illustrated that corrosion can lead to a substantial reduction in the load carrying capacity, which can eventually lead to a structural failure. Although the design of hollow core slabs typically assumes simply supported boundary conditions, the support conditions of these units in real structures are often restrained, especially in the central part of a large hollow core slab floor. In case of restrained end supports, compressive membrane action can be activated, which can considerably enhance the load-carrying capacity. This can delay or even prevent a progressive collapse, increase the structural reliability and consequently increase the robustness of the structure. This paper presents a numerical study on the positive effect of axial and rotational restraints and the formation of compressive membrane action in case of corroded prestressed hollow core slabs in relation to its ability to prevent a structural collapse in case of severe corrosion.

1 INTRODUCTION

Nowadays, prestressed concrete hollow core (HC) slabs are widely used for structural flooring, due to their economic design, highly automated production process and ease of installation. Due to their reduced self-weight they allow for longer spans up to 20 m, and shallower construction depths. Like all concrete members, HC slabs are vulnerable to corrosion, especially since traditionally they are designed with a limited concrete cover, considering the high quality control for prefabricated members. Experiments on corroded prestressed concrete members have illustrated that high degrees of corrosion can lead to a substantial reduction in the load carrying capacity (Vereecken et al., 2021). In some cases corrosion can also lead to a change in the failure mode, passing from a ductile to a brittle failure (Belletti et al., 2020). In case of severe corrosion, the capacity of prestressed members can be so severely reduced that it can cause the collapse of the structure under live loading (Nagi & Whiting, 1992).

In principle, HC slabs are designed to be simply supported. In practice however, HC slabs are assembled to form extensive floors, by filling the joints between the members or through the addition of a topping layer (Walraven & Mercx, 1983). Therefore, the support conditions of HC units are often restrained rather than simply supported, especially in the central part of a large HC slab floor. In case of restrained end supports, compressive membrane action (CMA), also referred to as compressive arching action, can be activated, which can considerably enhance the load-carrying capacity. This increased resistance to the applied loads originates from the vertical component of the compressive arching forces in the member (Wang, 2002), as illustrated in Figure 1.

The formation of CMA in HC slab floors can delay or even prevent a progressive collapse, increase the structural reliability and consequently increase the robustness of the structure (Thienpont et al., 2022a). This contribution studies the positive effect of axial and rotational restraints, and the formation of compressive membrane action in case of corroded prestressed HC slabs in relation to its ability to prevent a structural collapse in case of severe corrosion. To

Figure 1. Principle of compressive membrane action (Thienpont et al., 2022b).

this end, a detailed finite element model is developed in Abaqus. Load displacement simulations are performed to study the cracking patterns, displacements and failure loads. Subsequently, a parametric study is conducted to investigate the combined influence of a corrosion degree and a degree of restraint on the ultimate carrying capacity and failure mode of prestressed HC slabs.

2 NUMERICAL MODEL

To study the effect of axial and rotational restraint on structural behavior of prestressed concrete HC slabs with corroded reinforcement strands, numerical evaluations are performed using the Abaqus finite element analysis software (Dassault Systemes, 2014). Herein, a previously validated numerical model by the authors (Thienpont et al., 2022a) is extended to take into account the reduction in material properties of the prestressing strands if subjected to corrosion. In the following, the applied material models for corroded prestressing steel and concrete are briefly discussed. Subsequently, an overview of the modelling assumptions is provided.

2.1 Material model for corroded prestressing steel

Besides a reduction in cross-sectional area of the prestressing strands, corrosion also strongly affects the mechanical properties and stress-strain curve of prestressing steel (Lu et al., 2016, Belletti et al, 2020). Previous studies have identified that corrosion of prestressing strands typically results in a reduced elastic modulus and ultimate strength, as well as a reduction in the ultimate strain, and loss of the yielding plateau and strain hardening region if the corrosion degree is larger than a critical value (Vereecken et al., 2021).

To model the degradation of the prestressing steel due to corrosion both a reduction on strands area and reduced mechanical properties are considered. To account for the latter, an adapted stress-strain curve for the corroded prestressing steel is needed. Various models, which take into account the effect of corrosion on the stress-strain curve of prestressing steel, have been proposed (Wang et al., 2017, Tu et al., 2019, Jeon et al., 2019, Franceschini et al, 2022). In this contribution, the model by Lu et al. (2016) is used. The latter is a damage model based on a series of tests on prestressing strands subjected to chloride attack, in which the mechanical properties are dependent on the corrosion level $C(t)$. The proposed reduction factors for the elastic modulus k_E , ultimate strength k_f and ultimate strain k_{ε_u} are presented in Eq. (1), Eq. (2) and Eq. (3), respectively.

$$k_E = \frac{E'_s}{E_s} = 1 - 1.8 \cdot f(C) \quad (1)$$

$$k_f = \frac{f'_u}{f_u} = 1 - 2.8 \cdot f(C) \quad (2)$$

$$k_{\varepsilon_u} = \frac{\varepsilon'_u}{\varepsilon_u} = 0.1 + 0.9 \cdot e^{(-20 \cdot f(C))} \quad (3)$$

Herein, E_s is the elastic modulus, f_u is the ultimate strength and ε_u the ultimate strain, all of the virgin strand. Similarly, E'_s , f'_u and ε'_u are respectively the elastic modulus, the ultimate

strength and the ultimate strain of the corroded strand. The factor $f(C) = C(t)$ is the degree of corrosion at time t , and is defined in Eq. (4).

$$C(t) = \frac{A - A'}{A} \quad (4)$$

Herein, A is the uncorroded cross sectional area of the prestressing strand and A' is the corroded area at time t . The constitutive model is characterized by Eq. 5.

$$\sigma(\varepsilon) = \begin{cases} E'_s \cdot \varepsilon, & \varepsilon \leq \varepsilon'_y \\ 0.85 \cdot f'_u + \frac{0.15 f'_u}{\varepsilon'_u - \varepsilon'_y} (\varepsilon - \varepsilon'_y), & \varepsilon'_y \leq \varepsilon \leq \varepsilon'_u \end{cases} \quad (5)$$

Herein $\varepsilon'_y = 0.85 f'_u / E'_s$ is the yield strain of the corroded strand. Note that the model takes into account that the hardening plateau disappears for corrosion degrees larger than 8%, i.e. in these cases the stress-strain curve only contains the elastic branch. The stress-strain curves for various corrosion degrees are illustrated in Figure 2.

The above model by Lu et al. has been applied by Belletti et al. (2020) to model naturally corroded prestressed beams, with a good approximation of the ultimate displacement and the ultimate load obtained from experiments.

Figure 2. Constitutive model of corroded prestressing strand (based on Lu et al., 2016).

2.2 Material model for concrete

The excessive loading of concrete members usually involves crushing of concrete and/or severe cracking. Therefore, a non-linear concrete material model is used to simulate this behavior correctly. The compressive stress-strain relation of concrete is based on the analytical expressions provided in EN 1992-1-2 (CEN, 2004), as shown in Figure 3.a. The tensile behaviour is modelled based on *fib* Model Code 2010 (fib, 2012), as shown in Figure 3b and c. Herein, in the uncracked state, linear elastic behaviour is assumed up until the ultimate tensile stress is reached. Thereafter, a multilinear softening curve is applied. The area under this curve is related to the tensile fracture energy, which is calculated based on the recommendations in *fib* Model Code 2010.

2.3 Numerical modelling assumptions

In the numerical evaluations, the concrete is discretized using 8-noded hexahedral (brick) elements (C3D8) with an average size of 25 mm. For the prestressing steel, 2-noded linear truss elements (T3D2) are used. Assuming perfect bond, the prestressing strands are embedded within the concrete element, using the embedded constraint option in Abaqus.

Figure 3. Constitutive model for concrete with compressive strength $f_c = 50$ MPa: (a) stress-strain diagram concrete in uniaxial compression; (b) stress-strain diagram for uncracked concrete in uniaxial tension; (c) stress vs. crack opening relation for concrete in uniaxial tension.

Figure 4 shows a schematic overview of the boundary conditions of the numerical model. To evaluate the structural behavior of restrained HC slabs with corroded prestressing reinforcement, a four-point bending setup is employed. To simulate the influence of a stiff surrounding structure, the outward displacements and the rotations of the slab ends are partially restrained by a set of axial springs with stiffness K (in kN/mm) and a set of rotational springs with stiffness R (in kNmm/rad). It is assumed that the axial springs act on the section ends at the mid-depth of the slab, as shown Figure 4. A recent study by Zhu et al. (2021) has found a non-negligible influence of the eccentricity on the CMA capacity in reinforced concrete slabs. In a more elaborate analysis, other values of the eccentricity could therefore be considered as well, but this is considered outside the scope of the current contribution.

Figure 4. Schematic overview of numerical restrained four-point bending model.

3 SIMULATING THE EFFECT OF CORROSION ON CMA IN HOLLOW CORE SLABS

In the following a numerical parameter study is performed, in which the ultimate capacity and failure mode of precast HC slabs with corroded prestressing strands are investigated for a wide range of axial and rotational stiffnesses of the surrounding structure. Two HC slab sections with heights 320 mm and 500 mm are evaluated, which will be referred to as HC320 and HC500, respectively. The section geometries and corresponding reinforcement arrangements of the slabs are depicted in Figure 5.

In the figures below, the ultimate capacity of the studied sections is evaluated for various degrees of axial and rotational restraint. Herein, the degree of restraint is expressed in terms of a relative axial restraint stiffness k and a relative rotational restraint stiffness r , as defined in Eq. (6) and Eq. (7), respectively:

Figure 5. HC slab sections used in parameter study: (left) HC320; (right) HC500 (dimension in mm).

$$k = \frac{K}{K_{HC}} = \frac{K}{\left(\frac{E_c A}{L}\right)} \quad (6)$$

$$r = \frac{R}{R_{HC}} = \frac{R}{\left(\frac{E_c I}{L}\right)} \quad (7)$$

Where K and R are respectively the axial and rotational spring stiffness used in the numerical model, K_{HC} and R_{HC} are respectively the axial stiffness and rotational stiffness of the HC slab, E_c is the Young's modulus of concrete, A is the effective cross-section of the HC slab, L is the span of the HC slab and I is the cross-sectional moment of inertia of the HC slab.

3.1 Results HC320

Figure 6.a illustrates the effect of corroded prestressing steel on the load-displacement behaviour of prestressed concrete HC slabs, for a simply supported HC320 section, with a span length of 8 m. The curves clearly indicate that an increased degree of corrosion leads to a reduction in the load-carrying capacity. Additionally, the deflection at which the failure occurs also decreases with increased corrosion degree. This reduced deflection at failure can be attributed to the reduced ductility of the corroded steel. For HC320 slabs with a corrosion degree higher than 8%, the ductility of the steel is reduced to such extent that the slab tends to fail almost immediately after the formation of the first bending cracks. The figure also indicates that the degree of corrosion does not affect the mode of failure for this type of HC slab in case of unrestrained support conditions.

Figure 6.b depicts a similar set of load-displacement curves, but for a highly restrained HC320 section ($k = r = 1$). From the graph it is clear that the restrained boundary conditions result in a significant additional capacity, which can be attributed to the formation of CMA. For the cases where the degree of corrosion is below 8%, this additional capacity greatly counteracts the loss in capacity resulting from the degraded steel strands. Nonetheless, for higher corrosion degrees, no significant CMA can develop, and the slab fails in bending shortly after the formation of the first bending cracks. Unlike the unrestrained case, the results also indicate that the mode of failure of the studied HC slab changes depending on the degree of corrosion. The less corroded HC slabs tend to fail due to shear, whereas the highly corroded slabs fail in bending.

The above results are summarized in Figure 7, in which the ultimate capacities and failure modes from analyses for three degrees of restraint are considered, and compared to the results from a simply supported slab. For all considered degrees of restraint, the ultimate capacity tends to reduce when the degree of corrosion increases. Furthermore, all curves show a similar significant reduction in capacity when the degree of corrosion exceeds 8%. This drop can be directly related to the constitutive model for corroded prestressing steel, as discussed in Section 2.1. According to this model, the hardening plateau completely disappears when the corrosion degree exceeds 8%, and the stress-strain curve only contains the elastic branch.

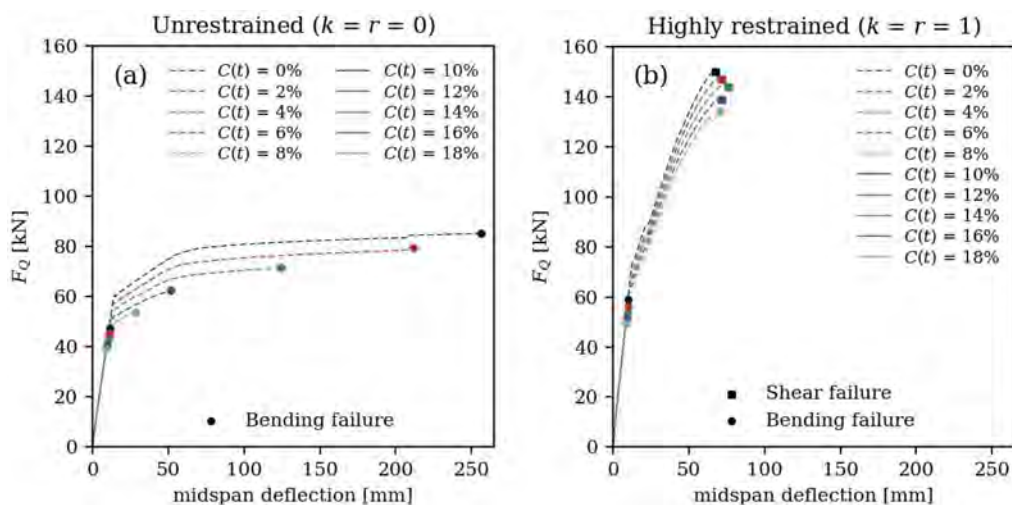

Figure 6. Effect of the level of corrosion on the load-displacement behaviour and mode of failure of restrained HC320 slabs with 8 m span length: (a) unrestrained ($k = r = 0$); (b) highly restrained ($k = r = 1$).

Figure 7. Effect of the level of corrosion on the ultimate load-carrying capacity and mode of failure of axially and rotationally restrained HC320 slabs with 8 m span length ($L/h = 25$).

3.2 Results HC500

The results from a similar set of analyses, performed on a taller HC500 section with a 12.5 m span length, are depicted in Figure 8. Overall, the graph indicates a similar effect of corrosion on the capacity of the HC slab members, both in the simply supported and restrained cases. When the degree of corrosion is below 6%, the additional capacity originating from the formation of CMA is able to counteract the reduced capacity resulting from the corroded prestressing strands. It is noted, that unlike the HC320 type slabs, the highly restrained HC500 members tend to fail due to crushing of the top flange, rather than due to a shear failure.

Figure 8. Effect of the level of corrosion on the ultimate load-carrying capacity and mode of failure of axially and rotationally restrained HC500 slabs with 12.5 m span length ($L/h = 25$).

4 CONCLUSIONS

In the present study, the effect of corrosion on the load bearing capacity and failure mode of axially and rotationally restrained concrete hollow core (HC) slabs is studied numerically. As a general conclusion, it is observed that the reserve capacity that can be achieved through the activation of compressive membrane action is in many cases larger than the loss in capacity resulting from corrosion in the prestressing strands. In case of severe corrosion however ($C(t) > 8\%$), the failure strain of the prestressing strands is reduced to such an extent that no compressive membrane action can develop to counteract the loss in load-carrying capacity caused by the corrosion. The presented results indicate that a mechanism like compressive membrane action may activate a certain level of reserve capacity in concrete structures which have suffered considerable damage associated with the effects of ageing and deterioration processes.

ACKNOWLEDGEMENTS

The authors wish to thank the Research Foundation of Flanders (FWO) for the financial support on the research project (Grant number 11F5520N) “Performance-based analysis and design for enhancing the safety of prestressed concrete hollow-core slabs in case of fire and unforeseen events”. The computational resources (Stevin Supercomputer Infrastructure) and services used in this work were provided by the VSC (Flemish Supercomputer Center), funded by Ghent University, FWO and the Flemish Government – department EWI.

ABSTRACT: Motorway bridges constitute one of the most crucial parts of transportation networks, with proper life-cycle cost (LCC) estimation being of paramount importance for cost-efficient projects. This paper introduces a probabilistic framework for concrete bridge LCC estimation based on dynamic Bayesian Network (DBN) modelling that stakeholders can consult in projects' preliminary stages for proper decision-making. Firstly, probability distributions of material quantities and construction costs for the superstructure and foundation are estimated. Subsequently, the maintenance costs of deck expansion joints are illustratively presented, as they are considered vulnerable bridge elements with frequent repairs. The proposed DBN contains continuous and time-dependent variables thoroughly registered over multiple time stages. The DBN is formulated using actual records of 60 concrete bridges' construction, inspections, condition and maintenance from the Egnatia Odos motorway in Greece. The presented approach is an effective tool for bridge management enhancement owing to stochastic dynamic interdependencies among parameters and continuous information updating.

1 INTRODUCTION

Bridges are considered a vital asset in transportation networks as communication channels that foster public prosperity. Although bridges constitute only a small percentage of a highway's length, their construction costs account for a substantial portion of the highway's total construction cost (Antoniou et al., 2018). Furthermore, a considerable proportion of their total cost is incurred after their construction (Ammar et al., 2013). Hence, robust models that can reliably predict LCCs in the preliminary stages of such projects seem to be of paramount importance.

Due to the crucial aspect of uncertainty associated with various design, deterioration and maintenance parameters of bridge structures, LCC analysis based on stochastic parameter modelling can improve the effectiveness of final decisions when conducting feasibility studies. The extant literature has focused almost exclusively on deterministic methods for construction cost estimation (Fragkakis et al., 2011, Lambropoulos et al., 2010) and LCCs analyses (Zhou et al., 2020) of concrete bridges. The existing probabilistic analyses are either restricted to the LCC of the bridge's single components, especially on decks (Shen et al., 2021), or individual cost categories, such as maintenance or repair costs (Gui et al., 2021).

The scope of this study is to introduce a dynamic perspective of a generalized probabilistic approach for pre-estimating construction and maintenance costs of concrete bridges and enlightening the stochastic relationships among modifying factors for providing reliable information to decision-makers during the life-cycle of bridge projects towards more adaptable asset management. Bayesian networks (BNs) are suggested for facilitating economically

sustainable asset management since they are acknowledged as one of the most effective modelling frameworks in the field of probabilistic knowledge representation and reasoning (Bertone et al., 2018), especially for engineering risk analysis (Luque & Straub, 2016).

2 PROPOSED DYNAMIC BAYESIAN NETWORK MODEL

A BN represents a set of stochastic variables and the causal probabilistic relationship among them using a Direct Acyclic Graph (DAG). For modelling the stochastic and dynamic behavior of the system in a sequence of time slices, BN was extended to a DBN by introducing temporal dependencies among its parameters. The proposed BN structure consists of 2 modules, the “Construction phase” and “Operational phase” modules, which altogether include 12 variables, both discrete and continuous, related to the construction, inspection, condition and maintenance actions of bridge components. Uncertainty is expressed through probability distributions attributed to random variables.

The first module refers the BN corresponding to the beginning of the project ($t = 0$) and its structure is different from the other stages. Material quantities and expected construction costs of the superstructure and foundation for specific construction methods were estimated. The second module investigates the maintenance costs specifically for the deck expansion joints since they constitute one of the most frequently maintained bridge components and their deterioration may affect components of pivotal importance such as superstructure (Lee Kelly et al., 2019). This module includes the time slices of the operational life of the bridge ($t = 1, 2, \dots, T$) and here is restricted to ten years since this is the life-cycle of the examined expansion joints. However, owing to the flexibility of BNs to readjust their parameters without any particular computational cost, both the number of time slices can be modified and additional sub-models can be added for representing features of different bridge components such as bearings, substructure etc.

2.1 A continuous variable bayesian network for construction costs ($t=0$)

The “Construction phase” BN module investigates the factors related to the construction of the superstructure spans consisting of cast-in-situ box girders and the construction of the socket foundation. The final sample includes complete actual data from 47 superstructure spans consisting of cast-in-situ box girders and 26 sockets used for the foundation of piers.

Regarding the socket foundation, previous statistical analysis (Fragkakis et al., 2011) indicated that among other explanatory variables, the length of the deck, “Lsup”, has significant impact on its material quantities. Likewise, for the cast-in-situ construction method of superstructure, the adjusted length of span, “Ladj”, was chosen to be used as explanatory variable (Lambropoulos et al., 2010). The concrete volume (Vc), the reinforcing steel weight (Bs), and the prestressing steel weight (Bp) represent the three dependent variables. All the parameters were modelled as oval nodes as they constitute random variables (Figure 1). Using Bayesian inference (Eq. (1)), the final product was the development of posterior distributions for the material quantities of Vc, Bs, and Bp and their corresponding costs.

$$p(y) = \int p(\theta)p(y|\theta)d\theta \quad (1)$$

where $p(\theta)$: the prior distribution, $p(y|\theta)$: the likelihood function and $p(y)$: the posterior distribution.

BNs do not necessarily imply influence by Bayesian statistics (Murphy, 1998), but it is common to utilise frequentist methods to estimate the probability distributions parameters (Horný & Lin, 2018). In this specific case, where the parameters of the DAG are continuous, the “maximum likelihood estimation” method (Paniego, 2019) (Eq. (2)) was used for establishing the parameters of the marginal probabilities for the parent nodes. The conditional distributions of child nodes were computed via Bayesian inference using multiple regression analysis as functional

Figure 1. DAGs of parent & child nodes for (a) cast in situ box girders and (b) socket foundation.

linkage forms among parent and child nodes. Specifically, the used regression equations were derived from previous studies of Fragkakis et.al. (Fragkakis et al., 2011, Lambropoulos et al., 2010) since they concerned our study parameters. The Kolmogorov-Smirnov and Anderson-Darling goodness of fit tests were used to validate the compatibility of the dataset fitting to certain theoretical probability distributions.

$$L(X_1, \dots, X_n, \theta) = f(X_1, \theta) f(X_2, \theta) \dots f(X_n, \theta) \quad (2)$$

Consecutively, for conducting Bayesian inference of construction quantities, the Python computer programming language was used, specifically the PyMC3 package specialized in Bayesian computation and analysis. The No-U-Turn (NUTS) sampling algorithm, a highly computationally efficient Markov Chain Monte Carlo (MCMC) method, was implemented for model fitting since it allows the sampling from models with continuous parameters (Salvatiere et al., 2016). Sixteen MCMC chains in a total of 5000 iterations were generated. Once the posterior distributions of material quantities (Vc, Bs & Bp) have been determined, the total expected construction costs can be determined by multiplying the obtained probabilities with unit prices of the published detailed price lists of the relative works.

2.2 A dynamic bayesian network for LCCs of deck expansion joints ($t=1,2, \dots, T$)

The “Operational phase” module comprises a DBN consisting of discrete variables associated with risk-based maintenance of deck expansion joints. For running the simulation model, the process was assumed to: a) follow the first-order of the Markov model, namely the state variables at time “t” depends only on the state variable at time (t-1) and other variables at time “t”, and b) be stationary, i.e., the structure and parameters of the model do not change over

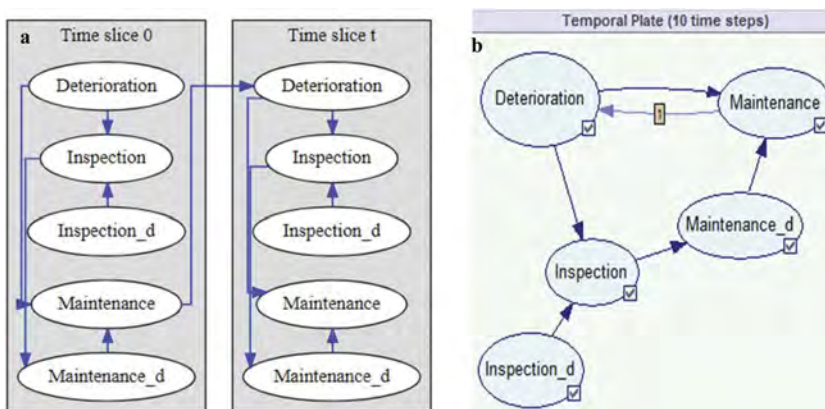

Figure 2. (a) The 2-TBN for “Operational phase” module & (b) temporal plate of the DBN in the GeNIe software.

time. In this case, the DBN can compactly be represented as 2-time-slice Bayesian network (2-TBN) (Koller & Friedman, 2009) (Figure 2a).

Figure 2b indicates the general form of the proposed DBN which was created in GeNIe (v2.1) software (Genie, 2016). The full specification of the DBN's nodes can be found in Table 1. Since the DBN was built as a homogeneous model, the transition probabilities matrixes remained constant over the examined time slices. The nodes included in the model concern deterioration before and after any given maintenance treatment, inspection occurrence, inspection outcome and maintenance actions. Indicatively, the decay types of I_t node range from cracking in injected asphalt mastic joint (state 8) to transition mortar breakage (state 7), joint failure (state 5) and elastomeric part failure (state 3). All maintenance treatments (e.g.: crack repairs, injected asphalt mastic joint repair, elastomeric part/anchor system replacement) corresponding to the decay types of I_t node assume 100% maintenance efficiency, i.e., the expansion joint is returned to its initial state (state 9).

It is noted that this module can be operated using different records derived from transportation agencies. Moreover, different condition-based or time-based maintenance strategies can be conducted using the proposed module for their direct comparison and optimal decision-making. For illustrative purposes, all the conditional probability tables of the nodes were fitted using actual records of 50 joints from the Egnatia Odos S.A. using the percentage prediction method. Also, in the presented numerical case, the captured maintenance strategy combines both minor and major treatments on examined joints of the Egnatia Odos network.

Table 1. Full description of DBN's nodes.

PARENT NODES			
Node name	Number of states	Conditional probability table structure & size	Description of states
Deterioration ($D_{t=0}$)	9	$P(D_o) \rightarrow n_D \times 1$: [1,0,0,0,0,0,0,0,0]	$D_{t=0} = \{9-1\}$: initial condition states using the FHWA scale
Inspection_d ($I_{d,t}$)	2	$P(I_{d,t}) \rightarrow n_{Id} \times 1$: [0,1]	$I_{d,t} = 0$: "No inspection" $I_{d,t} = 1$: "Inspection"
CHILD NODES			
Inspection (I_t)	8	$P(I_t D_t, I_{d,t}) \rightarrow n_I \times n_D \times 2$	$I_t = 0 = 0$: "No deterioration detection" $I_t = 0 = \{1-6\}$: Seven possible decay types $I_t = 7$: "No inspection" made
Maintenance ($M_{d,t}$)	2	$P(M_{d,t} I_t) \rightarrow n_M \times n_I$	$M_{d,t} = 0$: "No maintenance" $M_t = 1$: "Maintenance"
Maintenance (M_t)	9	$P(M_t D_t, M_{d,t}) \rightarrow n_D \times n_D \times 2$	$M_{d,t} = \{9-1\}$: Transition matrix of the adopted maintenance policy for each condition state
Deterioration ($D_{t>0}$)	9	$P(D_{t>0} D_{m,t-1}) \rightarrow n_D \times n_D \times 2$	$D_{t>0} = \{9-1\}$: Deterioration transition matrix under the adopted maintenance policy

Finally, the expected maintenance costs of a given expansion joint were calculated using the Eq. (3).

$$E[C_{M(t)}] = \sum_{s=1}^S P_{M,s} * c_{M,s} \quad (3)$$

Where S is the total number of independent condition states of the expansion joints, s is the condition state, $P_{M,s}$ is the probability that condition state s will occur at a given time t , $C_{M,s}$ is the unit cost associated with maintenance strategy at condition state s .

3 RESULTS & DISCUSSION

The implementation of the Bayesian analysis for the continuous variables of the “Construction phase” module yielded posterior distributions (Figures 3-5) together with their statistics results (Table 2 & Table 3) for the examined material qualities. The model checking incorporated two components, the convergence diagnostic and the goodness of fit test. The Gelman-Rubin convergence diagnostic R-hat was found < 1.1 (Table 2 & Table 3), namely the MCMC chains were concluded to be converged. Also, the stationary trace plots and divergence zero rate indicated the sample’s convergence. The goodness of fit was verified visually using appropriate PyMC3 functions.

As it becomes apparent, the bulk of the exported posterior distributions does not follow a normal distribution but rather Logistic, Laplace and Inverse Gauss distributions. This confirms that normality assumptions are not the case in real-world situations. Especially in infrastructure projects, uncertainties are inherent as the information tends to change frequently with the project’s progress. Various fruitful outcomes for decision-makers can be exported from the proposed probabilistic analysis. For instance, if the user intends to predict the V_c material quantities of the superstructure span with a risk of 20%, namely their occurrence range with 80% probability, these quantities would be between 236.771 m³ and 1,200 m³ per span. Furthermore, in light of new data, users can extract even more customized results via Bayesian updating.

Users could estimate probabilistic cost ranges considering the above material quantities ranges and appropriate unit values. A special case of cost ranges has been demonstrated in this study using unit prices from Greece’s detailed road price lists and 2017 as reference year (Table 2 & Table 3).

Table 2. Descriptive statistics of posterior distributions for the stochastic variables for the construction method of cast-in-situ for the bridge’s superstructure (using the summary() function of PyMC3).

Random Variables	Distribution type	Parameters (mean; sd)	Lower limit HPD _{97%}	Upper limit HPD _{97%}	Gelman-Rubin convergence test (R-hat)
$Ladj$ (m)	Normal	(35.13 m; 10.08)	16.126 m	53.565 m	1.00
V_c (m ³ /span)	InvGauss (Wald)	(349.98 m ³ ; 245.802)	63.226 m ³	767.911 m ³	1.00
C_{Vc} (€/span)	InvGauss (Wald)	(73,495.8 €; 51,618.42)	13,277.46 €	161,261.31€	1.00
B_s (Kg/span)	Logistic	(41,718.33 Kg; 14,145.39)	14,783.05Kg	68,372.07Kg	1.00
C_{Bs} (€/span)	Logistic	(41,718.33 €; 14,145.39)	14,783.05 €	68,372.07 €	1.00
B_P (Kg/span)	Logistic	(14,302.26 Kg; 6,730.641)	1,597.84 Kg	26,366.46Kg	1.00
C_{Bp} (€/span)	Logistic	(94,394.916 €; 44,422.23)	10,545.744€	174,018.64€	1.00

The result of the DBN simulation for the “Operational phase” module can be seen in Figure 6a. It is evident that the maintenance strategy followed by Egnatia Odos S.A. does not let the expansion joints fall below critical deterioration states since there are no joints reached the 1 and 2 states, guaranteeing the safe operation of the bridge. Moreover, only a percentage of the total joints returned to their initial state every year since budget constraints do not allow perfect preventive maintenance. Besides, this is the mainly common way of dealing with the maintenance treatments of infrastructure assets in practice. Owing to the homogeneous transition matrix used during the life-cycle of the expansion joints, a roughly steady line was formed from the fourth year onwards without extraordinary line peaks reflecting alternative maintenance strategies.

Subsequently, the obtained probabilities were multiplied by specific actual Greek maintenance unit costs to obtain the unit expected costs during the given lifetime span (Figure 6b). There was no significant increment in the maintenance costs for the considered states from the third year onwards, as the probability of each state remained approximately the same. Each user can consider the total number of damaged joints and their corresponding meters for calculating the total expected budget that should be committed for joints repair.

Figure 3. Posterior distributions and trace plots of the continuous random variables for the sub-model “Cast-in-situ” construction method of the superstructure.

Table 3. Descriptive statistics of posterior distributions for the stochastic variables of bridge’s socket foundation (using the summary() function of PyMC3).

Random Variables	Distribution type	Parameters (mean; sd)	Lower limit HPD _{97%}	Upper limit HPD _{97%}	Gelman-Rubin convergence test (R-hat)
L_{sup} (m)	Laplace	(94.823 m; 37.30)	21.212 m	165.255 m	1.001
V_c ($m^3/socket$)	Logistic	(972.218 m^3 ; 371.183)	236.771 m^3	1,658.726 m^3	1.001
C_{V_c} ($€/socket$)	Logistic	(82,444.086€; 31,476.318)	20,078.18 €	140,659.96€	1.008
B_s ($Kg/socket$)	Normal	(58,797.777 Kg; 30.736,16)	14,373.07Kg	109,399 Kg	1.001
C_{B_s} ($€/socket$)	Normal	(58,797.777 €; 30.736,16)	14,373.07 €	109,399 €	1.006

4 CONCLUSIONS

Cost estimation is a crucial management step facilitating optimal investment decisions and overrun avoidance during an asset’s life-cycle. For supporting decision-making under uncertainty during the early stages of a project, the proposed “Construction phase” module has two purposes for its users (either public authorities or a project manager); the prediction of the occurrence probability of a specific cost value and the derivation of the cost ranges based on their risk tolerance. Hence, the user can decide on the sustainable implementation of a project by referring to the fluctuation of its expenses using the probabilistic results within confidence intervals. Regarding the “Operational phase” module, although the exported results were affected by the monetary distribution of the available resources over the years, a change in the economic conditions or maintenance strategies implemented by each user may modify the management policy, which can be incorporated into the presented model owing to the adaptable environment of DBNs. Therefore, it can be readily used in practice for promoting viable alternative strategies. The Bayesian updating approach can be used in the current models in light of new data of uncertain parameters for supporting adaptive management. The proposed model is towards developing a comprehensive validated DBN that can be used by engineering practitioners and project managers for robust LCC analysis.

Egnatia Odos S.A., Thessaloniki, Greece

ABSTRACT: Prevention is an imperative necessity in all systems, whether natural or artificial ones for their proper functionality and life span's extension. Infrastructure assets are preeminently multi-components systems with existing dependencies between their components. The extant literature approaches generally the issue of maintenance models in multi-component systems without referring to specific items or deals mainly with systems of machinery and equipment. This research aims to conceptualize the necessary steps for determining the remaining economic status of infrastructure assets by calculating their "Service Value" via a probabilistic dynamic integrated predictive system and implement appropriate maintenance plans that can prohibit false life-cycle cost estimation. The model will be introduced on road bridges as ones of the most critical and difficult to analyze structures in road infrastructure systems. The proposed framework guarantees the financial sustainability of the project, its uninterrupted operation and unplanned traffic delays reduction, thus preventing adverse productivity, mobility and economic impacts.

1 INTRODUCTION

Prevention is arguably an imperative necessity in all systems, whether natural (human, environmental, etc.) or artificial ones (construction, equipment, etc.), for their (stable) proper functionality and life span's extension. This is the challenge of asset management which is properly recognized by the owners. Albeit, an efficient and sustainable approach is missing and within this context the tools and practices used are oversimplified by concentrating in single specific parts of the whole system. Infrastructure assets are preeminently multi-components systems with existing dependencies between their components. The incorporation of the componentization approach (the separate investigation of individual components that constitute integral elements of the asset system) seems to be of paramount importance in multi-component systems for the correct assessment of an asset's value as a whole since there are dependencies among individual components uncaptured in current evaluation methods (Leviäkangas et al., 2019). The extant literature approaches generally the issue of maintenance models in multi-component systems with reference to specific items without consider how each individual item reacts within the holistic system where it belongs. One possible reason might be the fact of the paucity of available data. Furthermore, the asset management is usually owned and managed by public institutions or concessionaires companies in addition the required data refers to sensitive economic issues where authorities or companies are unwilling to share let alone to publicize (Petrousatou et al., 2012). Moreover, the assessment of the condition of an infrastructure and the calculation of the investment needed for its maintenance and operation determine the life-cycle cost of the asset (Petrousatou et al., 2021). Thus, the objective of this research is to determine the remaining economic status of infrastructure assets by calculating their "Service

Value” (SV) via a dynamic integrated predictive system and to implement appropriate maintenance and/or replacement plans that can prohibit false estimation of life-cycle cost. This guarantees not only the financial sustainability of the asset but also the continuous and uninterrupted operation of the infrastructure, the operation of the neighboring settlements, the reduction of the unplanned delays and traffic disruptions and thus preventing any adverse impacts on productivity, mobility and economy in general.

Furthermore, saving resources are considered to be of high significance. The aim is to achieve cost efficiency in infrastructure development by the implementation of appropriate tools for the value of money, in addition when the available resources are limited (Marinelli et al., 2018). The challenge is the shift toward a life-cycle oriented construction cost analysis in order to reduce life-cycle costs of infrastructure assets (Biondini & Frangopol, 2018). This research aims to handle the inherent uncertainties during the whole life-cycle of infrastructure assets in line with construction analysis. A probabilistic framework based on dynamic Bayesian Network (DBN) modelling is introduced for adaptive management in different time stages of an infrastructure project and consulting stakeholders for proper decision-making. The definition of SV will be performed by the method of the “future economic benefits” expected of the asset, as adopted by the OECD (OECD, 2013). It is highlighted that in this method the asset incorporates all the economic benefits it will pay off in the future, as an accumulated wealth stock consumed throughout its service life. This is identical to the approach established by Certified Public Accountants of Australia (CPA), that the “future economic benefits” are equivalent to service potential (CPA, 2013).

The valuation of assets SV via the “future economic benefits” approach reflects the reality of their financial position and business ability, as opposed to the current accounting valuation which adopts the linear depreciation method used primarily for tax purposes and may provide the asset owners with a misleading view in terms of the essential actions to be taken for assets’ management. This thoroughly significant fact is highlighted by the theoretical pioneering research of (Leviäkangas et al., 2019), which refers to a road asset, and points out that the cumulative divergence of the two aforementioned approaches is about 11% only in the first 10 years of the road’s service life by ending up in 200% in approximately 30 years. The purpose of this research is to present a conceptual model for the “future economic benefits” of an asset as a correct asset management accounting that can prohibit over and under estimation of investments and repair debt.

This approach through a dynamic integrated predictive system guarantees the proper functionality and operation of the asset and prohibit false estimation of life-cycle cost. Moreover, the continuous and uninterrupted operation of the infrastructure, the operation of the neighboring settlements, the reduction of the unplanned delays and traffic disruptions and thus preventing any adverse impacts on productivity, mobility and economy in general are safeguarded. The conceptual model will be introduced on road bridges as ones of the most critical and difficult to analyze components in road infrastructure systems.

2 BIBLIOMETRIC ANALYSIS

A bibliometric analysis was performed over the last two decades via the VOS-Viewer software for extracting useful outcomes of maintenance models in multi-components systems, as can be seen in Figure 1 (Chen et al., 2018). The peer-reviewed articles’ searching was performed by the Web of Science (WoS) Core Collection and Scopus bibliographic databases, which are two of the most widely accepted and well-recognized databases for high-quality bibliometric analysis (Shukla, A.K et al., 2019). The two-level structure of keywords and Boolean operators used for data mining among the fields of titles, abstracts and authors keywords into the WoS and Scopus are presented in Table 1.

Our analysis identified researches that either approach generally the issue of systems maintenance with many interdependent components without referring to specific items (Nguyen et al., 2015), (Vu et al., 2014), (Zhang et al., 2015), (Olde et al., 2017) or deal mainly with systems of machinery (Liang et al., 2017), equipment (Iung et al., 2016), (Lee & Pan, 2017) vehicles (Bouvard et al., 2011) etc. The methods applied in the literature are limited to finding optimized maintenance solutions for interdependent system components. In contrary, this

Table 1. Literature search syntax used in WoS and Scopus databases.

WoS: "TS" field
Scopus: "TITLE-ABS-KEY" field
"service value" OR "economic evaluation" OR "multi component system" OR "accounting" OR "BCA*" OR "component*" OR "bridge" OR "asset management"
AND
road OR highway OR freeway OR transport* infrastructure OR transport* investment* OR infrastructure project*OR maintenace

research proposal will investigate the interdependencies of the bridges individual components and expand on the calculation of their SV according to the dynamics of their interactions to orient a more holistic approach to asset management.

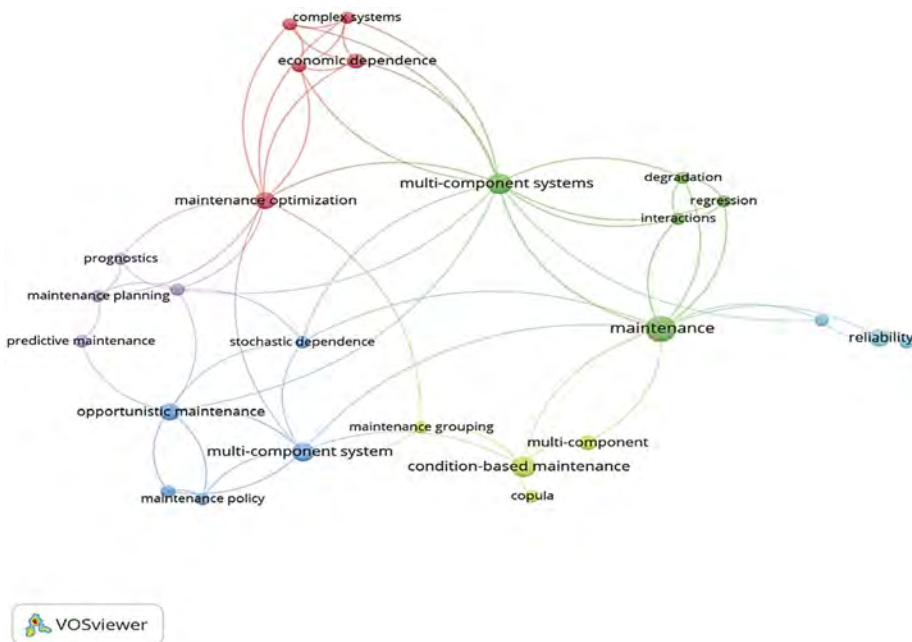

Figure 1. VOS-Viewer for searching maintenance models in multi-component systems.

This new “componentization approach” of infrastructure systems will be performed within a probabilistic framework, by estimating the variables within certain limits, based on experience and available historical data. According to this, the decision-makers will take into account the inherent uncertainties of bridges structures and they will be capable of predicting realistically bridges’ performance capacity in probabilistic terms (Frangopol, 2002), (Sirvio, 2017). Hence, the results will move within safe confidence limits giving more secure predictions. In this way, inadequate and non-optimal solutions derived from purely deterministic models, which does not include the inherent volatility of examined systems, will be avoided (Dhawan, 2005).

A dynamic Bayesian-based approach is a suitable tool that could incorporate the above issues for the reliability assessment of multi-component systems since they deal with interactions between the components of a system or time dependencies (Bensi et al., 2013). Moreover, Bayesian networks provide the merit of updating the probabilistic model in light of new information, hence improving the prediction of the system’s economic performance and reducing the uncertainty of the results (Ramírez & Utne, 2015).

3 CONCEPTUAL MODEL – METHODOLOGY AND IMPLEMENTATION

Bridges are the most neural parts of infrastructure projects not only because they contribute to the preservation of the network's consistency and continuity, offering precious time and cost savings, but also owing to their cost, difficulty in construction and the increased security they have to provide against natural deterioration and seismic hazard (Saeed et al., 2017) (Frangopol & Bocchini, 2012). Any cause that may induce restrictions, disruptions or hazards to their use should be avoided, as it is almost impossible to find alternatives-routes. It is therefore very crucial to acknowledge the bridges health status for the implementation of rational management strategies that maintain their performance at satisfactory levels of operation and safety throughout their service life. Supporter in this venture is the asset management which enables its owners to develop strategies to align their resources with the level of SV throughout the asset's life. Therefore, this process preserves the aforementioned parameters of functionality and safety, dealing timely with durability and reliability issues and keeping assets performance within acceptable levels throughout their life cycle (Frangopol et al., 2017). This knowledge gives an additional benefit because it requires assets' owners to ensure of allocating the required financial resources by avoiding prioritizing the short-term optimal solution. This latter approach hides the real picture resulting in higher future costs (Qiao et al., 2015). The bridge's SV reflects its condition and determines its future performance. The SV of the bridges proposed in this study is calculated using the "future economic benefits" method (OECD, 2013), which applies the annual rate of return generated by the assets and is essentially the same philosophy as the "Present Value" method. The proposed conceptual method will be implemented as a brand-new proposal since its application to infrastructure projects has not been found to exist via a thorough review of international academic articles conducted (Section 2).

The economic valuation of bridge assets will be accomplished by calculating the SV of bridges through a dynamic predictive system as shown in Figure 2. The proposed model will be fed with data from 1.200 bridges belonging to the main and vertical axes located along Egnatia Motorway that crosses North Greece from West to East borders, 640km of the main axe. Real data will be provided by the Inspection and Management Dept. of Egnatia Odos company responsible for the construction and operation of the motorway, based on systematic/frequent inspections and condition evaluations from the last 15 years. For the majority of the bridges, their inspection records start from the time of the first investment (the time of their construction completion and of their setting in service); for some of these bridges (10 % of the population), constructed in 80's or 90's, their deterioration records help to have a better understanding of the environmental/climate impact and of the life-cycle performance of the bridge components and of the whole structures. Various components of these bridges are considered, on the basis of their structural and functional representativeness; beams, slabs and box girders for the bridge superstructures, single or multi columns and walls for the substructures and bearings or monolithic for the connection between their two basic structural parts. Records of over-weighted oversized vehicles and traffic flows are also available to consider the traffic load impact to the deterioration of the proposed bridge network. Componentization based on different initial investment classes, governed by the three basic types of construction method, balanced cantilevering, incremental launching and pre-casting is also possible as it can be based on available as built cost records. Finally, routine, heavy maintenance and inspection cost records will be also available, of the last 15 years of bridge management. Egnatia Motorway is not only one of the biggest road bridge networks, belonging to Trans European Network (TEN), but it is also built with high, uniform and modern standards, and thus represents a typical European road bridge condition.

3.1 *Service value method*

As stated in subchapter 3, OECD (2013) guidelines recommends that an asset should be depreciated via the deduction of its consumed value from stock. The rate of return of unconsumed stock determines the value to be consumed. According Leviakangas et al. (2019), the formula to be used for the accumulated net benefits is shown in Equation 1 below:

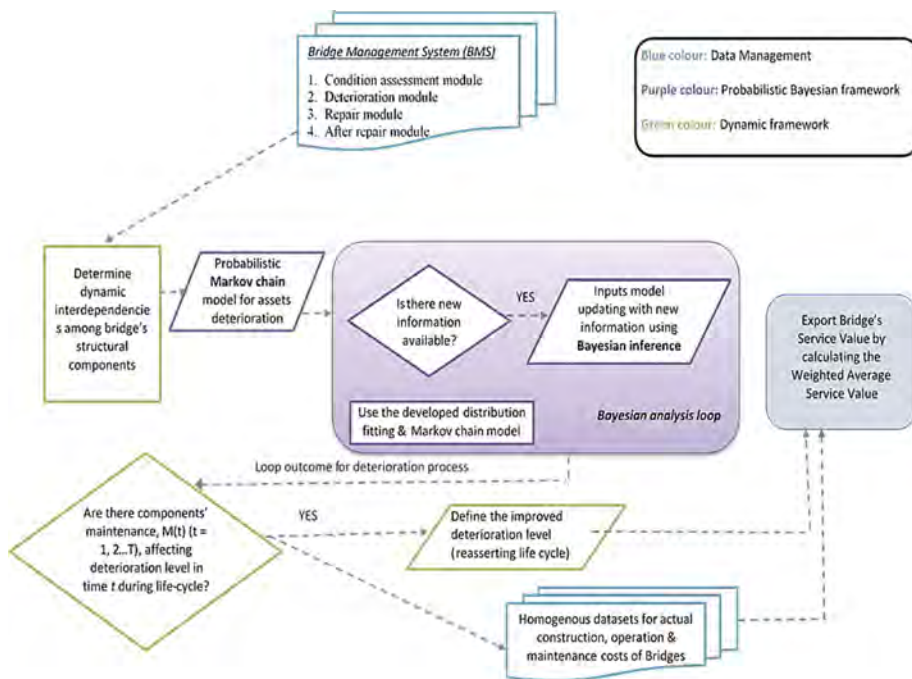

Figure 2. Proposed conceptual model.

$$B_n = (1 + i)^n - I_0 - I_n, \quad n = 0, 1, 2, \dots, t \quad (1)$$

where B_n is the accumulated stock in year n , i is the time value estimated by the asset managers and t is the SV of the asset or the component without any maintenance in its entire life. I_0 is the initial construction cost and I_n represents the improvements or additional investments made to the asset. The SV is given in percentage (%) presented in the Equation 2 below:

$$SV = \frac{(1 + i)^t - (1 + i)^n}{(1 + i)^t - I_0 - I_n} \times 100\% \quad (2)$$

If the return rate i is high then the asset's future benefits are higher, this results to different SV with different decline curves. Moreover, when repairs, renewals and maintenance in general take place for example in time t' , the expected service life of the asset is prolonged from t to k . Equation 3 incorporates these interventions as follows:

$$SV = \begin{cases} \frac{(1+i)^t - (1+i)^n}{(1+i)^t - I_0} \times 100\%, & m \text{ runs from } t' \text{ to } t + k. \\ \frac{(1+i)^{t+k} - (1+i)^m}{(1+i)^t - I_0 - I_{t'}} \times 100\%, & \end{cases} \quad (3)$$

3.2 Bridge componentization system

According the manual of structural and operation evaluation of bridge sufficiency of Egnatia Odos SA (2018), the structural components of a road bridge are: i. substructure, ii. bearings, iii. superstructure, iv. wearing surface, v. transmission embankment, as depicted in Figure 3. This is a system dynamic framework, the deterioration of one component affects the system structure

based on the evaluation system of the company that is similar to the American Valuation System PONTIS and the National Bridge Inventory (NBI). The sufficient rate (SR) used by the company (in line with the Federal Highway Administration (F.H.W.A.)) is based on the periodic visual inspections and structural instrumental measurements on field. According the company's data, the construction cost distribution of a bridge according the construction method is given in Figure 4.

Figure 3. Bridge's structural components.

Based on actual costs from the company's archives, the investment needed to construct a road bridge can be divided between components (accessories, superstructure, substructure, foundation) according the construction method used (incremental launching, balanced cantilever, precast prestressed beams, traditional scaffolding, travelling formwork). The weighted average service value (WASV) for the entire system of a road bridge takes the form given by Leviakangas et al. (2019) in Equation 4:

$$WASV = \sum_{j=1}^4 I_j \frac{(1+i)^{t_j} - (1+i)^n}{(1+i)^n - I_o} \times 100\% \quad (4)$$

where $WASV$ is in year n ; I_j is the relative share of component j of the total construction cost of bridge, expressed as percentage; $j = 1, 2, 3, 4$ the components (accessories, superstructure, substructure, foundation); I_o is the initial construction cost; when a component j is replaced or renewed for a second life cycle, t_j is changed to $2t_j$ and so forth (Figures 4–5).

3.3 Service value and accounting indexes for road bridges

The best asset management strategy is the one that maximizes SV always in relation with the investment (i.e. initial construction cost, repairs, renewals etc.), the last signifies the cumulative investment (CI) providing the value for money (VfM). The best strategy if the one that helps the curve of the ratio $WASV/CI$ to follow a smooth decline over the life-cycle of the asset.

Most accounting systems use the straight-line depreciation method. This method has a major risk that of over or under-depreciation if the real deterioration does not follow the depreciation line. This situation after 30 years (usually for bridges the life-cycle ranges between 50-70 years) can reach a high cumulative difference.

ID	Insp_Date	Bed Protection	SR	Maint_Date	Maint_Action	Units	Price per unit	Total_Cost
1	3/6/2011	5	82.91

4 CONCLUSIONS

By searching the extant literature, it was evident that there is a limited research regarding the dynamic interdependencies among an asset, in our case, the road bridge. This is a very important issue when comes to operation and maintenance of such structures. The componentization helps to reveal bridge's dynamic interdependencies and thus better estimate its life-cycle as a system and extending its service life. This entirely new approach of bridge's valuation in contrary with the accounting straight line depreciation method reveals that an asset such a road bridge might be seriously underestimated during its life-cycle, if system's structural interdependencies are not taken into consideration. Furthermore, managerial decision-making must be made by unbiased assessments of asset value something that could drive to overestimate its repair debt. The last one coupled with the "Grand Challenge" of reducing life-cycle costs of civil infrastructure projects by 50% by 2025 makes this venture even more noteworthy (Biondini & Frangopol, 2018).

Powder wastes from concrete recycling as a sustainable source of calcium carbonate mineral admixture

K.M. Masunaga & T. Iyoda

Shibaura Institute of Technology, Koto, Tokyo, Japan

ABSTRACT: Carbonation technology applied to cement-based materials from concrete recycling has been investigated as a promising approach to achieve carbon neutrality and to reintroduce these wastes into concrete's life cycle. In this research, carbon uptake potential of powder wastes from concrete recycling (PWCR) was evaluated. Samples were obtained from recycled concrete aggregate production – Recycled Concrete Aggregate Powder (RCAP), and from dewatered wash-out of returned fresh concrete – Concrete Slurry Waste (CSW). PWCR were used as mineral admixture replacing the sand, and it was observed that RCAP was naturally a fine powder with high CaCO_3 content, resulting in good mortar performance. In contrast, the coarse powder and with low CaCO_3 content CSW reduced mortar's performance. But with accelerated carbonation, carbonated CSW (CCSW) showed satisfactory performance when used in mortar. Therefore, there is high a potential to explore PWCR as a sustainable source of CaCO_3 to be reused as a mineral admixture.

1 INTRODUCTION

Concrete has been an essential material for the development of human society, and inevitably up to 10% of the ready-mix concrete returns to the industry (Xuan et al. 2018). Also, with the increasing deterioration of existing constructions, demolition and reconstruction sometimes is the most practical alternative, given the difficulties and costs of maintaining in use and safely recovering a deteriorated structure, and this generates large amounts of hardened concrete debris. Therefore, it is important to implement concrete recycling effectively to save the consumption of natural resources and to allow a circular and sustainable concrete industry economy (Lu et al. 2018, Ho et al. 2021).

Recycled concrete aggregates have already been reused, after being extracted from the demolished concrete, through a crushing process. A fine powder is produced as a final residue, which has been used as backfill and soil stabilization material, but it has not been incorporated into the life cycle of concrete. Also, from the returned fresh concrete, the aggregates can be separated from the fresh cement paste, through a washing process, and reused. But the solid agglomerated powder that remains, after decanting and filtering the slurry, usually is discarded.

These powder wastes from concrete recycling (PWCR) are composed of cement and aggregates particles, so usually they are not contaminated with other substances and are a high content calcium material. As cement-based materials can spontaneously uptake CO_2 from the air through the carbonation phenomenon, accelerated carbonation of PWCR may produce a material similar to ground limestone powder (calcium carbonate) to be reincorporated into the life cycle of concrete. That is the reason why combining carbonation and concrete recycling can be considered as a Carbon Capture, Utilization and Storage (CCUS) technology, and it has been investigated as one of the most feasible and valuable approaches to neutralize CO_2 emissions in the cement and concrete industry (WBCSD & IEA 2009). In this research, the viability of using PWCR as a source to obtain calcium carbonate mineral admixture was evaluated. Also, accelerated carbonation technology applied to PWCR was investigated as a technique to standardize these materials,

through analyses of the powder's chemical composition and the mechanical performance of mortars produced with non-carbonated and carbonated PWCR.

2 MATERIALS AND METHODS

2.1 Powder Wastes from Concrete Recycling (PWCR)

Two types of PWCR were evaluated: the by-product of recycled concrete aggregate production (Recycled Concrete Aggregate Powder – RCAP) and the dewatered slurry from returned fresh concrete (Concrete Slurry Waste – CSW). Material characterization was done by X-ray diffraction (XRD) and thermogravimetric analysis (TGA). The XRD patterns were obtained using a Bruker AXS D2 PHASER equipped with the LYNXEYE detector. The measurement range was 5° to 60° 2θ with a step-size of approximately 0.025° per second. TGA (Netzsch) was conducted on approximately 50 mg of manually ground samples in open vessel heated continuously in temperature range from 25°C to 1000°C , at a heating rate of $20^{\circ}\text{C}/\text{min}$, in a nitrogen atmosphere, with a flow rate of 150 ml/min.

2.2 Accelerated carbonation methods applied to the PWCR

For solid-air carbonation, the water content of the samples, water-solid ratio (w/s), was varied in mass by adding distilled water. The samples were placed at an accelerated carbonation chamber of 5% CO_2 concentration, 60% of relative humidity (RH), 20°C temperature for 7 days.

For aqueous carbonation, solutions containing samples at a concentration of 25g/l were prepared with potable water containing CO_2 dissolved in it, using a commercial carbonated water maker (Aqueous A) and with distilled water and a gas flow CO_2 concentration of 100% (Aqueous B) and of 5% (Aqueous C), blown into the liquid using a gas washing bottle (scrubbing bottle) with glass filter. In all methods, the solution was stirred at atmospheric pressure using a magnetic stirrer. After the solutions' pH dropped from 12.5 to approximately 8.3, indicating the change in the alkalinity, each mixture was filtered using a paper filter, which retains $7\mu\text{m}$ size particles, and the solid material was dried at 40°C to remove the free water.

2.3 Mortar tests using PWCR

For mortar mix design, Ordinary Portland Cement (OPC) and OPC with 50% ground granulated blast furnace slag (GGBFS) replacement were used as binder. The water/cement ratio (W/C) was set at 0.55 and the sand/cement ratio (S/C) at 3:1. The PWCR types used were RCAP, CSW and the CSW carbonated using solid-air method with w/s >0.50, identified as carbonated-CSW (CCSW). More powder information is presented in section 4. They were added as a sand replacement at 15% content. Also, pure limestone powder (LSP), with specific surface of $6,800\text{ cm}^2/\text{g}$ and average particle diameter of $3.26\mu\text{m}$ and D90 of $20\mu\text{m}$, was used as powder addition (Table 1).

Table 1. Mortar mix design.

Identification	Cement type	Powder addition	Slump flow
1 N	OPC	None	Control
2 B	OPC+GGBFS (50%)	None	Control
3 N-LSP	OPC	Limestone powder (LSP)	+ 39%
4 B-LSP	OPC+GGBFS (50%)	Limestone powder (LSP)	+ 38%
5 N-RCAP	OPC	Recycled concrete aggregate powder (RCAP)	+ 63%
6 B-RCAP	OPC+GGBFS (50%)	Recycled concrete aggregate powder (RCAP)	+ 63%
7 N-CSW	OPC	Concrete slurry waste (CSW)	+ 17%
8 B-CSW	OPC+GGBFS (50%)	Concrete slurry waste (CSW)	+ 9%
9 N-CCSW	OPC	Carbonated concrete slurry waste (CCSW)	+ 15%
10 B-CCSW	OPC+GGBFS (50%)	Carbonated concrete slurry waste (CCSW)	+ 25%

* Slump flow was controlled using polycarboxylic acid ether based high-range water reducer admixture.

2.3.1 Compressive strength test

The test was performed with cylindrical mortar specimens 50 mm diameter and 100 mm height cured in water.

2.3.2 Archimedes porosity test

Specimens were saturated with water in a vacuum chamber and the saturated and submerged masses were measured. After being kept in a chamber at 40°C and 40% RH until mass stabilization, the dry mass was obtained to calculate the porosity using the Archimedes principle.

2.3.3 Evaporation test

After finishing the 28 days curing period, mass variation due to the water evaporation was recorded continuously for mortar specimens 40x40x160 mm. Evaporation condition was 20°C temperature and RH of 60%.

2.3.4 Accelerated carbonation test

After 28 days of water curing, 40x40x160 mm specimens were dried at a 20°C and 60% RH environment for more 28 days and the 2 faces sealed specimens were carbonated in an accelerated carbonation chamber (20°C, 60% RH, CO₂ concentration of 5%). The carbonation depths were measured (in mm) using a phenolphthalein solution sprayed on a freshly split mortar surface. Average values were plotted as function of the square root of the exposure time *t* (in days) to determine the accelerated carbonation coefficient *K* (in mm/ $\sqrt{\text{days}}$).

3 RESULTS AND DISCUSSION

3.1 Material characterization

Figure 1 shows the XRD results of RCAP and CSW before and after being carbonated using solid-air and aqueous carbonation methods. For RCAP, there was a high peak of CaCO₃ and SiO₂, for both non-carbonated and carbonated samples, suggesting that previous natural carbonation occurred during concrete lifecycle and/or during the recycled concrete aggregate production. For CSW before carbonation, it was possible to find a high peak for Ca(OH)₂, but after the solid-air carbonation with w/s 0.50 and aqueous carbonation, the peak changed to CaCO₃. Especially for aqueous methods, the intensity peak for calcite was stronger, making clear the effectiveness of this method for CSW.

From TG-DTA, Ca(OH)₂ and CaCO₃ contents in the samples were quantified (Figure 2). RCAP showed no content of Ca(OH)₂, and high content of CaCO₃ even before carbonation (28%). And after 7 days of solid-air carbonation, changing w/s ratio from 0 to 1.00, or aqueous carbonation, in all samples there was a maximum increase of 4.6% in CaCO₃ content. Differently, for CSW as w/s ratio increased, solid-air carbonation progressed more than in lower water content samples and it was possible to verify complete change of Ca(OH)₂ to CaCO₃, specially for high water content samples.

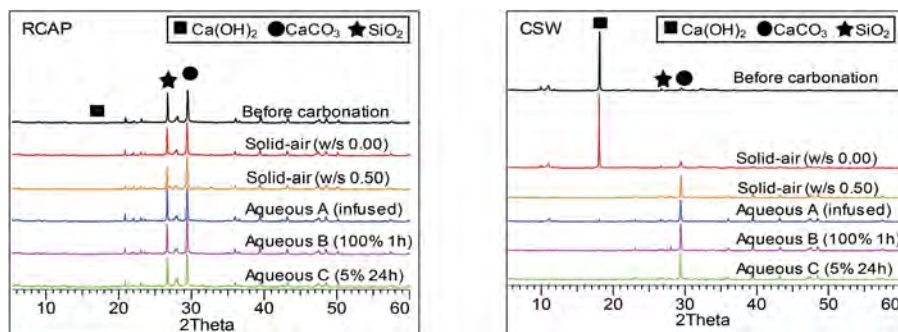

Figure 1. XRD pattern of RCAP and CSW carbonated using different methods.

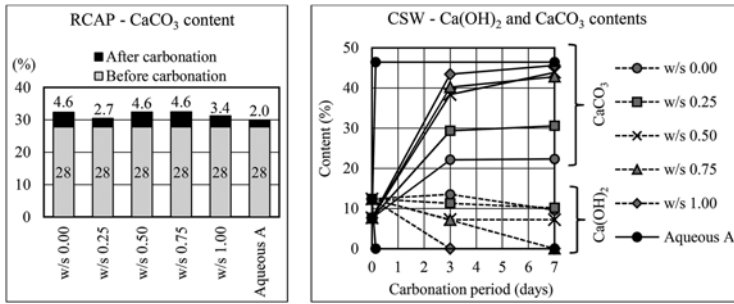

Figure 2. Ca(OH)_2 and CaCO_3 contents of RCAP and CSW carbonated using different methods.

3.2 CO_2 uptake determination

CO_2 uptake was determined as the amount of CO_2 absorbed by the powder during the accelerated carbonation and fixed in the solid phase as CaCO_3 . This was calculated from the mass loss due to CaCO_3 decomposition of the carbonated and non-carbonated samples after TGA (Xuan et al. 2016, Kaliyavaradhan et al. 2020). As shown in Table 2, CO_2 uptake of CSW for the solid-air method increased as the w/s ratio increased. The maximum value was obtained for the aqueous method and was 22.14%, which means that 1 kilogram of the CSW analyzed can absorb approximately 221.4g of CO_2 in optimum conditions. For RCAP, CO_2 uptake varied between 1% to 2% and there was no correlation with the amount of water in the sample. Ho et al. (2021) reported that smaller particles size, less aggregate contamination, and thus a higher content of effective Ca ions, favored carbonation reaction under atmospheric pressure and low CO_2 concentration. Oppositely, the presence of fines from crushed aggregates, which are usually composed of silicate and limestone, decrease the percentage of effective Ca ions slightly and are essentially inert in relation to the carbonation process, reducing the CO_2 uptake. This explains RCAP low CO_2 uptake and CSW high CO_2 uptake, especially for samples with water availability.

Table 2. CO_2 uptake of PWCR samples carbonated using different methods.

Carbonation method		RCAP	CSW
Solid-air	w/s 0.00	1.47	7.23
	w/s 0.25	1.02	12.54
	w/s 0.50	1.49	20.27
	w/s 0.75	2.01	20.96
	w/s 1.00	1.09	21.74
Aqueous	A	1.36	22.14

3.3 Mortar performance

3.3.1 Compressive strength test results

The axial compressive strength test results are presented in Figure 3. It was estimated that the highest resistances were obtained for LSP mixes (with pure limestone powder), but the use of LSP resulted in only early age resistance gain compared to the control mixes N and B and did not affect the final mechanical resistance. About the PWCR addition, mortars with RCAP resulted in high axial compressive strength values. The use of CSW resulted in significantly different strengths for non-carbonated (CSW) and carbonated (CCSW) powder. Carbonation of the CSW improved the mechanical performance of the mortars with this mineral admixture. It was expected to have a slightly increase in early age with the use of non-carbonated CSW, attributed to the high content of hydration products and the seeding effect of C-S-H, which it is said to provide nucleation sites for the growth of hydration products, accelerating the early hydration period and increasing the early strength, but the current results showed a different pattern than observed in the literature (Lu et al. 2018).

3.3.2 Accelerated carbonation test results

The relationships between porosity and carbonation coefficient K and evaporation ratio and the coefficient K are shown in Figure 4 for OPC mortars and OPC+GGBFS mortars.

For OPC mortars, a good correlation could be established between porosity and coefficient K, but for OPC+GGBFS mortars, the differences in carbonation resistance for the mixes could not be explained only by the mortar's porosity. This is an indication that porosity of mortars with GGBFS replacement may have a complex porosity network, which cannot be evaluated considering only the total porosity amount. But when the evaporation ratio was correlated with the coefficient K, a good correlation could be found, both for OPC and OPC+GGBFS binders. For both binders, reduced water evaporation ratio resulted in improvement of the carbonation resistance. This shows that the water available inside the pores is a crucial factor that affects the progress of carbonation. About the effect of powders addition, RCAP addition improved carbonation resistance both for OPC and OPC+GGBFS mortars. On the other hand, the worst performance was obtained for CSW addition.

Figure 3. Mortar's compressive strength.

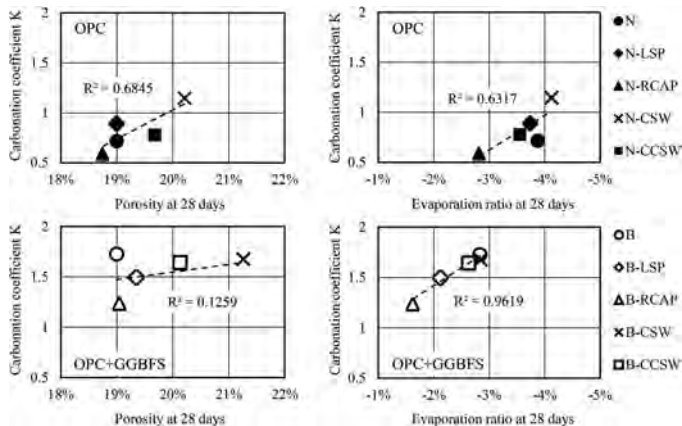

Figure 4. Relationship between porosity and carbonation coefficient K and evaporation ratio and carbonation coefficient K of mortars.

4 DISCUSSION

4.1 Effect of particle size and $CaCO_3$ content of PWCR

Limestone powder is a widely available and low-cost material. Its action combined with cement-based materials has been reported to be complex and dependent on several factors, such as particle size, dosage, polymorph of limestone, cement composition and supplementary cementitious materials (Wang et al. 2018). As shown in session 3.1, PWCR are composed of

hardened cement paste, which can be rich in calcium from $\text{Ca}(\text{OH})_2$ and C-S-H, and of fine aggregate particles, which may have CaCO_3 or SiO_2 in their composition. Therefore, they can be naturally or artificially a source to produce recycled limestone powder.

The effect of using PWCR in the mortar tests seems to be related to the particle size of the powders and the CaCO_3 content. As shown in Figure 5, RCAP is obtained after having undergone a crushing and grinding process, which naturally results in a fine powder. Oppositely, in CSW powder, hexagonal CH crystals and needle like ettringite are present from the ongoing hydration, which agglomerates the particles and results in a coarse powder without a proper treatment, such as drying and grinding. This difference in the particle size was not treated with the solid-air accelerated carbonation of CSW, showing to be one factor that influenced mortar's performance.

Another factor affecting mortar mixes performance was the CaCO_3 content. Cement producers add some percentage of calcium carbonate in industrialized cements, but many studies reported that there is an ideal amount of CaCO_3 to maximize performance of hardened cementitious materials, and that this can be higher than the tolerances regulated by current cement standards. Regarding the potential of reusing PWCR, it has been reported that precipitated CaCO_3 from carbonation of brines rich in Ca ions can potentially provide benefits to cement hydration (mineralogical changes), workability, strength and durability, when replacing cement at 10% mass content (McDonald et al. 2019). Also, carbonated hardened cement paste powder replacing 10% to 20% of cement increased strength up to 90 days in Lu et al. (2018) investigation. This is explained in literature, firstly, by the presence of calcite, that even in low weight percentages is sufficient to lead to formation of the calcium aluminates hemicarboxylate and monocarboxylate, thus to a stabilization of ettringite. And these chemical reactions can result in lower porosity and higher compressive strength. In the experimental tests results, the positive results obtained for the mixes with CaCO_3 from PWCR, especially when combined with GGBFS seems to be related to the extra amount of alumina from this supplementary cementitious material, that affected reactivity of CaCO_3 . The second reason in literature explaining the positive influence of CaCO_3 from PWCR is the combination of additional nucleation and growth sites for hydration products lead to a chemical activation of the hydration of cement (Lothenbach et al. 2008). And finally, even with the use of high levels of calcite, most of them can still act as a filler, filling pores and micro-cracks, and this also explains the strength increase with the use of carbonated powders containing CaCO_3 (Liu et al. 2021). However, for a higher (30%) substitution of cement, there would be less hydration products, causing performance to decrease (Lu et al. 2018).

In this experimental study, PWCR replaced sand, so the filler effect was already expected. Coincidentally, the percentage of CaCO_3 in the powder wastes RCAP and CCSW, was similar and around 40% (Table 3), which resulted in the mortar mixes containing around 4.5% CaCO_3 solid material content, except for the percentage content inside the OPC (Figure 6). This content resulted in satisfactory performance for the mortars evaluated. But for LSP addition, which is a 99% CaCO_3 , there was no increase in performance, even it was the finest powder.

Additionally, there are reports about carbonation of cement-based materials producing not only CaCO_3 , but also (alumina)-silica gel and that it can quickly react with CH and result in the formation of more C-S-H (Zajac et al. 2020). Lawrence et al. (2003) also reported that short-term degree of hydration in mortar containing chemically inert quartz powders for a wide range of fineness (between 180 and 2000 m^2/kg) and cement replacement rates (up to 75%) was always higher than the reference mortar. This experimental study focused only on the CaCO_3 and did not focus on the influence of the supposed inert SiO_2 , nor the amorphous phase of the non-carbonated and carbonated powder wastes. Therefore, these components may also have a positive effect on the hardened cementitious material, especially if treated properly to an adequate particle size, maybe nanoscale particles (Li et al. 2015).

Table 3. $\text{Ca}(\text{OH})_2$ and CaCO_3 content in PWCR.

Content	LSP	RCAP	CSW	CCSW
$\text{Ca}(\text{OH})_2$	0%	2%	10%	2%
CaCO_3	99 %	36 %	7%	44%

Figure 5. Particle size distribution of PWCR.

Figure 6. CaCO_3 content in mortars with RCAP and CCSW addition.

4.2 Carbonation applied to CSW for use as a value-added material

From session 3.3, the best mortar performance was obtained for B-RCAP mix, because of the combined filler effect for being a fine powder and hydration acceleration for containing CaCO_3 . However, setting other parameters for mortar mixes evaluation, as shown in Table 4, B-CCSW also showed a satisfactory mortar performance, adding the positive aspect of CO_2 uptake, compared to the mix B-RCAP. In this research, the carbonation technology applied to CSW, was the solid-air carbonation method, resulting in effective CaCO_3 formation, but without significant changes in the particle size distribution (PSD). As shown in Figure 5, the aqueous carbonation method can not only precipitate CaCO_3 , but finer CaCO_3 , not requiring grinding or other energy demanding processes. Therefore, it is expected to achieve even better performance for OPC+GGBFS mortars produced using CCSW carbonated with aqueous methods, transforming it into a value-added material and contributing holistically to the reduction in CO_2 emission, the CO_2 uptake and the concrete recycling.

Table 4. Evaluation of mixes' performance.

Mix design	Parameters			
	CO_2 emission reduction	CO_2 uptake	Concrete recycling	Mortar Performance
1 N	-	-	-	-

5 CONCLUSIONS

- Carbonation of PWCR: CSW showed high content of hydration products and it was a coarse powder. Both solid-air and aqueous carbonation changed the chemical

composition of CSW, transforming a still hydrating material to a chemically stable CaCO_3 . In the solid-air method, increasing the w/s improved the CO_2 uptake, but also stimulated the hydration of anhydrous cement from CSW, making it an even coarser powder. Therefore, it is necessary to have a grinding process (energy) to obtain fine powder material. But the aqueous method showed high efficiency for CO_2 uptake and also precipitated finer CaCO_3 , changing the particle size distribution. Differently, RCAP was naturally a fine powder, with high content of CaCO_3 and SiO_2 , from the crushing and grinding processes and/or previous natural carbonation, and its accelerated carbonation did not change the chemical composition nor the particle size distribution.

- Effect of PWCR in the mortar's performance: Compressive strength and carbonation resistance was improved with the addition of RCAP and CCSW, resulting in better performance than the control mixes. This indicates that there is an unexplored potential to reuse PWCR as a mineral admixture for mortar or concrete. This improvement showed to be related to the CaCO_3 content, which in RCAP and the carbonated CCSW samples was around 40%, resulting in approximately 5% CaCO_3 content of total solid material, and it was obtained regardless of the particle size of the powder, as RCAP was a fine and CCSW was a coarse powder. PWCR addition showed better performance combined with blended cement (OPC+GGBFS). This suggests that the mortar performance was influenced not only by an inert filler effect but also by a chemical effect (changes in hydration) caused by the CaCO_3 from the PWCR.

Therefore PWCR, both CSW and RCAP, can be a source of CaCO_3 . Also, the accelerated carbonation technology showed to be an adequate and valuable method to transform CSW to a value-added material and to promote its re-utilization, incorporating into the life cycle of concrete and leading to a circular and sustainable concrete industry economy.

Travel time gains VS time constancy - An irresolvable contradiction?

M. Hoffmann

Institute of Transportation, TU Wien, Vienna, Austria

Hoffmann - Consult, Vienna, Austria

ABSTRACT: Systematic analyses of market developments and transport trends are the basis for the evaluation of investments in transport infrastructure in common approval procedures. Traditional cost benefit analysis (CBA) considers time savings between connected locations as a key benefit of the expansion of transport infrastructure. With reference to almost constant time expenditures for mobility, some researchers argue that there are no relevant time savings and thus no real benefits. As the literature analysis and empirical data show, both the time savings between locations after expansion and approximately constant time expenditures for mobility in the transport system over the long term can be observed. Resolving this issue is therefore the key for consistent economic analysis of transport infrastructure investments. Using a location-theoretic model and empirical data, the paper shows that expansion projects reduce transportation costs, increase efficiency, and largely translate the time savings into accessibility benefits. The centralized production and division of labor is then the basis for economies of scale efficiency gains with diminishing marginal utility. As the resulting environmental impacts and resource consumption are not adequately reflected in standard economic theory, the development in transport is largely unsustainable yielding high external costs. A possible solution would thus be to contrast the efficiency gains in the market with the life cycle costs and external costs of these investments.

1 INTRODUCTION

1.1 *Impacts and comparison of projects*

The origins of such an economic evaluation of projects can be found in the development of welfare economics at the end of the 19th century. The first regular systematic comparisons of benefits and costs of public infrastructure projects are known from the U.S between 1930 and 1940. The pressure for more efficiency led to a subsequent standardization and increasing use of cost-benefit analysis (CBA) from 1950 to 1970. Between 1970 and 1980, the concept of life-cycle cost analysis (LCCA) considering all costs and benefits was established. The concept of “whole life cycle costing” (WLCC), developed in the period from 1990 to 2000 takes the stochastic nature of input parameters, possible risks and external effects into account. As life cycle cost analysis requires extensive data and knowledge, it has rarely used in decision practice.

Investigating transport investment projects and alternatives with a cost-benefit analysis (CBA) is a well-established practice in transport planning since decades. The main methods in CBA are Impact Analysis (IA), Utility Analysis (UA), Cost Effectiveness Analysis (CEA), Benefit-Cost Analysis (BCA). The IA is a pure comparison of the pros and cons without overall decision criteria as a first starting point. The UA allows an evaluation according to weighted criteria and is well suited for topics that are difficult to quantify. The CEA contrasts the quantitative costs with a qualitative benefit i.e. how much benefit can be achieved per cost unit. The BCA compares quantified costs and benefits in a limited time frame. Depending on the selected method and parameters the results may vary significantly.

Since no infrastructure project takes place in a vacuum, the decision is usually based on a comparison of existing transport networks without further investment (Option #0) and alternative courses of action (Option #1 to #n) in a given time frame (Figure 1). For any project assessment, the system delimitation regarding function, space, and time has to be assessed. In terms of investment costs considering initial investments or the entire life cycle is a crucial difference. Assessing benefits is critical if only revenues or greater economic effects such as time savings, traffic safety, etc. during service life are taken into account. Since the majority of the costs are incurred in the initial phase, and the benefits are mostly generated later during service life with increasing capacity utilization, the selected interest rate is also crucial as later benefits and costs are depreciated.

From a cost perspective, emissions and impacts on the environment occur primarily during construction and deconstruction, and to a lesser extent during rehabilitation. In the operating phase, there are generally negative effects as a result of traffic emissions which can have a negative impact on the economy. However, as environmental quality is not adequately represented in standard economic theory, mainly negative aspects of transport infrastructure are largely underestimated in decision making. The concepts to incorporate environmental costs range from inadequate (e.g. “willingness to pay”) to promising (e.g. “costs to repair/replace”). As there is still no functioning market for environmental quality in capitalist societies these aspects are underrepresented in economic decisions explaining the low sustainability in the sector (Hoffmann 2019).

Figure 1. Development and comparison of transport infrastructure projects and alternatives.

1.2 Travel time gains from A to B

In individual choice on traffic mode and route selection as well as in aggregated Cost Benefit Analysis (CBA) the travel time between locations is a key factor. In a typical Benefit-Cost Analysis (BCA) the monetized time savings between locations account for 70 to 80 percent of benefits. The remaining benefits are mainly related to reduced accident rates and lower emissions from fewer traffic jams. The main advantage of using monetized time savings is the possibility to predict and observe increased average speed and reduced average travel time on existing and new routes on the short run. Figure 2 provides an overview on the relevant literature on this topic.

Figure 2. Travel time gains from A to B due to infrastructure improvements with selected literature.

1.3 Time constancy in transport systems

With the CBA becoming more popular in the last five decades the critique regarding the methods, the system delimitation, and the parameters has been mounting. As Flyvbjerg et al. (2003) and others have shown there is ample evidence on deliberate systematic decreasing of costs and increasing of benefits to improve success in the approval process. With the focus on time savings as a key factor there is substantiated critique both regarding the methods and results. The literature survey consistently shows that the total travel time in the entire transport system has remained largely constant over decades (Figure 3). This holds true for regions all over the world despite huge differences both in population, regional development, economic growth and transport investments. According to the CBA that would mean that there are no benefits from time savings. Furthermore, building roads to fight congestion is mostly a temporary solution. Despite observed accessibility gains there are saturation effects on medium to long-term and the improved transport network is becoming congested again. The data consistently shows that increasing transport speed and efficiency leads to longer transport distances and higher transport volumes with overall negative environmental effects. As there is a clear relation between transport network length and efficiency to economic growth, investing in transport infrastructure is not a zero-sum game. In summary, the argument of a lack of benefits due to approximately constant time expenditures in the system is therefore just as untenable as the focus on local time gains of individual projects.

Figure 3. Time constancy in systems regardless of infrastructure improvements with selected literature.

2 AN EMPIRICAL LOOK AT THE WORLD

2.1 Motorization, highway length, and transport

Transportation infrastructure represent an essential social and economic resource. They structure the use of space and enable access to and exchange of people and goods between locations having a significant influence on economic development. The motorization rate increases with economic growth slowing down for a GDP/Capita of \$20,000 to \$50,000 (Figure 4). Apart from saturation effects the quality of public transport in agglomerations is the main explanatory factor. The network length of paved roads increases with the level of wealth, reaching about 4 m/C. on average at about \$10,000 and about 9 m/C. at \$50,000. A highway network emerges only above a certain level of development and wealth at a GDP/C. of \$3,000 to \$5,000 growing also slightly degressive with increases in wealth. In contrast, passenger and freight transport performance grows almost linearly with increasing levels of prosperity and is on average 12,000 pkm/C. and 5,500 tkm/C. per year for a GDP/C. of \$50,000. The large deviations at the same level of wealth are mainly related to territorial, spatial and other structural factors that are not considered here.

2.2 Energy consumption, emissions, investments, and travel time

Technological and economic development are major explanatory factors in relation to the increase in life expectancy, the reduction in birth rates and the development of energy

consumption. As shown in Figure 5 the energy consumption increases degressively with increasing wealth whereas the total CO₂ – emissions per Capita increase at first until a GDP/Capita of roughly \$10,000 and stagnates thereafter. This effect is related to the ability to afford cleaner technologies despite higher energy consumption. However, this currently does not hold true for the mobility sector as both the mobility and the emissions exhibit a degressive increase with increasing wealth.

As positive economic developments generate taxes and funds for further investments, there is a clear relation between economic welfare and investments in transport infrastructure. The wide range of data shows that a comparable level of prosperity does not necessarily require a large high-level transportation network. The degressive growth of the prosperity level with increasing network length, can be seen in the meta-analysis from the literature (e.g. Melo et al. 2013) confirming the decreasing marginal utility for consecutive periods. As the negative environmental impacts are largely not accounted for in the classical economic view it can be assumed that the benefits of additional highways in developed societies will be very limited in most cases.

As previously shown the time savings due to improved (road) transport infrastructure can be directly experienced and measured before and after the implementation of projects. Therefore, this aspect is very well known both at the level of planners and the general population. Revisiting and extending the data on travel time budget proves that the total time spent in traffic largely remains the same regardless of the level of welfare or the spending's on transport infrastructure (Figure 5). With both empirical observations being more or less true, the common models are clearly failing to account for previous and actual developments. Thus, there is a need for a conclusive unifying theory as a basis for an efficient and sustainable transport planning of the future.

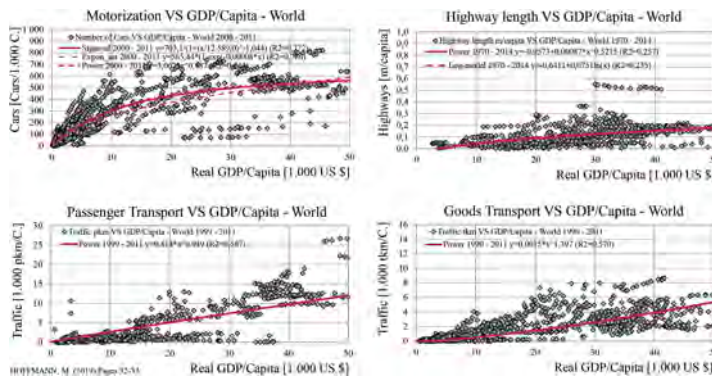

Figure 4. Motorization, highway length, passenger & goods transport VS real GDP/Capita in the world.

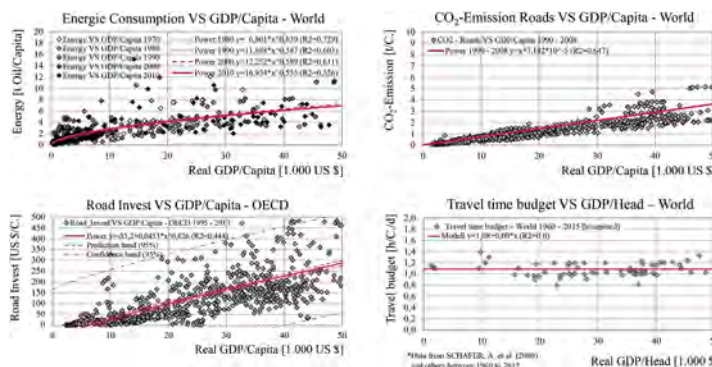

Figure 5. Energy consumption, emissions, investments, and travel time VS real GDP/Capita in the world.

3 SOLVING THE CONTRADICTION

3.1 *A new theoretical framework*

As current approaches are of limited value in solving these contradictions, there is a need for a theoretical framework providing a consistent explanation. This framework must be applicable both for developing and developed countries providing consistent explanation for past and predicted developments. As a framework accounting for all possible factors is beyond the scope, only the main factors shall be addressed here. A largely extended analysis and a vast array of empiric data on these issues can be found in the literature (Gruebler et al. 1991, Rodrigue et al. 2013, Hoffmann 2019).

The theoretical framework in Figure 6 provides an analysis of the impact of transport infrastructure on market equilibrium, consumer prices, regions, and population in three steps. Starting from two central locations each producing a comparable product (“A” \approx “B”) at defined unit costs, the costs for supplying the market will increase with the distance to the production location (costs for transport, wear and tear, loss, etc.). Price levels in this initial state before expansion of the transport network may differ due to differences in conditions at the locations (wage levels, materials, etc.). High transport costs will therefore have a prohibitive effect on the import of the particular product for similar products, thus staking out the primary catchment area of the market. Transport distances beyond the limit of equivalent product prices will accordingly be uneconomical and therefore the exception.

For the second step the transport network between the two locations is significantly expanded increasing transport capacity with decreasing travel time and transport costs as a short-term effect. As the transport costs of the connected locations are reduced equally, the geometric analysis directly shows that the location with lower unit costs in production is favored (expansion of catchment area). In the case of perfect competition and infrastructure equipment, the costs of expansion and any consequential costs for the environment and third parties are offset by the savings from lower prices (consumer return), and the use of additional opportunities of available services. In the case of imperfect markets and neglect of environmental impacts as external costs, there will be an over-provision of transport infrastructure and correspondingly unsustainable developments.

The third step includes the medium to long term reaction of the market participants to the new opportunities created by the expansion of the transport infrastructure. The combination of growth in the catchment area of central locations and further expansion of the transport infrastructure allows more economical central production of the product at location “A” due to falling unit costs for large quantities (economies of scale). This immediately increases consumer returns at both locations due to cheaper products, but leads to the abandonment of production at location “B”. As a consequence, additional jobs and opportunities are created at location “A”, which are lost at “B”. If these losses cannot be compensated by competitive or non-substitutable other products or opportunities, there will be a further migration of population, production, and services from “B” to “A” as an increasingly dominant central location.

An increase in transport costs by internalizing external costs of the transport infrastructure leads to a parallel shift of the cost function for all market participants in the case of one-time access costs (vignette). Mileage-based costs make products from central production locations more expensive and thus have the opposite effect as an expansion of transport networks. The life-cycle costs of transport infrastructure are therefore always paid for indirectly via taxes (with or without taking external effects into account) or directly as a user charge. However, this does not mean that the expansion of transport infrastructure is a zero-sum game. On the contrary, it is the expansion of the transport infrastructure that allows for a division of labor in production and efficiency gains.

As with any production function, there is a decreasing marginal benefit as shown in several meta-studies (e.g. Melo et al. 2013). Extrapolating the economic benefits from past projects generally leads to an overestimation of the benefit/cost ratio, since the benefit decreases degressively and the costs of higher-ranking transport infrastructures increase progressively, especially at central locations. Furthermore, the expansion of transport infrastructure has the effect of redistributing benefits and costs with a shift to high-ranking locations and low-cost production sites (globalization) and is accompanied in the medium to long term by emptying

peripheral areas and strengthening of agglomerations (polarization). Along developed routes, transport prices become less important with products and price levels converging on the global market (homogeneity).

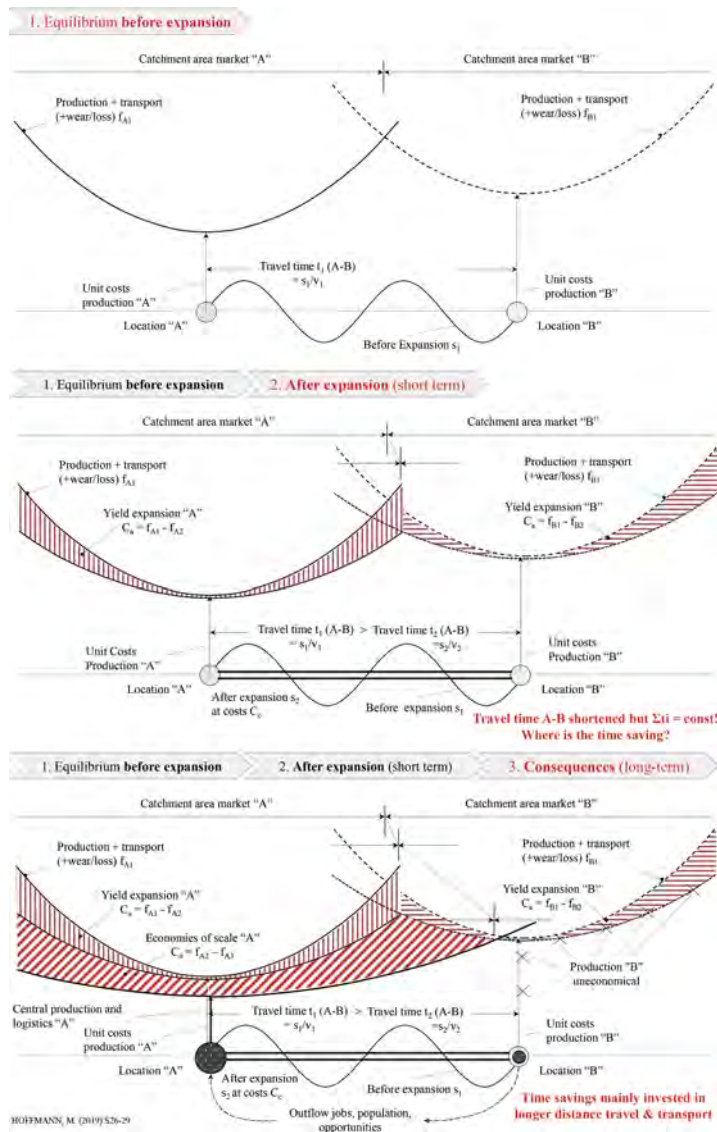

Figure 6. Impact of transport infrastructure on market equilibrium, consumer prices, regions, and population.

4 CONCLUSIONS

The development of regions, population and their economy are closely linked to their transport infrastructure enabling access to resources, products, and markets. The volume of the transport market can be seen as a function of population, economic power, production, and market shares in relation to surrounding locations. If the economic power and population in regions grow, the demand for goods, services and the possibilities increase and the transport market together with the demand for infrastructure rise accordingly. With transport infrastructures

demanding high initial investments and ongoing reinvestments, they constitute a long-term commitment of limited resources. Since decades it is therefore a well-established practice to investigate transport planning strategies and projects with different types of economic analysis.

Traditional cost benefit analysis considers local time savings and avoidance of traffic jams on project level as key benefit of transport infrastructure investments. As these investments have been mostly temporary solutions and the travel time budget in the transport system has remained largely constant critics argue that there are no relevant time savings. Using a location-theoretic model and empirical data, the paper shows that expansion projects reduce transportation costs, increase efficiency, and largely translate the local time savings into accessibility benefits. The centralized production and division of labor is then the basis for economies of scale efficiency gains with diminishing marginal utility. With environmental impacts and resource consumption not being adequately reflected in decision making, the development in transport was and is largely unsustainable yielding high external costs.

Econometric input-output analysis based on elasticities are also a classic method to assess the benefits of transport infrastructure investments on the economy. With diminishing marginal returns towards an economic saturation level looking to past benefits when there was no developed transport network is grossly misleading. Furthermore, the average benefits of projects bundles cannot distinguish between efficient and meaningless specific projects. In addition, the negative effects are systematically underestimated in this type of analysis as there are no functioning markets and limited awareness for environmental quality. Thus, even using revealed and stated preference approaches for accounting of environmental effects largely underrate these costs.

The provided theoretical framework in this paper explains both the short and long-term effects and interactions of transport infrastructure investments on market equilibrium, consumer prices, regions, and population. Furthermore, it explains why high-level transport infrastructure does not benefit all connected locations equally driving competition in extended markets. In this regard transport infrastructure investments are drivers of globalization increasing urbanization in agglomerations and depopulation in peripheral regions. Although this development is largely unsustainable, a radical turnaround with unilateral pricing of external costs has severe repercussions due to increasing consumer prices and loss of competitiveness. As a general strategy, a multilateral shift on a transnational level to a sustainable, efficient, multi-modal transportation system minimizing externalities would be optimal. With diminishing marginal returns and the majority of the environmental impact in the construction phase, an efficient operation and maintenance is key. Finally, with an intact environment as a key future resource countries prioritizing sustainable modes of transport and efficient investments will have a competitive edge on the long run.

Reliable estimation of investment and life-cycle costs from road projects to single road assets

M. Hoffmann

Institute of Transportation, TU Wien, Vienna, Austria
Hoffmann - Consult, Vienna, Austria

V. Donev

Institute of Transportation, TU Wien, Vienna, Austria

ABSTRACT: The estimation of investment costs of road projects is a key task at every stage of planning and implementation. From the initial project idea to detailed planning and legal approval, the costs of transport infrastructures play a decisive role for investors, authorities, and the public. Although each project is different and some deviations between estimation and actual costs are to be expected, there is ample evidence from the literature on systematic underestimation and the main reasons for this effect. Beyond investment costs, reliable estimations of life cycle costs from single assets and projects up to entire road networks are of an increasing importance to determine budgeting needs, preserve asset value, and define contracts between stakeholders. In all cases, systematic methods and a large database on road projects and individual measures are needed to provide a sufficient basis for cost estimations and validation. This paper tries to fill this gap by providing unit costs both at the project and asset level for construction and rehabilitation measures with adjusted prices for the year 2022. Thereby, the cost estimates are based on extensive research and collected cost data from projects on regional roads and highways in Austria over the last two decades. In addition, the paper presents calibrated standardized live cycle costs for key road assets together with life cycle cost factors providing the means to estimate life cycle costs based on construction costs alone. Finally, the adjustment of prices for different regions and years of construction are highlighted, allowing for a validation of individual project appraisals.

1 INTRODUCTION

1.1 *Construction costs and construction prices*

The provision of transport infrastructure requires high initial investments as well as ongoing reinvestment with a long-term commitment of funds due to extensive service lives of these assets. Therefore, the estimation of investment costs of these projects is a key task at every stage of planning and implementation. From the initial project idea to detailed planning and legal approval, the costs of transport infrastructures play a decisive role for investors, authorities, and the public. Despite their importance in many cases, the provided information is based on rather rough estimations instead of a thorough statistical analysis. Furthermore, the information on the price basis, the reference year or which items are included or not included in the calculation are rather vague. In many cases it is therefore difficult to distinguish between price inflation, price increases due to unforeseen circumstances or regulatory requirements, and deliberate deception about actual costs.

Apart from individual circumstances of projects, it is important to understand the principal connection between costs factors and the development of construction costs and prices. According to EUROSTAT, the output prices of contractors depend on the development of the factor prices (e.g. material, labour, energy), the productivity, and a profit margin. The total costs for the client include additional costs (e.g. VAT, planner fee) and an additional profit. Apart from cost factors, there will be a final selling price on the market depending on

the supply and demand. These final prices represent what was actually paid and what shall be analysed further in this paper (Figure 1).

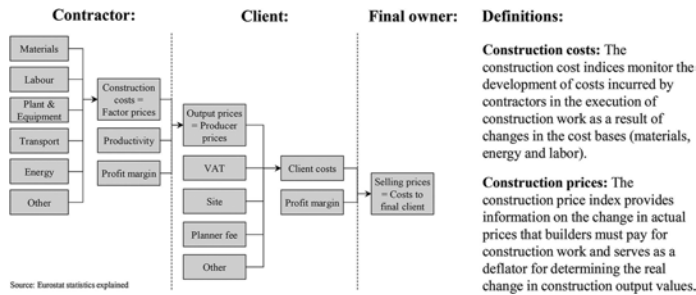

Figure 1. Input factors and difference between construction costs and prices explained.

1.2 Regional cost factors and price indices

Although every transport construction project is different, there are systematic similarities that have to be accounted for. In general, the prices for similar goods as well as construction works may differ both between regions and reference years due to differences and changes in the input factors as well as the market situation. Therefore, the national and international statistic bodies provide a systematic analysis on cost and price changes over time. The provided construction cost indices describe the monthly, quarterly, or yearly change of costs incurred by contractors based on the comparison of a weighted average of the prices of a basket of goods and services. The construction price indices describe the change of final market prices that builders must pay on a similar basket. Moreover, the construction costs and prices between different regions or countries can also be described in a similar way based on a representative basket. In this regard, Figure 2 provides the basis for the comparison of baskets as well as an example for adjusting projects costs for different years. In the second example project prices from one region are converted to those of another region based on purchasing power parities for civil works in Europe. As a rule for cost estimations and price comparisons, it should be mandatory to always provide information on the year and the region as well as adjusting for purchasing power and price changes over time. Furthermore, additional information on the project specifics and the sources of the price estimates should be provided to allow validation and updating.

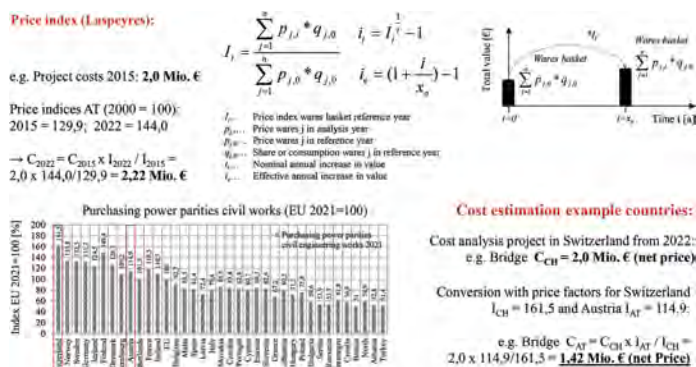

Figure 2. Price index from annual baskets of goods and purchasing power parities (PPP) with examples.

1.3 Development of construction costs and prices in Austria

Depending on the market situation, prices for goods and services may change over a comparative period. A general increase in prices in a sector is referred to as inflation, while falling prices are

referred to as deflation. The consumer price index indicates how the prices of weighted representative goods and services of private household's change compared with a reference year. The consumer price index is therefore an important benchmark for wage negotiations and overall market development. The cost and price indices also play an important role in life cycle cost analysis. They are the basis for the adjustment and comparison of project costs from different years of construction for a reference year as well as a prerequisite for the determination of future costs and prices. In addition, prices in contracts can be negotiated as fixed or as variable prices from a given base year and adjusted accordingly with these indices. According to the data from Statistics AUSTRIA, the consumer price index increased in average with +2,2% per year. The year 2022 was truly exceptional, as the consumer prices increased by +8,6%. The construction prices for civil engineering works, road works and bridges increased in average with +1,85%, +1,87%, and +1,55% per year in the analysis period. In contrast, the construction costs for roads and bridges increased in average by +3,66% and +3,49% per year. Comparing construction cost and price increases reveals a systematic annual gap of 1,79% and 1,94%.

Figure 3 shows an analysis of the development of construction costs and construction prices for roads and bridges from 1990 to 2022 with a simple forecast to 2030 based on linear regression. This systematic gap means that by doing nothing the profit margin of the civil construction sector in Austria would decrease by the same amount every year. However, as this is not an uncommon situation, there are a few ways out of this dilemma. The first possibility is to be more innovative and efficient, increasing the productivity every year. A second way would be to shrink market supply by reducing the number of companies and employees in the sector or by finding a cheaper work force. A third way are cartelization and price-fixing to ensure survival on a difficult market. A fourth possibility is reducing the quality of materials and civil works resulting in reduced functional quality, safety, and service life on the medium to long run. There is sufficient evidence in the construction sector showing the exploration of each of these possibilities with a varying degree of success. Beyond these systematic considerations, the price indices are used in this paper to adjust the provided unit prices to 2022 (Hoffmann 2019).

Figure 3. Construction cost and price indices development for road and bridge works in Austria.

2 ROAD CONSTRUCTION PRICES

2.1 Unit prices of highways and regional roads

The road construction costs are all final unit prices for the year 2022 per square meter or lane kilometer including 20% VAT. These unit prices include the entire range of construction works from pavements and civil structures in an unspecified amount (Figure 4). The construction prices of highways amount to an average of 1.522 €/m² and a median of 1.146 €/m² ($n=26$) resulting in an average of 9,0 Mio. €/lane.km and a median of 6,79 Mio. €/lane.km. The rehabilitation costs cover mainly small to medium size projects with average costs of 289 €/m² and a median of 226 €/m² ($n=32$) leading to 1,65 Mio. €/lane.km in average and a median of 1,41 Mio. €/lane.km. The adjusted unit prices for regional roads are significantly lower mainly due to lower share of civil structures (e.g. bridges and tunnels), lower traffic volumes, as well as lower legal requirements. The average unit prices for constructing regional roads amount to 713 €/m² and a median of 569 €/m² ($n=90$) resulting in an average of 2,82 Mio. €/lane.km and a median of 2,12 Mio. €/lane.km. As regional roads are comparatively older, the average costs of 205 €/m² with a median of 169 €/m² ($n=80$) translating into 0,71 Mio. €/lane.km in average and a median of 0,56 Mio. €/lane.km cover the entire range from

small repairs to replacement. The distribution of the unit prices can be approximated by a normal or other distributions, with unit prices being right skewed with the mean being larger than the median due to a few projects with exceptionally high unit prices.

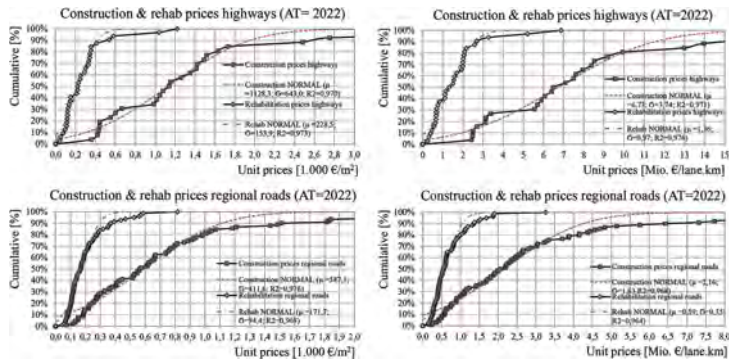

Figure 4. Unit prices highways and regional roads in Austria (prices 2022).

2.2 Unit prices bridges and tunnels

The analyzed unit prices for bridges and tunnels cover both projects on regional roads and highways of various size, materials and construction techniques in Austria. A deeper analysis on the contribution factors to the unit prices is feasible but beyond the scope of this paper. The unit prices of rehabilitation measures can be clustered depending on initial condition, type of M&R, and impact duration in small, medium and large measures (Hoffmann 2017, 2019, Hoffmann & Kammersberger 2012). As shown in Figure 5, the mean unit prices for road bridges in 2022 are 2.150 €/m² with a median of 1.896 €/m² ($n=125$) resulting in an average of 10,31 Mio. €/lane.km and a median of 9,00 Mio. €/lane.km. Very short bridges exhibit significantly higher average unit prices due to the foundation works being distributed over a limited bridge area. Bridges with a large span usually result in higher unit prices due to sophisticated statics and construction. The rehabilitation prices of bridges amount to 872 €/m² with a median of 717 €/m² ($n=230$) resulting in an average of 4,11 Mio. €/lane.km (median 3,59 Mio. €/lane.km).

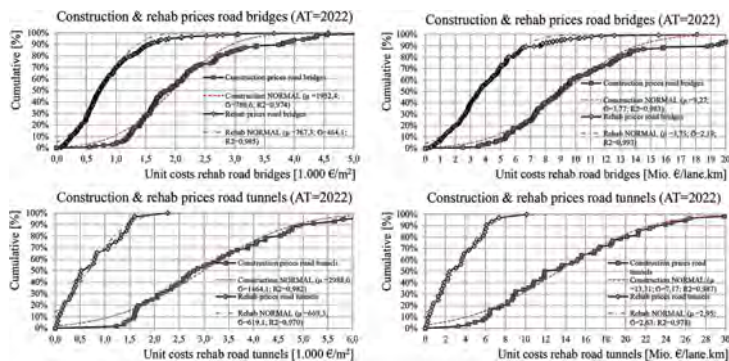

Figure 5. Unit prices bridge and tunnels construction and rehabilitation in Austria (prices 2022).

The mean unit prices for road tunnels are 3.229 €/m² with a median of 2.839 €/m² ($n=56$) resulting in 14,21 Mio. €/lane.km and a median of 12,62 Mio. €/lane.km. For rehabilitation, the mean unit prices are 753 €/m² with a median of 605 €/m² ($n=32$) resulting in 3,28 Mio. €/lane.km (median 2,73 Mio. €/lane.km). In contrast to road bridges covering the full range from small to large measures, the tunnel data on rehabilitation consist mainly of small to

medium rehab due to a rather young asset stock in Austria. With extensive distress type and M&R measures on asset element level already available, the price database on road assets can be extended even further.

2.3 Unit prices pavement works

In this paper, the unit price analysis of asphalt pavement works covers structural measures which result in a sustained substantial improvement of the pavement condition and a corresponding extension of service life. The analyzed measures cover full-depth asphalt replacement including improvements in the unbound layers as well as partial-depth asphalt replacement (surface and binder layer). Furthermore, surface layer replacement and surface treatments/micro-surfacing are covered. The unit prices are analyzed both based on their cost distribution per square meter as well as the economies of scale unit costs and the total paved area. Together with service lives these economy of scale costs functions is the key to an advanced pavement management with optimal treatment selection, timing, and work-zone length (Donev & Hoffmann 2020, Hoffmann 2019). Typical full-depth asphalt replacements exhibit mean unit prices of 84 €/m² or 0,29 Mio. €/lane.km ($n=95$) with typical asphalt layer thickness from 12 to 18 cm. Treatments with surface & binder replacement show unit prices of 39 €/m² or 0,13 Mio. €/lane.km ($n=166$) and typical asphalt layer thickness of 9 to 12 cm. The replacement of surface layers with a thickness of 3 to 5 cm has mean unit prices of 23 €/m² or 0,074 Mio. €/lane.km ($n=138$). Surface treatments have a typical layer thickness of 1 cm exhibiting mean unit prices of 7 €/m² or 0,023 Mio. €/lane.km ($n=40$). The analysis in Figure 6 shows consistently declining unit costs with increased work-zone length or pavement area as the fixed costs are distributed and a higher efficiency is achieved.

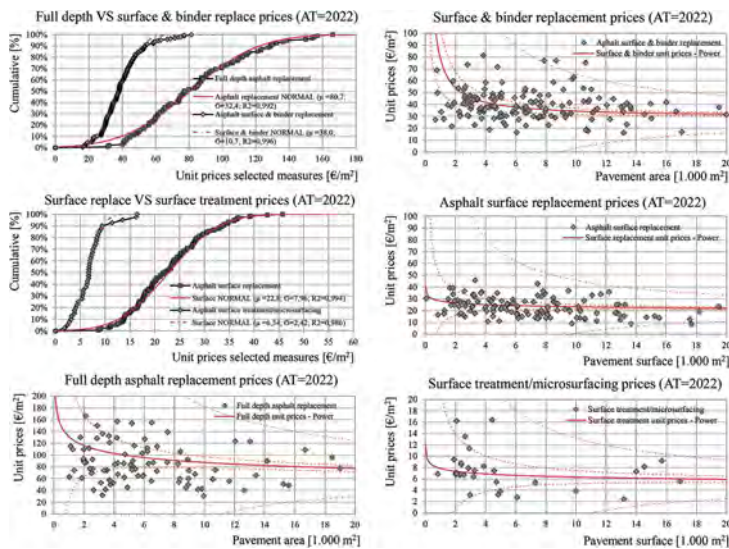

Figure 6. Unit prices pavement measures from full depth to surface treatment (prices 2022).

3 STANDARDIZED LIFE CYCLE COSTS

3.1 Standardized deterministic life cycle

In the fields of transport infrastructure cost-benefit analysis with aggregated condition grades and cost-benefit criteria are employed in Pavement Management (PMS) and Bridge Management Systems (BMS). Since 1970 these approaches have been extended towards considering economic

impacts from “cradle to grave” with deterministic life cycle cost analysis (LCCA). Starting between 1990 to 2000 extensive research has been conducted into the integration of user and environmental aspects in decision making. Due to the stochastic nature of material parameters and loading a quantitative assessment of structural condition, reliability and risk are the main focus in current research on life cycle costing of transport infrastructure (Dhillon 2010, Hoffmann 2019).

With the focus on generalized investment and life cycle costs in this paper the stochastic nature of both construction costs and service lives will not be addressed here. Instead, the emphasis will be on a standardized framework for calculating deterministic life cycle costs of selected road assets based on an extensive costs database. Deterministic continuous models describe a functional relationship between determined input parameters x_i and precise outcomes y_i based on a deterministic function $f(x_i)$ without any variation. In such models, a hypothetical exact relationship between input parameters and outcomes without uncertainty or unknowns is assumed. Thus, a predicted cost or condition performance will always be the same for all assets or asset elements, resulting in identical service lives. In order to account for deviations in asset costs or performance, these deterministic models are commonly aligned (calibrated) to the actual development.

The presented standardized framework for a deterministic life cycle cost analysis in Figure 7 provides the necessary terms, parameters, and formulas to calculate total costs, present value, annual costs, condition performance, and residual asset value. The example shows a comparison of a simple replacement cycle with a rehabilitation prior to failure. In this case, the rehabilitation option yields lower annual costs being the economic solution. The condition performance in the framework is modelled using a power function. The residual asset value is calculated based on the remaining service life of the assets. In the example, the comparison of the investment alternatives shows that there are no sunk costs if assets are still needed and a rehabilitation is efficient. The results of such standardized deterministic life cycles can be used in early planning stages, cost estimations, and asset valuation as well as a validation of M&R recommendations. Furthermore, such standardized deterministic LCC can be extended to full stochastic LCC both at the project and the network level e.g. with a Monte Carlo Simulation (MCS).

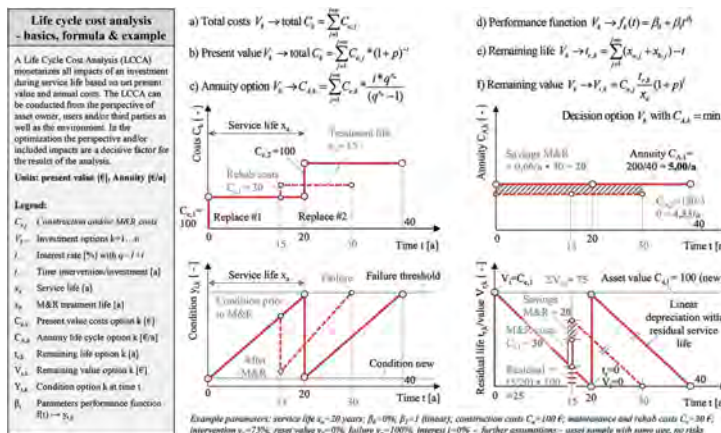

Figure 7. Standardized deterministic LCC with total costs, annual costs, condition, and residual value.

3.2 Standardized deterministic LCC for pavement, bridges & tunnels

The standardized deterministic life cycle costs for pavements, bridges and tunnels build on previous research (Hoffmann 2017, 2019, Hoffmann & Kammersberger 2012) with a largely extended database on costs of road projects from 2022. The standardized pavement life cycle covers planning, construction, crack sealing, surface replacement and a surface & binder replacement as well as operation and administration costs for 60 years (Figure 8). The

resulting pavement life cycle costs on this basis amount to 190-200 €/m², a present value of 120-125 €/m² and average annual costs between 5-6 €/m². For a typical regional road with 7,5 m width this translates into total costs of 1,5 Mio. €/km, a PV of 0,9 Mio. €/km and annual costs of 40 k€/km.

The standardized life cycle costs for road bridges and road tunnels are calculated based on median construction prices, as the costs distributions are skewed due to a few projects with very high unit prices. In the case of bridges, land use, planning, construction as well as small, medium and large-scale rehabilitation until deconstruction are considered in an 80-year cycle. The total costs including operation and administration amount to 4.800-4.900 €/m², a PV of 2.700-2.800 €/m² and annual costs of 110-120 €/m². The total bridge costs for a typical width of 10 m are thus roughly between 47,5-50,0 Mio. €, a PV of 26-28 Mio. € and annual costs of 1,1 to 1,2 Mio. €/km.

The standardized life cycle costs for road tunnels include land use, planning, construction as well as small, medium and large-scale rehabilitation together with decommission in a 90-year cycle. The total costs including operation and administration amount to 7.500-7.700 €/m², a PV of 4.100-4.300 €/m² and annual costs of 160-180 €/m². The total tunnel costs for a typical width of 10 m can be estimated with 75-77 Mio. €, a PV of 41-43 Mio. € and annual costs of 1,6 to 1,8 Mio. €/km. Although the presented standardized life cycle costs of pavements bridges and tunnels consider construction costs on highway level as well, the provided estimates mainly address the regional road network. For highways the provided life cycle costs would be at least 10-20% higher mainly due to the safety and environmental standards as well as significantly higher operation and administration costs.

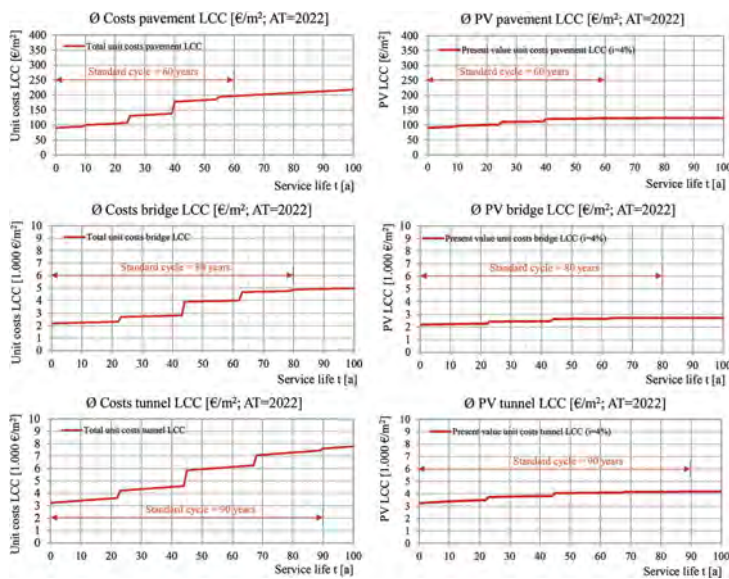

Figure 8. Standardized life cycle costs road pavements, bridges & tunnels in Austria (prices 2022).

4 CONCLUSIONS

The estimation of investment costs of road projects is a key task at every stage of planning and implementation. From the initial project idea to detailed planning and legal approval, the costs of transport infrastructures play a decisive role for investors, authorities, and the public. Despite their importance in many cases the provided information is based on rather rough estimation instead of a thorough statistical analysis. The presented research aims to close this

gap providing the basis for a reliable estimation of investment costs from road projects to single assets. Furthermore, calculating LCC from single assets and projects up to entire networks is of increasing importance to determine budget needs, preserve asset value, and define contracts between stakeholders. In all cases, systematic methods and a large database on road projects and specific measures with unit prices and impact duration are needed to provide a sufficient basis for estimation and validation.

Apart from individual circumstances of projects it is important to understand the principal connection between costs factors and the development of construction costs and prices. Adjusted prices for different regions and years of construction are a crucial precondition for any cost estimation and validation. Based on extensive research and projects on regional roads and highways in Austria over the last two decades, the paper provides unit construction and rehabilitation prices for highways and regional roads for the reference year 2022. Furthermore, the unit prices on asset level for construction and rehabilitation works on road bridges and road tunnels are given. The analyzed pavement measures cover surface treatments, surface layer replacement as well as partial-depth and full-depth asphalt replacement with local improvements in the unbound layers.

Beyond construction prices, the paper shows a framework for calibrated standardized deterministic life cycle costs. The provided terms, parameters, and formulas allow a simple calculation of total costs, present value, annual costs, condition performance, and residual asset value. Drawing on previous research and an updated database on construction and M&R measure unit prices from 2022, the paper provides standardized life cycles for pavements, bridges and tunnels in Austria. The provided total costs, present value and annual costs are a sound basis for the validation of project cost estimates, asset valuation and investment decisions. As standardized distress catalogues and M&R measures for all main road assets have already been developed, the next step will be the extension and implementation in an asset management software.

ACKNOWLEDGEMENT

The presented research on cost estimation and life cycle costs of road assets was not funded by others sources or third parties and is largely based on the methods and database from previous research. As a basis for several national guidelines on cost estimation and cost-benefit analysis the price database was largely extended in 2022 thanks to data from regional road administrations of Carinthia, Styria, Upper and Lower Austria as well as the highway operator ASFINAG. Without these valuable contributions the provided results would not have been possible.

Legal governance for BIM – rights management and lawful data use

B. Weber

Institute for Information Systems, Hof University, Hof, Germany

M. Achenbach

Office for Structural Safety, LGA, KdöR, Hof, Germany

ABSTRACT: The use of BIM-modeling (BIM) within the building life cycle depends on different (specialist) models as well as a detailed as-built-model. The legally compliant transfer of data and models is decisive for the vision of a consistent use of BIM. Past legal research has mainly dealt with the question of copy and IP rights in contracts. The new EU legal framework of data law is now a game changer as codified legal rules for data use are on their way. The paper will reflect these requirements and link them to the relevant ISO norms. The paper will show how legal governance of BIM-models can be designed by a consistent model rights management which is linked to the technical delivery of information and present guidelines for a legally compliant transfer of BIM-models and data, promoting the trustworthy sharing of data and models within the building life cycle.

1 OBSTACLES FOR COMPLIANT DATA USE IN CONSTRUCTION LIFE CYCLE

1.1 *Legal uncertainty as inhibiting factor of model exchange*

Sharing data and the exchange of BIM-models as “shared digital representation of a built asset to facilitate design, construction and operation processes to form a reliable basis for decisions” (DIN EN ISO 19650, hereinafter: ISO 19650) is often declined by participants of the building process referring to legal uncertainties. Changing paper-based or pdf-based (planning) to BIM, questions as the authentication of participants and the integrity of documents as well as the description of BIM-model rights within the construction life cycle arise. Moreover, sharing data including BIM-models in a common data environment (CDE) must be designed according to new EU Law. “CDE” is defined by ISO 19650 as agreed source of information for any given project or asset for collecting, managing and disseminating information through a managed process, whereas the term “data space” is used in a wider sense as market for data, data products and services (European Commission 2020).

1.2 *Different special models in the construction life cycle require open rights management*

The use of BIM within the complete building life cycle depends on different (specialist) models, i.e. planning models, structural engineer models and technical building equipment models as well as a detailed and correct as-built-model (Borrmann et al. 2021). There exist two general approaches to organize the rights management according to copy right and design law. In theory, a BIM-model could be created and then enriched by information of subsequent adaptations. Legal consequence would be installing one rights holder of one holistic model seeking to achieve all license rights for his legal entity. Any new model, i.e. of the structural engineer subsequently to the architect, would be legally based on the original model and then seen as a mere adaptation or transformation of the original model requiring consent of the original model author and/or holder of the right to exploitation.

A different approach prefers the use of linked models (Beetz et al. 2021; Scherer et al. 2014). From the legal perspective, linked models are easier to handle although rights of exploitation must be spread over different legal entities. Different models implicit the existence of different authors as rights holders and require therefore a rights management while transferring the BIM-model. If the use of BIM-models is limited to one contractual relationship within the planning period, i.e. between an architect and the builder or the general contractor, participants in the building period will not get all sufficient rights to use the model. In any case, there won't be a rights transfer to the period of use or reuse of a building as builder and operator of the building will often differ. Consequently, the transfer of rights must be agreed for contractual as well as subsequent purposes which go beyond the legal entities of contracting partners.

1.3 *Gap between delivery of models, technical and legal information*

Codified law and contractual agreements create legal obligations which are often not integrated into the technical processes. This creates harmful effects on the one hand as liability for contract breaches may arise. On the other hand, value-adding activities as sharing data or models are not undertaken due to the unclear legal situation although data sharing rights had been conceived. The separation of technical and legal information creates a serious obstacle to the use of a BIM-model during the construction life cycle. As long as the legal information is only stored in the frame of the contractual relationship of the initial participants, it is not very likely that the legal information will be transferred from planning to construction and then to operation requiring each a separate contract with the subsequent participant of the construction process. The separation of legal and technical information will also impede the use of the legal information for the "Digital Building Pass" and for possible conversion of buildings and therefore decline the sustainability of construction life cycles. The use and documentation of rights will only be successful if the legal information is handed over with the technical information within the complete life cycle, e.g. by annotated IFC-files. Three hypotheses are presented in this paper:

- (1) Legal uncertainty can be solved by a standardized Data Governance Model and rights management.
- (2) Data Governance and rights management should be developed from a legal-entity based to an open data ecosystem-oriented perspective.
- (3) The fulfilment of legal Data Governance and rights management can only be secured if legal data are transferred parallel or inclusive to technical data and models.

The paper will show how legal uncertainties can be resolved by a structured rights management as well as sharing data based on a legally compliant Data Governance model respecting the new EU legal framework. It will also demonstrate that data spaces within the complete construction life cycle depend on an open rights management enabling data sharing outside the limits of a contractual relationship. In Section 2 a brief description of the legal and interdisciplinary research method is given. The governing legal framework is analyzed in Section 3. Proposals are made in Section 4 to include the legal information into the general information delivery within construction projects. Finally, the results are summarized in Section 5. The paper does not deal with questions of liability apart from the rights management.

2 METHODOLOGICAL APPROACH

2.1 *Legal doctrine and interdisciplinary approach*

"Legal doctrine means the description and explanation of legal groundings and solution schemes for the law applicable. It seeks to explain the law by analyzing code regulation, jurisprudence and legal sciences based on a system of sentences as definitions and principles. In contrast to natural or technical sciences, normative criteria can be described and discussed but not verified as true or false." (Weber & Achenbach 2023). Legal research as normative science seeks to explain and justify ratio of value decisions and hierarchies (Möllers 2020). New technologies must be searched and interpreted in the light of existing or upcoming legislation. The method of legal doctrine was applied in this paper in the context of new technologies sharing data and models, i.e. BIM, as well as a new legislative framework of EU law regulating the use and sharing of data.

The interdisciplinary approach means applying methods of different disciplines aiming not only to set up multidisciplinary perspectives but to integrate them in order to resolve complex problems and create a better understanding of them (Repko et al. 2021; Roberts 2017). The research of technical norms and standards is mainly technical. Models and structures represent knowledge which can be transformed to information, e.g. by norms and standards. The combination of the technical models with the perspective of the legal doctrine aiming to integrate legal requirements into the technical process can create an interdisciplinary research approach (Weber & Achenbach 2023). In this way the structured compliance approach as transforming material law into technical processes creates an interdisciplinary method itself (Weber 2020).

According to the method described above, the codifications of IP rights, especially copyrights, have been analyzed including their traditional implementations in bi- or trilateral contracts. Secondly, the upcoming EU legal framework of data law, i.a. the Data Governance Act (DGA), has been considered with focus on the legal requirements of sharing data in data economies and of transferring BIM-models accordingly. In a third step, the existing bundle of technical and organizational standards related to information management in the construction sector has been researched as they state practical and technical sharing of data and delivery of information in a CDE as well as the question of handling BIM-models.

2.2 *Further development of data governance and rights model*

Whereas data governance is part of research in different disciplines since years (see Mahanti 2021 with a literature overview), legal data governance is an upcoming research field as the codification is just on its way (see below in section 3.2.). Some authors still deny the necessity of a general data law widening the existing data protection law (Kühling 2021). Based on a structured compliance approach, Weber has developed a data governance and rights model which implements the legal and ethical requirements in a holistic way aiming to include all legal disciplines, i.e. data law, data protection law, IT-law, competition law, antidiscrimination law as well as sustainability and ethics (Weber & Gernert 2022). This model was already linked to the postulate of “data sovereignty” within the construction process (Weber & Achenbach 2023) and was widened to the transfer of data and models in a CDE by the current research.

3 ANALYSIS OF LEGAL FRAMEWORK AND RELATED RESEARCH

3.1 *Intellectual property rights and contractual implementation*

xPast legal research and practice about BIM have dealt with the question of Intellectual Property (IP) and copy rights as well as their implementation in contractual provisions because a codified legal framework of data use and data rights was missing (Bellenger & Blandin 2019; BIM4INFRA 2020; Eschenbruch 2019; Klemm-Albert 2018; Richard 2020; Wessendorf 2019). It is no surprise that the indication of the missing or rudimentary codified legal framework for BIM in the field of construction law comes from French and partially German literature (Richard 2020; Weber & Achenbach 2023) as both countries are mainly governed by codified law in contrast to the Common Law governed countries as US and UK which are mainly based on case law. Whereas the legal work in the construction domain concentrates more on technical standards and norms below the level of codification, the field of general data law is still enlarging tremendously since the last wave started with the General Data Protection Regulation (GDPR) in 2018, followed by the DGA in 2022 and the draft of Data Act in 2022. The handling of BIM-models has therefore to be widened from the mere contractual to a holistic perspective of codified data law and technical standards.

3.2 *EU legal framework for data governance*

3.2.1 *Definition of data governance*

Data governance in general can be defined as a system of policies, rules, standards, processes, practices and structures, roles and responsibilities, controls, and decision rights to oversee the

management of data. It should not be confused with the technical management of data. Legal data governance is currently not defined by law. On 30 May 2022 the EU has adopted the so called “Data Governance Act - DGA” which will be applicable by 24 September 2023 for new and by 24 September 2025 for existing data intermediators (European Parliament & Council 2022). As the DGA does not provide a definition, legal data governance was defined by Weber (Weber & Achenbach 2023; Weber & Gernert 2022) as the legally compliant handling of data as part of the corporate governance or process compliance. A legally compliance data governance model therefore includes six dimensions of legal model check: (1) the compliant use of data, (2) data protection, (3) data quality, (4) data security as well as the (5) observance of competition law, IP rights, trade secrets (and other relevant law) and (6) the ethical, sustainable and non-discriminatory use of data including transparency and explainability of data use and methods. As the paper focusses on the legally compliant use and transfer of BIM-models with the construction life cycle, the aspects of data governance are described as follows: lawful data use which means sharing the BIM-data legally in a CDE and building up data infrastructures according to the DGA and a rights management handling the rights of the participants legally according to their contribution and role in data spaces within the complete life cycle of a building.

3.2.2 *Legal provisions of DGA for handling BIM*

Data Governance and compliance have been addressed as important aspects of digitalization of the construction sector (Weber-Lewerenz 2022). Data Governance for BIM was discussed even before the DGA was enacted (Alreshidi et al. 2018). The requirements of the DGA for BIM has been treated by the authors regarding data sovereignty within the construction process (Weber & Achenbach 2023). At first, the DGA regulates the exchange of data aiming to promote data sharing of sovereign data owners while separating data intermediation and the use of data (Art. 12 DGA). Data intermediation services are those which establish commercial relationships for the purposes of data sharing between an undetermined number of data subjects and data holders on the one hand and data users on the other. There are two important exemptions to the application of the DGA. The obligations of data intermediates do not apply to data services of aggregation, enrichment or transformation aiming to add substantial value to them and license the use of the resulting data to data users, without establishing a commercial relationship between (an undefined number of) data holders and data users. Secondly, the DGA is not applicable to closed contractual relationships (Art. 2 par. 11c DGA). This includes services which are exclusively offered to one data holder in order to enable the use of “his” data and services that are used by multiple legal persons, but in a closed group. Consequently, supplier or customer relationships and collaborations established by contract do not have to fulfill the provision of separation of services and data. Applying DGA to CDE and BIM, the relevant question is the open structure of the data sharing. BIM is enrolled in four variations (Borrmann et al. 2021) as described in Figure 1.

From the legal perspective the level of data exchange is decisive: “Little closed BIM” as an insular solution has the legal consequence that no data sharing with other legal entities is to be agreed upon, and the DGA is not applicable. “Little open BIM” can be within the scope of the DGA if the specialist model and data are shared multilaterally. “Big closed BIM” is excluded from the provisions of DGA if it is limited to a certain construction project with mutual but closed legal relationships. This leaves the main field of application of DGA in BIM for “Big open BIM” with the establishment of a CDE in open structures.

3.3 *Technical norms and standards referring to BIM*

Standardization organizations have set up certain norms regarding information management in the construction sector including BIM. ISO 19650 seeks to support the collaboration of stakeholders in the building life cycle. Rights management of data and IP rights are only linked to the contract management. Legal data governance is currently not included in the exchange information requirements. Nevertheless, information shall be stored in a suitable knowledge store for the use in future projects. This creates the obstacles described above for the open use of data beyond the current project. The DIN EN ISO 16739 (DIN EN ISO 16739-1) introduces the IFC classes for data sharing in the construction and facility management industries as

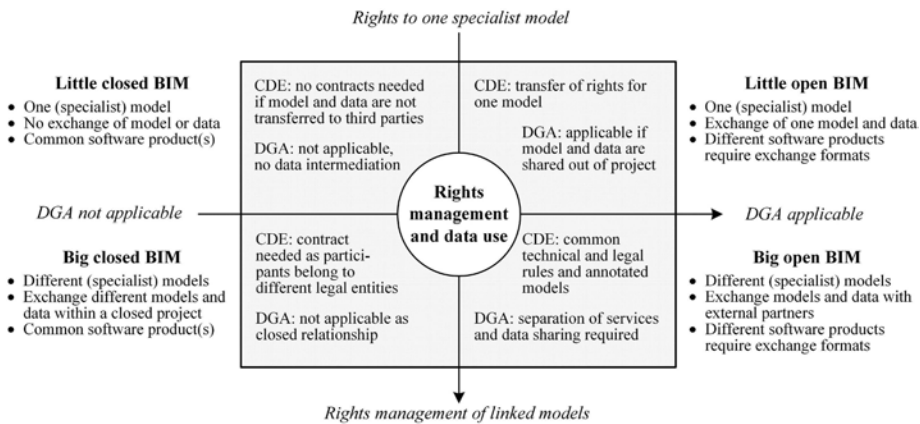

Figure 1. Rights management and application of DGA for different variations of BIM.

an open standard using XML for the data schema. The readability of XML as a text-based format bears the potential of transferring legal information in metadata. An automated rights management should therefore be compliant to IFC-based data sharing according to ISO 16739. Draft of ISO 17549-1 (DIN EN 17549-1) contains rules for BIM-modelling regarding the information structure to exchange data templates and data sheets for construction projects. Data exchange can take place including attributes as geometry, technical specifications, official requirements and economic aspects. Object association enables to associate sources of information such as documents, approvals or constraints to object definitions. Document association means to associate documents to objects indicating external files. Documents could even be referenced to their entirety, e.g. data sheets or product brochures. This means that document association would also work for associating legal materials, e.g. license sheets. The draft states that typical document meta data such as issue date, editor etc. could be covered by association whereas the document content would remain with the external files. This could reduce the volume of data exchange.

4 IMPLEMENTING LAWFUL DATA USE AND RIGHTS MANAGEMENT INTO INFORMATION DELIVERY AND LINKED MODELS WITH BIM

4.1 Compliant use of data

4.1.1 Data sharing and/or data intermediation according to DGA

The DGA applies to data spaces or infrastructures irrespective of the question if a platform or any virtual data environment is created. The DGA provides that data intermediaries are not entitled to offer data and services in one technical infrastructure by the same legal entity. The DGA therefore applies to the creation and transfer of BIM-models within a CDE, as BIM includes the design of a BIM-model as a service and the transfer and sharing of the respective data. There exist two possibilities to organize a construction project in a CDE compliant to DGA:

- (1) Operating the CDE in a closed project environment including all participants bound by contracts or
- (2) Separating the role of sharing data to an undefined number of participants (data hub) from offering services as designing a BIM-model (service hub).

Services as designing an architecture model or structural planning must then be provided by the stakeholders directly or via a platform being a separate legal entity from the data intermediary (service hub). BIM-models as result of planning services could be stored in decentralized information containers (Schmid & Blandini, 2021). The technical implementation has already been described according to ISO 19650 (Hagedorn et al. 2022). Separation of data and model can be handled via information referencing to an external information source (model referencing information) (Klemt-Albert & Bahlau 2017).

Figure 2 shows that CDE as “Big open BIM” can also be established compliant to DGA by a centralized data sharing while separating data and services in two hubs. If no separate service hub will be created, planner and other BIM service provider must offer their services decentralized, sharing only the data representing the models created as results of their services by the data hub, not the services themselves (Weber et al. 2023). A platform as data hub could support the stakeholders in acquiring data as asset-information and other resources. Essential prerequisite of the data hub is neutrality which creates trust and acceptance of the data holder and data user. Data cooperatives or adequate corporate structures could serve as trustworthy data intermediators.

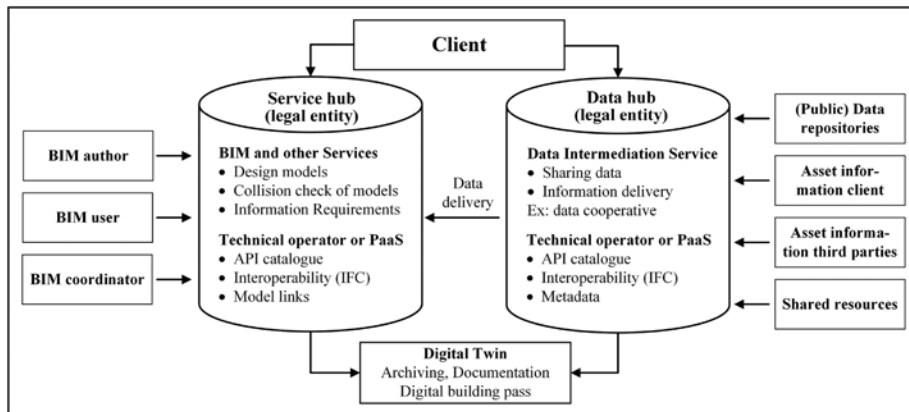

Figure 2. CDE separating services and data intermediation compliant to DGA; (PaaS: platform as a service).

4.1.2 Collision check of models as service

According to the provisions of DGA the check of model conflicts by the BIM-coordinator in open BIM is difficult to handle. On the one hand, the BIM-coordinator merges data from different sources and models which could create a role of intermediation. On the other hand, the BIM-coordinator himself offers the service of coordination and clash detection. Again, only data should be shared via the data hub while communicating the modification requirements of a model which are versioning, result of collision check etc. If practice shows that separation of data exchange and clash detection service will not work, the BIM-coordinator must fall back into the closed structure of a construction project. In both cases, the BIM-coordinator is not entitled to share data out of the project. Otherwise, he takes the risk to slide into the role of a data intermediary being forced to refrain from his services of coordination and model check.

4.1.3 Attribution of files exchanging data

Data sharing via decentralized, federated information container aiming to share data and BIM-models requires common standards in a CDE (BuildingSMART 2022). Challenges in decentralizing the data storage are a persistent, transparent storage management where data are up-to-date and findable by common formats and attributes. As shown above, technical standards, (open) data formats and common standards for the description of meta data as type of file, indexing and description of rights as comments in properties or attributes are suitable for legal information and should be agreed upon in the information exchange requirements. The exchange of IFC-files show that different attribution fields complicate the data exchange. If one field is marked as optional and the other participant rejects optional fields, data exchange won't work or at least not mutually (Borrmann & Koch 2021). Therefore, legal information should be linked to data drops obligatorily.

4.1.4 Legal authentication by qualified electronic signatures BIM- and XML-files

Personal signatures have the function of authentication of the author, integrity of the document and content proof. The signature must be tightly linked to the document. Paper-based documents can be annotated by handwriting and fulfil the said requirements. The legal requirement of authentication of BIM-authors or other annotating persons can be fulfilled by a qualified electronic

signature (QES), Art. 25 par. 2 (eIDAS 2014). The QES is based on an asymmetric encryption including a public and a private key. The certificate must be issued by an accredited certification provider. Signing a BIM-File by QES, i.e. an IFC-file, would meet the legal form. If a BIM-model should be annotated, i.e. by building permission authorities or for a structural safety check, the annotation of the original IFC-file would be saved to an XML-file which again have to fulfil the legal requirements which is to say a QES to be documented, i.e. signature element. Message integrity as non-alteration of parts of the content after signing and authentication as proof of possession are guaranteed. The trustworthiness of the certificate can be checked by the receiver (IBM 2022).

4.2 Rights management: Intellectual property rights and business secrets

The most preferable solution of BIM-rights management would be the integration of a standardized data and rights management scheme for metadata in relevant ISO norms. Limitation of data rights including business secrets and time limits could then be commented and serve for the rights management based on a standardized rights-and-role-concept. Until a common standard will enter into force, the rights management must be imposed by contract aiming legal certainty, preferably also via standardized contract templates which reflects the metadata descriptions.

5 CONCLUSIONS

The use of BIM for the description of the whole life cycle is based on the idea that models are enriched with information and can be passed over to subsequent steps. This requires a solid legal framework to share data. Data governance and rights management will only be legally compliant and to handle in practice within the complete construction life cycle, if data sharing and transfer of BIM-models include the technical and legal information shared. Standardized description of specialist models and typical data and rights management by standard contract clauses are a first step. Aiming the use and re-use of legal data in the whole building life cycle, legal data governance and legal information have to be included in the exchange information requirements to reach practicability. Technical data must be attributed at least with a legally binding description of (1) model or data task (2) quality, (3) author and (4) license information. Relevant information must be presented to the model user.

Further interdisciplinary discussions will focus on the practicability of implementing the legal information into the meta data attribution scheme, i.e. the relevant field of IFC-attribute, preferably not an optional but mandatory field of data exchange, as well as into link-models, i.e. into the index file or the creation of legal information containers.

Advanced life-cycle assessment of reinforced concrete bridges using digital twin concept

J. Rymeš, J. Červenka, M. Herzfeldt & R. Pukl
Červenka Consulting s.r.o., Prague, Czech Republic

ABSTRACT: This paper proposes a concept for enhancing the maintenance of aging reinforced concrete bridges using online bridge monitoring system coupled with advanced non-linear numerical modelling. Based on the on-site measurement data, a calibrated non-linear numerical model is developed and then further used for the simulation of the degradation mechanisms, such as chloride-induced reinforcement corrosion. This allows assessing the reduced structural load-bearing capacity and thus predict the rate of structural degradation. An example pilot study is presented showing the development and application of the digital twin for a two-span reinforced concrete bridge. The obtained numerical data are discussed and evaluated within the framework of the valid *fib* Model Code standard.

1 INTRODUCTION

In light of the ongoing climate change, the requirements for better environmental sustainability in the concrete industry becoming more and more urgent. It is estimated that the ecological footprint of the cement clinker production is up to 7 % of the total man-made CO₂ (Barcelo et al., 2014). Furthermore, as the World is still recovering from the COVID-19 pandemic, the global economy stagnates, and many contractors face a supply shortage of construction materials. Therefore, there is a demand for a long service life of the existing civil structures.

On the other hand, the long-term degradation acting on reinforced concrete bridges may compromise the serviceability and even safety of the civil infrastructure. One of the means how to face this issue is the development of computational models capable of estimating the impacts of long-term degradation on structural performance.

In this study, we present a pilot application example of a coupled system used for online bridge monitoring and subsequent advanced non-linear finite element (FE) simulation. Then, models for chloride ingress and reinforcement corrosion are incorporated into the FE static analysis, which allows for estimating the response of the structure affected by a chloride attack. By varying the duration of the degradation, the structural load-bearing capacity can be assessed at several stages of the structure's service life. Finally, the reduction of the design structural resistance in time is evaluated based on the method implemented in the *fib* 2010 model code for the safety assessment by nonlinear analysis.

This paper extended the previous study (Červenka and Rymeš, 2023) by implementing the reinforcement bond properties into the model and modifying the loading protocol used for the numerical simulation.

2 ON-SITE DATA ACQUISITION

2.1 *Vogelsang bridge*

The on-site data were measured on a two-span section of the Vogelsang Bridge located in Esslingen am Neckar, Germany. The monitored part represents a reinforced concrete bridge with spans of 13.8 m and 13.2 m. The girder has a constant height of 0.6 m.

The bridge is loaded by the traffic loads and subjected to deterioration mechanisms from the external environment, mainly carbonation of the concrete cover and the chloride attack due to the use of the de-icing salts for road maintenance in the winter period. Both these mechanisms gradually reduce the pH concentration in the concrete and may eventually lead to reinforcement corrosion and thus reduce the mechanical performance of the structure.

2.2 Bridge monitoring

The bridge monitoring was conducted within the framework of the European cyberBridge research project (www.cyberbridge.eu). The data acquisition took 61 days from January until March 2019. The iBWIM (Bridge-Weigh-In-Motion) system was provided by Petschacher, ZT-GmbH, and consists of strain gauges installed on the underside of the bridge deck coupled with a laser rangefinder for detecting the passing traffic. Coupling the structural monitoring sensors with traffic detection allows for obtaining the data needed for structural assessment as well as daily traffic data.

The sensitivity of the system is suitable for monitoring traffic with a gross weight above 3.5 t. Before the data acquisition, the monitoring system was calibrated by trucks of known weight. Further information about the bridge monitoring can be found for instance in reference (Červenka and Rymeš, 2023), including examples of the obtained data. These on-site data were further used to calibrate the numerical model.

3 NUMERICAL SIMULATION

3.1 Non-linear numerical modelling

A non-linear FE model for structural analysis of the bridge was developed using the ATENA software (Červenka, Jendele and Červenka, 2022). The software allows realistic simulation of the material behaviour, including concrete cracking in tension or crushing in compression according to the material model developed by Červenka et al. (Červenka, Červenka and Eligehausen, 1998) and Červenka and Papanikolaou (Červenka and Papanikolaou, 2008). In this model, the softening after tensile cracking is evaluated based on the amount of dissipated fracture energy using the smeared crack approach with a crack band while the plasticity approach is used for the simulation of concrete crushing in compression. Reinforcement can be implemented either as smeared or discrete while its material response follows a multilinear stress-strain diagram allowing simulation of reinforcement yielding or even rupture.

Figure 1. Finite element model of the Vogelsang Bridge.

These advanced numerical techniques can be applied in the development of a digital twin of the bridge. This concept is used in many engineering fields to simulate the behaviour of a real product. A suitable tool for covering the structural performance aspects of the digital

twin is the application of the non-linear FE method. Such an approach allows for the simulation of crack propagation in the model thus providing a realistic structural response. In this context, a non-linear FE model capable of simulation of long-term deterioration mechanisms represents an important step towards utilising the digital twin concept in the field of structural engineering and aging management.

The FE model of the Vogelsang Bridge is shown in Figure 1. The model was calibrated using the on-site measured data, mainly the information about the weights of the truck and the strain it induces when crossing. Further information can be found in reference (Červenka and Rymeš, 2023).

3.2 Chloride ingress and reinforcement corrosion

In the case of reinforced concrete bridges, one of the main degradation mechanisms reducing the structural performance is the use of de-icing salts for route maintenance during the winter season. The chloride ions presented in the salts gradually penetrate the concrete microstructure towards the steel reinforcement, which leads to a decrease in the pH level. Eventually, as the alkalinity of the concrete decreases, the corrosion protective function of the concrete cover is lost, and the reinforcement corrosion is initiated leading to the reduction of its cross-section. In the ATENA software, this mechanism is simulated with a chloride ingress model coupled with a reinforcement corrosion model.

The chloride transport through the concrete porous system is a combined diffusion/binding process as the transported ions are absorbed into the C-S-H gel or precipitate as new compounds within the concrete microstructure (Taylor, 1997). In engineering practice, this is commonly modelled using the diffusion equation with a time-dependent diffusion coefficient. Additionally, when cracks occur in the concrete cover as a result of mechanical loads, chloride transport is accelerated. In the case of the structural calculations, as the chloride transport is limited to the regions below the surfaces subjected to the chloride attack, the chloride penetration can be simulated as a 1D diffusion process. Such an implementation reduces the time needed for the solution of the diffusion problem, which reduces the overall computational time.

During the calculation, chloride concentration at the depth of the reinforcement is checked and once it exceeds a critical level, the reinforcement corrosion is initiated. Its rate depends on the chloride concentration, temperature conditions, and the duration of the corrosion process. Since the corrosion products are larger in volume than the uncorroded steel, the pressure builds up in the concrete cover, and eventually spalling of the cover occurs. In the corrosion model, this is considered by evaluating the corrosion depth against the tensile strength of the concrete and once the spalling occurs, it is assumed that the corrosion process continues at the rate controlled by conditions of the external environment.

The long-term chloride attack is simulated in multiple steps during this calculation. At each step, the degree of corrosion is calculated and then used to reduce the cross-section area of the reinforcement elements in the model. Based on this, a new static equilibrium is found and the crack width is updated. In the next solution step, the updated crack width is used to accelerate the chloride diffusion process.

The implemented models are mainly based on the research of Liu and Weyers (Liu and Weyers, 1998) and the recommendations published in the DuraCrete report (The European Union–Brite EuRam III, 2000). Further details about the simulation of the chloride penetration and the reinforcement corrosion and how it is implemented into the static FE calculation can be found in the reference (Hájková *et al.*, 2016), including validation of the approach.

3.3 Reinforcement bond

In the case of FE simulations of reinforced concrete structures, either smeared or discrete reinforcement modelling is generally used. In the case of the smeared reinforcement, the cross-

section area of the reinforcement is assumed to be smeared over the entire thickness of the concrete solid element thus effectively increasing the element's tangent modulus. Compared to the smeared modelling, discrete reinforcement modelling introduces additional one-dimensional finite elements in the model, which correspond to the actual reinforcement placement in the structure. During the analysis run, the strain continuity between the solid concrete elements and the 1D reinforcement links is assumed during the assembling of the stiffness matrix; however, in a real concrete sample, a slip between the concrete and reinforcement may occur.

For sufficiently fine meshes, the strain discontinuity between the concrete and reinforcement can be simulated as cracking of the elements surrounding the discrete reinforcement elements. It has been shown that this approach can reproduce the crack patterns and the crack width obtained in laboratory experiments if fine elements of the size of several centimeters are used (Cervenka *et al.*, 2022). However, in the case of typical engineering applications, the mesh size is often one or two orders higher. Such course meshes cannot adequately capture the localization process of the fine microcracking around the steel reinforcement bars. Therefore, to capture the bond-slip in engineering simulation, an additional degree of freedom is added to represent the slip between the steel. The bond strength-slip law then enters the simulation as a non-linear material constitutive law, which needs to be met during the iterative solution.

The bond strength-slip material law used in this study was based on the fib MC 2010 standard (International Federation for Structural Concrete, 2013). Furthermore, as the goal of the numerical simulation is to assess structural degradation due to reinforcement corrosion, the relationship between the reinforcement corrosion and relative bond strength by Bhargava *et al.* (Bhargava *et al.*, 2007) was used and is plotted in Figure 2.

Figure 2. (left) Reinforcement bond strength-slip function for the calculation with mean and characteristic material properties and (right) relative function for reducing the bond strength as a function of reinforcement corrosion (Bhargava *et al.*, 2007).

3.4 Analysis workflow

In the case of non-linear analyses, the structural response under a given load combination cannot be assessed as a simple superposition of the given load action as in the case of linear calculation. As the load induces irreversible material response mainly in a form of tensile concrete cracking, each sequence of load applications induces a unique structural response. Therefore, the application of load in a non-linear numerical model should respect the load sequence of the real structure. Furthermore, as the mechanical crack width influences the rate of chloride ingress, the load level also affects the rate of degradation when exposed to the chloride attack.

In this study, the investigated load combination at the ultimate limit state (ULS) includes the permanent load actions (i.e., the dead loads) and the variable load actions (i.e., the distributed and concentrated traffic loads). For the durability study, the following sequence of load intervals was used to simulate the service life structural history:

- 1) Design dead loads: self-weight and other dead loads,
- 2) Design live loads: concentrated and distributed traffic loads,
- 3) Unloading design live loads from 2),
- 4) Simulation of the chloride degradation,
- 5) Overloading with design live loads.

The application of the ULS design loads in intervals 1) and 2) should simulate a critical overloading situation, which may occur during the structure's service life. In the non-linear model, such an event results in crack development. On the other hand, the long-term degradation mechanism act on the structure at lower loads than the USL design load level thus the application of the chloride attack at the ULS load level may overestimate the real situation. Therefore, the model was unloaded to the design dead load level, which resulted in a partial reduction of the previously localized cracks. Subsequently, the chloride attack with a duration of 25, 50, 75, 100, 125, and 150 years was simulated. Finally, the live loads were again gradually applied until reaching the peak load.

3.5 Safety framework

The results from the non-linear calculations were evaluated based on the *fib* MC 2010 standard (International Federation for Structural Concrete, 2013), which permits the application of non-linear simulations for structural assessment. It is worth mentioning that a similar approach is about to be introduced into the new generation of Eurocodes.

Generally, the safety method can be divided into three categories: full probabilistic, global resistance, and partial factor methods. In this study, the ECoV method, which belongs to the global resistance category, is applied. The general design requirement specifies that the design structural resistance (R_d) should be greater than the effects of the design loads (E_d). Therefore:

$$E_d < R_d. \quad (1)$$

The underlying assumption of the ECoV method is that the structural resistance follows the log-normal distribution, which can be described by the mean (R_m) and characteristic (R_k) structural resistances. These values can be obtained by two analysis runs, one using the mean and one using the characteristic parameters for the applied material models. Then, the coefficient of variation (V_R) of the structural resistance can be calculated as:

$$V_R = \frac{1}{1.65} \ln \left(\frac{R_m}{R_k} \right). \quad (2)$$

The global resistance factor (γ_R) is calculated as:

$$\gamma_R = \exp(\alpha_R \beta V_R), \quad (3)$$

where $\alpha_R = 0.8$ and $\beta = 3.8$ are the sensitivity factor and reliability index, respectively.

Finally, the design structural resistance according to the ECoV method gives:

$$R_{d,ECov} = \frac{R_m}{\gamma_R \gamma_{Rd}}, \quad (4)$$

where γ_{Rd} is the uncertainty of the numerical model. In the case of the ATENA software, $\gamma_{Rd} = 1.16$ for all failure modes (Červenka, Červenka and Kadlec, 2018).

4 RESULTS

A typical outcome of the durability analysis is shown in Figure 3 using the model with mean material characteristics and a 150-year-long chloride attack. The crack patterns in concrete are shown for several stages of the calculation. First, when the ULS design load is applied, maximum cracks of approximately 0.3 mm open in the mid-span and above the center piers of the bridge. Upon unloading to the design dead load level, these cracks partly close, and their width is mostly below 0.1 mm. At this stage, the chloride penetration and subsequent reinforcement corrosion are simulated on the top and bottom surfaces of the bridge deck. As a result, the reinforcement cross-section area reduces, the cracks grow, and the mid-span deflection increases. Finally, after 150 years of chloride-induced degradation, cracks of approximately 0.3 mm are predicted in the mid-spans of the decks as well as above the center piers at the design dead load level. As the load level is increased, the reinforcement yielding soon occurs, which results in rapid crack growth. At the peak load, cracks exceeding 3.5 mm are predicted by the model.

Similarly, in Figure 4, the development of the stresses in the discrete reinforcement elements is plotted during the calculation. It can be observed how the reinforcement stress increases as a result of the reinforcement corrosion.

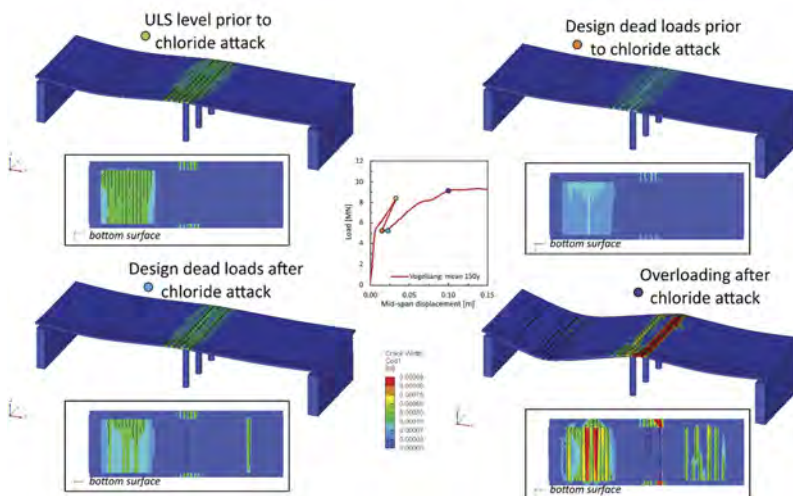

Figure 3. Distribution of the crack width in the concrete at various stages of the calculation for the model with mean material properties and 150-year-long chloride attack (deformation magnified 15x, only cracks larger than 0.1 mm are emphasized).

The structural response for each analysis run can be represented in a form of a load-displacement (L-D) diagram as shown in Figure 5 (left), where examples of curves for models with mean material properties are plotted. As described previously, the load is first increased to the ULS design load level to simulate a critical loading scenario; however, the chloride-induced reinforcement corrosion is simulated at a lower load level. This is exhibited by the increase of the deformation at constant load on the L-D diagram. While for the model of a 50-years-long chloride attack, the degradation is rarely visible, for longer degradation periods, it can be seen how the mid-span deflection increases because of reinforcement corrosion, and subsequently, both stiffness and maximum load-bearing capacity are reduced during overloading simulation.

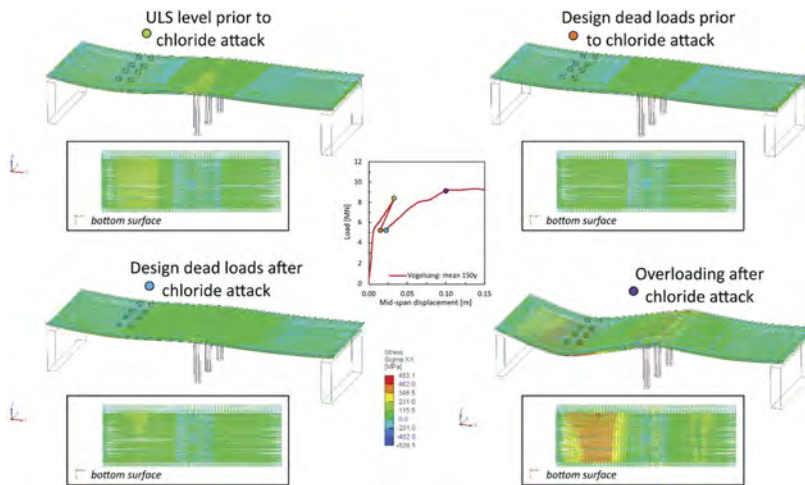

Figure 4. Stresses in the reinforcement at various stages of the calculation for the model with mean material properties and 150-year-long chloride attack (deformation magnified 15x).

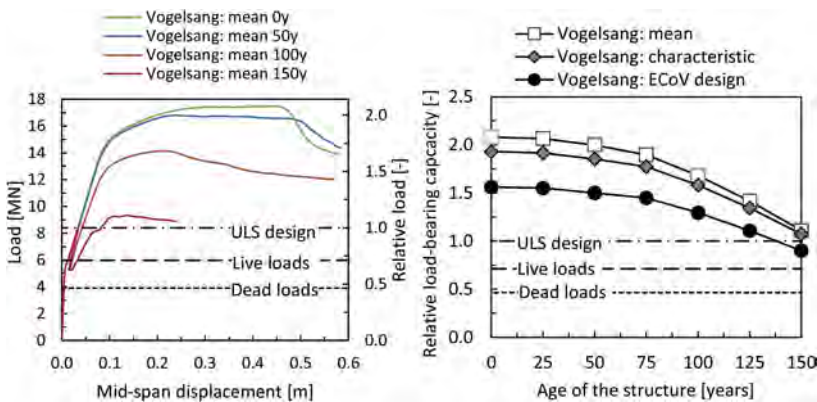

Figure 5. (left) Typical load-displacement diagrams for the calculation with mean material parameters for bridge unaffected by the chloride attack and for chloride attack of 50, 100, and 150 years and (right) reduction of the structural load-bearing capacity in time.

To deduce the design structural resistance, the analysis is conducted with mean and characteristic material properties for each duration of the chloride attack. Then, based on the maximum load from both analysis runs, the design load-bearing capacity is calculated using the ECoV method (see section 3.5) for the given age of the structure. From the plot in Figure 5 (right), it can be observed that the design load-bearing capacity exceeds the ULS design load level until the age of the structure of 125 years.

5 CONCLUSIONS

This study presents a comprehensive approach to the assessment of the long-term structural performance of reinforced concrete bridges. In the first step, a bridge monitoring system is used for the data acquisition from the existing reinforced concrete bridge. Subsequently, this data is used to develop a finite element model of the structure, which can be used for

structural assessment. Furthermore, advanced chloride diffusion model was used to simulate the structure degradation due to the use of de-icing agents. This model takes into account the degradation of reinforcement cross-sectional area and also its bond parameters due to corrosion. The presented approach can predict the reduction of the structural performance in time. The obtained results are evaluated according to the *fib* MC 2010 standard to obtain the design load-bearing capacity of the bridge.

ACKNOWLEDGEMENTS

Sustainable reuse of public real estate assets meeting structural, conservation and territorial needs

G. Concu, D.R. Fiorino & E. Pilia

Department of Civil and Environmental Engineering and Architecture, University of Cagliari, Italy

ABSTRACT: Currently, the recovery of existing buildings assumes a fundamental role, especially the restoration and reuse of the large state-owned properties characterised by significant cultural values, but often underutilised or even abandoned. This wide patrimony can instead represent an opportunity to satisfy the still existing needs of settlements, infrastructures, and services, without further consumption of land. The paper analyses the problem of integrating the conservation-architectural-social criteria for defining new uses of state-owned buildings with the need to meet structural requirements and performance according to current Italian technical standards for construction. A methodological protocol is proposed, based on the definition of sets of indicators, aimed at quantifying the degree of sustainability of new use design hypothesis according to the impact in terms of demand for structural performance upgrading compared with the overall sustainability of the intervention. The methodology application to the case study of a military building is presented and discussed.

1 INTRODUCTION

Approximately 70% of the Italian building heritage, by age, techniques, and construction materials, is approaching the end of its life cycle, and this exposes it to the risks of seismic and hydrogeological vulnerability, to degradation, to energy inefficiency. At the same time, the current European policies of urban regeneration push towards the effective zeroing of land consumption and the sustainability of any building and urban transformation that affects the building heritage (National Council of the Green Economy 2017).

In this context, the recovery of the built heritage assumes a fundamental role and place itself rightfully among the actions promoting sustainable development. In fact, the advantages associated with the reuse of existing buildings involves environmental, economic, and socio-cultural issues. The environmental advantages relate to i) the protection of the built heritage from degradation, ii) the waste reduction, iii) the energy conservation, iv) the reduction of urban decay. The economic advantages relate to i) the reduction of management costs, ii) the boost to the use of local resources, iii) new investment opportunities. The socio-cultural advantages relate to i) the positive impact in terms of job opportunities and income, ii) the promotion and preservation of historical memory, iii) the protection of the historical-cultural identity of places.

In this framework, special relevance assumes the restoration and reuse of large state-owned properties, which in Italy appear to be largely for military use (Fiorino 2021), characterised by cultural values, but often underutilised or even abandoned and which can instead represent an opportunity to satisfy the still existing needs of settlements, infrastructures, and services, without further consumption of land. The issue of the disposal and reuse of historic state-owned assets is very topical and pushes on the one hand to highlight the general institutional stalemate that has led to the abandonment of many assets of great historical value, and on the other to build sustainable reuse scenarios, capable of guaranteeing their conservation and, at the same time, of responding to the pressing needs of containing public spending and identifying new containers of services for the community.

The choice of the reuse scenario, or adaptive reuse, of the asset is a very delicate issue, which involves both cultural, social, and territorial aspects as well as technical, technological, and economic aspects. Morandotti (2012) effectively focuses on the fact that the sustainable refurbishment of the building heritage should be based on an integrated approach that takes into consideration i) the evaluation of the functional compatibility between the reuse and the building, in terms of both the compatibility between the facilities located in the building and the needs of the current users, and the need for regulatory, operating and system adaptation; ii) the prospect of optimizing the building's performance in relation to its material consistency, residual structural capacity, and state of conservation, but with a view to increasing its energy efficiency; iii) the long-term sustainability of the refurbishment, in the sense of minimizing future interventions, through a monitoring strategy aimed at the planned conservation/maintenance of the building. Besana et al. (2018) highlight the concept of resilience, which in case of the historical built heritage means tolerable transformation that an existing building can undergo without the resulting impacts generating undesirable effects. This means that the building can adapt to accommodate the transformations deriving from reuses maintaining its identity, distinguishability, functionality suitable for new uses and respectful of the historical values of the asset.

Several studies propose methodologies to support the built heritage reuse decision-making, analysing the factors affecting adaptive reuse decision-making and developing general models for adaptive reuse strategies for heritage buildings (Aigiwi et al. 2019, Alhojaly et al. 2022, Bertolin & Loli 2018, Della Spina 2021, Mısırlısoy & Günçe 2016, Ribera et al. 2020, Śladowski et al. 2021). However, to the best of the author's knowledge, the literature is lacking with respect to the specific theme of the influence of the residual structural capacity of the building, and the extent of the structural intervention necessary to meet the reuse needs, on the choice of the reuse scenario.

The present paper aims to bring a contribution to this theme by proposing a qualitative methodology to support the decision-making process in which the impact of the structural intervention on the reuse scenario of the asset is made explicit. The methodology, which is divided into a series of steps, is substantially based on the comparative and integrated analysis of i) the structural performance required by the reuse scenario, ii) the residual structural capacity of the asset, iii) the definition of the category of structural intervention necessary to fulfil the reuse scenario demand. The methodology application to the case study of a military building is presented and discussed.

The research illustrated in this paper is part of a larger project, SOS Labs - Research-action laboratories for urban sustainability - funded by the Italian Ministry of Ecological Transition, aimed at supporting the development of the Sardinian SRSvS (National Strategy for Sustainable Development). The research was carried out thanks to a special agreement between the Italian Ministry of Defence and the University of Cagliari.

2 THE METHODOLOGY

The proposed methodology is based on the concept that the choice of possible strategies for the reuse of the asset should necessarily deal with the structural scheme of the building and with the material with which it was built. Therefore, an essential action is the verification of structural compatibility between the current state of the building and the requirements necessary for the reuse scenario, in terms of structural configuration and load conditions. The outline of the methodology is illustrated in Figure 1, which presents a flow chart whose steps are detailed below.

2.1 *Step 1. Identification of reuse scenarios*

The identification of the possible reuse scenarios of the asset derives from the confluence of various factors, among which, i) the possible need to assign to the asset a specific function already identified a priori, ii) needs deriving from the system of relationships that rest on the territory in which the asset is inserted, iii) willingness to satisfy demand of a social nature, iv) previous successful experiences of regeneration of abandoned assets, v) options arising from discussions with stakeholders. This last factor is fundamental to guarantee the correct inclusion of the new function of the asset in the socio-economic-territorial fabric.

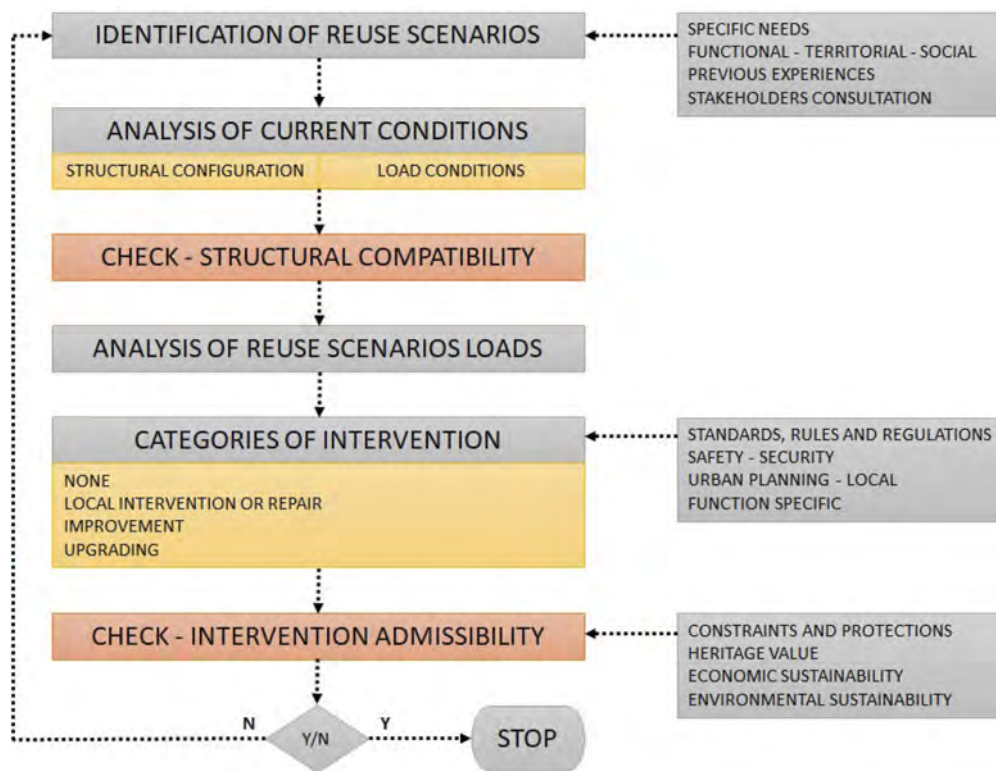

Figure 1. Methodology outline. Step-by-step process.

2.2 Step 2. Analysis of current conditions

The analysis of the actual conservation condition of the asset should lead to recognising and evaluating the residual capacity of the building in terms of quality of materials, static scheme, loads and load-bearing capacity, and global behaviour, for better orientating the strategies of any interventions. This also to comply with the needs of restoration and conservation, i.e., to preserve the existing historical materials, stratigraphies, structures (foundations, load-bearing walls, arches and vaults, horizontal elements, chains), minimising the interventions to replace the historical constructive elements and materials with new ones.

2.3 Step 3. Check of structural compatibility

The check of structural compatibility between the current conditions of the asset and the performance request linked to the reuse scenario has the purpose of avoiding important alterations of the overall structural behaviour of the building, which could affect the original distribution of loads requiring significant structural interventions. Making the most of the static characteristics of the existing structural system allows minimizing the invasiveness of the intervention, and consequently the impact on the identity of the asset itself and, last but not least, the maintenance costs over time.

The decisive aspect in the check of structural compatibility is linked to the entity of the overloads, or imposed loads, which include the loads linked to buildings intended use, and the seismic action, with respect to which the existing buildings, especially the historic ones, can be lacking. Technical regulations, such as the Italian NTC (Technical Standards for Constructions 2018), provide indications for the assessment of the loads, and therefore of the actions, acting on buildings according to their type and intended use.

2.4 Step 4. Categories of intervention

Depending on the outcome of the structural compatibility check, the type of structural intervention to be carried out on the asset is by and large defined to satisfy the performance requirement linked to the reuse scenario.

It should be noted that the type of intervention may also be influenced by other factors linked to other standards, rules, and regulations, such as urban planning and local ones, those relating to safety requirements (fire prevention), those specific to the new function of the property (space, systems, facilities), etc.

According to Italian NTC, the following three categories of intervention are identified.

- Local interventions or repair. Interventions involving individual structural elements and which, in any case, do not reduce the pre-existing safety conditions.
- Improvement interventions. Interventions aimed at increasing the pre-existing structural safety, without necessarily reaching the safety levels established for new buildings.
- Upgrading interventions. Interventions aimed at increasing the pre-existing structural safety, achieving the safety levels set for new buildings.

In the case of assets of cultural interest, upgrading interventions are to be considered, in general, not compatible with conservation needs, since to achieve upgrading it is almost always necessary alter the material and significantly modify the structural behaviour of the building. Therefore, improvements interventions and local interventions or repair are considered acceptable for these assets. Some factors useful for discriminating the improvement intervention from the upgrading one are the following:

- increase in foundation loads less than 10% compared to the original loads,
- modification of the position of the stiffness barycentre, for each floor, by an amount less than 10% of the dimension of the building measured perpendicular to the direction of application of the seismic action,
- modification of the position of the mass barycentre, for each floor, by an amount less than 5% of the dimension of the building measured perpendicular to the direction of application of the seismic action.

2.5 Step 5. Check of intervention admissibility/sustainability

The last step of the methodology involves checking the eligibility of the intervention (upgrading, improvement, repair) to be carried out on the asset. The extent and outcomes of the intervention should in fact be assessed in terms of i) compatibility with the heritage value of the asset, and therefore with any constraints and protections that concern it, ii) economic sustainability, iii) environmental sustainability. The positive outcome of this check implies the admissibility of the intervention, while the negative outcome requires rethinking the specific reuse scenario.

As stated in GBC (GBC Historic Building® HandBook 2017), the need to recover and improve assets of cultural significance focuses on safeguarding the structural behaviour and historical material. Regardless of the assets in which strategic or relevant functions are performed, it can be accepted that the intended use of a building, in general, can be chosen based on the response of the consolidated and restored structures to the overload. In this way, forced upgrading that distort the behaviour of historical structures could be avoided.

3 CASE STUDY. THE CARLO EDERLE BARRACKS

The proposed methodology was tested on the case study of the Carlo Ederle Barracks.

The Carlo Ederle Barracks is a military complex, located in Cagliari (Italy) in the so-called S. Elia promontory, named after the Major of artillery, Gold Medal for Military Valour, Carlo Ederle, who fell heroically on the Piave in 1917. The area, owned by the State Property Administration since 1860, moved from civil to military state property in 1925. It is a complex of buildings built on the initiative of the Ministry of the Interior and to be used as a correctional home for minors, then completed and partly adapted as a military district headquarters. Historically, the first Department encamped in the Barracks was the 13th Engineering Battalion of the Savoy Division, which was followed over time by further and various departments, up to hosting, starting from 1993, the Military District of Cagliari.

Currently, the Barracks is closed into a trapezoidal perimeter wall long about 633 m that encloses an area of 23380 m² and consist of 16 buildings used for different military uses. In particular, the entire area can be divided into two distinct sub-areas, one rectangular and one triangular, separated by the driveway entrance on the north side. The rectangular area, based on the difference in elevation, can be divided into three zones, zone 1 including buildings A, B and C with a difference in height of -3 m compared to zone 2, including buildings E, D, Q which in turn has a difference in height of -3 m compared to zone 3, including buildings G, F, P, H, I, L, M, N, O (Figures 2 and 3).

Figure 2. The Carlo Ederle Barracks. Aerial view.

Figure 3. The Carlo Ederle Barracks. Location of buildings and construction evolution.

The Barracks reuse scenarios were defined based on a review of successful regeneration experiences of abandoned buildings and preliminary interviews with stakeholders, as well as on a preliminary recognition of the current state of conservation of the asset. Considering this, the adaptive reuse of the military site considers four possible scenarios: i) hotel complex, ii) residential and social housing, iii) creative hub, and iv) community cooperatives.

Table 1. The Carlo Ederle Barracks. Main information.

Location	S. Elia Promontory - Cagliari
Chronology of the construction	1860 1926 1945
Current use	Barracks
Surface	23317 m ² (7694 m ² indoor 15623m ² outdoor)
Restriction measures	Military state property Restriction of cultural interest
Protected areas in which the asset is inserted	S. Elia Promontory – Cagliari Environmental restriction
Availability/Accessibility	Available and accessible only to employees of the barracks. Extraordinary openings for cultural events. Seasonal public connections only.
Agreements	Protocol agreement between Italian Ministry of Defense and Local Administration for the coordination of military activities in the Region of Sardinia

The state of conservation of the asset was detected through an investigation protocol consisting of indirect and direct analyses. The indirect analyses, aimed at the reconstruction of the historical and architectural evolution of the complex, as well as the identification of its cultural values, were carried out through the critical-interpretative and cross-reference study of the historical documentary and iconographic sources found. This historical-critical analysis was aimed not only at acquiring all the documentation relating to the building history of the asset, but also to that of its past restorations, allowing for a broader understanding of the state of conservation considering previous interventions. The direct analyses consisted of the experimental investigation on the asset through geometric, architectural, and structural surveys, analysis of materials and techniques and state of conservation, aimed at understanding the architectural, material, structural and chronological components of the buildings. All the information were collected within a framework based on the so-called Raumbuch methodology, in which all the constructive elements are represented in details and assessed both in terms of consistency and cultural value.

The overloads relevant to each of the reuse scenarios were extracted from Italian NTC Tab. 3.1.II - Overload values for the different categories of use of buildings.

The comparison between the current structural condition of the Barracks and the structural performance required by the reuse scenarios led to the by and large identification of the type of intervention necessary for each of the buildings making up the complex.

Finally, the compatibility of the interventions with the need to protect the heritage value of the asset was assessed, aiming at quantifying the degree of sustainability of the proposed reuse scenarios. Since now no assessments have been made regarding the environmental and economic sustainability of the interventions.

4 RESULTS

As an example of the analysis process carried out on each building of the military complex, the results relating to the building identified as block 4 (Figure 4) are reported below.

Table 2 shows the overloads associated with possible reuse scenarios and previous use. Table 2 refers to the intended use categories indicated in Italian NTC Tab. 3.1.II - Overload values for the different categories of use of buildings.

The integrated analysis of the performance required by the reuse scenarios, including the fulfilment of standards, rules, and regulations other than NTC as mentioned in 2.4, and the current static conditions of the building led to the by and large identification of the type of intervention to be carried out on the building according to the reuse scenario. The result is shown in Table 3.

The outcome of the integrated analysis shows how the level of intervention is different according to the building reuse scenario. It can be noted that one of the scenarios would require an upgrading intervention, involving substantial changes in the overall structural behaviour of the building.

Figure 4. The Carlo Ederle Barracks. Building's labelling.

Table 2. Overloads according to the reuse scenario (Italian NTC Tab. 3.1.II - Overload values for the different categories of use of buildings).

Overload* (KN/m ²)	Use Scenario				
	Previous Offices (B1)**	Scenario 1 Hotel Complex (C2)	Scenario 2 Housing (A)	Scenario 3 Creative Hub (C3)	Scenario 4 Community Coop (D1)
q _k	2	4	2	5	4
Q _k	2	4	2	5	4
H _k	1	2	1	3	2

*q_k = uniformly distributed vertical loads; Q_k = concentrated vertical loads; H_k = linear horizontal loads
 **B1 = internal offices; C2 = fixed seating areas; A = residential areas; C3 = Areas susceptible to crowding;
 D1 = shops.

Table 3. Categories of intervention according to the reuse scenarios (Italian NTC Tab. 3.1.II - Overload values for the different categories of use of buildings).

Intervention	Scenario 1 Hotel Complex	Scenario 2 Housing	Scenario 3 Creative Hub	Scenario 4 Community Coop
Local/Repair Improvement	X	X		X
Upgrading			X	

The illustrated procedure was applied to all the buildings of the Barracks, leading to a framework of general interventions which constitutes a fundamental tool for the decision-making process relating to the choice of final reuse scenario.

The framework of the interventions to be carried out on each building should obviously be evaluated as a whole and should be included in the set of useful indicators for evaluating the sustainability of the intervention itself and of the reuse scenarios.

5 CONCLUSIONS

The present paper presents a methodology to support the choice of the reuse scenario of large state-owned assets focused on the impact of the structural intervention that the asset should

undergo to satisfy the demand for structural capacity connected to the reuse scenario. The key element of the methodology is the check of structural compatibility between the current conditions of the asset and the performance demand of the reuse scenario, whose main factor is given by the entity of the overloads, imposed by the specific standards, depending on the intended use. The methodology was applied to the case study of a military complex, the Carlo Ederle Barracks in Cagliari (Italy).

The results support the concept that the structural capacity of the asset should be considered a key indicator for the choice of the reuse scenario. The methodology could become an important tool to support the public administration in the recovery and reuse strategies of state-owned real estate assets.

Evaluation of low-velocity impact damage in metal/composite layered structure

Stephanie TerMaath & Benjamin Ingling
University of Tennessee, Knoxville, TN, USA

John Noland & Daniel Hart
Naval Surface Warfare Center Carderock Division, Bethesda, MD, USA

ABSTRACT: Internal damage caused by low velocity impact loading, such as hail, tool drops, and daily use, is a concern when evaluating the lifecycle of composite overlays used to repair or reinforce metallic structure. To investigate internal damage relative to external visible damage, inform inspection/maintenance, and provide validation data for future computational modeling, five configurations of composite/metal structure were experimentally tested by impact at two energy levels to cause low velocity impact damage. Plates were fabricated with an E-glass/epoxy or a carbon fiber/epoxy composite co-cured to an Aluminum 5456 substrate. In addition to collecting test data such as force/displacement and impact conditions, computerized tomography imaging was performed on the impacted plates to analyze the internal damage in 3D. Primary findings illustrate that both applied impact energies damaged all configurations and that the internal damage was more substantial than indicated by external (visible) damage.

1 INTRODUCTION

Repair and reinforcement solutions using composite overlays of complex shape effectively restore damage tolerance and load-carrying capacity of damaged metallic structure (Figure 1a), as proven through widespread applications encompassing aircraft, ships, offshore platforms, infrastructure, and vehicles (Baker et al., 2003, Zhao and Zhang, 2007, Hollaway, 2003, Bakis et al., 2002, Grabovac, 2005). While composite overlays provide significant benefits over traditional repairs and single material designs, for example (Noury et al., 2002, Weitzenböck, 2012), a continuing concern is the internal damage accumulated throughout the structure's lifetime caused by low velocity impact loading, such as hail, tool drops, and daily use (Figure 1b).

Figure 1. (a) Composite overlay installed on a ship deck and (b) Low velocity impact on a ship deck (Photos courtesy of the US Navy).

The impacting object may rebound, partially penetrate, or completely penetrate (Belingardi and Vadori, 2002). Permanent damage caused by partial or complete penetration will be visible and thus readily identified for additional evaluation or repair during inspection. However, a rebound event, common with low velocity impacts, can result in visually undetectable internal damage that is significant enough to reduce the structural stiffness and load carrying capability (Katunin et al., 2020). Strength reduction from matrix and fiber damage hampers the overlay's effectiveness in transferring and carrying loads from the metal. And, delaminations can significantly reduce the load-carrying capacity by reducing load transfer across the layers, acting as a stress concentration with the potential for subsequent growth, and increasing susceptibility to buckling (De Freitas and Reis, 1998). Given the lack of non-destructive evaluation (NDE) techniques to reliably identify delamination in the composite and disbond at a bi-material joint (Roland et al., 2004, Floros et al., 2015, Katunin et al., 2020), it is imperative to correlate impact conditions such as size, velocity, and visible external damage to internal damage (Baker and Jones, 1988) to inform inspection intervals and evaluation techniques to predict subsequent damage propagation and determine maintenance schedules.

1.1 *Impact damage overview*

As an impactor strikes, its kinetic energy is initially transferred to the plate as elastic strain energy (Lopes et al., 2009). When the ultimate material strength is reached at a location within the plate, elastic strain energy dissipates through permanent damage, such as delamination, disbond, matrix cracking, fiber breaks, and plastic deformation. As the impactor's velocity reaches zero, all of its kinetic energy has either been transformed to elastic strain energy or dissipated through damage. If elastic strain energy remains, the impactor and plate deformations reverse and accelerate in the opposite direction, transforming this strain energy back into kinetic energy and causing the impactor to rebound. The plate then continues to vibrate, dissipating more energy.

While the resulting damage in composites and metals individually from impact loading has been widely studied, investigations on the effect of low-velocity impact on the bi-material interface between a composite overlay and metal base have not been as widely published, especially for the thick metal structure common in infrastructure and marine applications. Impact studies on Fiber Metal Laminates (FMLs) and ceramic/metal structure dominate the literature. While similar in terms of layering metal and composites, FMLs tend to be significantly thinner (metal layers on the order of 0.5 mm or less) as are the other plates investigated for the primary application of aircraft (Akimoto et al., 2000a, Akimoto et al., 2000b). This thinner structure tends to result in visible damage, such as cracking and petaling, from a penetrator impact instead of the non-visible damage associated with the much thicker patched structure investigated herein (Lee et al., 2018, Bieniaś and Jakubczak, 2017, Carrillo et al., 2019, Sadighi et al., 2012, Sharma and Velmurugan, 2022). And, ceramic is typically adhesively joined to metal as ballistic protective armor, and therefore, the ceramic layer is intended to sustain destructive damage to absorb the impact energy thus protecting the metal layer underneath (Lee and Yoo, 2001, Goncalves et al., 2004).

In the current study, the composite is co-cured to the metal resulting in an adhesive layer comprised of the resin used to fabricate the composite. As delaminations in composites tend to occur between plies of differing orientations due to interlaminar shear stresses (Evcı and Gulgeç, 2012, Lopes et al., 2009), disbonds similarly occur in such interfaces due to the differing impact behaviors and stiffnesses of the joined materials (Soutis et al., 1999).

1.2 *Objectives*

This research was performed to achieve 3 objectives:

1. Correlate internal damage to visible external damage to inform inspection and maintenance of composite overlays;
2. Compare the effects of varying materials, configurations, and impact energy on structural performance to inform composite overlay design; and,
3. Provide validation data for future computational modeling of impact events and the prediction of damage propagation after impact.

2 MATERIALS AND METHODS

A summary of the panel configurations and testing information is provided as follows, and additional details are available in the test report (Hart et al., 2016). This paper expands on the initial test program by investigating internal damage using computed tomography (CT).

2.1 *Materials and composite overlay configurations*

Composite overlays were co-cured to 6.35 mm 5456 aluminum substrate to fabricate 406.4 mm square test panels (Table 1). Five composite overlay configurations were investigated (Tables 2–4), and four test panels were fabricated for each configuration. All overlays consisted of an open plain weave (PW) fabric (Hexcel 7500) at the metal/composite interface, followed by a symmetric schedule, and a tight satin weave (SW) fabric (Hexcel 7781) as the final cover ply. The 7500 PW fabric has a warp-to-fill fiber ratio of 16:14, while the 7781 SW has a fiber ratio of 57:54. The higher fiber count of the 8 harness SW results in a tighter weave with approximately the same aerial weight. Overlay stiffness was calculated using Classical Laminate Theory, and overlays were designed to provide varying levels of theoretical stress intensity reduction for semi-infinite cracks in the aluminum using Rose’s model. The same toughened resin epoxy system (Pro-Set M1002 with 237 hardener) with a mix ratio of 100 parts resin to 28 parts hardener by volume was used for all panels and required an elevated temperature post-cure.

Table 1. Specimen fabrication process.

* Unidirectional on a chopped mat base

2.2 *Impact testing*

Experimental testing was performed at the US Naval Academy using an Instron Dynatup model 9250HV spring-assisted drop tower. The impactor was a 50.8 mm diameter steel cylinder with a 9.652 mm face depth and a 2322.58 mm² maximum impact area. The lab temperature was 70°F with an approximate RH of 80% per the environmental condition of Room Temperature Dry, the ambient temperature of a temperature-controlled lab with the as-manufactured moisture content. To simulate an object falling from 3.048 m, two impact energies (406.7 J and 813.5J) were tested using a constant impact velocity of 7.62 m/s. Each panel configuration was tested at both target impact energies with two panels of a single configuration tested at each energy. Panels were 406.4 mm square with a 355.6 mm square unsupported region. Samples were clamped in place using a bolted frame with the bolt pattern outside of the 16-inch specimen perimeter. Specimens were centered in the frame and the bolt pattern was evenly torqued enough to not cause laminate

Table 3. Overlay configurations.

Configuration/Abbreviation	Laminate Schedule

damage but to secure the panel. Impact velocity was determined by the control computer. Mass of the impact sled was adjusted to obtain the desired impact velocity, and a plywood and foam sandwich panel was used as a catch block to prevent secondary impacts.

2.3 Imaging

The CT method involves the use of x-ray beams rotating around the object being scanned. As the x-ray beams pass through the object, special detectors capture the remnants of the beam and digitize an image. CT is different from X-ray, because the CT scans in a circle around the object instead of from one vantage point, allowing for a 3D view of the scanned object. Thus, viewing the composite overlay is possible, because for portions of the scan the aluminum isn't exposed to the x-ray beam and doesn't distort the image due to its higher density (Garcea et al., 2018, Gao et al., 2021). Alternatively, a strong enough wave of particles is needed to penetrate the lighter density of the composite and the higher density of the aluminum. If the wave isn't sufficient to penetrate the aluminum, then beam hardening occurs and the aluminum in the image turns white, distorting the rest of the image. All specimens were scanned to evaluate internal damage.

3 RESULTS AND DISCUSSION

Force/displacement curves (Figures 2 and 3) and imaging data (Figure 4 and Table 5) are provided for all but two of the impacted panels. The carriage weights were loose during the testing of panels, 8PlyQuasiGlass-1A and 10PlyQuasiGlassUni-1A, causing noisy and erroneous data; therefore, these results are not included in the comparisons and discussion.

3.1 Overview of test data

As seen in Figures 2 and 3, all 6 and 8 layer panels exhibited similar force/displacement curves at both impact energies. The 10 ply panels all have smaller displacements but higher forces than the 6 and 8 layer panels, although, the total energy absorbed is not significantly different statistically. At the lower energy, the 10 Ply Directional E-glass panel had higher maximum and total displacements than both 10 Ply Directional E-glass/Carbon panels, while they

exhibited larger forces throughout the test. At the higher impact energy, the trend is the same except that the 10 Ply Directional E-glass/Carbon panel (2B) has a total displacement equal to that of the largest total displacement of the 10 Ply Directional E-glass panels (2B).

Figure 2. Force/Displacement curve of impacts at a target energy of 406.7 J.

Figure 3. Force/Displacement curve of impacts at a target energy of 813.5 J.

3.2 External and internal damage comparison

For consistent comparison across panels, all damage was measured along a vertical line perpendicular to the top of the panels and passing through the center of the impact strike location (Figure 4). This view orientation had the smallest length scale between image slices allowing for higher resolution in identifying maximum damage. External composite damage was characterized by visible damage areas centered around the impactor strike location (Figure 5). At the lower impact energy, visible external composite damage was less than the impact diameter for all panels except for the 6 Ply QuasiCarbon panels. At the higher impact energy, the 6 Ply panels in general had larger visible damage areas.

The depth of the composite indentation ranged from 0 for all 10 Ply panels at the lower impact energy up to 7.9 mm for the 8 Ply E-glass panel (2B) at the higher impact energy. While small, impact locations are visible on the composite side and could be identified during an inspection as locations for internal evaluation. On the Al side, plastic deformation manifested as a smooth slope from the edge of the panels to the location of maximum deformation

Figure 4. Through the thickness CT images showing the measurements for disbands, visible composite indentation, and visible aluminum plastic deformation. (a) The representative image of the 6 and 8 ply overlays (specimen 6 Ply QuasiCarbon 2A) exhibits a large disbond with damage growing into the composite. Evidence of fiber breaking and matrix cracking is visible. External composite indentation and aluminum plastic deformation is observable on the physical panels. (b) 10 ply overlay behavior (for representative specimen 10 Ply QuasiCarbon 1A) shows a much smaller internal disbond and no visible aluminum or composite deformation externally.

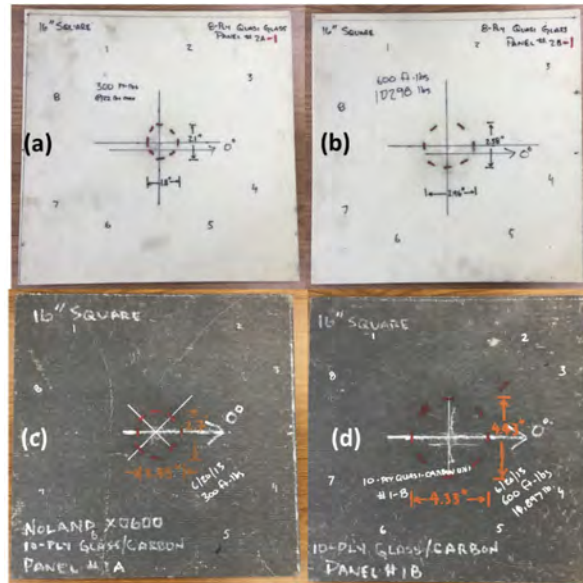

Figure 5. Comparison of external damage on the composite side of representative 8 Ply E-glass Panels (a,b) with 10 Ply E-glass/Carbon Panels at both energy levels (low-left, high-right).

directly under the impact location. Given the relatively small deformations, ranging from 0 to 8.3 mm, and the resulting low grade of the slope across the panel, identifying areas for internal evaluation would be challenging when inspecting the AI side.

Internal damage was identified in the CT images as two forms. All 6 and 8 ply panels at both impact energies, exhibited the damage shown in Figure 4a characterized by a disbond between the composite and Al which extended through the composite with continued growth as delamination between composite layers. Additional damage in the form of fiber breaks and matrix cracking was also identified in the images. At the lower impact energy, the 10 Ply panels contained internal damage that was distinct from the other configurations (Figure 4b). Given that there was no visible external deformation for these panels and a small region of visible surface damage, this internal damage would be difficult to locate during an inspection.

Table 5. Summary of data collected from testing and CT image measurements.

Panel Designation	Energy (J)	t (mm)	Visible External Damage			Internal Disbond	
			Comp Depth (mm)	Comp Length (mm)	AI Depth (mm)	Length (mm)	Depth (mm)
8PlyQuasiGlass-2A	365	10.6	3.8	20.8	3.0	23.9	1.5

8PlyQuasiGlass-1B	708	10.3	5.3	80.9	7.1	92.2	3.0
8PlyQuasiGlass-2B	701	10.6	7.9	80.0	8.3	93.9	3.0
10PlyQuasiGlassUni-1B	670	12.7	2.4	55.5	4.7	62.5	2.4
10PlyQuasiGlassUni-2B	691	12.2	3.0	69.8	6.4	102.4	3.7
10PlyGlassCarbonUni-1B	677	13.9	2.3	63.8	4.7	92.8	3.7
10PlyGlassCarbonUni-2B	725	13.1	2.3	74.3	6.2	109.8	3.9
6PlyQuasiCarbon-1B	724	10.1	3.0	100.5	3.4	111.8	3.0
6PlyQuasiCarbon-2B	691	9.9	4.7	91.8	6.7	102.1	3.2
6PlyCarbonUni-1B	702	10.2	7.0	92.0	6.8	117.6	3.1
6PlyCarbonUni-2B	697	10.1	6.8	87.0	7.3	102.8	3.0

While initially relatively smaller, this damage forms a stress concentration which could propagate under service loads. At the higher impact energy, the 10 Ply panels did show visible damage. The 6 Ply panels on average had larger disbond lengths, followed by the 8 Ply and 10 Ply panels respectively, while the disbond depths were slightly higher on average for the 10 Ply panels. The depth and length of this internal disbond damage depended on panel configuration and impact energy. For the 6 and 10 Ply configurations, doubling the impact energy caused an approximate average increase in disbond length of 1.5 while disbond depth increased moderately. The 8 Ply panels, however, demonstrated a nearly 4 time increase in disbond length with double the average disbond depth than the 8 Ply panel impacted at the lower energy level (though it should be noted there was only one valid specimen).

4 CONCLUSIONS

The primary finding from this investigation is that low velocity impact can result in significant internal damage with minimal externally visible damage. This non-visible damage state can be detrimental to the structural reliability of composite overlays to adequately transfer loads from the metal substrate, especially given that the damage state is of the form of disbond and delamination. Future work in computational modeling of the impact event using the obtained images for validation will enable a comprehensive investigation of composite materials and configurations to optimize overlay design. Moreover, analysis and computational simulation of damage propagation based on models of the existing internal damage using the 3D data collected through this research will inform inspection by quantifying the size of damage area that degrades performance and the rate of damage propagation under service loads. This information can then be used to schedule inspection intervals to identify and repair damage before it causes structural degradation.

Development of high durable precast PC deck with ultra-high-strength fiber-reinforced concrete layer

H. Hayashi & Y. Yasukawa

East Nippon Expressway Company Limited, Tokyo, Japan

N. Oba & K. Sasaki

Obayashi Corporation, Tokyo, Japan

ABSTRACT: In the renewal of old road bridges, precast decks are used to make construction time shorter and quality better. A waterproof layer is applied at the top surface of the deck to avoid the intrusion of water accelerating concrete deterioration. However, waterproofing is one of the causes of construction time delays because waterproof work must be conducted under dry conditions. From this reason, we have been hoping to develop a precast deck to omit waterproofing at the site. To satisfy this hope, we have just developed a high durable PC deck with waterproof performance by ultra-high-strength fiber reinforced concrete (UFC) on the top surface of the deck. On this report, we are going to state the feature of this new deck and the experiments conducted to confirm the waterproof performance required for 100 years of road track service.

1 INTRODUCTION

The East Nippon Expressway Company Limited (hereinafter referred to as NEXCO EAST) has been conducting large-scale renewal work of bridges and tunnels as part of an expressway renewal project since 2015. The purpose of this work is to maintain the safe and comfortable highway network to contribute social and economic activities from 100years. In case of bridge work, we replace deteriorated RC decks of existing bridges with more durable deck, that is prestressed concrete decks as standard. And as a construction, it is desirable to maximally shorten working days because traffic restrictions, such as a decrease in the number of lanes over a long period have a large impact on traffic. Precast decks are widely adopted to minimize the impact of traffic restrictions during construction and to shorten the process.

Deck replacement work is conducted to avoid busy traffic seasons, such as year-end and New Year holidays, long holidays, and summer vacations. Currently, Japan is experiencing a rainy season and snow and ice season. Deck waterproofing, which cannot be installed in rainy weather, hinders the shortening of traffic restrictions. Therefore, if the types of work affected by weather that cannot be controlled by human power during on-site construction can be eliminated, it is expected to contribute significantly to process control.

In this study, we focused on ultra-high-strength fiber-reinforced concrete (UFC), which is high-strength, dense, and excellent in waterproofing, and attempted to develop a precast PC deck with a UFC layer for waterproofing (hereinafter referred to as UFC PC DECK).

2 UFC PC DECK

2.1 Outline of UFC PC DECK

Figure 1 shows an outline of the UFC PC DECK. It is a precast deck with UFC layer on lower based concrete. To prevent cracks from occurring under the designed load during service, a deck thickness of 220 mm and a UFC thickness of 20–50 mm (that changes according to tensile stress), and this UFC layer is used as a waterproof.

Figure 1. Outline UFC PC DECK.

Contrary to the method of overlaying the UFC on the top surface of hardened deck concrete, the UFC is poured by layering before the lower based the concrete hardens. This method can reduce the binding force acting on UFCs with large self-contractions. In addition, the UFC layer and concrete could be attached more strongly. And furthermore, prestresses can be introduced in the lower based concrete as well as in the UFC layer.

The minimum thickness of the UFC was set to 20 mm, considering the viscosity of the material at the time of fabrication, crack suppression after curing, and variations in construction thickness. Decks are manufactured at the factory and joined onsite. By adopting the UFC for deck connections, the entire bridge surface can be covered with the UFC for waterproofing.

2.2 UFC used for the precast PC deck and deck connection

The mix proportions of the UFC used in this method are listed in Table 1. The premixed powder includes cement, silicate filler, fine aggregate, water, and special superplasticizers. High-strength steel fibers with strengths greater than 2 GPa are used to form the UFC. The shape of the fiber is straight, and its length and diameter are 13 and 0.16 mm, respectively. The volume fraction of the fibers is 2.0%. This UFC have a compressive strength of 180 MPa and tensile strength of 8.8 MPa by standard curing (both characteristic values).

Table 1. Mix proportions of UFC used for the precast PC deck and deck connection.

Unit content (kg/m ³)				Steel fiber (kg/m ³)
Water	Premixed powder	Sand	Superplasticizer	
230	1830	350	32	157

3 WATERPROOFNESS OF UFC LAYER

3.1 Required performance of the waterproof layer

The required performance of the waterproofing layer of the UFC PC DECK must be equal to or higher than the current waterproof layer material in the technical standards of

expressways. The design service life is set to 100 years, which is the same as the design service period of the bridge.

Hydraulic conductivity is used as an index for the evaluation of waterproof performance. As waterproof performance is required for the deck, the upper limit value of the hydraulic conductivity is set assuming the water pressure and action time acting on the deck during the service period.

The time required for the moving vehicle to pass in the wet state is determined as the cumulative time for the water pressure to act on the deck. The number of times the vehicle passed is assumed using data measured on actual expressways, and the number of days when the upper surface of the deck is in a wet state is assumed using meteorological data.

The load by the tires is calculated with a ground pressure of 0.5 MPa assuming a large vehicle, and the relationship between the depth of water penetration into the waterproof layer and hydraulic conductivity is calculated during the 100 years of service. The calculation results are listed in Table 2.

The hydraulic conductivity required for the UFC layer is determined to be 1.0×10^{-13} m/s or less with a certain margin for the calculated value of the water penetration depth, that is not to reach the lower base concrete, in the design life at the minimum thickness of the UFC layer of 20 mm.

Table 2. Hydraulic conductivity requirement of waterproof layer.

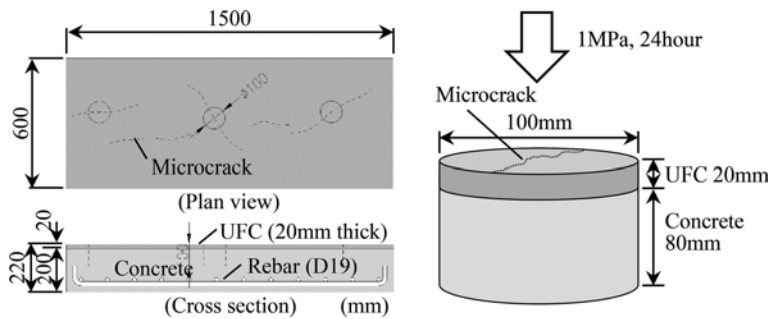

hydraulic conductivity (m/s)	water penetration depth (mm)
1.0×10^{-11}	49.3
1.0×10^{-12}	15.6
1.0×10^{-13}	4.9
1.0×10^{-14}	1.6
1.0×10^{-15}	0.5

3.2 Performance confirmation test (water permeability test)

Using a specimen simulating the UFC PC DECK, the hydraulic conductivity was confirmed via a hydraulic permeability test. Figures 2 and 3 show the outline of the specimen. The UFC was placed on the upper 20 mm layer of the UFC PC CECK with a thickness of 220 mm. The lower based concrete is high-early-strength with a design standard strength of 50 MPa, assuming an actual structure. In addition, we intentionally have induced microscopic cracks (hereafter referred to as microcracks) on the surface of the UFC layer that cannot be observed by close visual observation. Hydraulic conductivity was measured by collecting test specimens with a diameter of 100 mm and height of 100 mm from the site where the microcrack occurred. In the water permeability test, water was infiltrated into the test piece with a water pressure of 1 MPa and pressurization time of 24 h using the input method. After completion of pressurization, the specimen was split along a microcrack to measure the penetration depth, and hydraulic conductivity was determined from the penetration depth of the split surface. The maximum hydraulic conductivity obtained by the test was 1.78×10^{-14} m/s, and it was confirmed that both were less than 1.0×10^{-13} m/s.

Furthermore, we confirmed the waterproofing performance after applying tensile fatigue and freeze-thaw loads to the UFC layer. Using a specimen that was intentionally induced microcracks, a specimen of $100 \times 100 \times 400$ mm was drawn from the location where the microcrack occurred.

In the tensile fatigue test, the tensile stress at the design load of the deck is simulated, and the bending tensile tension was applied such that a tensile stress of 4 MPa acted on the outermost edge of the UFC layer, and tensile tension was applied for two million cycles at a stress amplitude of 0–4 MPa. In the freeze-thaw test, freeze-thaw action was performed for 300 cycles. The hydraulic conductivity was measured in the same manner as described above, and it was confirmed that the maximum was 1.48×10^{-14} m/s, and that both were 1.0×10^{-13} m/s or less.

Figures 2 & 3. Layered concrete for making microcracks; Specimen of water permeability test.

4 STRUCTURAL INTEGRITY OF UFC PC DECK

4.1 Outline

Because UFC PC DECK is overlaid before the lower based concrete hardens, it is essential to ensure the adhesion between these dissimilar materials. And furthermore, other important adhering points are the asphalt pavement - UFC and UFC - concrete. At the deck connection, there is a joint between the UFC of the connection and UFC layer of the precast deck. In addition, the adhesion between the UFCs is important.

4.2 Asphalt pavement - UFC adhesion performance

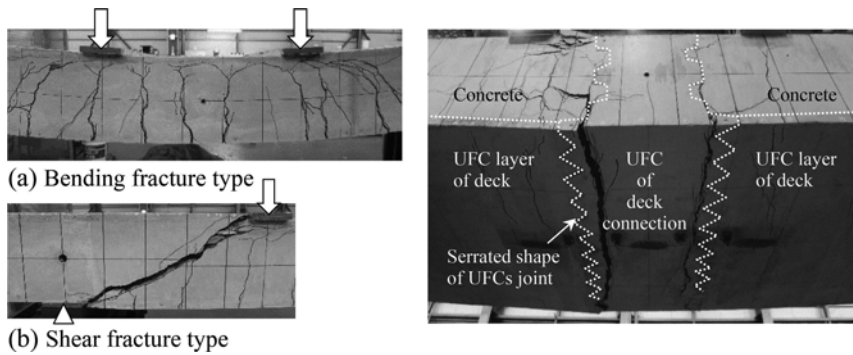

According to the condition of temperature and load, the performance of pavement, that is adhesion and shear, is changing. So, each test ruled as NEXCO's technical standards has been done. The result of tensile adhesion tests and shear adhesion tests under each test condition were satisfied required level.

4.3 UFC - concrete adhesion performance

The adhesion between the UFC and concrete was confirmed by tensile adhesion tests, shear adhesion tests, and bending loading tests of the beam specimens. In the bending loading test, the adhesion between the UFC and concrete at the time of fracture was confirmed using bending fracture type and shear fracture type specimens. The beam height was 220 mm and UFC was 20 mm, assuming the thickness of the deck, and the shear span was 1000 mm for the bending fracture type and 500 mm for the shear fracture type. The bending fracture is shown in Figure 4a. In the bending fracture specimen, the tensile rebar yielded as in a general concrete beam, the UFC was finally crushed, and the load was reduced. The shear fracture situation is shown in Figure 4b. In the shear fracture specimen, after the tensile rebar yielded, the oblique crack extended and eventually penetrated the UFC layer, thereby reducing the load. None of the specimens exhibited any phenomenon in which the UFC layer peeled off until the maximum bearing capacity was reached. Thus, it was confirmed that adhesion could be secured even if the UFC was layered on fresh concrete.

4.4 UFC - UFC adhesion performance

The adhesion performance between the UFCs was confirmed by fabricating test specimens with vertical joints between UFCs and measuring the tensile strength of the joint surface using a uniaxial tensile test. The average tensile strength was 6.8 MPa, which was lower than the crack initiation strength of the UFC, 8.0 MPa. Therefore, the tensile stress acting on the joint must be lower than the tensile strength of the joint.

Figures 4 & 5. Cracks of the bending test; Cracks of the bending test at UFCs joints.

Additionally, a bending loading test of the beam test specimen at the joint was conducted. The UFC joints were serrated, as shown in Figure 6. The UFC layer was loaded such that the joint was tensile in nature. The crack did not expand at the UFC joint but was destroyed at the deck connection UFC (Figure 5). Although the tensile strength of the UFC joint surface was lower than the crack initiation strength, it was confirmed that the tensile performance was equal to or better than that of the UFC base part by adopting a serrated shape of the joint part.

5 CONNECTION OF UFC PC DECK

UFC PC DECKS are joined using the same UFC as the decks (Sasaki 2021). The upper layer had a serrated shape, as shown in Figure 6. As mentioned above, because the tensile performance of the joint between UFCs is lower than the crack initiation strength, the stress acting by giving the joint surface an angle is reduced, and this is not a weak point. As shown in Figure 7, the interface between the UFCs was resisted by tension and shear, and the joints did not fail.

6 FATIGUE DURABILITY OF UFC PC DECK

6.1 Outline

As we mentioned before, we have had several tests to confirm the required performances, however, it is necessary to have tests similar to the utmost to real state for adopting this new UFC PC DECK on site. So, we have conducted a wheel load running test using UFC PC DECK specimen that simulated a full-scale.

6.2 Specimen

An outline of the specimen used in the wheel-load running test is shown in Figure 8. The plane dimension is 4,500 mm in the longitudinal direction and 2,800 mm in the perpendicular direction. The thickness of the deck is 220 mm, and the upper UFC layer is 20 mm. The deck span is 2,500 mm. A hanch thickness of 50 mm is provided at the fulcrum, and the total thickness is 270 mm. The UFC on the upper layer of the specimen is poured after the lower layer of concrete is poured and hardened, as in other specimen production. After concrete hardening, using PC steel bars arranged as shown in Figure 8, prestress was introduced in the direction perpendicular to the bridge axis using the post-tension method. The prestress amount introduced was 312 kN per PC steel rod, to ensure that the stress degree of concrete was 5.0 MPa.

6.3 Loading method

The wheel load running tester is a crank type, and loading range is 1,500 mm front and rear from the center of the tester, with a total length of 3,000 mm. The loading rate was 30 times/min.

Figures 6 & 7. Deck connection of UFC PC DECKS; Stress at serrated shape joint.

Iron wheels with a width of 500 mm were used. The loading conditions are shown in Figure 8, and the test status is shown in Figure 9.

The loading conditions are as follows: Step 1 under drying conditions and Step 2 under immersion conditions, both of which had a load of 100,000 cycles of 250 kN. A load of 100,000 cycles of 250 kN corresponded to the simulated fatigue load in designed period of 100 years. After completion of Step 1, Step 2 is performed with the surface filled with water. The water is filled a space 10 mm × 3,800 mm × 2,000mm. And red colored water is used to make it easier to observe leakage.

The static loads are loaded at times 1, 1000, 10,000, 40,000, 80,000, and 100,000 for both steps. For each static load, the deflection of the deck was measured and cracks were observed.

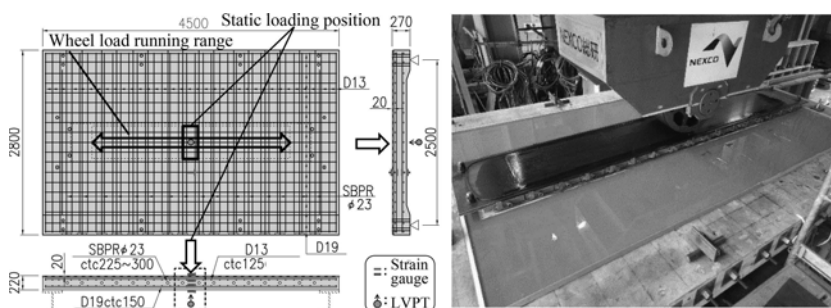

6.4 Test results

6.4.1 Cracks and deflection on the lower surface of the specimen

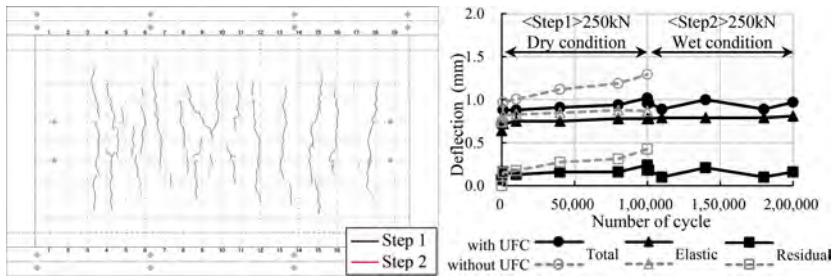

Figure 10 shows the occurrence of cracking on the lower surface of the specimen after the test is completed. No remarkable crack extension was observed from Steps 1 to 2. Figure 11 shows the change in deflection over time immediately below the loading point. The figure shows the transition of the residual deflection, elastic deflection, and total deflection at the center of the specimen. The figure also shows the test results for an existing PC deck specimen without a UFC layer, under the same test conditions. The PC deck without the UFC layer showed a gradual increase in total deflection owing to the increase in residual deflection in Step 1, while the UFC with deck showed stable fatigue properties without a large increase in residual deflection. From this result, we have confirmed the remarkable effect of the UFC layer from the point of load carrying capacity.

6.4.2 Cracks on the upper surface of the specimen and water penetration

Figure 12 shows the cracking situation on the upper surface of the deck after the test, and Figure 13 shows an example of the cut surface. Cracks are primarily microcracks that are intentionally generated during specimen preparation. Visual observation of the cut surface revealed no water penetration of the underlying concrete through the UFC layer to the lower based concrete.

Figures 8 & 9. Wheel load running test.

Figures 10 & 11. Cracks of lower surface; Deflection-cycle relationship.

6.4.3 Hydraulic conductivity of cracked areas

Collecting the specimens collected from the positions shown in Figure 12, a hydraulic permeability test was performed on six specimens. The maximum hydraulic conductivity obtained by the test was 1.92×10^{-14} m/s, and it was confirmed that both were less than 1.0×10^{-13} m/s.

6.4.4 UFC - concrete adhesion performance

The cut surface was visually checked to determine whether the adhesion of the UFC and concrete was secured. As shown in Figure 13, no peeling was observed at the interface between the UFC and concrete on the cut surface after the test.

7 MANUFACTURE OF UFC PC DECK

The UFC PC DECK is manufactured in a factory that manufactures conventional precast PC decks. For UFC PC DECK, the adhesion between the concrete and UFC is important, and it is necessary to layer the UFC layer before the lower based concrete hardens. Therefore, we start pouring the UFC layer approximately 30 min after the casting of the lower based concrete, and strictly manage the time to ensure that the UFC layering work has been completed within 2 h after casting the lower based concrete (Figure 14). The surface of the underlying

Figures 12 & 13. Cracks of upper surface; Status of deck cross section after the test.

Figure 14. Powering of UFC on fresh concrete.

concrete is roughened to achieve better adhesion to the UFC. After a certain period, the surface of the UFC is smoothed with a steel trowel, covered with a curing mat, and flooded, and the entire deck is steam-cured. After steam curing is completed, it is confirmed that the concrete has reached the specified strength, and prestressing is introduced to the deck. Subsequently, they are cured in water for 7 days.

8 LIFE CYCLE COST

By the adoption of UFC PC DECKs on bridges with a length of 277 m and width of 10 m, the construction cost has increased by 154 million JPY compared to conventional precast PC decks due to the high cost of UFC materials. However, in the case of conventional technology, it is estimated that deck waterproofing work needs to be updated three times in 100 years, and that the initial deck waterproofing work is 26 million JPY, and the waterproofing work at the time of renewal is 43 million JPY per time. When the life cycle cost of the design service life of 100 years is calculated, it is almost equivalent to this technology and conventional technology (Table 3). In addition, the traffic restriction period for one pavement renewal is 25 days because deck waterproofing work is required with conventional technology, however, with this technology it is shortened to 5 days (Table 4).

Table 3. Direct effects of UFC PC DECKs (life cycle costs).

	(A) With UFC layer	(B) Conventional technology	(A-B)
	million JPY	million JPY	million JPY
100 years LCC (a+b)	154	169	- 15
(a) Construction cost (incremental)	154	26	+ 128
(b) Maintenance cost:	0	143	- 143
Delay cost due to bad weather	0	17	- 17

Table 4. Indirect effects of UFC PC DECKs (traffic restriction period).

	(A) With UFC layer	(B) Conventional technology	(A-B)
	days	days	days
Traffic regulation period through 100 years (a+b)	51	121	- 70
(a) Regulation period for deck renewal	34	37	- 3
(b) Regulation period for pavement renewal	17	84	- 67
Additional period due to bad weather	0	25	- 25

9 CONCLUSIONS

By developing the new technology of UFC PC DECK, it is possible to realize a precast deck with high durability and waterproof function for the entire bridge surface. In addition, because deck waterproofing is not required, it is possible to shorten the traffic restriction period and avoid the risk of process delays owing to unseasonable weather. In the future, to make effective use of this technology, we aim to standardize the deck replacement business in NEXCO EAST.

Development of digital rules for optimal auto-routing design of pipe

S.-E. Park, S.-W. Choi & E.-B. Lee

Pohang University of Science and Technology (POSTECH), Pohang, Gyeongsangbuk-do, Korea

ABSTRACT: Due to the recent retirement of engineering personnel, the number of piping engineers is rapidly decreasing. They are not actively responding to frequent design change requests from the owner. This study aims to develop digital rules for auto-mating pipe routing design. To this end, the piping design rules of EPC plants, codes and standards for piping design, and owner's requirements were collected. A total of 8 stages of piping design rule taxonomy were established to categorize the piping design rules. The collected piping design rules were analyzed by experts, and a digital code of account for system recognition was established based on the classified rule taxonomy. Finally, the code of account for pipe route design was converted into a digital rule. The digital rule developed in this study can be used as a database for efficient information management as well as pipe route design.

1 INTRODUCTION

As the plant industry is intensive with high added value, it is a convergence with the characteristics of manufacturing and service industries simultaneously. It contributes greatly to the advancement of the industrial structure. The domestic plant industry has seen rapid growth as a new export power source, with overseas orders soaring more than 50% annually since 2003. However, many parts of the core design sector and equipment supply depend on developed countries. As profitability deteriorates due to low-priced orders, various improvement efforts are being made simultaneously to overcome this. Among them, piping design occupies the most prominent portion of all plant project design tasks, and many related tasks need to be considered during design. The result of route selection has a significant influence on subsequent work. In addition, most of the estimated amount is not only determined by the quantity calculated during the pipe design but also is one of the most burdensome industries due to the complex design conditions.

Due to the recent aging and retirement of engineering personnel, the number of experienced piping, electrical, and instrumentation engineers is rapidly decreasing, and they are not actively responding to frequent design change requests from the owners. In addition, as the plant becomes more extensive and complex, the type and amount of piping increase. Furthermore, the design of the piping route is not automated yet, so the designer's capabilities significantly affect the design quality. Therefore, there is a need for a plan to increase work efficiency in the entire design process for piping design engineers by presenting an optimal route by automating the piping route design in the initial design stage. The need for piping auto-routing systems is increasing by applying artificial intelligence (AI) technology. This study aims to develop a digital rule for pipe design that can be recognized by machines necessary for developing AI-based piping auto-routing technology. To this end, pipe design rules of Engineering, Procurement, and Construction (EPC) plants, codes & standards for pipe design, and owner's requirements were collected. Subject matter experts (SMEs) analyzed the collected design regulations for pipe design. It was digitally categorized based on the analyzed piping design rules. A piping design rule taxonomy for digital categorization was established according to the Work Breakdown Structure (WBS). Finally, a digital rule for system recognition was developed by making

code for each pipe design rule so that computers could recognize it. The scope of the study was limited to pipe routing design among the engineering fields of EPC plant projects, and the study was conducted on the codes & standards and owner's requirements for piping design.

2 LITERATURE REVIEW

Previous studies were reviewed by classifying the contents to be performed in this study into two categories. The first is a prior study on the piping process, and the second is a study on the code classification system. The authors reviewed the approaches of similar studies and analyzed limitations through this.

2.1 *Piping design automation*

Yan and Ubald (2012) implemented a system that derives assembly sequence information automatically by algorithmizing constraints in a pipe installation plan. However, there is a limitation that auto-routing cannot be performed in the initial design stage, considering only the constraints. Nguyen et al. (2016) developed an improved Dijkstra algorithm that exports the shortest route with minimal bending and elbow in piping design. However, this study has a limitation: optimal route design is impossible considering only the shortest route. Shin et al. (2020) studied the automation of piping route design in a ship's engine room using reinforcement learning in the initial design stage. Nevertheless, there is a limitation that unlearned routes cannot be designed due to the failure to consider the design conditions applied to the actual industry and the AI model that selects routes based on learned information. Min et al. (2020) proposed a Jump Point Search (JPS)-based pipe automatic routing algorithm to find the optimal pipe route. However, this study has a limitation: nodes in the preference area should be allocated as temporary targets to optimize the route.

2.2 *Code of account in engineering*

Lee and Kang (1994) attempted to develop a standardized information classification system of construction that can be applied to construction management techniques. To this end, a construction division system was developed that was classified into three stages: facility element, structure element, and construction element. Kang and Kwak (2001) developed and proposed an integrated standard of specification classification code centered on the quantitative calculation standard code system. However, there is a limitation that code composition is impossible if there are specific items that cannot be classified based on quantitative calculation. Wang et al. (2010) developed a classification system for electric construction industries. Moreover, an effective management method using an integrated management system was presented through the computerization of the specifications of the electric work used. However, this study has a limitation in that it takes much time to build a DB, and it is difficult to respond quickly to new technologies or new construction methods by organizing different types of specifications for each public institution into a unified format. Moon and Han (2014) added work management units and expanded the site classification in developing the river sector work classification system based on the construction information classification system. Lee et al. (2015) identified the problems with the existing piping material code classification system. They derived an improvement structure of the piping material code classification system through a hierarchical classification structure. However, this study had limitations in that it was challenging to distinguish material specifications through codes due to the increased number of code digits up to 20 digits.

This study established a digital category and taxonomy of piping design rules in consideration of the approaches and limitations of previous studies. The authors classify more detailed piping design rules to overcome the limitations of previous studies and levels 0 to 7, a total of eight stages. This study aims to overcome the limitations of previous studies and develop digital rules according to the code of account for pipe design that the system can recognize for rule-based piping auto-routing.

3 RESEARCH OVERVIEW

This study aims to develop digital rules for pipe design that can be recognized by the system during auto-routing. To this end, in addition to the design rule and piping installation manual, codes & standards and owner's requirements were collected. A digital category structure for system recognition was defined for the collected piping design rules. A piping design rule taxonomy for onshore plants was established according to the WBS. Based on the rule taxonomy, the pipe design specification of codes & standards, ITB, and other pipe design rules were discussed with pipe design SMEs to analyze pipe design rules and classify them. Based on the design rules analyzed above, a code of account for pipe route design was established for efficient design rule classification and the establishment of a digital category structure for system recognition. The code classification system for pipe path design consisted of four categories: main category, sub-category, sub-sub category, and others. The attribute classification was subdivided into seven levels, and the code consisted of 11 digits. Digitally coding rules developed digital rules and owner's requirements are analyzed according to the classified code system. Each rule was composed of a total of 11 digits systems with a classification symbol indicating the classification status of each type. Details of this are described in Chapter 4. This study was conducted in 5 steps, as shown in Figure 1, and the details of each step are as follows.

- Step 1: Collection of rules related to piping design among codes & standards and owner's requirements for piping design
- Step 2: Development of digital categories and taxonomy of piping design rules
- Step 3: Analysis of piping design rules
- Step 4: Establishment a code of account for piping auto-routing
- Step 5: Development of digital rules for piping auto-routing

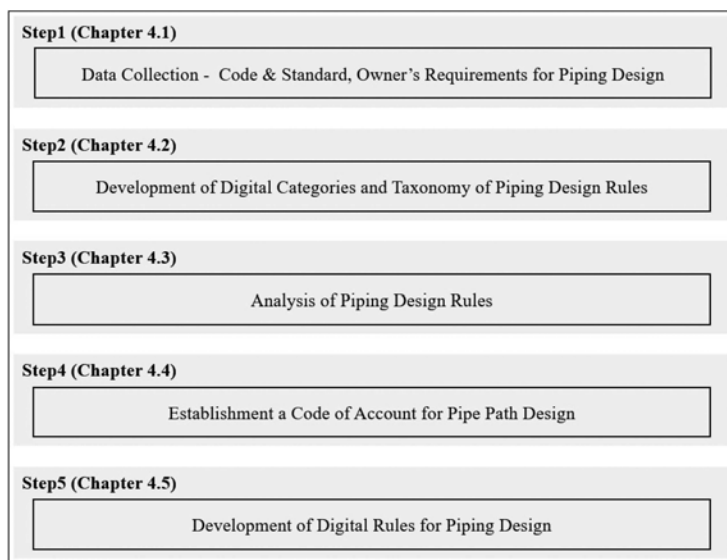

Figure 1. Research process.

4 MODELLING AND IMPLEMENTATION

4.1 Data collection

EPC plant design reflects various design regulations and requirements, including design rules and guidelines, piping installation manual, and classification, as well as international codes & standards such as API, ASME, and owner's requirements. Therefore, in this study, piping design rules applied to EPC plant projects were collected through large EPC companies carrying out EPC plant projects.

4.1.1 Collection of codes & standards for piping auto-routing

The design regulations of the plant project are prepared with international codes & standards as well as the basic data provided by the owner (Kim et al., 2018). This is used as primary data for the basic and detailed design stages, and standardizes details such as engineering design work and manufacturing inspection to reduce repetitive time and cost and enable standard design. In addition, the ultimate goal of codes & standards is to enable mutual compatibility when the same standard is applied.

The major codes & standards used in the piping system of plant projects are the American Petroleum Institute (API), American Society of Mechanical Engineers (ASME), and American Society for Testing and Materials (ASTM), which are American standard codes. In addition, there are European Standards (EN), Norwegian Standards (NORSOK), and Canadian Welding Beuro (CWB). Depending on the type and location of the project, the standards used are different.

Korean EPC companies' plant projects carried out overseas followed the US standard codes API, ASME, and ASTM. Some projects used European Standard (EN) and Japan Industrial Standards (JIS) were used. Recently, it has been a trend that follows group standard codes such as API, ASME, and ASTM. This study collected piping-related codes among ASME Standard (ASME, 2021).

4.1.2 Collection of owner's requirements for piping auto-routing

Since the ultimate purpose of an EPC plant project is to provide results that meet the owner's needs, the owner's requirements must be reflected in design rules and, codes & standards. However, in the initial design stage, it is difficult to format in the form of information that can be reflected in the design, such as the large variability of the owner's requirements and the lack of specific information provision. Such a situation reduces the reliability of the project's direction and goals, causes a delay in decision-making and reversal of work, and results in deterioration of design quality. Therefore, this study collected Invitations to Bid (ITB) and Scope of Work (SoW) of 20 EPC plants to identify the owner's requirements. Table 1 below lists a part of the collected ITB and SoW.

Table 1. Collected owner's requirements data list.

Owner's Requirements	
No.	Projects name

4.2 Development of digital categories and taxonomy of piping design rules

Based on the collected codes & standards and owner's requirements, a digital category structure for system recognition of piping design rules was defined. A rule taxonomy of piping design for EPC plants was established for digital categorization. Taxonomy originated from the Greek word taxis+nomos (law or science), also known as containment hierarchies, as a classification of tree structures for a set of objects (Choi and Lee, 2022).

To this end, the hierarchical structure of the EPC plant project was first analyzed. EPC plant projects are divided into engineering, production, and construction, and engineering disciplines are subdivided into the process, civil and structure, mechanical, piping, and electrical. Among them, piping is primarily classified into Material, Installation, and Stress analysis & supports, and piping installation can be divided into layout modeling and piping routing. This study further subdivided pipe routing for accurate pipe design rule analysis. In the case of pipe routing, it was separated into Above Ground piping (AG piping), a line passing over the ground, and

Under Ground piping (UG piping), a line buried under the ground, depending on the location of the pipeline. In addition, it was further divided into Rough and Detailed in consideration of the possibility of developing a system that automatically optimizes the piping route when designing pipes in the future. Rough refers to a design rule for quick routing, including control and PSV valves, to check the results, adjust the layout, and adjust the equipment position and P/R Dimension. Detailed refers to routing, including all components of P&ID.

Rule taxonomy was established based on the hierarchical structure of the EPC plant project. To this end, this study adopted the WBS system. WBS is a system that visually classifies a classification system into multiple layers based on dependencies and has the advantage of being able to classify complex project ranges and visualize the results linked to projects and dependencies. Therefore, this study classified digital rules for pipe design according to the WBS system, and classified them into a total of eight stages from level 0 to 7 for more detailed pipe design rule classification.

- Level 0: EPC Plant Project
- Level 1: Engineering, Procurement, Construction
- Level 2: Process, Civil and Structure, Piping, Electrical,
- Level 3: Piping Materials, Piping Installation, Piping Stress Analysis & Supports
- Level 4: Plant Layout Modeling, Pipe Routing
- Level 5: AG Piping, UG Piping
- Level 6: Rough, Detail
- Level 7: General, Local, Global

4.3 Analysis of piping design rules

Rule analysis was performed on the pipe design specifications and other pipe design rules of the collected owner's requirements (ITB). EPC plant pipe design experts classified pipe design rules based on the previously established pipe design taxonomy.

Most of the rules are common to the project, and not only do the original sentences and source data for each rule are not accumulated, but there are many rules for ordinary design

Table 2. Analysis of design rules according to the classification of pipe path design rules.

L1	L2	L3	Rule Description
Pipe Routing	Piping	General	Piping shall be routed to ensure the shortest practical length.
			Piping, break flanges and valves at grade shall not be located above manholes or drain trenches, nor supported from grade above buried lines and cables.
			Special considerations shall be given to lines with two-phase flow particularly with regard to the supporting systems.
Piperacks	Piping	General	Adequate space shall be provided to support instrument cable racking and electrical lighting conduits from the piperack structure.
			For units requiring overhead installation of electrical power, space for electrical cable racking shall also be included.
			Piperacks shall include for 20% unoccupied space for each level of piperack for the addition of future lines.
Offsite Piping	Piping	General	All piping shall be located on pipe tracks at grade and supported on concrete sleepers.
			Individual pipes can be supported from concrete piers.
			Consideration shall be given to the size of headers and the size of supporting steel and the thickness of any insulation.

experiences. Therefore, in this study, in addition to the collected codes & standards and ordering requirements, about 2,000 of know-how accumulated from design experience when carrying out projects (about 20) were classified and organized into 400 design issues. The following figure is a part of the Excel data sheet for pipe rule analysis and is the result of detailed design regulations for each level.

4.4 Establishment of a code of account for pipe route design

Based on the analyzed design rules, a code of account for pipe route design was established for design rule classification and rule analysis. The design codes can be used as databases for procurements, construction, estimation, cost control, and design, and are essential for providing the shape of 3D modeling of pipes. It is crucial to design them with the value of information use and future scalability. The design code classification systems should be carefully reviewed in consideration of automation and efficiency before coding.

In this study, based on the functions and types of codes reviewed in Chapter 2 and the analysis and classification of design rules performed in Chapter 3, a piping code system was established to develop a digital category structure for system recognition. The code classification system for pipe route design consists of four categories: main category, sub-category, sub-sub category, and others, and the attribute classification was subdivided into seven levels. A category is structured so that rule properties can be specified as it descends to the lower classification structure, as shown below (Figure 2).

- Main category: Layout/Routing Classification, Applied Location, Applied Method
- Sub-category: Applied Range, Item Classification
- Sub-sub category: Item Detailed Classification
- Others: Rule Description

Figure 2. The classification of a rule code system for piping design.

The number of code digits consisted of 11 digits. The design rule code consisted of letters, numbers, arbitrary symbols, or a combination of them assigned to item properties for information processing according to the order of the already defined classification system.

4.5 Development of digital rules for piping auto-routing

For efficient data processing during auto-routing, data coding that the system can recognize is required. It is challenging to maintain data consistency and causes a decrease in efficiency if the data code used in the actual model is not clearly defined. Therefore, in this study, the digitally coded rules and owner's requirements analyzed according to the code system classified above were named digital rules.

Each rule is assigned a classification symbol indicating the classification status of each type to form a digital rule in a total of 11 digits, and each rule has an independent rule code. The set of digital rules becomes the basis for generating the rule table's attributes; eventually, the rule table consists of a set of rule attributes and parameters. This rule table is a criterion for selecting an appropriate design rule according to the design situation condition during auto-routing. Design rules for general and local issues of AG piping and UG piping among pipe routing are coded and displayed as digital rules. Figure 3 below displays a part of the digital rule table for onshore plants.

L1		L2		L3		L4		L5		L6		L7		Code		
Code	Name	Code	Name	Code	Name	Code	Name	Code	Name	Code	Name	Rule Description				
R	Pipe Routing	A	AG Piping	R	Rough	G	General	B	Base	BS	Basic	The lowest point of all flanges or insulation on pipe running in trenches shall be minimum 150 mm from the bottom of trench.		RUD-BGTR080		
												Process piping shall not be buried.		RUD-BGTR030		
												Where individual pipes at grade are required to cross a road, they shall be buried and pass under the road with a minimum cover height of 1200mm.		RUR-GBSD040		
												Changes in direction shall be accomplished by flat turning.		RAD-BPPR170		
												Regulating, throttling or control valves shall be accessible for hand operation.		RAD-GBBS370		
												A suction line to a centrifugal pump with side or end entry shall be installed with an eccentric reducer (top flat) adjacent to the pump nozzle or nozzle size valve.		RAD-LPCN070		
								P	Pump	CN	Pump Centrifugal	All overhead suction lines shall drain toward the pump without vapour pockets.		RAD-LPCN010		
												The reducer shall be located 2D apart from pump suction nozzle.		RAD-LPCN080		
												CO	Tower	Adequate space shall be allowed between adjacent lines and between lines and the vessel shell to allow the installation of pipe supports and insulation.		RAD-GBSD010
														The back of pipe to vessel shell distance shall normally be 450mm for non-insulated lines and 550mm for insulated lines.		RAD-GBBS420
												VS	Vertical Vessel	Piping for vertical vessels should be located radially around the vessel on the pipe rack side, or should align with adjacent equipment.		RAD-LVCO050

B	Global	P	Piping Way	PR	Pipe Rack	If pipe racks intersect, establish different elevations for lines running north-south versus east-west.		LSS-SPPR041								

Figure 3. An example of a digital rule table.

5 CONCLUSION AND FUTURE WORKS

5.1 Conclusions and contributions

This study developed a digital rule for pipe design that machines can recognize for automating pipe routing design. To this end, design rules and guidelines, piping installation manuals, and classification rules, as well as international codes & standards and owner's requirements, were analyzed. In addition, a rule taxonomy according to the WBS system was established. Based on the established rule taxonomy, about 2,000 design issues, including know-how accumulated from experience, were collected, classified, and organized into about 400 issues by a discussion with piping design experts. Based on the analyzed design rules, a code of account for pipe route design was established for efficient design rule classification and analysis. A digital rule was developed according to the established code system.

Digital rules developed through this study can be used not only as primary data to check consistency and inconsistencies between various documents such as design regulations, installation manuals, and advanced rules but also for developing systems for pipe route design. In addition, it can be used to develop training datasets for AI models, such as rule-set classification algorithms and automatic route placement learning algorithms based on digital rules for classified piping design. The developed digital rules can be applied as a database for procurements, construction, estimation, and cost control. The code classification system can be widely used in the design stage, such as generating commodity codes, establishing piping material specifications, and creating piping 3D specifications. In addition, it can be combined with the latest AI technology to develop a piping auto-routing design system. This not only makes it possible to shorten the design period drastically but also gives an advantage to bidding competitiveness by confirming the pipe design quickly during project bidding and responding quickly to the owner's requirements. It is expected that the design errors and quality degradation caused by the lack of experienced engineers in most Korean companies can be supported by automatic designing by computers, which also contributes to improving the firm's competitiveness and management efficiency.

5.2 Limitations and future works

The limitations of this study and the discussions on further research are as follows. First, most of the pipe design rules are common to the project and not only accumulate source data for each rule, but there are many rules for everyday design experience; therefore, the support from pipe design experts is essential for rule analysis. Also, there is a limitation in that it takes time to build an initial code classification system. Second, since the number of code digits is limited to 11, there is a problem in that the number of digits cannot be expanded according to the user's convenience. This problem can eventually cause user randomness when new rules or additional elements are required. Research on adding code digits for new rules is required in the future.

Finally, the authors plan to develop training data for AI models, such as a rule set classification algorithms based on the digital rules of piping route design developed in this study. Additional research is needed on developing 3D model-based piping optimal route automatic placement technology. In addition, developing a system that automatically optimizes the piping route of an engineering plant by applying AI technology is also required.

Structural response of corroded concrete columns with different rebar confinements under cyclic compressive loading

H.O. Aminulai, N.S. Ferguson & M.M. Kashani
University of Southampton, Southampton UK

ABSTRACT: The new codes have recently introduced seismic detailing for new structures, but there are still older reinforced concrete structures without proper ductile detailing for earthquake resistance. These structures are further impacted by the corrosion of their embedded rebars which further reduces the strength and ductility under loading. This paper presents summary of the results of an experimental investigation performed on short RC columns, with different confinement configurations subject to varying degrees of corrosion, to investigate the structural responses to cyclic loading. The experiment was conducted on 20 short RC columns (square and circular) with two levels of confinements and steel reinforcement corrosion loss ranging from 0% to to ~30% subjected to cyclic compressive load. The test results show that corrosion and rebar confinements significantly impact the structural responses of corroded columns.

1 INTRODUCTION

Reinforced concrete (RC) columns are commonly used to construct civil engineering structures. They are affected by factors such as dry and wet cycles, freeze-thaw cycles, ageing of the materials, and the corrosion of reinforcement steel (Chen et al., 2022, Luo et al., 2020). Among all these factors, steel corrosion has been the most devastating, with chloride-induced corrosion the most severe, leading to catastrophic failure and collapse of structures (Ma et al., 2022). The corrosion of reinforcements in RC members significantly degrades their structural performance leading to structures with reduced load-carrying capacity, ductility and structural safety (Biswas et al., 2020). Furthermore, corrosion significantly reduces the confinement effectiveness of transverse bars and the buckling resistance of longitudinal bars in RC columns, especially structures in severely corrosive environments and subjected to seismic loading (Luo et al., 2020).

Numerous old RC and steel bridges in the marine environment and cold regions (using deicing salt) are suffering from steel corrosion resulting in the durability degradation of RC bridges (Akiyama et al., 2011, Ou et al., 2013, Kashani et al., 2019, Ni Choine et al., 2016). In addition, these bridges are designed with the old codes without proper confinement detailing and seismic resistance, making them vulnerable to collapse under seismic excitation.

While several studies have been dedicated to investigating the structural vulnerability of corrosion-damaged RC members, there is paucity in the literature on the influence of corrosion damage, confinement levels and cross-sectional shape on the seismic behaviour of ageing RC bridge columns/piers. Several numerical and analytical models have been used to investigate the effect of corrosion and transverse reinforcement confinements on RC members' seismic response and failure (Kashani et al., 2016a, Kashani et al., 2016b, Kashani et al., 2018, Su et al., 2015). However, these works have mostly not been validated with experimental tests. Therefore, there is a need for experimental investigation of the seismic response of corroded RC columns to corrosion damage and inadequate confinements under cyclic compressive loading.

Cyclic experiments are a major method to provide insight into the seismic performance of the structural component. However, although it is recognised that the corrosion-induced

damage on coastal bridge piers significantly affects the safety of the structures during the long-term service period, the damage mechanism and the mechanical behaviour are still seldom understood. This paper investigates the effect of corrosion and confinement on the cyclic performance of ageing low-strength concrete RC columns.

2 EXPERIMENTAL CAMPAIGN

2.1 Specimen preparation and material characterisation

Twenty RC columns (ten squares and ten circulars) with five targeted corrosion mass losses (0%, 5%, 10%, 20% and 30%) and two confinement ratios, high ($L/D=5$) and low ($L/D=13$), were used and labelled as shown in Table 1. All the columns have the same length (600mm), with the square columns having 125×125 mm cross-section incorporating 4 $\Phi 10$ mm longitudinal bars, while the circular columns are 125mm diameter with 5 $\Phi 10$ mm longitudinal bars. The columns are confined with $\Phi 6$ mm stirrups in the middle 400mm zone, while the 100mm ends have the stirrups at 25mm spacings. Furthermore, the 100mm ends were strengthened with epoxy-coated GFRP to prevent localised damage at the top and bottom ends of the columns and ensure that the failure occurs at the 400mm middle zone.

Table 1. Experimental test matrix.

Circular columns			Square columns		
Specimen label	Confinement level	Targeted corrosion (%)	Specimen label	Confinement level	Targeted corrosion (%)
C5A0	5	0	S5A0	5	0
C5A5	5	5	S5A5	5	5
C5A10	5	10	S5A10	5	10
C5A20	5	20	S5A20	5	20
C5A30	5	30	S5A30	5	30
C13A0	13	0	S13A0	13	0
C13A5	13	5	S13A5	13	5
C13A10	13	10	S13A10	13	10
C13A20	13	20	S13A20	13	20
C13A30	13	30	S13A30	13	30

The concrete was designed as low-strength concrete representing ageing columns with an expected mean compressive strength of 20MPa. Concrete samples with the same configuration as the square and circular columns were collected during the casting to determine the actual strength of the concrete. The test was done with the servo-hydraulic 630kN Instron Schenk machine at the Testing and Structures Research Laboratory (TSRL), University of Southampton. The average compressive strengths of the concrete are 13.8MPa and 12.6Mpa for the square and circular columns, respectively.

2.2 Accelerated corrosion procedure

The electrochemical method was applied to the corrosion process to hasten corrosion process in the laboratory. This method has been shown to have similar results as natural corrosion (Hou et al., 2019, Mak et al., 2019, Yuan et al., 2007).

The rebars were joined together and connected to the anode, while the stainless steel sheet was linked with the cathode of the direct current (DC) power supply. The power supply was adjusted to supply a constant current of 2Amp for the corrosion of the rebars in the columns submerged in 10% sodium chloride solution (Figure 1(a-b)). Faraday's 2nd law of electrolysis (Equation 1) was used to estimate the expected corrosion mass loss by calculating the duration to achieve such mass loss (Kashani et al., 2013a). The actual mass loss, γ , is estimated at the

Figure 1. Accelerated corrosion procedure; (a) Schematic setup drawing, (b) laboratory setup (c) corroded columns after completion of corrosion and (d) corroded rebars after cleaning.

end of testing by weighing the rebars after removing and cleaning the rust (Figure 1(c-d)) and concrete from the surface (Equation 2). Equation 2 gives an average corrosion loss (mass loss) along the length of the rebar.

$$m_l = \frac{MIT}{ZF} \quad (1)$$

$$\gamma = \frac{m_0 - m}{m_0} \times 100 \quad (2)$$

where m_l = estimated mass loss (g), M = molar mass of the iron (56g/mol), Z = ionic charge for iron ($Z=2$), F = Faraday's constant (96500 C/mol), I = applied current (Ampere, A), T = estimated time to achieve the desired corrosion (s), m_0 = mass per unit length of the uncorroded rebar, and m = mass per unit length after cleaning.

2.3 Cyclic loading protocol and instrumentation

The RC columns were tested under axial compressive cyclic loading. The loading protocol was set to have 20 cycles with ten different mean strains, each strain peak repeating twice, as shown in Figure 2. The mean strain was estimated from the displacement values of a similar experimental test done on corroded RC under monotonic loading. The first five lower strain peaks were applied at 0.1mm/sec loading rate while the remaining peaks were at 0.15mm/sec. The cyclic loading protocol was set up using the Instron Wavemetrics software.

Figure 2. Cyclic compressive loading protocol.

3 EXPERIMENTAL SETUP

The RC columns were tested under axial cyclic compressive load using displacement control with a lower loading rate for the first ten cycles. After that, the remaining cycles were at a slightly higher rate. Also, the test is conducted under complete axial cyclic compression loading, with each loading cycle repeated twice without going into the tension zone. The setup of the experiment is shown in Figure 3(a). The displacement at the middle 400mm zone of the RC columns is

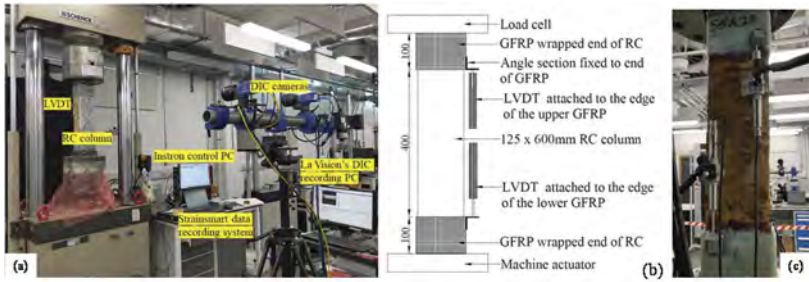

Figure 3. Experimental test setup (a) laboratory setup; (b) schematic of the LVDT connection; (c) Image of the LVDT connections to the RC samples.

measured with the Linear Variable Differential Transformers (LVDTs) fixed to the edge of the Glass fibre-reinforced polymers (GFRP) strengthened ends (Figures 3(b) and 3(c)). This ensures that the LVDTs measure the axial deformations in the differently confined 400mm section of the columns, which are recorded via a data acquisition unit (Strainsmart 8000).

4 EXPERIMENTAL RESULTS

4.1 Calculation of corrosion and mass loss ratio

The actual mass losses resulting from the accelerated corrosion process estimated from Equation 2 are presented in Figure 4. The results showed that the transverse bars had more severe corrosion than the longitudinal bars under the same constant current and duration (Li et al., 2022) in all the columns.

Figure 4. Accelerated corrosion mass loss for the RC columns (a) circular and (b) square.

This mass loss results from the closeness of the transverse bars to the surface of the concrete, leading to a higher concentration of chloride ions and an early start of corrosion (Gu et al., 2020). Furthermore, the diameter of the longitudinal rebar (10mm) was greater than that of the stirrups (6mm). In this regard, the mass loss ratio of transverse stirrups with smaller diameters was higher than that of the longitudinal rebar, according to Faraday's second law of electrolysis (Kashani, 2017).

4.2 Axial cyclic testing of the RC columns

The stress-strain responses of the RC columns to the applied axial cyclic compressive load are presented in Figure 5(a-h). The observed cyclic responses of the RC columns are similar at the elastic range until yield and afterwards becomes nonlinear beyond the peak stress due to the corrosion and confinements of the rebars. The hysteretic curve of the corroded columns within each

confinement's configuration was compared with the non-corroded ones. It showed a gradual decrease in the strength, stiffness and ductility of the columns as the corrosion increased. Consequently, columns with very close mass loss have their maximum strengths relative to each other, especially at low corrosion between 5% and 10% (Figure 5(a, c, e and g)). For example, the strength loss between the highly confined circular columns (Figure 5(a-b)) was reduced by 13%, 22%, 26%, and 37% for the 5%, 10%, 20% and 30% estimated mass loss, respectively. This trend is also observed in the lowly confined ($L/D=13$) columns having between 10% to 48% reduction (Figure 5(c-d)).

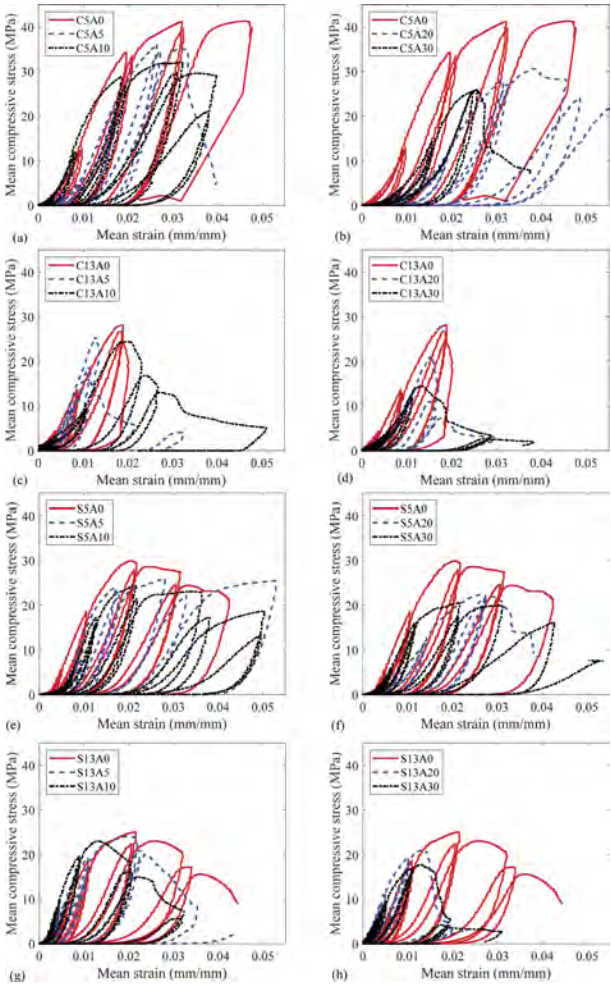

Figure 5. Axial cyclic stress-strain response of the RC columns; circular ($L/D = 5$ (a-b) and $L/D = 13$ (c-d)) and square ($L/D = 5$ (e-f) and $L/D = 13$ (g-h)).

4.3 Impact of corrosion on energy dissipation capacity

The plots of the normalised accumulated hysteretic energy dissipated by the RC columns against the number of cycles are presented in Figure 6(a-d). The graphs showed similar behaviour for all the columns, with very low energy dissipated at the smaller loading cycles (low strain loading rates) and a steep increase in the energy dissipated after the 10th cycle. The steep increase in the dissipated energy is more significant at high corrosion and low confinement in both the circular and square columns.

Figure 6. Normalised dissipated energy of the RC columns; circular ((a) $L/D = 5$, (b) $L/D = 13$); square ((c) $L/D = 5$, and (d) $L/D = 13$).

4.4 Impact of corrosion on buckling of vertical reinforcement

Figure 7. Observed buckling failure of the longitudinal reinforcement in the RC columns. Circular; $L/D = 5$ (a-c), and $L/D = 13$ (d-f), square; $L/D = 5$ (g-i), and $L/D = 13$ (d-f).

The corrosion and confinement of rebars affect the buckling behaviour of the longitudinal bars. This buckling is more pronounced in bars with pitting corrosion, resulting in a localised reduction of the cross-section area along the corroded bar (Kashani et al., 2013a). As a result, the bars in the highly confined circular columns had less buckling at low corrosion (Figure 7(a-b)). Conversely, the buckling of the rebars in the highly confined columns is more pronounced at high corrosion (Figure 7(d)), where the effect of pitting corrosion is prevalent (Kashani et al., 2013b, Kashani, 2017). Furthermore, the buckling of the rebars in the lowly confined columns is more severe even at low corrosion levels from the combination of corrosion and inadequate confinement of the column (Figure 7(d-f)). Similar behaviour is observed in the buckling response of the square columns (high confined Figure 7(g-i) and low confined (Figure 7(j-l)).

5 CONCLUSIONS

Twenty RC column specimens with five different reinforcement corrosion levels and two confinement configurations were tested under axial cyclic compressive load. Moreover, the relationship between the seismic behaviour, such as rebar corrosion loss ratio, ultimate strength, normalised dissipated energy, and inelastic buckling of rebar, was investigated. The following conclusions can be drawn from this study.

Transverse reinforcement showed much higher vulnerability to chloride-induced deterioration in the RC columns than the respective longitudinal reinforcement. Consequently, the ultimate failure of the columns reduced as corrosion damage increased and confinement effectiveness was diminished. Well-confined specimens showed a lesser loss in strength and deformability after corrosion than under-confined specimens.

Corrosion of transverse confining steel affects the strength and deformability of confined concrete. The effectiveness of confinement reinforcements in confining the core concrete reduces as the corrosion increases. Higher corrosion levels and low confinement lead to more severe degradation of the seismic behaviour of RC columns. The highly corroded columns, where the corrosion loss ratio is 20–30%, have reduced seismic response: poor hysteretic response, stiffness degradation, steep descending branch in the envelope curve, and energy dissipation reduction. It can be concluded that the design of new confined concrete elements should consider the possible/anticipated loss due to corrosion during the structure's life to enable a safe ductile response, which is crucial in earthquake-prone regions.

Structural behaviour of axially loaded corroded low-strength RC columns with different confinement ratios

H.O. Aminulai, N.S. Ferguson & M.M. Kashani

University of Southampton, Southampton, UK

ABSTRACT: Many ageing structures in earthquake-prone regions are vulnerable to failure by seismic actions resulting from poor detailing, environmental degradation and quality of materials used. Insufficient column confinement and corrosion of the embedded rebars have been identified as some of the problems with structures in such environments leading to severe damage during earthquakes. This paper presents summary of the result of an experimental investigation on low-strength reinforced concrete (RC) columns with different confinement levels and varying degrees of corrosion. The experiment was done on 20 short RC columns (10 squares and 10 circulars) with two confinements ratios and steel corrosion loss (0% to 30%) subjected to monotonic axial load. The result showed that the axial load carrying capacity and ductility of corroded RC columns reduced with increased in the corrosion mass loss ratios.

1 INTRODUCTION

Over time, the ageing in reinforced concrete (RC) structures results in the degradation of the engineering properties of structures by limiting the capacity and resistance to failure (Karapetrou et al., 2017, Yang et al., 2016). This failure is more pronounced in RC structures in aggressive and marine environments located in seismic regions subject to corrosion effects and poor quality of materials used in construction. Corrosion of reinforcement in concrete is one of the most common and dangerous environmental deteriorations affecting the structural performance of ageing structures in chloride-laden and high seismic environments (Kashani et al., 2015a, Vu et al., 2017). Furthermore, it significantly reduces the diameter (Du et al., 2005), strength (Vu and Bing, 2018) and axial load-bearing capacity of reinforcing bars in corroded RC structures (Shen et al., 2021), which further results in the reduction in the concrete core confinement leading to the degradation in ductility and the long-term performance of the RC structure (Ma et al., 2022, Fang, 2020). Chloride-induced corrosion significantly degrades RC structures, resulting in substantial economic loss worldwide (Altoubat et al., 2016). For example, the United States of America reported needing about \$125 billion to repair ageing and existing bridges (American Society of Civil Engineers (ASCE), 2021). In comparison, the United Kingdom estimated the cost of corrosion damages to highway bridges in Wales and England (approximately 10% of the total bridges in the United Kingdom) at £1 billion per year (Wallbank, 1989).

Ageing RC columns/piers generally fail through the buckling of the vertical reinforcement bars together with the crushing of core confined concrete and the fracture of the longitudinal bars (Kashani et al., 2019), resulting from inadequate confining transverse reinforcements. This confinement reinforcement provides the compressed concrete with higher flexibility and stability, which helps to prevent collapse during vibrations (Mander et al., 1988). Thus, the higher the level of confining stress in the concrete, the more its ductility and strength gain (Zeng, 2017).

Several numerical and analytical models have been developed to investigate the effect of confinement on the axial load capacity and stress-strain behaviour of RC columns (Zeng, 2017, Saatcioglu and Razvi, 1992, Mander et al., 1988, Liang et al., 2015, Hoshikuma et al., 1997). However, these models are primarily on plain normal and high-strength RC columns without considering the effect of corrosion. These models have been incorporated into design guidelines for new RC bridge columns/piers. However, many inadequately confined old bridge columns with low concrete strength are still in the seismic regions. Therefore, their response to the combined effects of degradation and axial load needs to be investigated.

The stress-strain responses of non-corroded RC columns have been extensively investigated numerically (Andisheh et al., 2021). Still, there are very few experimental investigations of the effects of corrosion on the stress-strain behaviour of confined concrete columns. This research presents the results of an experiment on ageing low-strength circular and square RC columns subject to reinforcement corrosion, confinement ratios and axial load. Twenty low-strength RC columns were designed and grouped into five targeted corrosion losses (i.e., 0%, 5%, 10%, 20% and 30%) with two confinement ratios ($L/D = 5$ and $L/D = 13$) under monotonic axial load. The different degrees of reinforcement corrosion was obtained by accelerated corrosion technique using the electrochemical process. In addition, the effect of reinforcement corrosion and confinement ratios on the load-deformation responses of the RC columns was analysed.

2 METHODOLOGY

2.1 Specimen details and material properties

A total of twenty RC columns (ten squares and ten circulars) were designed, as shown in Figure 1, with two confinement levels and five targeted corrosion losses. The square columns are $125 \times 125 \times 600\text{mm}$, incorporating 4 No. 10mm diameter longitudinal bars, while the circular samples (125mm diameter $\times 600\text{mm}$ long) have 5 No. 10mm longitudinal bars. The columns were designed with two different confinement ratios in the middle 400mm zone, while the 100mm ends have transverse bars spaced at 25mm (Figures 1a and 1b). Furthermore, the 100mm ends are wrapped with epoxy-coated GFRP to prevent localised damage at the top and bottom ends of the columns and ensure that the failure occurs at the RC columns' middle zone. All the rebars in the columns were connected with tie wires to ensure that the transverse and longitudinal bars corrode simultaneously during the corrosion process.

Figure 1. Specimen details; (a) schematic drawing and (b) Reinforcement layouts (cages) of the high and low confinement (circular and square columns).

The concrete was designed as low-strength concrete representing a non-code conforming column with an expected mean compressive strength of 20MPa and a nominal cover of 10mm. Compressive strength tests were done on concrete samples collected during the casting of the columns at the Testing and Structures Research Laboratory (TSRL), University of Southampton, using the servo-hydraulic 630kN Instron Schenk machine. The columns were tested using the displacement control at a constant loading rate of 1mm/min until failure. The samples used for this test were not the conventional cube/cylinder samples but with the same configurations as the reinforced ones. The compressive strength of the concrete is estimated to be 12.1MPa.

2.2 Accelerated corrosion procedure

The natural corrosion process usually takes a more extended period which could be several years or decades (Kashani et al., 2019). As such, the electrochemical process known as the accelerated corrosion method is often adopted in the laboratory to simulate the corrosion process. The RC samples' corrosion was done by passing a constant current of 2A through the reinforcing bars connected to the anode of the DC power supplies while also connecting the stainless steel plate to the cathode. Then, the connected specimen is placed in a salt bath with 10% sodium chloride (NaCl) by water weight to simulate the corrosive environment (Figure 2 (a and b)).

This process is used to get an estimated corrosion mass loss by calculating the duration expected to achieve the desired mass loss using Faraday's 2nd law of electrolysis (Equation 1) (Kashani et al., 2013b). Conversely, the actual mass loss is estimated at the end of testing by weighing the rebars after removing and cleaning the rust and concrete from the surface (Equation 2). Equation 2 gives an average corrosion loss (mass loss) along the length of the rebar.

$$\Delta m = \frac{MIT}{ZF} \quad (1)$$

$$\gamma = \frac{m_0 - m}{m} \times 100 \quad (2)$$

where Δm = mass loss (g), M = molar mass of iron (56g/mol), Z = ionic charge for iron, F = Faraday's constant (96500 C/mol), I = applied current (A), T = time to achieve corrosion (s), m_0 = mass per unit length of original rebar, and m = mass per unit length of the corroded rebar.

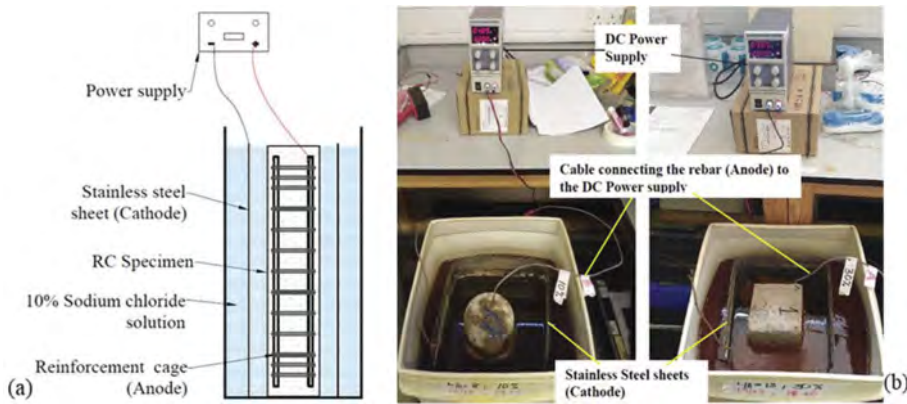

Figure 2. Accelerated corrosion procedure; (a) Schematic setup drawing, (b) laboratory setup.

3 EXPERIMENTAL SETUP

This experiment studies the response of low-strength RC columns to axial compressive loading using the servo-hydraulic 630kN capacity Instron Schenck machine having a 250mm travel at the Testing and Structures Research Laboratory (TSRL) of the University of Southampton. The test is conducted at a constant loading rate of 1mm/min using the displacement control settings in the Instron software. The laboratory setup of the experiment is shown in Figure 3(a). The displacement at the middle section of the column is measured with two Linear Variable Differential Transformers (LVDT) fixed to the edge of the GFRP strengthened end Figure 3(b-c).

4 EXPERIMENTAL RESULTS

4.1 Calculation of corrosion and mass loss ratio

The mass loss results are illustrated in Table 1 for the circular and square columns. The results indicate that the transverse stirrups had more severe corrosion than the longitudinal bar under the same constant current and duration (Li et al., 2022). This results from the closeness of the transverse bars to the surface of the concrete, leading to a possibly higher concentration of chloride ions and an early start of corrosion (Gu et al., 2020). Furthermore, the diameter of the longitudinal rebar (10mm) was greater than that of the stirrups (6mm). In this regard, the mass loss ratio of transverse stirrups with smaller diameters was higher than that of the longitudinal rebar, according to Faraday's second law of electrolysis (Kashani et al., 2013b).

4.2 Axial stress-strain response of RC columns

The stress-strain responses of the circular and square columns to the applied axial compressive load are presented in Figures 4 (a-b) and 4 (c-d). The stress-strain response plotted was from the LVDTs data, which captures the deformation of the sample at the 400mm middle section. The compressive response of the columns is similar at the elastic range until yield and afterwards reduces beyond the peak load due to corrosion and confinements of the rebars (Dong et al., 2018).

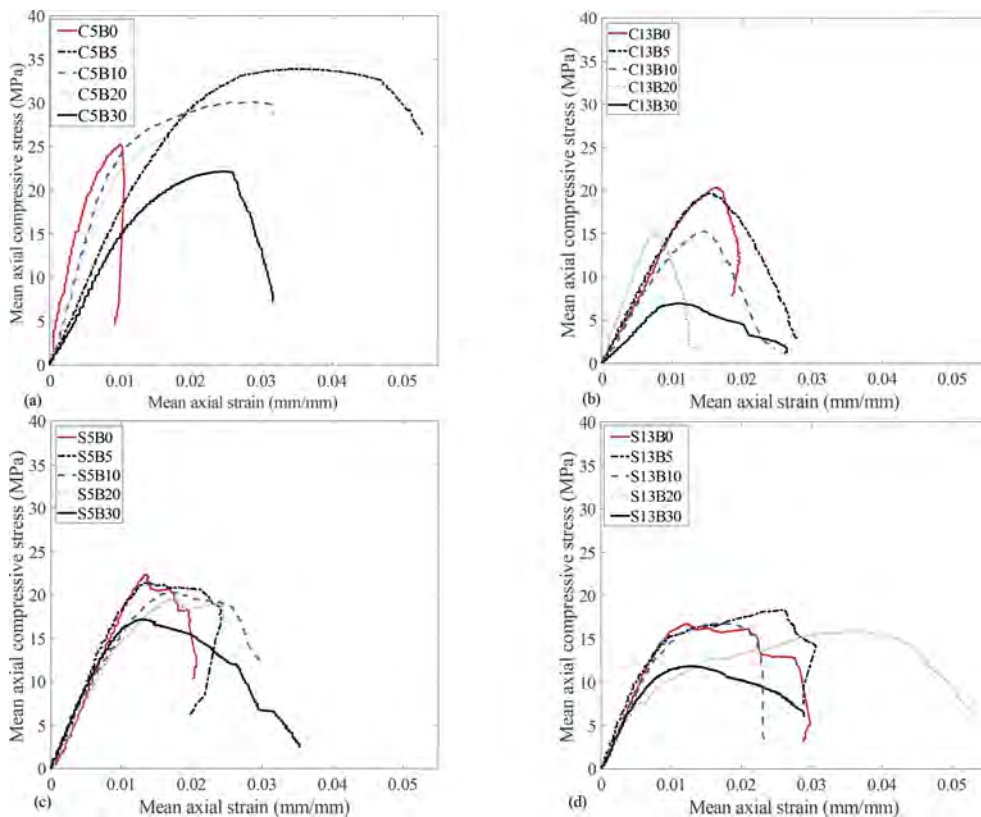

Figure 4. Axial compressive stress-strain responses of RC columns (a) circular $L/D = 5$, (b) circular $L/D = 13$, (c) square $L/D = 5$, and (d) square $L/D = 13$.

The axial load-carrying capacities of the columns generally decrease with an increase in the corrosion level within each confinement configuration of columns, except in some cases where the control sample (0% corrosion) recorded low capacity due to the premature failure of the strengthening GFRP at the top/bottom of the column. The failure of the GFRP at the

top/bottom of the column leads to stress concentration and premature failure of the columns. It is observed that the circular columns generally have better axial load-carrying capacities and axial strain than the square columns (Liang et al., 2015, Dizaj and Kashani, 2020). This results from the effectiveness of the transverse ties in the circular column, which has more significant confinement effectiveness coefficients than the square columns (Liang et al., 2015)

4.3 Impact of corrosion on the strength of confined RC column

The strength loss resulting from the corrosion and confinement ratios of the RC columns is determined by normalising the ultimate strength of the corroded columns to the ultimate strength of the uncorroded. The normalised strength loss of the differently confined RC columns is plotted relative to the percentage of corrosion mass loss. Linear trend lines are fitted to the test data to estimate the strength reduction due to corrosion and confinement ratios. The R-square values obtained from the trendlines are 0.95 and 0.90 for the circular columns with high and low confinement ratios, respectively, while the variation for the square columns is 0.99 and 0.96 for similarly confined columns (Figure 5). The ultimate strength of the confined corroded RC columns is reduced with an increase in the confinement degree and corrosion mass loss. For example, the high-confined circular columns (Figure 5(a)) have a strength reduction range of 4.7%, 14%, 26% and 36.7% for the 4.1%, 7.3%, 10.8% and 20.6% corrosion mass loss, respectively. Also, the high-confined square columns (Figure 5(b)) have a strength reduction range of 5.1%, 10.6%, 19.6% and 29.6% for the 3.4%, 6.8%, 13.8% and 18.4% corrosion mass loss, respectively. A similar trend is observed in the low-confined columns, with the strength reduction increasing with an increase in the corrosion mass losses in the circular and square columns.

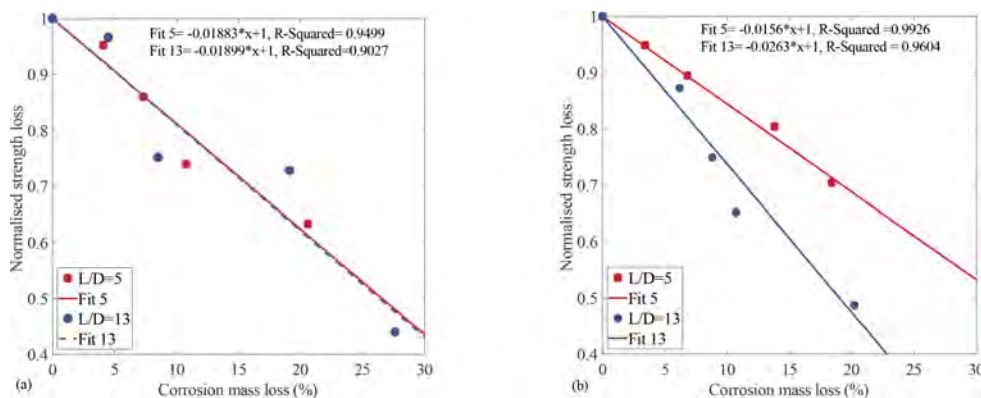

Figure 5. Strength variation of the confined RC columns with corrosion (a) circular and (b) square.

4.4 Impact of corrosion on inelastic buckling behaviour of vertical reinforcement

Corrosion generally reduces the cross-sectional areas of bars available to sustain the applied load (Kashani, 2017). This reduction becomes more severe in bars with pitting corrosion, resulting in localised reduction in the cross-sectional areas of the bars, causing rebar fracture and localised buckling. Longitudinal bars in columns with $L/D = 5$ confinement had less buckling failure, especially at lower corrosion than bars from the $L/D = 13$ configurations. The buckling from the columns with $L/D = 5$ rebars at higher corrosion levels results from the unsymmetrical cross-sections arising from the pitting corrosion causing imperfections in the bar and leading to additional bending moment and local stresses at the pitted sections (Kashani et al., 2013b, Kashani et al., 2013a). Meanwhile, the buckling from the columns with $L/D = 13$ results from the combination of pitting corrosion and inadequate confinement provisions leading to premature yielding and squashing of the weakest section even at lower corrosion degrees (Kashani et al., 2015b).

Figure 6. Observed buckling failure of the longitudinal reinforcement after testing; $L/D = 5$ (a-d) and $L/D = 13$ (e-h).

5 CONCLUSIONS

The effects of corrosion on the axial load capacity of differently confined RC columns have been studied experimentally. The primary conclusions drawn from the analysis of the experimental data are as follows.

Corrosion of reinforcements severely reduces the load-carrying capacity and stiffness of RC columns. Therefore, local buckling is more severe for specimens with high corrosion rates and buckling always occur in the sections with more rust products. This is evidence that the local buckling of the rebar is strongly related to its corrosion condition. Furthermore, the inelastic buckling mechanism of bars is affected by non-uniform pitting corrosion. The observed buckling modes showed that the buckling mechanism of corroded bars is a function of the mass loss due to corrosion and the distribution of pits along the bar length. Hence, the bars with more corrosion mass loss experienced more buckling and fracture than columns at low corrosion losses.

Confinement also significantly impacts corroded rebars' stress-strain response and buckling, as the high-confined columns have higher load-carrying capacities than the low-confined ones. Also, highly confined columns at low corrosion have less buckling than columns with the same confinement at high corrosion. Meanwhile, low-confined columns fail due to inadequate confinement and corrosion, even at low corrosion levels.

ABSTRACT: The experience from the past seismic events shows that the accumulated damage induced by the previous earthquakes increases the vulnerability of Reinforced Concrete (RC) structures. Moreover, RC structures constructed in aggressive environments such as those located in the coastal area suffer from the ageing and degradation phenomena. Therefore, the concurrent influence of successive seismic hazards and corrosion-induced degradation might result in undesired seismic failure of these RC structures. From this perspective, this paper investigates the seismic performance of RC frames affected by chloride-induced corrosion of reinforcements subject to as-recorded (real) mainshock-aftershock excitations. To this end, a prototype RC frame is analysed under real mainshock-aftershock ground motions at different times since corrosion initiation. First, a suite of mainshock-aftershock records is selected from a unique database using the Conditional Mean Spectrum (CMS) methodology. Then, an advanced numerical model capable of tracking the low-cycle fatigue degradation and inelastic buckling of reinforcements is used to simulate the nonlinear dynamic behaviour of the studied frames with different levels of corrosion. Finally, the seismic performance and fragility of the considered structures are evaluated using the outputs of nonlinear static and incremental dynamic analyses. The results show that the vulnerability of corroded reinforced concrete frames is significantly increased under successive earthquake events. Moreover, the results of this paper show that the probability of failure of corrosion-damaged RC frames depends crucially on the magnitude of the aftershocks.

1 INTRODUCTION

The past decade witnessed several disastrous sequential earthquakes globally (Jeon et al. 2015, Raghunandan et al. 2015, Salami et al. 2019). The experience of past earthquakes shows that civil engineering structures are more vulnerable under multiple earthquake events than a single excitation. The consequence of such earthquake chains is significant damage/collapse of RC structures (Manafpour & Moghaddam 2019). Consequently, investigating the seismic performance of RC structures subject to mainshock-aftershock sequences has received considerable attention during the last decades. The outcome of these studies shows that the accumulated damage during the mainshock (MS) event significantly affects the probability of failure of structures under the second event, i.e., aftershock (AS) (Goda & Taylor 2012, Iervolino et al. 2020, Hosseinpour & Abdelnaby 2017, Salami et al. 2021).

RC structures are generally exposed to multiple stressors in their lifetime. Among the several degradation mechanisms, the chloride-induced corrosion of reinforcements has been classified as

one of the leading causes of the premature collapse of several RC structures/infrastructures (Afsar Dizaj & Kashani 2020, Afsar Dizaj et al. 2021, Cui et al. 2019, Panchireddi & Ghosh 2019). Several researchers have investigated the adverse influence of corrosion-induced damage on the structural performance of RC structures (Apostolopoulos & Papadakis 2008, Du et al. 2005a,b). Moreover, the seismic performance of such structures has been extensively investigated. The outcome of these studies confirms the poor seismic performance of corroded RC structures compared to their pristine status (Alipour et al. 2011, Kashani et al. 2019, Afsar Dizaj & Kashani 2022a).

The accumulated damage in the first seismic event, coupled with the increased corrosion-induced damage, can exacerbate the seismic performance of RC structures located in high seismicity regions. However, the literature review shows a significant scarcity in investigating the vulnerability of corroded RC structures subject to mainshock-aftershock excitations. To this end, this study aims to study the nonlinear dynamic behaviour and fragility of corroded RC frames subject to real (as-recorded) mainshock-aftershock ground motions. In the following sections, the details of the study are presented.

2 PROTOTYPE RC FRAME

2.1 Structural details

Figure 1 shows the geometry and structural details of the prototype RC frame considered here to study the combined effects of earthquake sequences and corrosion-induced degradation on the seismic fragility of RC structures. The frame is located in California, US, with harsh environmental conditions. It is designed according to the requirements of ACI 318–02 (2002) and ASCE 7–02 (2002). In Figure 1, H and B denote the depth and width of components; ρ_l is the vertical reinforcement ratio; ρ_v is the volumetric ratio of transverse reinforcements; S_h is the spacing of hoops; and ρ_{top} and ρ_{bot} are longitudinal reinforcement ratio at the top and bottom of beam section, respectively. Further information on design assumptions and details of this frame is available in (Afsar Dizaj et al. 2022).

Different corrosion statuses, including (i) pristine, (ii) slightly corroded and (iii) highly corroded conditions, are considered to investigate the influence of corrosion degree on the structural performance of the considered RC frame. The material and geometrical properties of the frame are updated using the mass loss ratio of rebars (ψ) in any of the corrosion statuses mentioned above. This parameter can be calculated using Equation 1 (Afsar Dizaj 2022):

$$\psi = 1 - \left(\frac{XD - 1.05 \times (1 - W/C)^{-1.64} \times t^{0.71}}{XD} \right)^2 \quad (1)$$

where X is cover thickness, D is the diameter of main bars; W/C is the water-to-cement ratio, and t is the time from corrosion initiation. In order to induce the hypothetical corrosion degrees mentioned above, t is assumed to be 0, 10, and 100 years for pristine, slightly corroded and highly corroded conditions, respectively. Further details can be found in (Afsar Dizaj 2022).

2.2 Numerical model

In this study, the advanced nonlinear finite element model developed in (Afsar Dizaj et al. 2018a, b) is employed to simulate the nonlinear behaviour of the case-study RC frame. Figure 2 shows the numerical model of the hypothetical RC frame. This model can simulate the inelastic buckling behaviour and low-cycle fatigue degradation of reinforcements. As Figure 2 shows, columns and beam are divided into several fibre sections in their entire length in this model. Moreover, each component is modelled using three force-based elements: a zero-length section element to simulate the slippage of reinforcement at connection adjacent, a force-based element with three integration points and another element with five

integration points. The details of this modelling technique are presented in the systematic modelling guidelines provided in (Afsar Dizaj & Kashani 2022b).

The material properties used in numerical modelling are tabulated in Table 1.

Table 1. Steel and concrete material properties.

Notation	Description	Value	Unit
f_y	yield strength of main bars	420	MPa
f_u	ultimate strength of main bars	620	MPa
f_{yh}	yield strength of hoops	300	MPa
E_s	modulus of elasticity of steel	210	GPa
f_c	compressive strength of concrete	35	MPa
ϵ_u	ultimate strain of main bars	0.18	-
ϵ_s	strain at maximum stress of hoops	0.15	-

Figure 1. Structural details of the prototype RC frame.

Figure 2. Finite element model of the prototype RC.

3 PUSHOVER ANALYSIS

In order to quantify the time-dependent damage limit states, nonlinear pushover analysis is carried out on the considered RC frames with different hypothetical corrosion statuses. Before conducting the pushover analysis, the material and geometrical properties of the frame are modified to incorporate corrosion-induced degradation. Moreover, the bases of the columns are assumed to be fully fixed. The P-delta effects are also included in the analyses.

Figure 3 shows the time-dependent pushover analysis results for each considered time from corrosion initiation. Results show that as the corrosion level increases, the ductility and lateral load capacity of the frame significantly decrease. The onset of bar yielding, cover concrete spalling, core concrete crushing, and bar fracture are mapped on each capacity curve. The results indicate that each of these damage limit states reaches in lower drift ratios for higher corrosion degrees. For instance, while the core cover spalling occurs at approximately 0.021 drift ratio for the slightly corroded frame, it took place at the vicinity of 0.015 drift ratio for the highly corroded frame. These time-dependent damage limit states are used in this study to develop time-dependent fragility curves.

Figure 3. Time-dependent pushover analysis results.

4 MAINSHOCK-AFTERSHOCK GROUND MOTION SELECTION

The selection of aftershocks is a critical step toward conducting incremental dynamic and fragility analysis of structures. The review of previous studies shows that improper selection of mainshock-aftershock ground motions can significantly bias the expected seismic performance of RC structures (Goda 2015). Several researchers have welcomed using as-recorded MSAS ground motion records in recent years (Goda & Taylor 2012, Goda 2015). Similarly, in this study, as-recorded (real) MSAS record sequences are selected to conduct vulnerability analysis of studied RC frames with varied corrosion levels.

Here, conditional mean spectrum (CMS) methodology is used to select a sufficient number of MSAS sequences. To this end, the spectral acceleration at the first fundamental period of the frame is considered as the intensity measure (IM). Moreover, the local seismicity level and soil class of the site are taken into account. Further details about the MSAS ground motion selection are presented in (Afsar Dizaj et al. 2022). In total, forty-eight MSAS ground motion records are selected to be utilised in IDAs. Figure 4 shows the disaggregation data and spectral acceleration response of selected ground motions. The summary of the selected as-recorded MS-AS ground motion sequences is available in Afsar Dizaj et al. (2022).

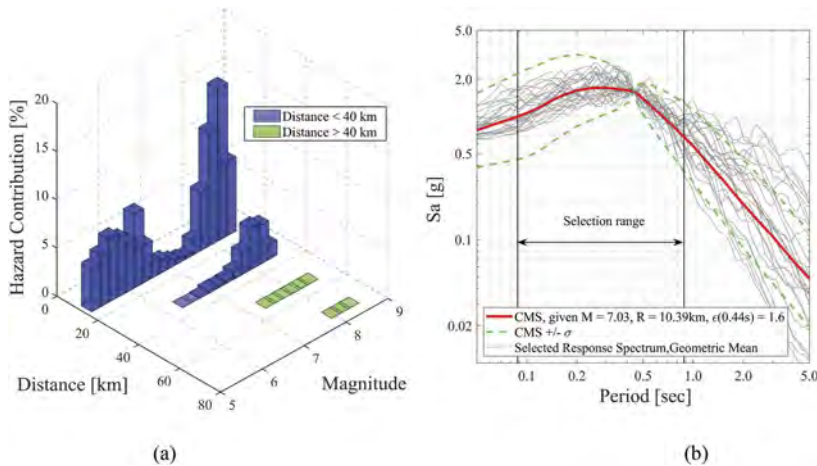

Figure 4. Selected ground motions: (a) disaggregation data, and (b) selected MSAS sequences.

5 RESULTS AND DISCUSSION

5.1 IDA results

Using the selected MSAS ground motion records, IDA is conducted on studied RC frames. First, the MS acceleration histories with scaled-up intensities in $Sa(T_1)$ were applied to the frames, and the structural response in terms of maximum lateral drift was recorded. Then, a 60 seconds rest time was inserted between the MS and AS records, and the assembled MSAS sequence was used as input to conduct MSAS IDAs.

Figure 5 compares the IDA results under MS event with MSAS excitation. This figure shows that for a drift ratio less than 0.025, the median MSAS IDA curves are approximately the same as MS IDA curves. However, for higher drift ratios, for a specific intensity of earthquake record, the frame experiences greater drift ratios under MSAS sequence rather than a single MS record (Figure 5a). As Figure 5b shows, a likewise trend can be seen for $t=10$ years. However, as Figure 5c shows, the median IDA response of severely corroded frame under MSAS sequence is approximately the same as that of MS. Such a trend in median IDA outputs can be attributed to premature material failure in higher corrosion levels. Consequently, the frame fails under the MS event before the upcoming event (i.e., AS) occurs. The results obtained in the shake table experiment of severely corrosion-damaged RC columns (Ge et al. 2020) confirm the results obtained in this study.

5.2 Fragility curves

In this section, the failure probability of examined frames under MS and MSAS records is investigated. To this end, the following fragility function is used:

$$P[EDP \geq DS | IM = x] = 1 - \Phi \left(\frac{\ln(DS) - \ln(\mu)}{\beta} \right) \quad (2)$$

where $P[.]$ is the probability that the engineering demand parameter (EDP) exceeds a damage state (DS) provided that the intensity of the earthquake equals x . Here, the EDP is assumed to be the peak drift ratio. On the right side of Equation 2, $\Phi(.)$ is the lognormal distribution function with the logarithmic mean, and standard deviation of $\ln(\mu)$ and β , respectively, which can be obtained using Equations 3-4:

$$\ln(\mu) = \frac{\sum_{i=1}^n \ln(EDP_i)}{n} \quad (3)$$

$$\beta = \sqrt{\frac{\sum_{i=1}^n (\ln(EDP_i) - \ln(\mu))^2}{n - 1}} \quad (4)$$

In Equations 3-4, n is the number of records, and EDP_i is the peak drift ratio associated with a given value of IM for the i_{th} record.

Figure 6 shows the MS and MSAS fragility curves for all frames. Figure 6 shows that the probability of exceeding the collapse threshold under MSAS records is somewhat greater for a given IM than MS records. This indicates that the studied RC frames with varied corrosion levels are slightly more vulnerable under MSAS ground motions sequences than MS records. Therefore, it can be concluded from the results that, as observed in IDA results (Figure 5), the real MSAS records have a negligible impact on the nonlinear dynamic behaviour and fragility of corroded RC frames.

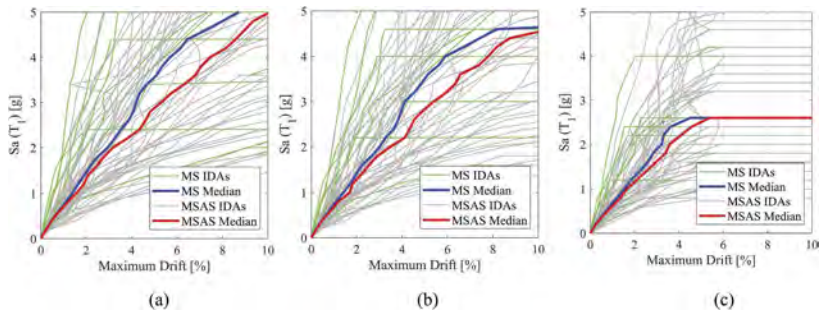

Figure 5. IDA results: (a) pristine frame, (b) $t = 10$ years and (c) $t = 100$ years.

Figure 6. Fragility curves: (a) pristine frame, (b) $t = 10$ years and (c) $t = 100$ years.

Figure 7. IDA results for records with higher AS/MS PGA ratio: (a) pristine frame, (b) $t = 10$ years and (c) $t = 100$ years.

5.3 Impact of aftershock intensity

The results presented in the previous section indicated that the MSAS records slightly increase the failure probability of RC frames, regardless of aftershock magnitude. In this section, the influence of aftershock to mainshock intensity ratio on nonlinear dynamic behaviour and fragility of studied RC frames is investigated. To this end, from the entire 48 selected MSAS sequences, those with aftershock PGA to mainshock PGA greater than or equal to unity are selected. There are eight ground motion records with this property. In Figure 7, presents the median IDA results of the frames under these eight records. As Figure 7 shows, under the stronger aftershock records, all the frames experience significantly higher drift ratios in all the frames. This implies that the response of a RC frame under MSAS sequence crucially depends on the intensity of the aftershock records.

Figure 8 shows the failure fragility curves under the selected MSAS sequence records with higher PGA of aftershocks to their MS. As this figure shows, the collapse probability of the pristine frame and the slightly corroded frame is not remarkably affected by the PGA ratio of

Figure 8. Fragility curves for records with higher AS/MS PGA ratio: (a) pristine frame, (b) $t=10$ years and (c) $t=100$ years.

aftershock to the mainshock. However, as shown in Figure 8c, the highly corrosion-damaged frame is much more fragile under the MSAS sequence than MS records. This infers that the PGA ratio of aftershock to mainshock is a critical factor in the fragility analysis of corrosion-damaged RC frames.

6 CONCLUSIONS

In this study, the seismic performance of corrosion-damaged RC frames under MSAS sequences is investigated. To this end, an advanced modelling methodology was employed to accurately simulate the nonlinear behaviour of RC frames with varied corrosion levels, including an uncorroded frame, a slightly corroded frame and a highly corroded frame. First, nonlinear pushover analysis is carried out on the studied RC frames to quantify the time-dependent seismic damage limit states. Subsequently, IDAs conducted using a suite of 48 as-recorded mainshock-aftershock ground motion records. Finally, the fragility curves were developed using the IDA outputs for the frames under MS records and MSAS sequences.

Overall, the results show that using the real mainshock-aftershock sequences, the failure probability of corrosion-damaged frames slightly increases with respect to MS events. Notably, for the highly corroded frame, the results show that in most cases, the structure fails under the MS record before the subsequent event (i.e., aftershock) comes up. This is due to the brittle failure mode of extremely corroded RC frame due to premature failure of confinements.

Moreover, results show that the PGA ratio of aftershock to mainshock plays a critical role in the vulnerability assessment of corroded RC frames. This conclusion is drawn based on eight MSAS records with higher PGA of aftershock records, where the results showed a significantly higher failure probability of structure under MSAS records.

ABSTRACT: Reinforced Concrete (RC) bridges in over crossings are typically constructed with unequal-height piers. The resulting substructure irregularity triggers an unbalanced seismic behaviour of these bridges, which increases their seismic vulnerability. The seismic irregularity of such bridge structures might be further intensified if the piers of varying heights expose to unsymmetrical chloride-induced corrosion damage. To accurately evaluate the seismic vulnerability of corroded irregular RC bridges, this paper studies the seismic fragility of a benchmark multi-span irregular RC bridge with five different corrosion damage scenarios, including unsymmetrical corrosion of piers. Toward this objective, first, monotonic nonlinear pushover analysis is used to quantify the time-dependent seismic capacity limit states by employing an advanced three-dimensional nonlinear finite element model. Then, Incremental Dynamic Analysis (IDA) and seismic fragility analysis are carried out to investigate the nonlinear dynamic behaviour and vulnerability of selected corroded bridges. The results show that, depending on the corrosion scenario, the distribution of seismic ductility demands can be varied in unequal-height bents, which can change the critical bent within a bridge system. Furthermore, results indicate that severe unsymmetrical corrosion damage can cause a synchronised failure of unequal-height piers.

1 INTRODUCTION

Bridges supported on piers of unequal heights are commonly the only construction choice in over-crossings (Kappos et al. 2002, Guirguis and Mehanny 2012). The substructure irregularity of such bridges triggers unbalanced distribution of seismic ductility demand among the piers of varying heights. Some design codes provide recommendations to ensure the regular seismic behaviour of multi-span RC bridges (AASHTO 2011, Caltrans 2013). Moreover, several methodologies have been proposed in the literature to mitigate the unbalanced distribution of seismic demand in irregular multi-span RC bridges (Priestley 2007, Xiang and Li 2020, Ishak and Mehanny 2017, Jara et al. 2013).

The seismic behaviour analysis of irregular RC bridges has been widely studied in the literature (Soleimani et al. 2017, Soltanieh et al. 2019, Hu & Guo 2020, Saiidi et al. 2012, Camacho et al. 2022). Gomez-Soberon et al. (2019) evaluated the seismic behaviour of highway bridges with different irregularity conditions. Their results showed that the adjacent piers of unequal heights considerably affect the vulnerability of concrete bridges. Sensitivity analyses on RC bridges with various irregularity conditions conducted by Soleimani et al. (2017) indicated

that earthquake intensity level, pier height, pier diameter, longitudinal reinforcement ratio, concrete compressive strength, and span length are the most important parameters determining the seismic performance of RC bridges with the irregular layout. Hu and Guo (2020) evaluated the seismic response of high-speed railway bridge-track systems with unequal-height pier configurations. The results showed that increasing the height difference of adjacent bridge piers intensifies the seismic displacement responses of the shear alveolar, moveable bearings, and sliding layer. Jara et al. (2015) found that hard soil ground motion records cause moderate damage in bridge columns, whereas soft soil records trigger considerable damage in columns.

Over the past few years, corrosion damage and ageing of RC bridges have become a challenging problem among structural engineers and bridge owners (ASCE 2021, Ghosh & Sood 2016, Afsar Dizaj& Kashani 2022, Afsar Dizaj et al. 2021). A survey conducted by Department for Transport and Highways England estimated that corrosion damage to concrete bridges costs about £1 billion/per year in England and Wales (Comptroller and Auditor General 2014, Broomfield 2007). Previous studies on seismic fragility assessment of corroded concrete bridges commonly supposed a uniform corrosion scenario, where the average time-dependent corrosion level of piers is assumed to be the same (Choe et al., 2009, Zhang et al. 2019). However, constructing bridges over highways, rivers, railways, and valleys leads to various corrosion scenarios in bridge piers. Therefore, the seismic behaviour of concrete bridges with substructure irregularity can be significantly affected if they are located in chloride-laden environments.

The nonuniform chloride-induced corrosion of piers can exacerbate the unbalanced seismic demand and affect the transverse seismic behaviour of irregular bridges. Moreover, it can change the pattern of demand distribution, affect the damage mechanisms, and alter the failure sequence of bents of varying heights. This paper aims to investigate the seismic performance and fragility of irregular nonuniformly corroded bridges.

2 BRIDGE DETAILS AND NUMERICAL MODELLING

2.1 Geometry and details

In this study, the details of a two-span RC bridge tested in the shake table facility of the University of Nevada are considered here to study the combined effects of corrosion damage and substructure irregularity on the seismic fragility of RC bridges (Johnson et al. 2008). Figure 1 shows the geometry and structural details of this prototype irregular benchmark RC bridge. As shown in Figure 2, the total bridge length is 2050.0 cm, and the span length is 914.0 cm; the clear height of the piers from the top of the foundation is 182.9 cm, 243.8 cm and 152.4 cm for bent 1, bent 2 and bent 3, respectively. Six 9.1 tons, two 10.8 tons, and two 2.3 tons of super-imposed weights are placed on the superstructure. Moreover, the diameter of all columns is 30.5 cm; the longitudinal reinforcement ratio is approximately $\rho_l = 1.56\%$, and the spiral reinforcement ratio is $\rho_s = 0.9\%$. Further details on the structural details and material properties of this bridge specimen can be found in (Johnson et al. 2008).

Figure 1. Geometry of the benchmark bridge.

Figure 2. Three-dimensional finite element model of benchmark RC bridge.

2.2 Finite element model

In this study, the advanced nonlinear finite element modelling technique developed by Afsar Dizaj and Kashani (2022) is extended to simulate the nonlinear structural response of the benchmark RC bridge. The adequacy of this model in simulating seismic response of bridge piers under biaxial loading was demonstrated by Salami et al. (2019). Figure 2 shows the three-dimensional numerical model of the considered reference RC bridge. This model can simulate the inelastic buckling behaviour and low-cycle fatigue degradation of reinforcements. As Figure 2 shows, bridge piers and deck beams are divided into several fibre sections in their entire length in this model. Moreover, each component is modelled using five force-based elements: two zero-length section elements at the top and bottom to simulate the slippage of reinforcement at connection adjacents, two force-based elements with three integration points at the top and bottom and an intermediate element with five integration points. Further details about the developed model and numerical validation are available in Afsar Dizaj et al. (2022, 2023).

2.3 Corrosion damage scenarios

To investigate the influence of corrosion damage on the seismic fragility of the benchmark irregular concrete bridge, three corrosion statuses of piers, including (i) pristine, (ii) slightly corroded and (iii) highly corroded conditions, are considered. The material and geometrical properties of the corroded hypothetical bridge piers are updated using the mass loss ratio of rebars (ψ) in any of the corrosion statuses mentioned above. This parameter can be calculated using Equation 1 (Afsar Dizaj 2022):

$$\psi(t) = \left(\frac{d_b d_c - 1.05(1 - W/C)^{-1.64} t^{0.71}}{d_b d_c} \right)^2 \quad (1)$$

where d_c is cover thickness, d_b is the diameter of main bars; W/C is the water-to-cement ratio, and t is the time from corrosion initiation.

In this study, five different corrosion scenarios are considered. Scenario 1 is the benchmark bridge specimen tested by Johnson et al. (2008) where all the piers are considered pristine (uncorroded). In scenario 2, all the piers are assumed to be slightly uniformly corroded. For this scenario, it is assumed $t=5$ years; therefore, from Eq. (5), the mass loss ratio of spiral and longitudinal reinforcement is obtained as 15.8% and 5.5%, respectively. For scenario 3, it is assumed $t=5$ years; therefore, for this condition, the mass loss ratio of spiral and longitudinal reinforcement is calculated to be 50% and 18.9%, respectively. Therefore, in this scenario, all piers are severely corroded uniformly.

In addition to the uniform corrosion damage scenarios (scenarios 2 and 3), two non-uniform corrosion statuses are considered where the corrosion levels of different piers are assumed to be spatially variable. To this end, in scenario 4, the piers of bent 2 are taken to be severely corroded, and the others are slightly corroded. Finally, in scenario 5, while the piers of bent 1 and bent 2 are slightly corroded, the piers of bent 3 are assumed to be severely corroded.

3 CAPACITY LIMIT STATES

Nonlinear pushover analysis is carried out on the three bents of hypothetical bridge layouts with different corrosion levels to quantify the time-dependent capacity limit states. To this end, the material and geometrical properties of the frame are modified to incorporate corrosion-induced degradation. Moreover, the bases of the columns are assumed to be fully fixed, and the P-delta effects are also included in the analyses.

Figure 3 compares the capacity curves of bents with different corrosion percentages. The capacity limit states associated with bar yielding, cover concrete spalling, and core concrete crushing are mapped on each curve. Moreover, the onset of core concrete crushing is considered the onset of the collapse as it takes place just before a significant drop in capacity curves. As Figure 3 shows, the ductility and capacity of each bent significantly decrease as the corrosion level increases. Remarkably, the severely corroded bents experience a sudden drop in their post-peak response, showing a considerable decrease in their ductility. The capacity limit states quantified in this section are used in Section 4.3 to develop seismic fragility curves.

Figure 3. Capacity curves and capacity limit states: (a) uncorroded bents; (b) slightly corroded bents, and (c) severely corroded bents.

4 INCREMENTAL DYNAMIC ANALYSIS (IDA)

4.1 Selected ground motions

To carry out incremental dynamic analyses, 32 individual earthquake records are selected from the far-field ground motion records available in FEMA P695 (2009). Detailed information on the characteristics of selected ground motion records is provided in Afsar Dizaj et al. (2022, 2023). It should be noted that the primary transverse vibration mode of the reference bridge specimen is its second mode; therefore, selected ground motion records were scaled up by 0.1g steps (from 0 to 2.2g) in terms of $S_a(T_2, 5\%)$ and used as input for incremental dynamic analyses.

4.2 IDA results

Figure 4 compares the median IDA curves of each bent to investigate the nonlinear behaviour and failure mechanism of the hypothetical bridge layouts. Figure 4 shows that median IDA response of all bents becomes a plateau at approximately $S_a(T_2, 5\%) = 1.2g$. However, results show that for a given $S_a(T_2, 5\%)$, bent 1 experiences higher drift ratios. For example, while $S_a(T_2, 5\%) = 1g$ corresponds to approximately 0.039 peak drift ratio in piers of bent 1, for the same median intensity measure of ground motion records, bent 2 and bent 3 tolerate about 0.019 and 0.022 maximum drift ratios, respectively. This shows that 1 in scenario 1, bent 1 is more vulnerable than the other two bents. However, as Figure 4(c) shows, the median IDA response of all bents in the severely uniformly corroded bridge (i.e., scenario 3) is approximately identical. This can be due to the insufficient confinement in the piers of this bridge specimen as a result of the premature fracture of severely corroded spirals.

Figure 4(b) indicates that the slight uniform corrosion of piers causes a 25% reduction in the associated intensity level with the plateau response of bents. However, like the uncorroded bridge (scenario 1), bent 1 sustains higher displacement demands. This infers that the failure sequence of bents has not experienced a significant change compared to scenario 1. Figure 4(c)

show that the considerable reduction in the capacity of bents due to the severe uniform corrosion of piers results in near-synchronised flexural failure of all piers. Therefore, it can be inferred from the results presented in Figure 4(c) that all the bents fail almost simultaneously for the RC bridge supported on severely uniformly corroded piers. This can be attributed to the premature fracture of extremely corroded spirals, where the core concrete is almost unconfined.

Figure 4(d) shows that the onset of failure of columns of bent 2 (taller columns) coincides with that of columns of bent 3 (shorter columns). This implies that the higher ductility demand attracted by the stiffer piers of bent 3, is regulated significantly by the greater corrosion percentage of bent 2. Consequently, the columns of these two bents with different stiffnesses are collapsed at approximately the same intensity of input ground motions. Finally, Figure 5(e) shows that the nonuniform corrosion of piers in scenario 5 has resulted in the near-synchronised collapse of bent 1 and bent 3 at approximately $Sa(T_2, 5\%)=0.6g$.

4.3 Seismic fragility curves

In this section, the failure probability of studied RC bridges is investigated. To this end, the following fragility function is used:

$$P[MDR \geq CLS \mid IM = y] = 1 - \Phi \left(\frac{\ln(CLS) - \ln(\mu)}{\beta} \right) \quad (2)$$

where $P[.]$ is the probability that the maximum drift ratio (MDR) exceeds a capacity limit state (CLS), given that the intensity measure (IM) equals y . Moreover, $\Phi(.)$ is the lognormal distribution function with the logarithmic mean, and standard deviation of $\ln(\mu)$ and β , respectively, which can be obtained using Equations 3-4:

$$\ln(\mu) = \frac{\sum_{i=1}^n \ln(MDR_i)}{n} \quad (3)$$

$$\beta = \sqrt{\frac{\sum_{i=1}^n (\ln(MDR_i) - \ln(\mu))^2}{n - 1}} \quad (4)$$

In Equations (3-4), n is the number of records, and MDR_i is the maximum drift ratio associated with a given value of IM for the i_{th} record. It is noteworthy that the MDR associated with concrete crushing (as shown in Figure 5) of piers is assumed as the collapse capacity limit state in Equation. (2).

Figure 5(a) shows that in scenario 1, the probability of failure of bent 1 is higher than in other bents. For instance, for $IM=1.2g$, while the failure probability of bent 1 is approximately 94%, it is around 62% and 71% for bent 2 and bent 3, respectively. Likewise, in Figure 5(b), the same trend can be seen with a slightly higher probability of collapse due to the uniform corrosion of piers. However, Figure 5(c) indicates that in scenario 3, the fragility curves of bent 2 and bent 3 are almost in line with that of bent 1. Especially for higher IMs (i.e., higher than $IM=0.6g$), the probability of collapse of all bents is approximately the same. This implies the near-synchronised brittle failure of bents, which is consistent with the conclusion of the IDA results presented in Figure 4(c).

Figure 5(d) compares the failure probability of bents in the nonuniformly corroded bridge scenario 4. As this figure shows, due to the higher degree of corrosion in the intermediate piers, the fragility curves of bent 3 and bent 2 are similar. This implies the synchronised failure of these two bents just after the failure of bent 1. Finally, Figure 5(e) shows that the fragility curve of bent 3 is on top of others.

This indicates that, in this scenario, the collapse probability of shorter columns is higher than others. Therefore, it can be concluded that various corrosion scenarios can result in diverse seismic behaviour and failure sequences of multi-span RC bridges with unequal-height piers.

Figure 5. Collapse fragility curves of bents: (a) scenario 1; (b) scenario 2; (c) scenario 3; (d) scenario 4, and; (e) scenario 5.

5 CONCLUSIONS

This study evaluated the seismic performance and vulnerability of corrosion-damaged multi-span RC bridges with substructure irregularity. To this end, an advanced three-dimensional modelling methodology was employed to simulate the nonlinear behaviour of multi-span

irregular RC bridges accurately. The developed numerical model was then successfully verified against the large-scale shake table test results of an irregular two-span concrete bridge. Five hypothetical corrosion damage scenarios were considered, including uniform and nonuniform corrosion scenarios of piers. The failure modes and nonlinear dynamic behaviour of studied bridges with varied corrosion scenarios were assessed using nonlinear pushover and incremental dynamic analyses. Finally, the time-dependent fragility curves were developed using the IDA outputs for the frames under the selected ground motion suite.

The obtained results indicated that the unbalanced seismic demand distribution due to the substructure irregularity of the uncorroded bridge (scenario 1) causes the earlier failure of medium-height piers. This causes the higher vulnerability of bent 1 in this bridge specimen. The slight symmetrical corrosion level (around 5.5% in terms of rebar mass loss, $t=5$ years) of the bridge columns (Scenario 2) causes an approximately 25%, 35%, and 20% reduction in median failure IM of bent 1, bent 2, and bent 3, respectively. However, it does not affect the failure sequence of bents, where bent 1 tolerates higher seismic ductility demands than other bents. Moreover, results showed that the severe uniform corrosion of bridge piers (scenario 3) results in near-synchronised flexural failure of bents. This can be attributed to insufficient confinement in severely corroded bridge piers, resulting in brittle failure. The other important finding of the current study was that, depending on the corrosion damage scenario of piers, the nonuniform corrosion of bridge piers in an irregular RC bridge could regulate or exacerbate the unbalanced seismic ductility demand distribution across piers of unequal heights. For example, results showed that, in scenario 4, the adjusted seismic demand on severely corroded bent 2 results in the near-simultaneous collapse of taller and shorter piers.

Study on the applicability of repairing rubber bearing covers by resurface vulcanization in the field

A. Matsumoto & R. Takahara

Nippon Expressway Research Institute Company Limited, Tokyo, Japan

T. Imai & W. Abe

Rubber Bearing Association, Tokyo, Japan

ABSTRACT: In Japan, where earthquakes occur frequently, rubber bearings are used in many road bridges because of their effectiveness in improving the seismic resistance of bridges. NEXCO (Nippon Expressway Company) has adopted the use of rubber bearings as a standard. The rubber bearings have a 10 mm cover rubber on the side surface to protect them from the environment (ultraviolet rays, ozone, etc.). But cracking due to ozone deterioration have been reported in the cover rubber manufactured according to standards prior to 2000. In recent years, ozone cracking has been observed not only in cold regions in Japan, but also throughout the country. Repair methods for ozone cracks include covering the surface of rubber bearings with tape or paint-based repair materials. However, such repair methods have problems, such as floating or peeling of the repair material. In this paper, the applicability of a new and effective repair method, in which vulcanization (reconstruction) of the cover rubber performed in the field, is examined.

1 INTRODUCTION

As one of the main structural components of a bridge, bearings have an important function in ensuring the safety of the entire bridge. This function must be maintained over the long term. And proper maintenance is vital to continuously maintain the function of the bearings.

Bearings are broadly classified into two types, rubber bearings and steel bearings, depending on the materials used. Since the Hyogo-ken Nanbu Earthquake, a major earthquake that struck Japan in 1995, rubber bearings have been used in many road bridges because of their effectiveness in improving the earthquake resistance of bridges.

The sides of the rubber bearings are covered with a rubber coating of about 10 mm (Figure 1) to protect the rubber bearing body from the environment (ultraviolet rays, salt, humidity, heat, ozone, etc.). In recent years, however, there have been reports of cracking of rubber bearings in service due to ozone deterioration. Natural rubber used for rubber bearings has an unsaturated structure called a double bond in its molecular structure. These double bonds are highly reactive with ozone. Ozone degradation is a phenomenon in which ozone molecules act on the double bonds of the rubber surface and break the molecular chains. Under tensile strain, this phenomenon develops into a crack, which is called an ozone crack. Initially, ozone cracking was observed only in cold climates. And have been taken against this problem, such as improving the formulation of weathering protectants. However, in recent years, ozone cracking has been observed not only in cold regions in Japan but also throughout the country. To deal with ozone cracks, repair work using tape or paint-based repair materials to cover the rubber bearing surface and prevent ozone from entering the bearing has been promoted. But these repair materials have problems, such as peeling and floating. This paper reports on a study on the applicability of a new repair method, the in-situ vulcanization of the cover rubber.

Figure 1. Covered rubber of rubber bearing.

2 STUDY ON THE APPLICABILITY OF REPAIR BY RE-VULCANIZATION IN THE FIELD

2.1 Repair by re-vulcanization

In the manufacturing process of rubber bearings, reinforcement, compounding materials, etc. are added to raw rubber and kneaded together. Next, the compounded rubber is laminated with adhesive-treated steel sheets, etc. and formed. Finally, the molded product is pressurized and heated to cross-link the rubber molecules to complete the process. Repair by re-vulcanization is a method of repairing existing rubber bearings by applying pressure and heat to the molded rubber to form chemical bonds between the rubber molecular chains, a reaction called vulcanization.

In this study, the applicability of on-site repair by vulcanization was examined.

2.2 Shear deformation performance test using 420mm size specimen

2.2.1 Examination overview

Because rubber materials harden by heat, the effect of heat applied during the vulcanization repair process on the shear deformation performance of the rubber bearing was checked. The test specimens are shown in Figure 2. The main material is natural rubber. The specimens are 420 mm in the bridge axis direction \times 420 mm perpendicular to the bridge axis, and 138mm in height, with 6 layers of 9 mm thick rubber, and 10 mm of cover rubber. Their shear modulus of elasticity is 1.2. Three test specimens with the same dimensions and configuration were made.

- (1) Rubber bearing in its as-made condition (hereinafter referred to as “no processing”)
- (2) Rubber bearing with simulated cracks (hereinafter referred to as “with simulated cracks”)
- (3) Rubber bearings with simulated cracks repaired by vulcanization (hereinafter referred to as “simulated crack repaired”)

Shear deformation performance tests were conducted on the above three types of bearings.

Ozone cracks tend to occur perpendicular to the direction of force action, and often occur near the upper and lower steel plates in the plane perpendicular to the bridge axis. Therefore, simulated cracks were placed at four locations, two at the top and two at the bottom, on the plane perpendicular to the bridge axis. The depth of the cracks was 15 mm to confirm whether or not 10 mm of cover rubber could be vulcanized.

2.2.2 Processing of test pieces

The flow for fabrication of the specimen is shown in Figure 3. First, a simulated crack was placed and a fixture was attached to hold the specimen under shear deformation of 70% (37.8 mm for this specimen). Although it is desirable to repair rubber bearings with the rubber body in an upright position as much as possible, the actual work is expected to be performed

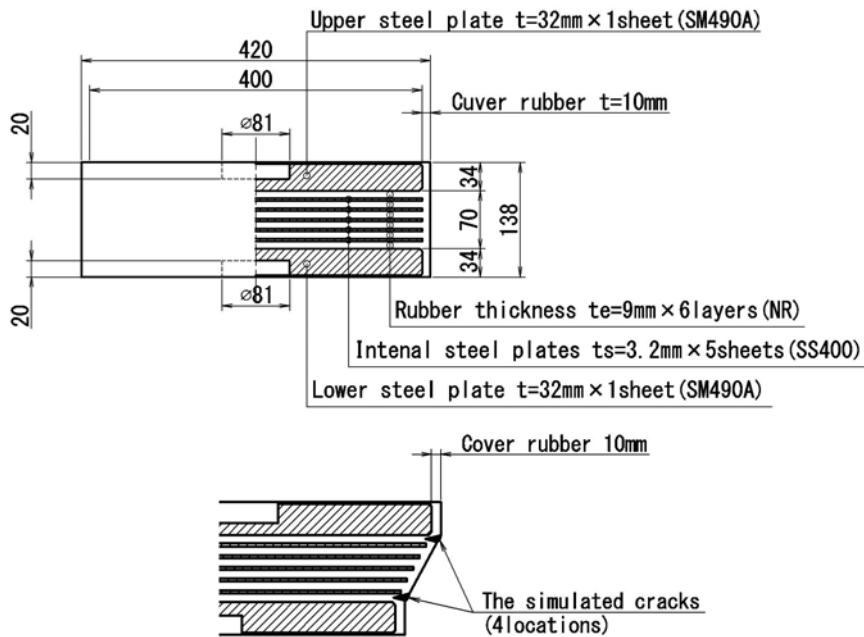

Figure 2. Cross-sectional view of the test specimens.

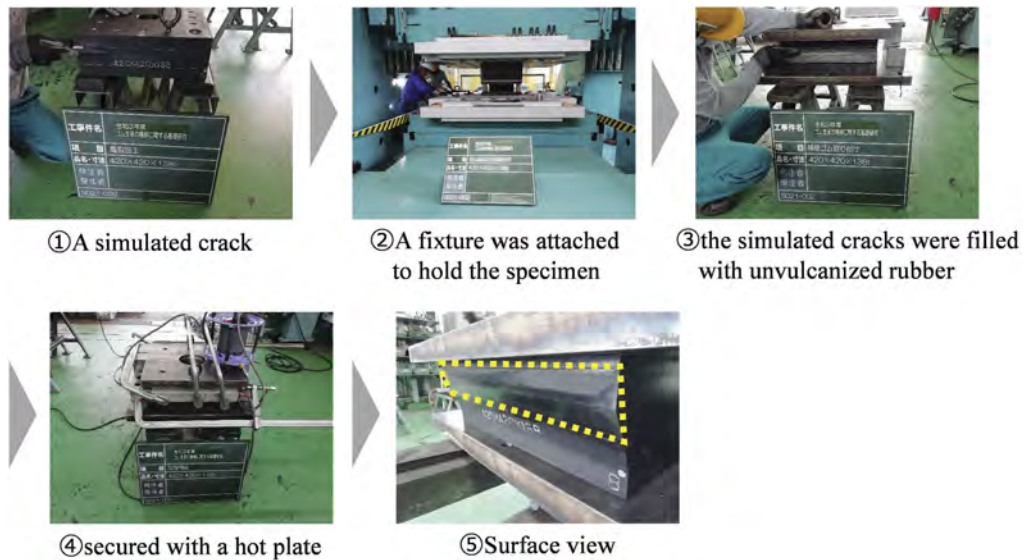

Figure 3. The flow for fabrication.

in a deformed state. In the present study, the rubber bearing was deformed by 70% of the allowable shear strain at any given time, and the vulcanization repair was performed while the bearing was fixed with a fixture.

Next, the simulated cracks were filled with unvulcanized rubber and secured with a hot plate. The heat plate was held at 110°C for 30 minutes until the surface temperature reached 110°C, and then held at 110°C for 90 minutes. The vulcanization temperature was set not to exceed 140°C -150°C, as vulcanization is generally performed at 140°C -150°C when producing the main body of the rubber bearing.

2.2.3 Test conditions

The test conditions are shown in Table 1. A biaxial load testing machine was used for the tests, and the test conditions were based on the bearing manual. Test D was terminated when the shear strain exceeded 330% to 340% to prevent damage to the testing machine.

2.2.4 Results

The results of Tests A, B, and C are shown in Figure 4. Each figure shows horizontal displacement (mm) on the horizontal axis and horizontal force (kN) on the vertical axis. The history curves for each test show almost the same history trend. The results of each test indicate that the difference in shear stiffness is about 1%-2%, which is considered to be within the range of variation of each product. This confirms that there is no influence of hardening due to the heat of the vulcanization process. In Test D, each specimen was subjected to shear deformation of 330% or more, but they did not fracture, and the test was terminated.

The surface of the specimens could be visually confirmed to be vulcanized, but the condition of the interior was not visible. Therefore, in order to confirm whether vulcanization had progressed to the inside, the specimen was cut after the test was completed and the inside condition was observed. The condition after cutting is shown in Figure 5. Some parts of the vulcanized rubber were found to be not vulcanized on the body side. Vulcanization is controlled by temperature and time, but once again, the heating temperature and time control were found to be the issues.

Table 1. Shear deformation performance test condition.

Test name	Test A	Test B	Test C	Test D
Temperature	23±2°C			
Share strain	175%	250%	300%	Break off
Vertical load	Equivalent to surface pressure 6.0N/mm ²			
Number of horizontal excitation	5	6	2	monotonic load

2.3 Shear fatigue test using 920mm size specimen

2.3.1 Examination overview

Rubber bearings are subjected to repeated shear deformation due to expansion and contraction of the girder caused by temperature variation. Therefore, shear fatigue tests were conducted to confirm whether or not the vulcanized rubber bearing dropped, protruded, or peeled off under repeated shearing.

The test specimen is shown in Figure 6. The dimensions of the specimen for shear fatigue tests were close to the 1,000 mm square, used in the NEXCO test method 418, to confirm whether repair by vulcanization is possible even if the dimensions of the rubber bearing enlarge. The main material of the specimens was natural rubber. The specimen was 920 mm in the direction of the bridge axis x 920 mm perpendicular to the bridge axis, and 296mm in height, with 6 layers of 22 mm thick rubber, 10 mm of cover rubber. The specimen had a shear modulus of elasticity of 1.2.

As with the 420 mm square specimen, simulated cracks with a depth of 10 mm were made in four locations, two on each side perpendicular to the bridge axis. The specimens were then subjected to shear deformation of 70% (92.4 mm for this specimen) and the simulated cracks were repaired by vulcanization.

2.3.2 Test conditions

The test conditions are shown in Table 2. The test conditions were set with reference to the bearing manual.

2.3.3 Results

The appearance of the specimen after the fatigue loading test is shown in Figure 7. No abnormalities such as dropout, protrusion, or peeling of the re-vulcanized area were observed.

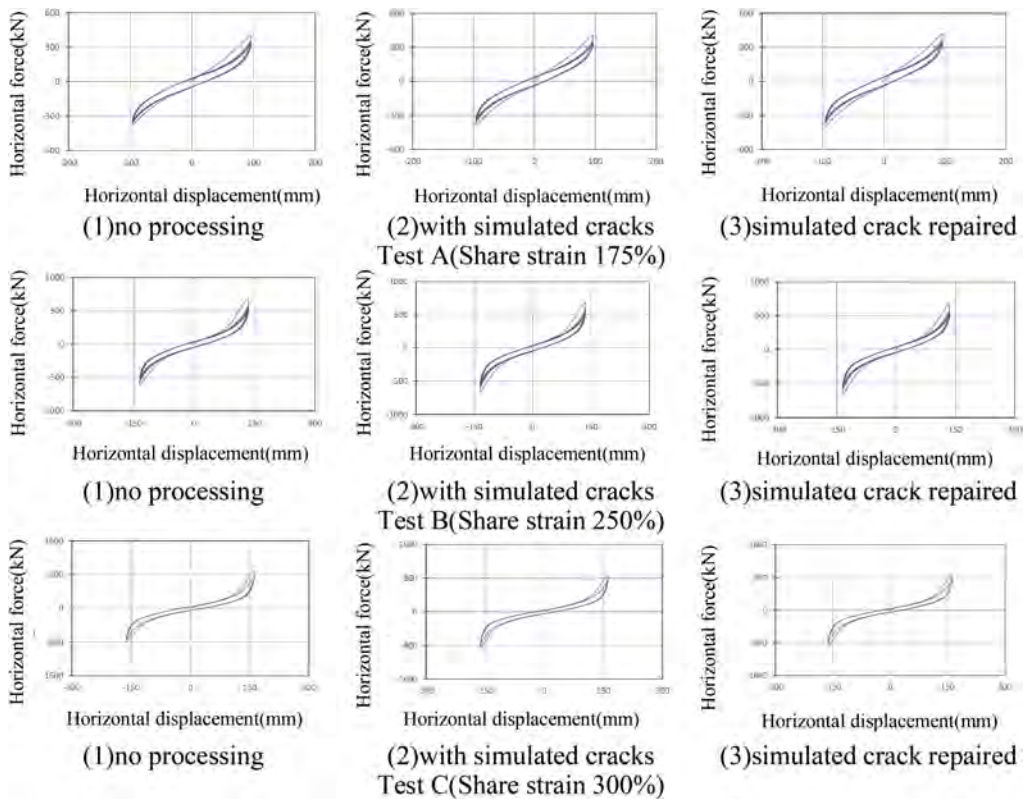

Figure 4. History curve for each test.

Figure 5. The condition after cutting.

The cut specimen is shown in Figure 8. Though no deformation was observed at the vulcanized area (Left side of Figure 8), cracks were seen (Right side of Figure 8). But the cracks did not reach the main body rubber and were contained within the area (10 mm) of the vulcanized cover rubber.

2.3.4 Confirmation of changes in physical properties in vicinity of re-vulcanization repair area

The effect of heat applied during the vulcanization process on the vicinity of the vulcanized area was confirmed. Specimens were cut out and tested for elongation at break and tensile

Figure 6. Cross-sectional view of the test specimens.

Table 2. Shear deformation fatigue test condition.

Temperature	23±2°C
Share strain	70%
Vertical load	Equivalent to surface pressure 6.0N/mm ²
Number of horizontal excitation	5,000 times

Figure 7. The appearance of the specimen after the fatigue loading test.

strength, which are basic properties of rubber materials. The locations where the test specimens were cut out are shown in Figure 9. Test specimens (dumbbell No. 3 specimens) were cut from the first layer (N①, S②) and the second layer (N③, S④) of the body rubber that had undergone the resurface vulcanization repair. The test results are shown in Table 3. The elongation at break and tensile strength were above the specified values, even in the vicinity of the vulcanized area. This indicates that heat hardening did not occur during vulcanization. No significant difference in the test results was observed between the first layer near the vulcanized area and the second layer away from the vulcanized area.

Figure 8. Cut surface.

3 CONCLUSIONS

In this study, various experiments were conducted to confirm the applicability of in-situ vulcanization as a new repair method for rubber bearings. The main results at present are as follows:

- (1) It was confirmed that shear deformation performance was not affected by the heat of vulcanization under the temperature and time set in these tests.
- (2) It was confirmed that the vulcanized portion did not drop out, protrude, or delaminate due to repeated shear deformation.

Going forward, we will continue to study the standardization of the construction procedure and quality control method for the vulcanization repair method. Eventually, we plan to develop draft technical standards that include a flow chart for selecting repair methods for covered rubber

Figure 9. Cutting surface of 920mm.

Table 3. Specimen results.

Test items	Standard value	Initial value (Sheet)	1st layer		2nd layer		
			N①	S②	N③	S④	
Elongation at break	%	450over	550	480	500	490	480
Rate of change			1.00	0.873	0.909	0.891	0.873
Tensile strain	N/mm ²	15over	28.3	26.5	27.3	28.1	28.3
Rate of change			1.00	0.936	0.965	0.993	1.00

bearings. This repair method eliminates the need to replace the rubber bearing if only the rubber coating is cracked. This is expected to reduce the construction cost required for the replacement, enabling effective repair at a lower cost, leading to a reduction in maintenance and management.

Application of BIM in design review processes for buildings

M. Achenbach & P. Rivas
LGA KdöR, Nürnberg, Germany

B. Weber
Hof University, Hof, Germany

ABSTRACT: The design review process – as part of the building permit – is mandatory for numerous construction projects in Germany. The paper-based review process is currently state of the art due to the obligation of documentation by law with legally binding signatures, e.g. for the construction process.

The application of BIM in the construction industry is increasing. Though the process of model sharing is specified in EN ISO 19650-4, the integration of the design review process has not been examined using BIM yet. In the review process, it is necessary to check structural analysis and other documents, too. Hence, the process of design review using various documents shall be linked to the steps proposed in ISO 19650-4.

The authors recommend a BIM-based digitalized design review process based on ISO 19650-4. It is shown how the template for the review process can be adjusted to legal requirements for digital proceedings and can be used for the complete life cycle of a building better than the paper-based documentation.

1 INTRODUCTION

The life cycle of a building can be characterised by different stages and perspectives. Regarding sustainable transformation, the stages production, construction process, use and end-of-life are identified (DIN EN 15978 2011). But it must be remembered that buildings are also part of the built environment. Therefore, buildings are embedded in building regulations in order to ensure that public interests, e.g. structural or fire safety, are considered. The process and life cycle of buildings from the view of building authorities are displayed in Figure 1, using the IDEF0 notation (IDEF – Integrated DEFINition Methods (IDEF) 2022). It can be shown that approved construction drawings are a necessary input for the execution on site. The complete documentation, containing as-built drawings and accompanying documents, e.g. the structural analysis and the check of fire safety, is needed for commissioning and the stages to follow. The life cycle shown in Figure 1 can be run in many cycles in case of refurbishment, e.g. by a change of usage from an office to a residential building. The life cycle can also be finished by demolition, following the permit of demolition issued by building authorities.

The review process of the structural analysis, the check of the fire safety and the corresponding drawings are mandatory for most public buildings in Germany (MBO 2020). This review process is part of the building permit: executing members and parts of the building as well as the commissioning of the building require legally a successful review process. The aim of the review process is proving compliance with building codes, i.e. that structural and fire safety are fulfilled by the proposed design according to legal codes and technical standards. Therefore, approved drawings and approved corresponding documents, i.e. documentation of the structural analysis

and check of the fire resistance, are part of the life cycle of a building. In fact, refurbishment and predictions on the service life of existing buildings require the documentation of the complete construction process including permits and other relevant conditions. If no documentation is available, expensive and time-consuming measurements on site and the determination of material properties are necessary.

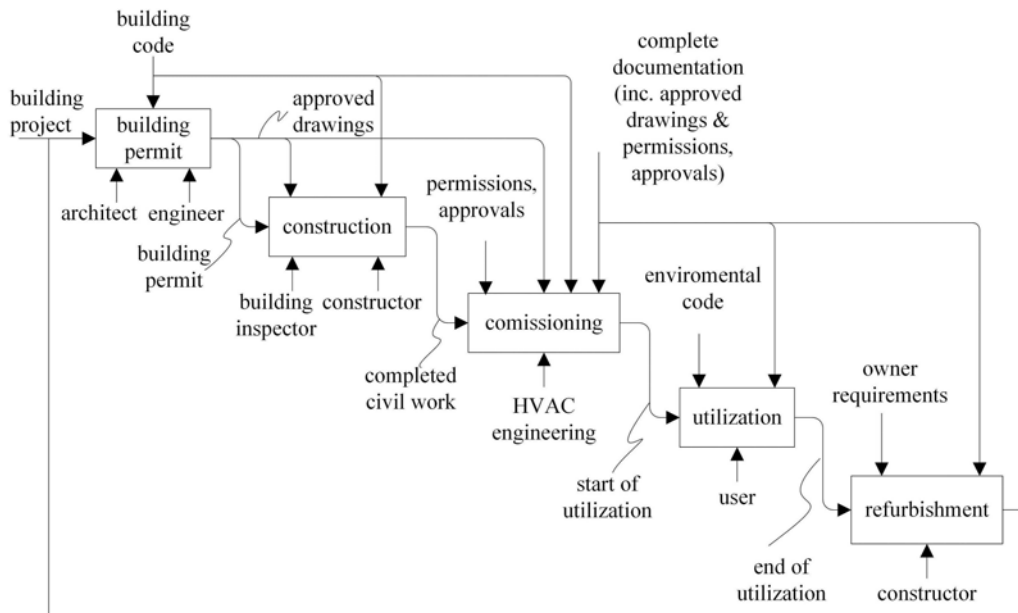

Figure 1. Life cycle of building according to IDEF0 – view of building authorities (HVAC: heating, ventilation, air conditioning).

Whereas the application of the BIM method in design, construction and operation of buildings is widely accepted (Borrmann *et al.* 2021), the application of BIM for the process of building permission in Germany is limited to research projects (König *et al.* 2022). It has to be noted, that the process of design review is part of the building permit: if BIM is not applied for the building permit, the field of application in design review is very limited accordingly. Hence, the use of BIM for the design review process in Germany is currently limited to the exchange of models to generate structural models suitable for commercial design software (Oltmanns *et al.* 2019).

On the other hand, the application of BIM for federal buildings and highways in Germany is stimulated by the government (Bundesministerium des Inneren, für Bau und Heimat and Bundesministerium der Verteidigung 2021, Bundesministerium für Verkehr und digitale Infrastruktur and Bundesministerium der Verteidigung 2021). Therefore, there is a need to integrate the process of design review in the BIM methodology as prerequisite for the application of BIM in the complete building permit process.

The state of the art of the design review process and the concepts for sharing data using BIM is given in Section 2. A proposal for a BIM-based digitalized design review process is developed in Section 3. The proposal is worked out according to the German building code template (MBO 2020), but can be easily transferred to other countries or other review processes.

2 APPLIED METHODS AND STATE OF THE ART

The process of building permission, design review, execution and commissioning is described in the German federal building code template (MBO 2020), which is adapted in each of the 16 federal states to state building law. The necessary documents and corresponding formats are detailed in the federal template for the required building documentation template

(MBauVorIV 2020) which stipulates the use of documents in the electronic PDF format as standard format. As the dynamics of change in the federal states varies widely from establishing the electronic form as standard in Lower Saxony (NBauVorIVVO 2021) including optional data formats as IFC, to adhering to the paper-based form as standard with experimentation clauses, e.g. in Bavaria (DBauV 2021) in autumn 2022, only a part of building authorities allowed the use of PDF instead of paper not yet including BIM. Others still insist in practice on a paper-based building permit process. The corresponding process of design review (M-PPVO 2012) is illustrated in Figure 2 using the BPMN 2.0 notation (ISO/IEC 19510 2013), which allows to visualize the process and the exchange of documents and messages.

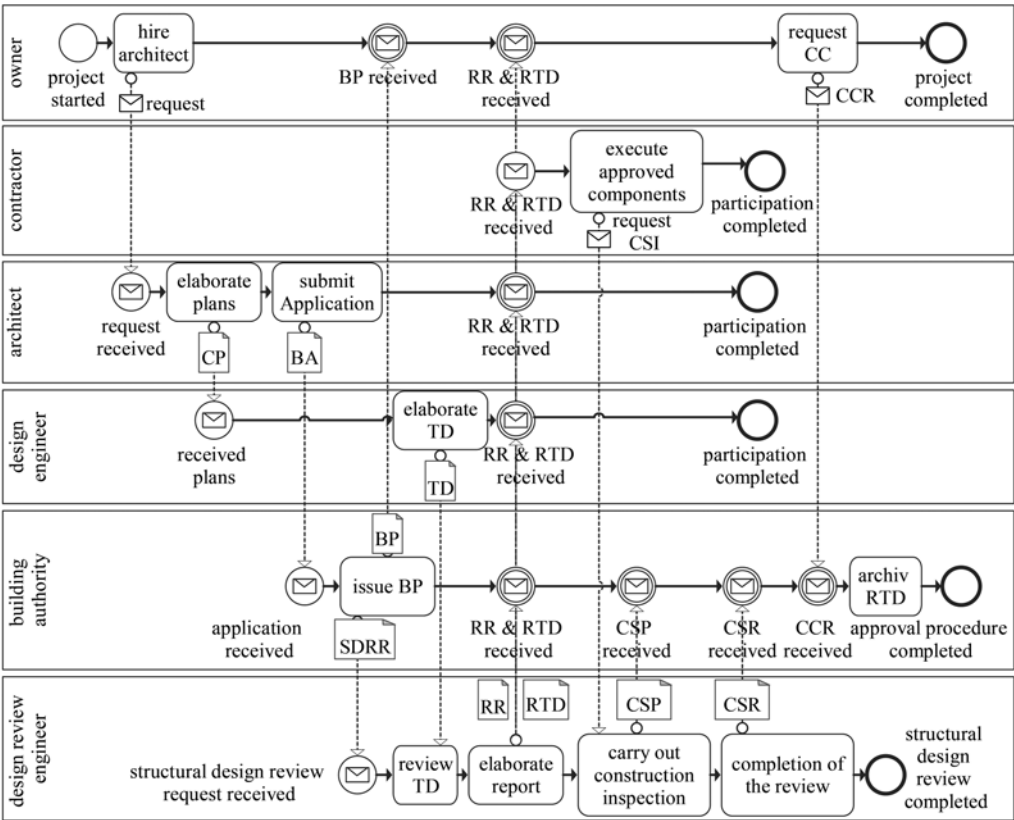

Figure 2. Paper-based design review process, abbreviations given in Table 1.

RTD	reviewed technical documentation
RR	revision report
SDRR	structural design review requirement
TD	technical documentation (structural analysis and drawings)

The well-established paper-based design review process using additional, signed copies of the original revised and signed documents allows a paper-based documentation of the building. The reviewed documents shall be signed by legally binding signatures in handwriting to identify and authenticate the reviewing engineer. In case of a replacement of paper by PDF, which can be seen as first step towards the digitalization of the review process, qualified electronic signatures (QES) representing the person or qualified electronic seals representing the organization shall replace legally binding manual signatures. The transition from paper to PDF becomes more and more accepted by design engineers and design review engineers, but needs agreement by local building authorities, as described above. Legally, the substitution of hand-written signatures by QES is compliant to EU regulation of electronic identification (eIDAS 2014).

The application of BIM in the construction industry is increasing and many fields of application are established (Borrmann *et al.* 2021). The benefits of BIM for the owner, namely collaboration between involved parties and a comprehensive documentation, cover the whole life cycle of a building. The EU leaves the application of BIM for public work contracts to the discretion of the member states (Art. 22 par. 4 Directive 2014/24/EU and Art. 40 par. 4 Directive 2014/25/EU). The EU member states have imposed different national legislations (Bidaut & Hassine 2021). Whereas France leaves the decision to the public authority in the respective procurement procedure, if BIM is seen as “necessary (Art. R.2132-10 Code de la commande publique 2022), Germany, for example, is restricting the choice of the authorities (§ 12 par. 2 VgV) for the application of BIM for public work contracts stepwise. BIM becomes mandatory during the next years for federal infrastructure planning starting with federal traffic road construction, widening to rail- and waterways and finally to building construction related to the contract volume (Bundestag 2022; BMI 2021). In order to allow the collaboration, the use of a common data environment (CDE) (DIN EN ISO 19650-1 2019) is stipulated. The process of information exchange using a CDE is described in DIN EN ISO 19650-4 (2021) and displayed in Figure 3 in the BPMN notation (ISO/IEC 19510 2013).

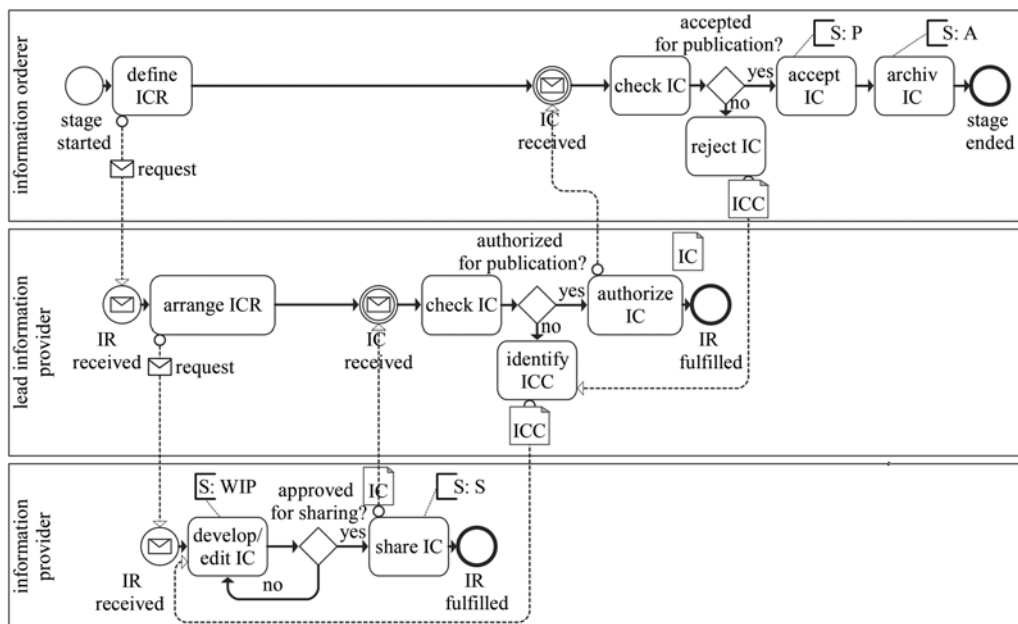

Figure 3. Information exchange according to DIN EN ISO 19650-4, abbreviations given in Table 2.

An information container is described as a set of information, e.g. a folder containing several files or a BIM model including meta data. Information is interpreted as readable representation of data, in which the reader can be human or a machine. The information orderer starts the

Table 2. Abbreviations for the information exchange acc. to DIN EN ISO 19650-4.

IC	information container
ICC	information container correction
ICR	information container requirement
IR	information required
S:A	status: archived
S:P	status: published
S:S	status: shared
S:WP	status: work in progress

process of information exchange by a request for information. The request is passed over to the lead information provider, which passes it over to the decisive information provider. The provider processes the request and prepares the needed information. This information is shared to the lead provider at first and then passed on to the orderer of the requested information. The information orderer has to confirm that the provided information fulfills the request (DIN EN ISO 19650-4 2021). After approval, the requested information is also available for general use in subsequent phases. If the stage of work is finished, the retrieved information can be archived.

It is obvious, that the process of information exchange can be transferred to the process of design review. In the following section, the considered roles are specified and the status is adjusted to the needs of the review process. In addition, the options for each stage and the possibility to publish must be adapted in compliance to the legal framework in the design review process.

3 PROPOSAL FOR A BIM-BASED DIGITALIZED DESIGN REVIEW PROCESS

The process of design review can be transferred from a paper-based version to a BIM-based process. Models of the building are necessary to carry out the structural analysis. The structural analysis is a requirement for the design of structural members and the corresponding drawings for the execution on site. Technical documents, i.e. structural analysis and drawings, can be reviewed and approved with comments or amendments and it is possible to sign them by legally binding signatures as QES, which are mandatory in the design review process according to building regulations. Technical models, like a BIM-model of the building, can be reviewed and comments can be submitted within the review process, e.g. using the BIM Collaboration Format ((BCF) 2022). If the comments are given in a separate file, it is possible to seal and encrypt these files for a safe transfer and authentication. The problem of integrating legally binding signatures in BIM models is under development (Siebenhütter 2020) and not yet common in commercial applications. Therefore, the review process must be split in a review process for documents and one for models, because signatures and the treatment of annotations differ. The review process for documents is displayed in Figure 4 and for BIM models in Figure 5.

The responsible structural engineer submits the technical documentation, e.g. structural analysis and drawings, to the design review department for review, as shown in Figure 4. The review is carried out by a co-worker or the design review engineer itself. If the technical documentation is incomplete, the review process cannot start and a revised version of the documentation must be submitted. After the review of the documents is done, the status of the document can change to “shared” and the structural engineer can view the annotations. The submitted technical documentations are collected and published together with the report to other interested parties. Note, that the design review engineer attributes the status “published”. According to German building regulations, the design review engineer has to assign the revised documents to the report (M-PPVO 2012). This is done by stamping and signing all reviewed documents. This step allows to use documents, e.g. drawings, without report, because it is proved, that the review process is completed. In a digitalized review process, electronic signatures are used to replace manual signatures. For the design review engineer, QES are necessary to replace legally binding manual signatures. For the co-worker, other forms of authentication and authorization as an advanced electronic signature may be sufficient.

For drawings on site, it is common practice to revise the drawings by the structural engineer according to the comments by the design review. It depends on the type of review process, if these revised drawings must be re-submitted for a final review to check, if the comments have been addressed. The proposed process in Figure 4 can be repeated in many cycles until the last set of documents is submitted. The technical documentation can be archived if the complete review process is finished.

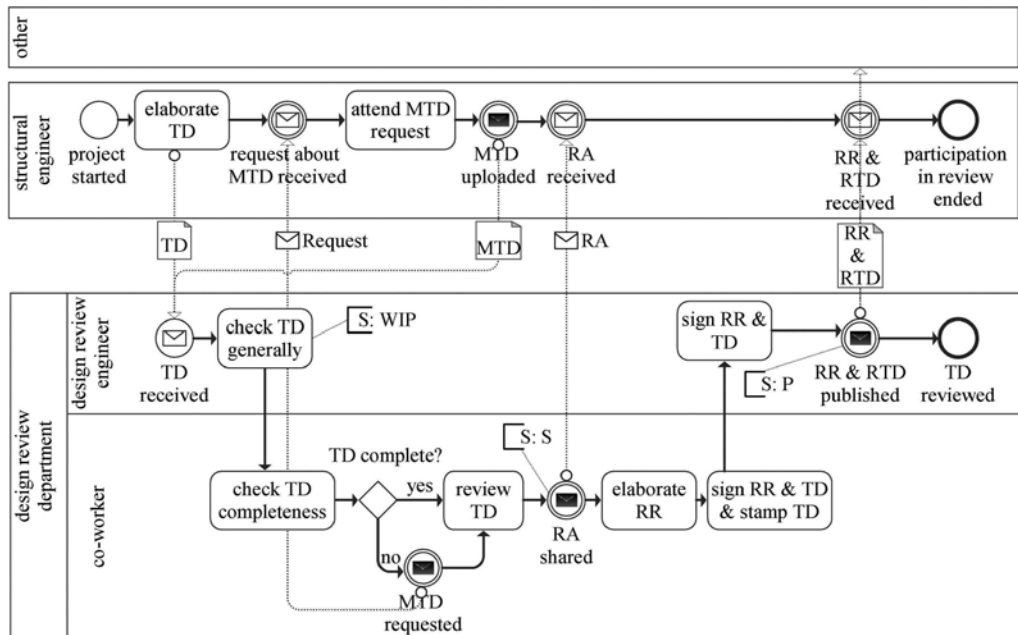

Figure 4. BIM-based design review process for documents, abbreviations given in Tables 2 and 3.

Table 3. Abbreviations for the BIM-based design review process for documents.

MTD	missing technical documentation
RA	review annotations
RR	review report
RTD	reviewed technical documentation
TD	technical documentation (structural analysis and drawings)

The review process of the technical model is initiated by the start of the workflow in the CDE as indicated in Figure 5. First steps are the checks by the design review engineer and the co-worker in order to check if the model is complete, i.e. if all necessary parts for review are involved and if the required level of detail is given. In case of an incomplete submission, an updated model must be provided to start with the review. If the model or the considered parts are complete and have the required level of detail, the status changes to “work in progress”. Annotations can be shared within the review process, e.g. by BCF (BIM Collaboration Format (BCF) 2022). After the review is finished by the co-worker, the report is prepared. The legally binding signed report lists the submitted BIM model including the date, file name and a unique identifier. Also, it is mentioned if there are annotations to the model. These annotations are contained in the BCF file, which is published together with the model. Integrity and content proof can be achieved by encrypting the BCF file. The report is uploaded and the design review engineer sets the status “published” at the same time.

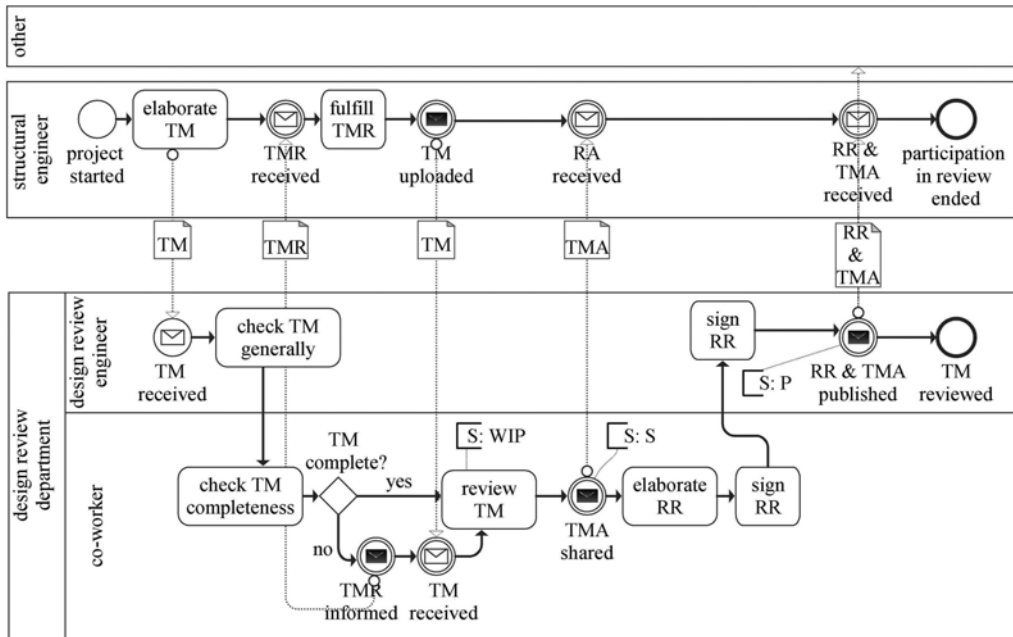

Figure 5. BIM-based design review process for models, abbreviations given in Tables 2 and 4.

Table 4. Abbreviations for the BIM-based design review process for models.

CTM	corrected technical model
RA	review annotations
RR	review report
RTM	reviewed technical model
TM	technical model
TMA	technical model annotations
TMR	technical model requirements

It must be pointed out, that the process of design review in Germany is well regulated by building authorities (M-PPVO 2012, MBauVorIV 2020, MBO 2020). This gives legal certainty for the review process, but causes special requirements regarding documentation and authentication. In case of PDF documents, these requirements can be transferred easily. Annotations can be embedded in the PDF and can be signed using QES. All reviewed documents can be listed in the reports. For BIM models, the legally compliant transfer of annotations binding all participants is object of current research. The reviewed BIM model is listed together with separate BCF file containing annotations in the review report and can be used for following stages of the life cycle as indicated in Figure 1.

4 CONCLUSIONS

The design review process for buildings can be fully integrated in a BIM workflow using a CDE. This allows to use the benefits of BIM: collaboration between the involved participants and a full documentation, which can be handed over to following stages of the life cycle of the building. The paper-based process can be transformed to a digitalized process with the same level of security. Legally binding manual signatures can be replaced by qualified electronic signatures signing electronic documents, which allows the authentication of the design review engineer. The legally binding electronic signature of BIM-models is still object of current research. A suitable rights and roles concept in a CDE can substitute the corresponding roles in a paper-based process. The status of the revised documents and BIM-models can be announced in a CDE using the proposed status of DIN

EN ISO 19650-4 (2021). At least, two different workflows are necessary for a document-based process and for a process handling BIM models. Whereas documents can be annotated, revisions of BIM-models require a modified model and a BCF-file transferring the comments. Summing up, the design review process can take part in the consistent use and sharing of data in the complete building life cycle making available its results and certificates to use and reuse of buildings.

ACKNOWLEDGEMENTS

A basic study on the evaluation of the protective effect of silane-based impregnation on mortar using electrochemical impedance spectroscopy

S. Nagaoka, K. Nakayama & M. Iwanami
Tokyo Institute of Technology, Tokyo, Japan

ABSTRACT: In this study, we investigated the electrical properties of silane-based impregnated mortar to quantitatively evaluate the effect of silane-based impregnation on the mitigation of chloride ions penetration. Electrical resistivity and frequency characteristics were measured using electrochemical impedance spectroscopy on mortar specimens simulating the incomplete modification effect and deterioration of the silane-based impregnating. The diffusion coefficients of chloride ions were also determined by chloride migration tests. As a result, we found a correlation between the electrical resistivity and the effective diffusion coefficient of chloride ions. Using the frequency response of impedance, the electrical resistivity of the silane-impregnated layer and that of the unimpregnated mortar could be extracted in a single measurement. These results showed the possibility of quantitatively evaluating the effect of silane-based impregnation on the mitigation of chloride ions penetration from the electrical properties of silane-impregnated mortars.

1 INTRODUCTION

Silane-based impregnations are widely used to modify the surface of concrete structures to improve their durability. These surface treatment agents are mainly composed of silicone molecules such as silane and siloxane, which have water-repellent properties (Vries et al. 1997). After being applied to the concrete surface, silanes penetrate several millimeters to several centimeters into the concrete to provide a water-repellent effect. This effect prevents water and deterioration factors from penetrating into the concrete, thereby mitigating the deterioration of the structure caused by salt damage, frost damage, and ASR. In addition, silanes have many advantages, such as being relatively easy and inexpensive to apply and not altering the appearance of the concrete, allowing direct visual inspection of the concrete surface even after the application. Previous studies on silane have shown that in some cases the protective effect lasted for more than 20 years (Christodoulou et al. 2013). On the other hand, it has been pointed out that depending on the application conditions and environment, the performance and durability may be deteriorated relatively quickly. Quantitative and nondestructive evaluation of the protective effect and durability of the effect by silanes is important for structural maintenance.

This study fundamentally investigated a method to evaluate the chloride ion penetration of mortar specimens modified by silane-based impregnation by electrical properties. It is known that electrical properties are correlated with the diffusion coefficient of chloride ions in non-surface treated concrete (Meilun et al. 1999, Minagawa et al. 2010). However, few studies have been conducted on surface-treated concrete with silanes. Therefore, we simulated inadequate modification of the mortar specimens by the application method of the silane and accelerated deterioration after the application of the silane. The electrical resistivity and impedance of each specimen were measured. The water contact angle test, penetration depth test, and migration test were conducted as indices for evaluating the protective effect of silane. From the relationship between these test results and electrical properties, an evaluation of the protective effect of silane by electrical properties was investigated.

2 MATERIALS AND METHODS

2.1 Materials and specimens preparation

This study conducted tests on cylindrical mortar specimens of $\Phi 100 \times 50$ mm. The mortar was mixed with a water-cement ratio of 50% and a cement-fine aggregate ratio of 1:3 by volume. Ordinary Portland cement with a density of 3.16 g/cm^3 , crushed sand with a surface dry density of 2.62 g/m^3 and water absorption of 1.30 % were used as cement and fine aggregate. The specimens were demolded 24 hours after casting and cured in water until 12 days of age. The specimens were then cured in the air at 20°C in a room until 21 days of age. On the 21st day of age, a silane was applied to one side of the specimens, and they were cured in a room at 20°C until 28 days of age.

The flow of this experiment is shown in Figure 1. In addition, application and deterioration acceleration conditions are listed in Table 1. Two specimens were prepared for each condition. Silane-siloxane silicone with a concentration of 80 % was used as the silane-based impregnation. Normal condition in Table 1 indicates that 0.2 kg/m^2 silane was applied to specimens with a surface moisture content of 6 %. For Dilute, 0.2 kg/m^2 of silane diluted 5-fold with water was applied. These specimens were used to evaluate the protective effect of silane with a low amount of active ingredient. Masking specimens were covered with 6 mm wide aluminum tape on a portion of the coated surface, as shown in Figure 2. These specimens were used to investigate the effect of the incomplete application on the electrical properties. Silane was applied over the seal, and the tape was removed after curing. Wet specimens were immersed in water for 1 hour, and silane was applied when the surface moisture content was 10%. Dry specimens were dried in an automatic oven at 50°C for 6 hours before silane was applied. Since the penetration depth of silane depends on the surface moisture content of the applied surface, the effect of silane penetration depth on electrical properties was investigated in these specimens. Alkali specimens were immersed in a saturated calcium hydroxide solution with sodium hydroxide at $\text{pH} = 13$ for 7 days, starting 7 days after the silane application under normal conditions. These specimens were used to investigate the effect of reduced water repellency due to strong alkali on the electrical properties.

2.2 Electrochemical Impedance Spectroscopy

Electrochemical Impedance Spectroscopy (EIS) is one of the effective measurement methods to evaluate the pore structure of concrete. It is a method to evaluate the electrical properties of an object to be measured using impedance, which is the ratio of current to voltage in an AC circuit. To evaluate the electrical properties of concrete, an equivalent circuit of concrete is used for analysis. Figure 3 shows a simplified equivalent circuit of concrete. The equivalent circuit of concrete consists of solution resistance (R_0), concrete resistance (R_c), and capacitance (C). The impedance of this equivalent circuit, represented as a complex number, is shown in Equation (1).

$$Z = R_0 + \frac{R_c}{1 + j\omega R_c C} \quad (1)$$

Where $j = \sqrt{-1}$ and ω is frequency of AC current (Hz).

From this equation, the Nyquist diagram in Figure 4 is plotted, from which the values of the solution resistance and concrete resistance can be determined.

Figure 5 shows the condition of measurement. A stainless-steel electrode of 85 mm in diameter and 6 mm thick was brought into contact with the specimen via a gel electrolyte mixture of NaCl, carboxymethyl cellulose, and water in the ratio of 3:3:94, and measurements were made using

Figure 3. Equivalent circuit of a simplified model of concrete.

Figure 4. Nyquist diagram ($R_b=30\Omega$, $R_c=100\Omega$).

Figure 5. Condition of EIS.

a Potentiostat. In this measurement, the potential difference was 100 mV, and the impedance was measured at five frequencies, each order of magnitude, within the range of 500 mHz to 500 kHz. The concrete resistance was identified from the Nyquist plot to calculate the electrical resistivity.

2.3 Water contact angle test

To evaluate the water-repellent performance of silane, the water contact angle was calculated by photographing using a digital microscope. If the water contact angle is 90° or greater, the silane is deemed to have water-repellent performance.

2.4 Penetration depth test

To observe the depth of silane penetration, the specimen was split in two. Water was sprayed on the split surface, the length of the water-repellent layer was measured at four points equally divided into five sections, and the average value was determined as the depth of silane penetration. For Masking, the area directly under the aluminum tape was also observed.

2.5 Migration test

A migration test was conducted following JSCE-G 571-2003 by applying a DC with a potential difference of 15 V with the silane-applied surface on the cathode side to obtain the effective diffusion coefficient of chloride ions.

3 RESULTS AND DISCUSSION

3.1 Electrical resistivity

Figure 6 shows the electrical resistivity of each specimen on the seventh day after the silane application. In this figure, the average electrical resistivity of the two specimens is plotted.

Comparing Blank and Sound, the electrical resistivity of Sound was about twice that of Blank. This is because the surface of the specimens was modified by silane, which is thought to result in higher electrical resistivity. The silane-impregnated area (water-repellent layer) has a lower water content due to the water-repellent effect. The electrical resistivity of the silane-impregnated mortar was high because the electrical resistivity of the hardened cement is high when the water content is low. In addition, the electrical resistivity of the silane-impregnated mortar specimens was compared. Alkali and Masking showed lower electrical resistivity than Sound. In contrast, the electrical resistivity of Dry was significantly higher. It is believed that the electrical resistivity was increased because the specimens were strongly affected by drying.

3.2 Penetration depth

The results of the penetration depth test are shown in Figure 6. Only Dry had a significantly greater penetration depth, while other specimens had similar penetration depths. This result is consistent with previous studies showing that the lower the surface moisture, the greater the silane penetration depth (Hosoda et al. 2010). In Masking, no silane penetration was observed in the area covered by the aluminum tape (Figure 7), which is thought to be responsible for the low electrical resistivity of Masking.

Figure 6. Electrical resistivity and penetration depth of silane-based impregnation.

Figure 7. Water-repellent layer of Masking.

3.3 Water contact angle

The water contact angle test results showed that Alkali and Dilute had low water repellency (Figure 8). The water contact angle of the other specimens was greater than 90 degrees, like Sound, indicating that they were water-repellent. Alkali had a water contact angle of more than 90 degrees before immersion in the strong alkaline solution. However, after immersion, the water repellency decreased. Therefore, it is thought that the decrease in water repellency was caused by the alkali solution. However, the water contact angle of Dilute exceeded 80 degrees, indicating that it was more water-repellent than Alkali. These results suggest that the low electrical resistivity of Alkali was due to its low water repellency. The water repellency of Dilute was higher than Alkali, suggesting that the water repellency did not affect the electrical resistivity of Dilute.

Figure 8. Water contact angle of Sound, Alkali, and Dilute.

3.4 Effective diffusion coefficient

Figure 9 shows the results of the migration test. The effective diffusion coefficient of Sound was about half of Blank. Minor differences in effective diffusion coefficients were observed between the silane-impregnated specimens. Therefore, it is thought that the effect of incomplete modification of silane on the effective diffusion coefficient was small.

Next, the relationship between the effective diffusion coefficient and electrical resistivity was investigated. The results are shown in Figure 10. In this figure, the results for Dry, which had a higher electrical resistivity due to water content, are not plotted to investigate the influence of the protective effect of silane on the electrical resistivity. For this result, an approximate curve was obtained using the power of the electrical resistivity as an explanatory variable (Minagawa et al. 2010). The coefficient of determination of this approximate line shows that there is a correlation between the effective diffusion coefficient and electrical resistivity even in silane-treated mortar. These results indicate the possibility of evaluating the protective effect of silane by electrical properties.

Figure 9. Results of the migration test.

Figure 10. Relationship between electrical resistivity and effective diffusion coefficient.

3.5 EIS

The EIS results for Blank and Sound are plotted on the Nyquist diagram (Figure 11). Blank plots a single semicircle, whereas Sound plot an irregular semicircle. This distorted semicircle can be thought of as a plot of two partially overlapping semicircles. From this plot, the equivalent circuit of Sound can be assumed to be the circuit shown in Figure 12. CPE (Constant Phase Element) is an element used in fitting to the distorted semicircle and represents the electrical capacitance affected by material inhomogeneity. Then, by fitting the EIS data for Sound using the equivalent circuit in Figure 12, an electrical resistance of 587Ω for R_{c1} and 1108Ω for R_{c2} can be obtained. The EIS data for Blank were fitted using the equivalent circuit in Figure 3, and the electrical resistance R_c was calculated to be 764Ω . Since R_{c1} and R_c are close in value, it is assumed that the electrical resistance of the part of the specimen non-modified with silane is R_{c1} , and that of the part modified with silane is R_{c2} . Figure 13 shows the fitting results for each specimen. In each specimen, R_{c1} is close to R_c . Focusing on R_{c2} , which is the electrical resistance of the modified part, it is assumed that the electrical resistance of the poorly modified specimen is lower than that of Sound due to the effect of the modified state. In addition, the electrical resistance R_{c2} of Dry was significantly higher, but the effective diffusion coefficient was not smaller than that of the other specimens. This high electrical resistance was not due to the protective effect, but to the greater depth of silane penetration and lower water content in the modified part. These results indicate that the electrical resistance of the modified area is strongly affected by the low water content at the time of silane application.

The migration test results do not provide an accurate evaluation because of the difference in principle from the actual diffusion of chloride ions. In particular, it is difficult to accurately evaluate the diffusion of chloride ions by the migration test because the penetration of chloride ions is mitigated in concrete treated with silane due to its water-repellent effect. Therefore, in future studies, we plan to conduct accelerated permeation tests based on principles similar to those of actual chloride ion permeation. In such tests, the diffusion of chloride ions is mitigated by the modified part, and thus only the protective effect of the modified part should be focused on. In future studies, we plan to investigate the evaluation of the effect of silane on

Figure 11. Nyquist diagram of Sound and Blank.

Figure 12. Equivalent circuit of silane-modified mortar.

Figure 13. Electrical resistance R_c , R_{e1} , and R_{e2} obtained by the analysis.

the reduction of chloride ion penetration by silane by using the electrical properties of the modified part. Since it was found in this study that the electrical resistance of the modified part by silane can be determined, a more accurate evaluation will be possible.

4 CONCLUSIONS

To establish a method for evaluating the protective effect of silane-based impregnation, evaluation by electrical properties was attempted. The following tests were conducted on mortar specimens to simulate the deterioration of the protective effect due to silane application conditions and post-application environmental conditions. 1) electrochemical impedance spectroscopy (EIS), 2) water contact angle test, 3) penetration depth test, and 4) migration test.

The following findings were obtained from this study.

1. In the silane-impregnated mortar, the approximate curve using the power of electrical resistivity as an explanatory variable revealed a correlation between electrical resistivity and effective diffusion coefficients of chloride ions. This indicates the possibility of evaluating the protective effect of silane by electrical properties.
2. From the Nyquist plot obtained by the EIS, an equivalent circuit for the silane-impregnated specimen was proposed. Using this equivalent circuit, the electrical resistances of the silane-modified and non-modified layers were obtained. By obtaining the electrical resistance of the silane-modified part, the possibility of a more accurate evaluation of the protective effect of silane was indicated.

Life-cycle of existing asphalt to build new highway foundation pavements: Environmental procedures according to new Italian standards, geotechnical and durability performance assessments, construction methods

M. Biasioli, F.T. Isfahani, D. Giometti & C. Beltrami

Lombardi Ingegneria s.r.l., Milan, Italy

G. Piovano, F. Vergano & M. Marino

Co.Ge.Fa. SpA, Torino, Italy

ABSTRACT: An innovative design and construction procedure has been implemented for the life cycle assessment of geo materials in highway pavement renovation. In most cases old asphalt material after demolition is considered a “waste” material and therefore it is not allowed the recycle directly as construction material. In this case a specific study has been carried out developing different items: implement an environmental testing and administration procedure in order to obtain the positive approval by local Italian authority on the “end of waste” legislation (according to the new Italian law D. 69/18); develop a large prequalifying testing procedure by sampling existing asphalt material and studying in laboratory all the mechanical and chemical transformations and performances, also by the study of cement mix add; implement a construction field procedure that makes the demolition of an existing asphalt pavement possible and locally provides a mechanical and chemical transformation in order to give new life to the material as sub foundation layer of a new highway pavement. The result of the process was successful and could show an innovative prospective in the life cycle use of asphalt and geotechnical materials in existing highway renewal process.

1 ENVIRONMENTAL MANAGEMENT OF ASPHALT DERIVED FROM GRINDING OPERATIONS

1.1 *Recent changes on environmental Italian legislation concerning management of wastes from asphalt grinding operations*

Asphalt from grinding operations is typically manages, across EU, as waste, with EWC (European Waste Code – EER in Italian) 17 03 02.

In 2018, a major change in legislation was approved by implement an environmental testing and administration procedure in order to obtain the positive approval by local Italian authority on the “end of waste” legislation (according to the new Italian law D. 69/18).

The abovementioned law (D. 69/18), named “*Regolamento di disciplina della cessazione della qualifica di rifiuto (End of waste) di conglomerato bituminoso*” introduced criteria and management specifications to be fulfilled in order to consider asphalt (strictly deriving from grinding operations) as an End of Waste material (i.e. no longer a waste) and reuse it for construction operations.

In particular, according to Ministerial Decree 69/2018 the grinded asphalt (“fresato d’asfalto” in Italian) ends to be classified as a waste if it fulfills the following criteria:

- a) will be reused for the specific operations listed in part a) of Annex 1 to the decree;
- b) it is compliant to the standards listed in UNI norms EN 13108-8 (serie 1-7) or EN 13242 in relation with the specific scope;

c) it is compliant to the specific of part b) of Annex 1 to the decree.

In a few words, if the grinded asphalt fulfills both environmental and geomechanical parameters, it can be de-classified from “waste” to “non-waste”, in order of ad immediate reuse in construction operations.

The Decree was originally conceived by the Legislator to be mainly applied to production plants that typically verify the asphalt they are receiving (from grinding operations) and, if this latter results in compliance with criteria of the decree 69/2018, re-use it in new production activities.

However, in the case described in the current article (maintenance interventions on the Italian A4 highway), the new Decree was successfully applied On Site, to a construction lot of maintenance and enlargement operations, resulting as a consequence in:

- a massive reuse of what would have been otherwise considered as a waste;
- a drastic reduction in external supply of construction material;
- an overall major increase of sustainability and circular re-use of the construction Site.

1.2 Field application of the End-of Waste concept

In the case study described Co.Ge.Fa. contractor, with the technical support of Lombardi Engineering staff has applied the Decree 69/18 to an enlarging and renewing intervention on the A4 highway Turin-Milan.

The works included the grinding of about 44 000 m³ (about 88 000 t) of old asphalt. According to the design of the works, this material had to be considered as a waste and transferred off-site for disposal to Authorized plants.

The choice of the Contractor, instead, was to propose to the Local Authorities and to the Client, the adoption of the Decree 69/18 directly on the construction Site and, once fulfilled the criteria, consider the grinded asphalt as an “End of Waste” and re-use it in the same construction activity.

This was done applying, after obtaining Environmental Authorization from the Municipality of Milan, a sampling and analytical protocol according to the UNI norm 10802:2013 on the existing asphalt before its removal. The protocol was applied on a regular sampling grid through taking a composite sample resulting from 5 sub-samples from each grid. Then, comparing geomechanical and environmental results from the samples taken, once verified their compliance with what described in Annex 1 to the Decree 69/18, the material resulting from grinding operation could be already considered as a non-waste and therefore either immediately re-used on site (with cement treatment) or transferred to the deposit areas of the construction works to be reused in other lots of the intervention.

Figure 1. On site activities.

The activities were carried out during the period 2021-2022. At the end of 2022, an overall amount of 55 890 t of asphalt managed as End-of-Waste (i.e. compliant with the requirement of Decree 69/18) was reused in the same construction Site as material for new embankments and foundation pavement.

2 MATERIAL ASSESSMENT

The usage of stabilization agent is aiming to restore the properties or recover the cold recycled mixtures performance. Various type of stabilization agent could be used in the recycling technology such as lime, fly ash and cement [F. Xiao et al., 2018]. In this study cement has been used as the stabilization agent.

In order to obtain the required performance in terms of compressive strength and indirect tensile strength prescribed by the client, a tentative procedure has been employed to adjust the ingredient of the final mixture. There are several parameters playing a role in the strength performance of the cement stabilized recycled asphalt: bitumen type and pH, cement content and type, moisture content, granulometric distribution of the aggregates, etc.

Bitumen emulsion has been utilized to fabricate the existing asphalt pavement in this study. In the emulsification process, bitumen and water are put through a high shear mill with an emulsifier chemical and eventually the bitumen is dispersed in the water and an oil-in-water condition form. The emulsifier dominates the charge of the bitumen emulsion. Since the surface of bitumen droplets are charged, the interface between the bitumen emulsion and aggregate is enhanced when the aggregate particles are oppositely charged. When emulsified bitumen is mixed with aggregate, the bitumen tends to separate from the water and adhere surround the surface of the aggregate particles. Moreover, the mineral source and moisture of aggregate have a significant influence on the emulsion breaking. In this process, the bitumen emulsion places a role of lubrication agent, and the breaking is required to occur before compaction procedure.

The bitumen emulsion is classified as anionic and cationic. The anionic type possesses high(alkali) pH and the cationic possesses low(acidic) pH.

The compatibility between type of bitumen and aggregate is an important factor in their adhesion. Anionic bitumen emulsion has excellent adhesion with acidic aggregate. On the contrary, the cationic bitumen emulsion has good adhesion with alkaline aggregate. Therefore, type of bitumen emulsion shall be determined so that the type of cement and aggregate, to be added to the final cement-stabilized cold recycled asphalt mixture, could be selected in compliance with the bitumen type.

By reference to Table 3, the bitumen type of the grind asphalt is anionic as the pH is alkaline. For anionic bitumen emulsion, a cement type containing high lime content is recommended because adhesion between the anionic bitumen and alkaline solids (aggregates/cement) is favorable. Therefore, based on Table 1 of EN 197, "Portland-limestone cement" is recommended for this study. Cement content should also be adjusted, and the range is normally between 3%-5% [Mollenhauer et al. 2016].

Normally a portion of virgin aggregates are needed to meet the required performance for the cement-stabilized cold recycled asphalt mixture. In order to improve strength performance, fine aggregates with the size $<0.063\text{mm}$ are essential. Therefore, it is necessary to investigate the granulometric curve of the grinded asphalt and the portion of fine aggregates $<0.063\text{mm}$ should be adjusted so that the best strength performance could be achieved. The recommended value for the fines $<0.063\text{mm}$ is 4%-10%.

The moisture content of the final cement -stabilized cold recycled asphalt mix is another factor which leads to enhancement of the strength performance. The optimum moisture content should be tentatively investigated in conjunction between the initial moisture content of grinded asphalt and cement content. The range of moisture content of the final cement-stabilized cold recycled asphalt is in the range of 3%-10%.

The following tests are planned to investigate tentatively the optimum value of the above-mentioned parameters, which result in the best strength performance of the finale mixture. The performance requirements for each specific test in the following is complaint with Supplemento al Bollettino Ufficiale della Regione Toscana n. 22 del 31.5.2006.

3 GEOTECHNICAL TESTS

3.1 *Qualification tests*

Laboratory tests were performed on samples withdrawn from a highway stretch where the on-site grinding had been carried out. Tests were articulated in two phases:

Phase 1: preliminary tests to assess that samples fit technical specification and literature requirements.

The stratigraphy of the existing highway pavement was first determined on two 150 mm diameter and 50mm high bituminous concrete cores.

Two samples were contextually withdrawn from the grain-size reduced bituminous concrete, first sample after a single run of *pulvimixer*, second sample after two runs. The following tests were performed on these two samples:

- grain-size analysis on the milled asphalt and on the aggregates after extracting bitumen;
- determination of moisture content;
- determination of bituminous binder content;
- determination of the quantity of impurities in recovered bituminous concrete;
- petrographic test on aggregates and measure of pH of bitumen emulsions (to identify the type of bitumen in the existing pavement and assess suitability to treatment with Portland cement).

Phase 2: tests on samples defined by means of phase 1 tests, added with Portland 32.5 III/B-LL cement (4% in weight) to verify resistances properties.

Second phase was aimed to evaluate properties of a cement-bound material made with on-site grinded material added with 5% sand and 4% Portland 32.5 II/B-LL cement. Based on the experimentally determined properties, suitability of the cement-bound material to form the pavement foundation was evaluated, according to the quoted “Technical specifications”.

Samples were obtained by two runs of *pulvimixer* and the following tests were carried out:

- determination of void index;
- uniaxial compression strength;
- indirect traction tests (so called “Brazilian test”).

Three mixes were prepared with water content respectively 3%, 5% and 7%, after 180 cycles of gyratory compactor at 20°C. On such mixes, uniaxial compression strength and indirect traction tests (together with void index and mass density) were carried out after 7 days ageing, on three samples/each test.

It was thus determined an optimum water content of 5%.

Uniaxial compression and indirect traction tests were then repeated after 3 and 7 days on bituminous concrete added with 5% sand (see below) and 4% Portland CEM II/BLL 32.5, and then compacted with 5% water content.

3.1.1 Requirements

The following tables resume the grain size and resistance requirements provided by the “Technical specifications for work control and realization – Cement bound granular material” issued by the Client.

Table 1. Grain size requirements.

UNI Sieves	Minimum passing fraction [%]	Maximum passing fraction [%]
31.5	100	100
20	80	100
16	66	87
8	41	61
4	24	39
2	18	30
0.5	9	19
0.063	5	10

Table 2. Resistance requirements of the mix, prepared by gyratory compactor.

Property	Reference code	Unit measure	Requirements	
			3 days	7 days
Indirect traction resistance at 25°C	UNI EN 13286-42	MPa	0.30÷0.50	0.32÷0.60
Uniaxial compression strength at 25°C	UNI EN 13286-41	MPa	1.40÷3.60	2.50÷5.50

3.1.2 Test results

Main results of phase 1 tests are summarized hereafter.

Table 3. Phase 1 main results.

Bitumen content	<5%
Impurities	none
Water content	2.50%
pH	8.1
suitability to treatment with Portland cement	suitable

Grain size distribution fulfilled requirements in Table 1 except for the fine sand percentage which was slightly below the lower limit; fine sand was added in the measure of 5% in weight. Main results of phase 2 tests are summarized hereafter.

Table 4. Phase 2 main results.

Uniaxial compression strength UCS	[MPa]	3gg ageing			7gg ageing		
		3.11	2.94	3.4	3.91	3.74	4.19
Average UCS	[MPa]	3.15			3.95		
Mass density after compaction	[t/m ³]	2.176	2.163	2.181	2.175	2.182	2.178
Dry mass density	[t/m ³]	2.072	2.060	2.077	2.071	2.078	2.074
Void index	[%]	13.4	13.9	13.2	13.4	13.2	13.3
Indirect traction strength ITS	[MPa]	0.42	0.44	0.43	0.51	0.55	0.53
Average ITS	[MPa]	0.43			0.53		
Mass density after compaction	[t/m ³]	2.244	2.246	2.240	2.206	2.204	2.130
Dry mass density	[t/m ³]	2.137	2.139	2.133	2.1	2.099	2.208
Void index	[%]	10.7	10.6	10.9	12.2	12.3	11.9

All results fulfill technical specification requirements.

3.2 Control tests

After the treatment, some in situ and laboratory tests were performed on samples withdrawn from material treated following the described procedure.

In situ tests:

- n. 2 plate load test after 15h from compaction + n. 2 plate load tests after 3 days from compaction;
- n. 4 Light Weight Deflectometer tests after 15h from compaction

3.2.1 Laboratory tests

- grain size analysis;
- determination of maximum mass density;
- determination of apparent unit weight;
- n. 3 uniaxial compression tests at 3, 7, 14 days after compaction;
- n. 3 indirect traction resistance (Brazilian) tests at 3, 7, 14 days after compaction.

During the trial pit operations, moreover, the water content of the treated material was determined to check the achievement of the goal value of 5% (see above).

3.2.2 Requirements

The reference technical specifications for cement-bound mix require the following.

- Minimum results of LWD:
 $M_{LWD} = 60 \text{ MPa}$ 4 h after compaction
 $M_{LWD} = 200 \text{ MPa}$ 24h after compaction
- In situ density:
 $\geq 94\%$ of laboratory compacted samples (180 rounds in gyratory compactor), in 100% of measures.
- Plate load modulus M_d , at first load in load interval 150÷250 kPa and 12÷24h after compaction:
 $M_d \geq 150 \text{ MPa}$.

Moreover, same prescriptions on grain size distribution and resistance, as seen about pre-qualification tests, apply.

3.2.3 Results

Main results of control tests are summarized hereafter.

3.2.3.1 Plate load tests

Tests were carried out in two separated points on the surface of treated material and gave the following values of modulus in the load interval 150÷250 kPa.

15h after compaction:

point 1: $M_d = 214.3 \text{ MPa} > 150 \text{ MPa} = M_d$ minimum design requirement

point 2: $M_d = 176.5 \text{ MPa} > 150 \text{ MPa} = M_d$ minimum design requirement

72h after compaction:

point 1: $M_d = 214.3 \text{ MPa} > 150 \text{ MPa} = M_d$ minimum design requirement

point 2: $M_d = 157.9 \text{ MPa} > 150 \text{ MPa} = M_d$ minimum design requirement

3.2.3.2 LWD Light Weight Deflectometer

Tests were carried out in same points as plate load tests:

point 1: $M_{LWD 1.1} = 187.5 \text{ MPa}$
 $M_{LWD 1.2} = 189.1 \text{ MPa}$

point 2: $M_{LWD 2.1} = 218.5 \text{ MPa}$
 $M_{LWD 2.2} = 177.2 \text{ MPa}$

Obtained moduli are:

- satisfying requirement at 24h in one case (LWD 2.1)
- within 89÷95% interval of requirement at 24h in all other cases

When considering that tests were carried out at 15h after compaction, it can be concluded that obtained values are fulfilling the technical specification requirements.

3.2.3.3 Laboratory test resistance

Table 5. Strength test results on treated material.

		ageing		
		3 days	7 days	14 days
Uniaxial compression strength UCS	[MPa]	3.59	3.98	4.30
Indirect traction strength ITS	[MPa]	0.41	0.55	0.54

It can be observed that results lie within the reference intervals (and in the upper half of the intervals themselves) according to the design technical specifications at both 3 days and 7 days ageing.

3.2.3.4 In situ density

Two determinations gave respectively 95.9% and 99.3% of reference mass density, i.e. of average dry density of samples compacted by gyratory compactor for resistance tests, which is 2179 g/cm³. Both values fulfill the design requirement ($\geq 94\%$).

Moreover, the residual void index in 6 determinations lies within the interval:

$$e_{\text{res}} = 8.5 \div 10.4 \%$$

$$(e_{\text{res}} = 9.1 \div 9.6\% \text{ in 4 tests out of 6}).$$

Such values are lower than those obtained in laboratory during prequalification tests, which mean a better compaction.

3.2.3.5 Grain size distribution

Grain size analyses confirmed the absence of particles with $D > 31.5\text{mm}$, as required by the design technical specifications.

Figure 2. Grain size analysis on the treated material (grinded + sand + cement).

Figure 3. On site activities.

4 CONCLUSIONS

Because of the extension of the construction in large cities and industrial area and the closure of more and more natural quarries materials induce the road and the geotechnical engineering to improve the technology and the optimal material to build for embankment or pavements by recycled materials. The innovative procedure that has been presented could build a new highway pavement using the old asphalt with a new role: foundation strata.

The results showed that the grinded asphalt aggregate could be recycled as the aggregate for construction of a new road base, by adding 4% of a limestone cement. The fine sand by weight percentage of the 5% was added and moisture content of the mixture was adjusted to 5% as the optimum value. The performance requirements such as compressive strength and indirect tensile strength were measured based on the prescriptions of the highway manager and [6]. The results showed that the compressive strength and indirect tensile strength of 7 days curing was in the range of 2.5-5.5 MPa, 0.32-0.6 MPa, respectively.

It is concluded that recycled asphalt aggregates as demolition waste containing 5% bitumen residue could be reused by following a tentative and planned laboratory tests prior to the execution of road construction. The cold cement-stabilized recycled asphalt mixture was successfully used as a base for the new road in the same construction site.

This type of road “circular performance” we hope would be implemented in future works in the asphalt and road engineering, implemented in technical standards. Providing and innovative step head in the “life cycle” of materials, according to the best practices of circular economy.

ACKNOWLEDGEMENTS

The authors would like to acknowledge Peletta Luigi Srl for the specific construction know-how provided and the original machine work implemented for this construction and material cycle process. In addition, the authors would like to acknowledge for the technical support of Ing. Salvatore Buscemi and for laboratory and in situ tests Studio Sperimentale Stradale srl. and in particular Ing. Paolo Ferrari. Finally, the authors would like to acknowledge the final client highway manager SATAP S.p.A. and construction supervision SINA S.p.A. for their support for this innovative project in road engineering.

Infrastructure asset management and the role of structural health monitoring

A. AlBanwan, A. AlFoudari & R. AlBehbehani

Kuwait Institute for Scientific Research, Kuwait City, Kuwait

ABSTRACT: Although modern-day infrastructure is designed to ensure structures operate safely in harsh environments under various loading conditions, deterioration and damage can occur during their operational life. Consequently, the protection, maintenance, and repair of infrastructure assets are crucial. Achieving optimal asset management is challenging, as the lifecycle costs of these activities must be minimized while ensuring infrastructure performance and reliability related to the asset's condition, serviceability, safety, and capacity are adequately addressed. Structural Health Monitoring (SHM) is a modern technology that can address these challenges. It is used to assess structural performance, detect damage, and monitor structure conditions, enabling data collection to support asset management analysis and evaluation. However, SHM does not provide actionable information to support asset management decision-making. This paper reviews current infrastructure asset management practices and identifies literature gaps. We examine SHM's role in asset management and identify areas where it can have the most impact.

1 INTRODUCTION

Infrastructure is defined as the essential facilities and systems that help societies operate, such as but not limited to buildings, roads, and bridges. Through the design phase of any infrastructure project, there is an intended and specified lifespan where the structure will continue to operate safely. However, due to environmental and operational effects, structures tend to degrade and fail before the end of their design lifespan. Given how crucial it is to maintain a country's economy and standard of living, the structural health of its infrastructure requires ongoing care. This calls for constant inspection, monitoring, and repair against damage, which is defined by Li & Hao (2016) and Farrar & Worden (2006) as the emergence of changes in a structure's material and geometric properties, boundary conditions, and connectivity of the system, that impacts its current or future performance, but has not yet interfered with the user's ability to utilize the system, which is known as failure.

Currently, asset management methods rely heavily on visually inspecting structures for signs of damage, which is challenging because inspections are inherently subjective and qualitative (Phares et al. 2007). Therefore, the need for strategies that can help evaluate bridge damage, condition, and performance and ultimately resolve these issues is imperative. Structural health monitoring systems can collect reliable data and provide continuous real-time information regarding bridge condition and performance to assist asset managers in making informed decisions (Omenzetter et al. 2011). However, in order to achieve the potential benefits of SHM and use it in a cost-effective manner, an understanding of the underlying drivers of asset management and its current shortcomings is necessary.

The general literature on SHM and asset management is extensive. However, there are very few studies that link them together. In this paper, we briefly examine the traditional approach to developing decision tools for asset management and discuss the value of using SHM to support asset management decision-making. The research question is addressed through a comprehensive literature review of recent advances in structural health monitoring in the emerging bridge asset management discipline. The discussion focuses primarily on bridges but is intended to apply to a wide range of infrastructure projects.

2 ASSET MANAGEMENT OVERVIEW

Asset management is a recognized process used to ensure that an asset, such as a bridge, operates in a way that enhances the asset's life, optimizes maintenance and management costs, and meets present and long-term needs (Kim et al. 2010).

2.1 *Asset management process*

There are various models that describe the asset management process, and asset managers are encouraged to assess what works best for them depending on their assets' nature and context (The Institute of Asset Management 2022). The UN Handbook on Managing Infrastructure Assets provides an asset management framework that identifies what needs to be in place for an asset management system (Figure 1). To implement asset management, bridge managers should define service levels, performance measures, and targets. Furthermore, data should be collected to identify issues, and decisions must be made to adapt solutions to meet the changing risk profiles of a network. Additionally, bridge managers must ensure that strategic goals are met and that the network is maintained in a manner that meets the needs of all end-users (Bush et al. 2012).

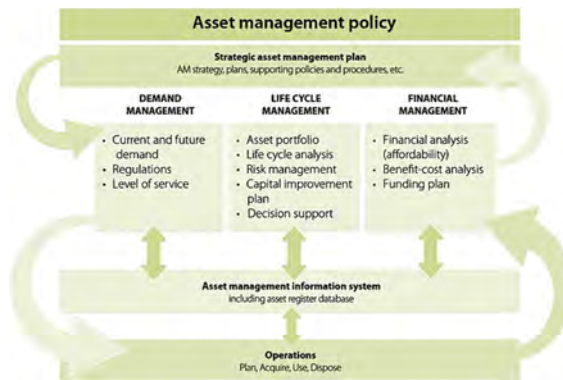

Figure 1. Asset Management Framework (From Managing Infrastructure Assets for Sustainable Development, by United Nations, © 2021 United Nations. Reprinted with permission of the United Nations).

The International Infrastructure Management Manual (IIMM) developed an internationally recognized asset management process that links level of service, performance measures, data collection, decision-making, and implementation (Hughson et al. 2006). The manual promotes two levels of asset management: core and advanced. The primary goal of core asset management is to understand the asset and its requirements. In contrast, advanced asset management involves understanding the relationship between performance, funding requirements, as well as the risks associated with failing to meet service-level agreements (Bush et al. 2012).

According to audits undertaken by the US Government Accountability Office USGAO (2008) and The New Zealand Office of the Auditor General NZOAG (2010), data gaps exist in existing asset management practices that have hindered the development of advanced asset management practices. Many bridge managers still follow the more traditional data collection approach, where decision-making is based purely on scheduled visual inspections and basic performance assessments. A move away from this perspective and toward a strategic decision-making system will significantly improve asset management outcomes by providing better information to strategic decision-makers (Bush et al. 2012).

2.2 *Asset management decision-making*

Effective asset management decision-making is critical in order to maximize the value realized over the lifetime of an organization's assets (The Institute of Asset Management 2015). Decisions made at each stage of an asset's lifecycle will impact subsequent stages. The choice of asset

acquired will impact its performance, risk, and maintenance requirements during its operational life, as well as the methods and costs of its decommissioning. Furthermore, how an asset is operated and maintained determines the length of its useful life and the costs and complications associated with its end-of-life. Therefore, asset management decisions must balance competing priorities, such as asset performance vs. asset maintenance, capital expenditures vs. operating expenses, and short-term benefits vs. long-term sustainability (The Institute of Asset Management 2015).

2.3 *Data collection practices*

Three approaches are available to help bridge managers understand how an asset is functioning. This includes visual inspection (VI), non-destructive evaluation (NDE), and structural health monitoring (SHM). A review of bridge asset management practices found little evidence of the full integration of all three systems (Bush et al. 2012). Furthermore, visual inspections have significant drawbacks, such as high outcome variability, lack of repeatability, and low accuracy, as data is based primarily on inspectors' judgment (Phares et al. 2007). Therefore, for an advanced asset management approach to be successful, the data and the data collection practices must be updated. This can be achieved by integrating NDE and SHM into the data collection processes (Omenzetter et al. 2015).

3 STRUCTURAL HEALTH MONITORING OVERVIEW

SHM is commonly defined as the procedure of obtaining and evaluating data acquired from the installation of sensors to assess the structural health of a structure (Güemes et al. 2020). It puts in place a strategy for locating and repairing damage in infrastructure and plays a valuable role in the management and maintenance of structures (Farrar & Worden 2007). For instance, condition-based maintenance (CBM) is an approach that prevents severe damage to structures by actively monitoring asset conditions to perform maintenance only when it is needed (Phares 2018).

3.1 *SHM technologies*

Technologies for structural health monitoring can be classified into two categories: Local techniques, in which damage detection is limited to the area directly under the sensor, as well as global techniques, in which damage detection is possible anywhere in the structure via an adequately distributed network of sensors (Güemes et al. 2020). The type of data measured determines the type of sensor that is used for damage detection. Hassani et al. (2021) present various sensor types that can be used to monitor various mechanical properties of a component.

3.2 *SHM primary goals*

According to Li & Hao (2016), SHM is intended to achieve the following six primary goals: I) validation of design assumptions and assessment of structural performance; II) early identification of potential damages to ensure structural and operational safety; III) provision of real-time information for safety assessment following disasters and extreme events; IV) assessment of structural conditions, load-carrying capacities, and prediction of remaining service life; V) provision of a decision tool for optimal inspection, rehabilitation, and maintenance planning; and VI) collection of massive amounts of in-situ data for cutting-edge research to improve design specifications and guidelines. These applications make SHM a valuable resource for bridge asset managers as the collection of reliable data is essential for ensuring that bridges continuously perform at the required level, and SHM can supplement this by developing advanced knowledge about bridge condition and performance.

3.3 *SHM limitations*

SHM has been the subject of many global studies due to its dual goal of preventing catastrophic failure and empowering infrastructure owners with quantitative data for designing a reliable and cost-effective asset management plan (Li & Hao 2016). While SHM has the potential to

improve asset management, it has only been able to make limited development from research to application due to its relatively high installation and operation costs (Phares 2018). A key aspect of transitioning SHM into an economically feasible asset management strategy is the ability to quantify the tangible benefits of the system to justify capital costs (Lynch et al. 2016).

4 ROLE OF SHM FROM AN ASSET MANAGEMENT PERSPECTIVE

Asset management offers significant potential for integrating SHM systems, especially ones designed considering operations and maintenance performance metrics. The information generated by the SHM system may be integrated with an owner’s asset management platform to facilitate the issuance of work orders and provide better situational awareness for the bridge management personnel (Dubbs 2018). SHM could also be used to update deterioration forecasts in real-time, enabling owners to have a realistic and accurate representation of their bridge condition. The main challenge, however, lies in the ability of SHM systems to report actionable information that can be utilized for decision-making (Wong 2001) (Dubbs 2018) (Heldt et al. 2019).

Wong (2001) presents that SHM, alone, is of little value other than a latent technical accomplishment, as it is an integral part of a value chain (that focuses on “understanding” the risk) and argues that the information generated by SHM should be used to assist the owner in making financial decisions (thereby “managing” the risk). To achieve this and fully transition SHM into a commercially viable asset management strategy, Heldt et al. (2019) emphasize the need for decision-mapping before scoping and implementing SHM. This includes understanding what decisions SHM is trying to inform, what the likely outcomes are, how the data will be used, what the value proposition of SHM is, and how it can be targeted to support decision-making at all levels.

4.1 Frameworks for the integration of SHM into bridge asset management

The process of identifying the place of SHM in the emerging bridge asset management discipline has been under development by a few authors. A data collection and monitoring strategy for asset management of road bridges has been developed by Bush et al. (2011). Bridges in a network are classified into one of three data collection categories: core, intermediate, or advanced. The classification considers the risk profile and the criticality of each bridge in the network, and a simple scoring scheme is proposed. Depending on a bridge’s level of criticality and risk, its data collection regime shifts from core to intermediate to advanced, as illustrated in Figure 2.

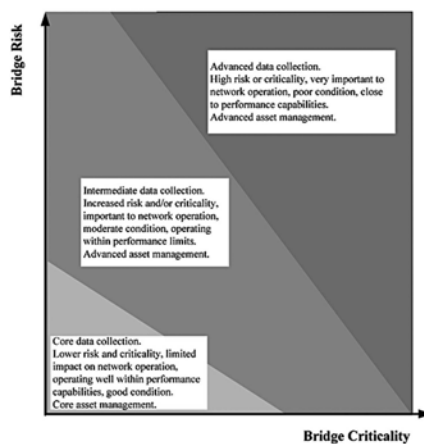

Figure 2. Risk and criticality-based bridge classification for data collection (Bush et al. 2011).

Correspondingly, the bridge is moved towards higher levels of data collection that involve collecting more detailed and reliable data, as presented in Table 1. High-level data collection

regimes require proactive and planned integration of SHM systems for asset management. By providing some degree of flexibility in the data collection regime, the bridge asset manager can tailor the strategy following local network requirements, risk tolerance, and budget, thereby ensuring cost-effective strategy implementation. For example, increasing the number of bridges assigned to intermediate and advanced regimes will require additional resources as more comprehensive data will be collected for those bridges. Alternatively, keeping more bridges in the core regime will be more economical since data collection techniques will be limited.

Table 1. Risk and criticality-based bridge data collection strategy (Bush et al. 2012, © 2012 NZ Transport Agency. Amended with permission from Waka Kotahi NZ Transport Agency).

Data collection regime	Bridge risk-criticality	Risk assessment reporting	Inspection frequency	Data collection techniques
core	low	overall bridge risk	visual inspections every 3-6 years	limited, usually reactive SHM
intermediate	intermediate	individual element risk	visual inspections every 2-3 years	some, reactive and proactive SHM
advanced	high	individual structural component risk	visual inspections every 1-2 years	extensive, mostly proactive SHM

Omenzetter et al. (2011) propose a similar philosophy for integrating SHM into broader data collection and asset management by focusing on the risk that failures of individual bridges can pose to the overall functionality of the transportation system. The recommendation is that detailed and real-time data on the condition of all bridges is not necessary, but only for those bridges whose failure is likely to have more significant consequences on the network operation. In other words, only bridges with higher risk should receive priority for enhanced data collection using SHM.

4.2 Successful cases of SHM integration with asset management

A few authors have shown that the integration of SHM into bridge asset management has proved successful.

Figueiredo et al. (2011) developed an approach to integrate SHM into a bridge asset management system to analyze engineering and economic factors and to assist authorities in determining how and when to make decisions regarding the maintenance, repair, and rehabilitation of structures. This approach was validated on standard data sets from a real-world bridge. It was concluded that bridge safety, repair, and maintenance were successfully achieved with visual inspections accompanied by results from long-term monitoring.

Ni & Wong (2012) designed and implemented an integrated SHM and maintenance management system for 21 sea-crossing viaduct bridges on the Hong Kong Link Road. In this system, the structural degradation of the bridge was monitored through SHM and assessed evolutionarily to facilitate CBM. The inspection and monitoring results were linked to an updatable rating system based on criticality and vulnerability, as in the work of Bush et al. (2011). This linkage enabled decision-makers to utilize SHM data directly to prioritize and make bridge inspections and maintenance decisions. This provided solutions for minimizing and eliminating unnecessary repairs, preventing catastrophic bridge failures, and reducing the negative impact of maintenance on the profitability of the in-service bridges under study.

More recently, Phares (2018) developed a bridge asset management system utilizing real-time performance and condition data to prioritize bridge repairs and maintenance in a similar fashion to Ni & Wong (2012). By combining the continuous real-time bridge condition data collected by SHM with bridge inventory data, a CBM framework facilitated by SHM was developed. Through implementing this framework on Iowa's Sugar Creek Bridge, Phares (2018) determined that the potential extension in the service life of the bridge and the expected savings in maintenance, repair, and monitoring costs make SHM economically justifiable.

Dubbs (2018) presents a case study that demonstrates how an in-service SHM system has been integrated into a bridge agency's asset management software platform. The integration

of SHM into asset management provided valuable, actionable information on five discrete areas, as shown in Figure 3. This includes maintenance work orders, operations, public safety, structural safety, and security. This suggests that the integration of SHM can inform decisions regarding the structural performance of the structure, as well as maintenance and operations, thus paving the way to the realization of an advanced asset management system.

Figure 3. Potential Uses of SHM-Asset Management Integration (Dubbs 2018, © 2018 ASCE. Reprinted with permission from ASCE).

5 RESULTS AND DISCUSSION

5.1 Key challenges

Based on the literature review, it appears that the key challenges of infrastructure asset management are characterized by the need for advanced knowledge about the condition and performance of the concerned asset, in addition to the need for reliable data for planning to ensure that assets continue to perform at the expected level well into the future. Moreover, when it comes to utilizing SHM systems in asset management, the main obstacle faced is the challenge of effectively transforming the complex and often noisy data generated by SHM into actionable information to support the decision processes inherent in asset management.

5.2 Key findings

From the literature that has been reviewed, we can summarize our findings on how to achieve the best practice use of SHM as an asset management tool as follows:

5.2.1 Appropriate application of SHM

Since SHM is not meant to replace visual bridge inspection, it is best used after a visual inspection has deemed a bridge to be structurally inadequate in order to objectively determine the actual state of the bridge. As highlighted by Bush et al. (2011), SHM is not required for every structure but for structures that, when correctly assessed, have a high potential of resulting in considerable cost savings for the owner. Whether SHM is appropriately applied depends on the significance of the network being monitored, specifically whether the bridge network is critical or part of a group of routine bridges. Since both these situations involve diverse bridge management choices, the SHM requirements specified for each will be considerably different from one another.

5.2.2 Shift from core asset management to advanced asset management

NZOAG (2010) and Bush et al. (2012) suggest that bridge asset managers must transition to an advanced asset management approach and improve the connection between operating

processes and strategic outcomes by applying SHM. Since not all bridges on a given network share similar conditions, demands, and importance, not all bridge managers will require an advanced asset management approach. Whereas some critical bridges will require a more advanced asset management approach, more basic asset management approaches will be sufficient for other simpler bridges. In order to achieve advanced asset management, managers need to increase the amount of data collected and the precision of data for the most critical bridge routes. To achieve this, Omenzetter et al. (2015) propose better integration between VI, NDE, and SHM, as well as a data collection model that accounts for broader performance requirements for bridges.

5.2.3 Risk and criticality

Bush et al. (2011) emphasize the importance of considering risk and criticality as factors in the data collection strategy in bridge asset management. To do so, rather than collecting data as if all bridges are the same, we need to adopt a more systematic, individualized approach for managing bridge assets and gathering relevant data. It is necessary to integrate SHM data into asset management in a planned and proactive manner as bridge risk and criticality increase. Accordingly, a simple asset management approach must be adopted for lower-risk and criticality bridges, and an advanced asset management approach for higher-risk and criticality bridges.

5.2.4 Shift from Time-Based Maintenance (TBM) to Condition-Based Maintenance (CBM)

Implementing an asset management framework that includes SHM can improve the maintenance strategy of a bridge by shifting from the current time-based approach (whereby maintenance is performed according to a planned schedule) to the modern CBM approach (whereby asset conditions are actively monitored to perform maintenance only when it is needed). This enhances the execution of inspection and maintenance activities of bridges and substantially decreases the inspection and maintenance costs (Ni & Wong 2012). Phares et al. (2018) list the advantages of SHM-CBM integration for asset management decision-making as follows:

- I. Continuous and near real-time SHM data to support maintenance decisions
- II. Improved collection of a variety of quantitative data
- III. Reduced uncertainty about structural performance
- IV. Elimination or reduction of over-maintenance and deterioration caused by insufficient information about the actual condition of a bridge

6 CONCLUSIONS

In this paper, the literature was thoroughly reviewed to determine the role of SHM in the asset management of bridges. The current trends in bridge asset management were summarized, the value proposition for using SHM was explored, and the key factors for successfully integrating SHM and asset management were outlined. Through a detailed review, the authors observed that the reliability and efficiency of both asset management and SHM systems could be improved when these two systems are properly integrated. Additionally, the authors have discussed the importance of SHM in asset management, not only as an asset management tool but as a means to achieve advanced asset management. Through an examination of different frameworks and strategies, this paper presents key conclusions from various authors in a collective manner to assist future asset managers in realizing SHM's role in the asset management practice. As a final note, we have identified three areas for future research. First, a comprehensive set of performance and maintenance metrics that provide real value to bridge asset managers must be established. Second, a bridge asset management system that utilizes data to determine bridges' performance and maintenance requirements must be developed. This system must include strategies for optimizing the management of bridge assets. By developing these metrics and bridge decision-making tools, SHM can maximize the value of data collected and, in turn, allow the data to directly contribute to asset management decision-making. Finally, to achieve the potential benefits of SHM and use it cost-effectively, a deeper understanding of management aspects such as the cost-benefit ratio is necessary, as well as its impact on the type of issues to be monitored and the probability of detection.

ACKNOWLEDGEMENT

The University of Nottingham, Nottingham, UK

J. Wallis, R. Brook & K. Morosiuk

XAIS Asset Management Ltd, Doncaster, UK

ABSTRACT: Maintenance of road drainage systems requires efficient use of public funding and resources. Current periodic gully pot cleansings can be improved through risk-based decision-making tools that use inspection and historical data. This paper proposes a framework to define gully cleansing regimes making use of stochastic Petri nets and Machine Learning. The stochastic Petri net model is used to predict gullies' sediment level ranges over time based on historical data. Machine learning techniques are used to classify gullies and overcome data absence. The probabilistic distributions used to predict sediment levels are also utilized to derive the probability of reaching a limit state given an assigned cleansing frequency. The framework enables a risk-based analysis to optimize maintenance costs. The results show that the stochastic Petri net model is suitable for representing sediment level condition states and the risk-based tool is useful for maintenance decision-making.

1 INTRODUCTION

Infrastructure networks are vital for the economy and society. Under the Highways Act 1980, Highway Authorities are responsible for maintaining the highway and drainage systems in a safe and functional condition. Gullies are important for preventing solid materials from flowing into the sewerage system and causing blockages. An inadequate cleansing regime can lead to flooding of the carriageway and subsequent damage to the highway surface or sub-structure, shortening its lifespan. Moreover, inadequate maintenance can also increase hazards for motorists and pedestrians, especially during wet and freezing conditions. Local Highway Authorities (LHA) have been forced to manage their assets effectively due to austerity and take risk-based approaches according to UK Department for Transport (2016). Some LHAs have reinforced their cleansing programs with subsequent reactive maintenance measures to deal with faults or blockages. However, current cyclical cleansing approaches involve cleaning road gullies on a planned and regular basis, irrespective of the need for cleaning that specific item. Austerity has led to a reduction in gully cleansings to cover cyclical activities, resulting in a substantial increase in emergency cleanses due to intense rainfall, which is predicted to increase due to climate change. Emergency cleansings disrupt the cyclical cleansing program and are more expensive than a planned route. Therefore, the current methods of assessing cleansing operations and planning on-site works need to be re-evaluated to optimize available resources and ensure effective maintenance of the drainage systems.

This paper proposes a framework for defining gully cleansing regimes using Machine Learning and stochastic Petri nets. The approach includes probabilistic functions to model transitions between consecutive gully conditions, allowing the definition of cumulative distribution functions for different limit states that can be used in a risk analysis. A case study of East Sussex County Council (ESCC), one of the largest Highways Authorities in the United Kingdom, is provided to demonstrate the framework's application.

2 METHOD

The framework is based on historical data collected during the cyclical cleansing programme defined by ESCC, which includes information about the sediment level and time interval between consecutive interventions. Using these data, the monthly sediment level rising rate is calculated, and gullies are classified as slow, medium, or fast deteriorating, based on historical values of sediment accumulation. The Classification learner, available in Matlab Machine Learning Toolbox, is used to train a model that generates predictions of gully classification based on environmental variables, gully stock properties, and other road section variables. The resulting model is employed when historical cleansing data is poor or unavailable. A stochastic Petri net formalism is used to model the condition of gullies over time. This approach includes the definition of consecutive condition states and timed transitions, between states, that represent the time that a gully lasts in the prior condition before moving to the next. Timed transitions are represented by probabilistic distributions with parameters estimated using the maximum likelihood method. This aims to obtain the best set of parameters that fit the condition score data obtained through in-situ measurements. The probability of reaching distinct limit state levels is derived based on the probabilistic functions used to model the transition times between states. The framework comprises a risk analysis to provide a decision tool for gully cleansing regimes that considers different road maintenance hierarchies and flood risk zones.

3 CASE STUDY: EAST SUSSEX COUNTY COUNCIL

The ESCC road network has six different categories of roads based on classifications proposed by the UK Department for Transport (2016). The road hierarchy is structured as Strategic Route (2), Main Distributor (3a), Secondary Distributor (3b), Link Road (4a), Local Access Road (4b), and Minor Road (5). Strategic Route includes trunk and principal ‘A’ class roads with limited pedestrian crossings and parking restrictions. Main Distributor routes link urban centres to the strategic network with limited frontage access and parking restrictions. Secondary Distributor includes ‘B’ and ‘C’ roads with frontage access and unrestricted on-street parking. Link Road hierarchy includes interconnecting residential or industrial roads with 20 or 30-mph speed limits and uncontrolled parking. The Local Access Road hierarchy includes roads serving limited properties carrying only access traffic, and the Minor Road hierarchy includes roads serving very few properties. These road classifications help to determine gully cleansing frequencies and risk management strategies in the maintenance of road drainage systems. The Drainage Management System (DMS) used by ESCC helps identify the location of surface water runoff assets in various road hierarchies. The historical data available at the DMS comprises around 849k complete cleansings since 2008, where the sediment levels are recorded. Table 1 shows the distribution of gullies in different road hierarchies and the number of assets in different zones of the flood risk maps. The framework proposed does not distinguish between road gullies and kerb inlets. If the asset has a sediment pot, it will be treated as a road gully pot.

Table 1. Distribution of gullies per Road Hierarchy and Flood Risk Level.

Road Hierarchy	Flood Risk Level				Total
	High	Medium	Low	Very Low	
Strategic Route (2)	1583	831	1593	2007	6014
Main Distributor (3a)	1613	1012	1942	3521	8088
Secondary Distributor (3b)	2899	1788	3935	7117	15739
Link Road (4a)	2433	1739	3460	4059	11690
Local Access Road (4b)	12991	8824	16553	1605	54419
Minor Road (5)	24	13	23	41	101

4 CLASSIFIER LEARNER FOR GULLIES

The proposed decision-making tool classifies gullies into three categories based on their mean monthly sediment level rising rate (SLRR): slow, medium, and fast. This rate is calculated for each gully based on consecutive inspections recorded in the DMS. Slow gullies have a mean SLRR below the 16th percentile, while fast gullies have a mean SLRR above the 84th percentile. Medium gullies have mean SLRR between the 16th and 84th percentiles. To ensure statistical significance, only gullies with more than 4 consecutive inspections are considered. The complete gully stock has an average SLRR of 4.95% per month and a standard deviation of 1.87% per month. The SLRR values are assumed to follow a normal distribution. However, insufficient data exist for some gullies in the stock to accurately classify them and determine a cleansing regime. To address this, a Machine Learning model is trained on a labelled dataset to identify the relationship between input features (such as environmental variables, gully stock properties, and other road section variables) and their corresponding SLRR classes. The objective is to enable the model to learn a general pattern that can predict the SLRR class of gullies based on input features.

4.1 Features and output variable

ESCC flood event location data is used to tag gullies located less than 100m from a flood spot as “near a flood spot.” The Environment Agency’s flood risk maps are also used to identify potential hazards related to the gully stock. The XAIS Asset Management Ltd system (XA) provides information on the longitudinal gradient of road sections, used to identify sag points where floating debris accumulates. Gullies within 100m of a sag point are tagged as “near a sag point.” The classification learning app in Matlab considers variables such as road hierarchy, gritting routes, zone type, and the average time between cleansings recorded in the ESCC database. Table 2 summarizes the variables considered in the classification learning app.

Table 2. Variables used to classify gullies.

Variables	Values					Type	
	High	Medium	Low	Very Low			
Flood Risk						Categorical	
Road Hierarchy	2	3a	3b	4a	4b	5	Categorical
Gritting Route	Yes	No	-	-	-	-	Categorical
Zone Type	Urban	Rural	-	-	-	-	Categorical
Near Flood Spot	Yes	No	-	-	-	-	Categorical
Near Sag Point	Yes	No	-	-	-	-	Categorical
Avg. Time Between Cleansings	ranges from 4.9 months to 27.1 months						Numerical
Gully Deteriorating Class	Slow	Medium	Fast				Categorical

4.2 Gullies regime classification

The Fine Tree model is used to predict the gullies’ cleansing regime. It is a Decision Tree model that uses Gini’s diversity index as the split criterion with a maximum of 100 splits. The model is validated using holdout validation, where the training and test sets are partitioned into 75% and 25%, respectively. The feature importance scores are sorted using the Maximum Relevance – Minimum Redundancy MRMR algorithm (Zhao, Anand, and Wang 2019) and the Confusion Matrix obtained through the Matlab Classifier Learner is shown in Figure 1.

The model achieved an 81.6% validation accuracy, with normal and fast gullies correctly classified 82.1% and 85.4% of the time, respectively. Slow gullies were correctly classified in 75.4% of cases. The False Discovery Rate (FDR) values are evaluated to determine if the model provides distant predictions. None of the gullies predicted as fast were classified as slow. Moreover, only 0.1% of the gullies predicted as slow were classified as fast. According to the MRMR algorithm, the most influential feature in classifying gullies is the average time between cleansings, meaning that the SLRR is greater with a shorter time between cleansings.

Other factors include the flood risk zone, location on a gritting route, and whether the gully is in a rural or urban area. The model suggests that the road hierarchy and proximity to a flood spot or sag point have minimal impact on the results. The Fine Tree model exported from Matlab was employed to classify the gullies with insufficient cleansing data, and the resulting predictions were merged with the previous classifications based on historical cleansing data. Most gullies (49957) were classified as having a medium SLRR, while 10280 gullies were classified as fast, and 35815 gullies were classified as slow.

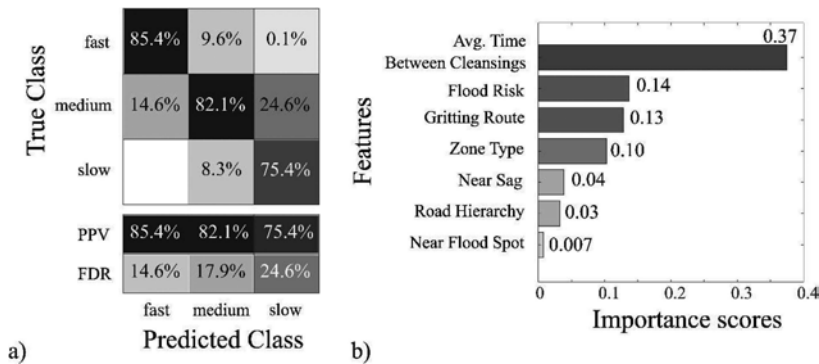

Figure 1. Confusion Matrix and Feature Importance scores using the MRMR algorithm.

5 CONDITION PROJECTION CURVES BASED ON STOCHASTIC PETRI NETS

A Petri net formalism is used to predict the condition of gullies. The method is based on Dugan et al. (1984), which walked on the road paved by Petri (1962), which developed the original concept. The Petri net considered herein has four components: Places, Transitions, Arcs, and Tokens. In this case, 5 places are associated with distinct sediment level ranges, as presented in Figure 2. The state of a gully is represented by the location of the token, while transitions model the time that a token lasts in the previous place. An arc transports Tokens and connects a place with a transition, or vice-versa. This formalism has been successfully applied to model the deterioration of assets based on qualitative condition scores (Andrews 2013; Yianni et al. 2017), which is the case of sediment level at gully pots since surveyors usually define the sediment level as a percentage of the pot height through a visual inspection. Compared to alternative methodologies used to model discrete conditions states (e.g. Markov Chains), Stochastic Petri Nets (STP) allow for the use of a range of distributions to model transition times, the use of the same model for different classes of structure, by assigning colours to tokens, and the ability to integrate advanced modelling features, like the effect of maintenance and inspection actions.

Figure 2. Petri net scheme of a gully with a sediment level between 25% and 45% of the underlying pot.

The term stochastic is used to classify the Petri net given that timed transitions are represented as random variables. A similar approach was applied to predict the degradation of ceramic claddings (Ferreira et al. 2020) where the transition times were modelled with five probabilistic distributions (Exponential, Weibull, Log-Normal, Gumbel and Normal distribution), which provides higher versatility when compared to other competitor models such as Markov based models. In the present work, exponential distributions are used to model transitions with parameters obtained through the maximum likelihood method (Kalbfleisch &

Lawless 1985). The likelihood is defined as the predicted probability of occurrence of the observed transitions:

$$L = \prod_{i=1}^n \prod_{j=1}^k p_{ij} \quad (1)$$

where i is the condition in the initial instant; j is the condition in the final instant; n is the number of elements of the historical database; k is the number of intervals between inspections; and p_{ij} is the probability of transition from condition level i to condition level j . The log-likelihood is commonly used to improve optimization algorithms' robustness in the estimation of the probability function parameters. The log-likelihood is given by:

$$\log L = \sum_{i=1}^n \sum_{j=1}^k \log p_{ij} \quad (2)$$

The probability of occurrence of the observed transitions, p_{ij} , is estimated by Monte Carlo simulation. The Latin Hypercube Sampling (LHS) (Olsson and Sandberg 2002) was used in this work to generate a set of transition times (simulations), in which each realization corresponds to four timed transitions that are assumed as random variables following the exponential distribution. The parameters that define each timed transition of the Stochastic Petri Net can be obtained through numerical optimization methods, where the objective is to maximize the likelihood function given by equation (2). The constrained optimization by linear approximation (COBYLA) created by Powell (1994) is used in this work and is suitable for constrained problems where the derivative of the objective function is not known. Figure 3 summarizes the steps required to reach the parameters of the exponential distributions used to represent each transition. For each gully classification (slow, medium, and fast) one must upload the historical condition data available. Each entry of the historical condition data corresponds to consecutive measurements of silt level at a gully pot at two spaced times. The number of simulations (n_{sim}) is equal to 1000, while each timed transition is initialized with a mean value of 1 month.

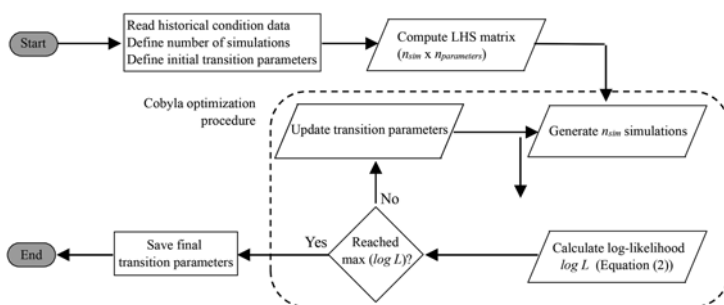

Figure 3. Optimization procedure used to determine timed transition parameters.

Table 3 shows the optimal parameters obtained for the timed transition exponential distribution functions. The Latin Hypercube sampling can be further used to present condition projection curves based on the optimal parameters.

Table 3. Optimal parameters obtained for timed transitions.

Classification	Mean Value (months)				$- \log L$
	T_1	T_2	T_3	T_4	
Slow	17.4	6.2	21.2	10.6	119561
Medium	7.8	3.8	12.5	7.9	850293
Fast	5.8	1.4	7.3	5.6	280196

6 RISK-BASED ANALYSIS FOR CLEANSING REGIME DEFINITION

During the design phase, the spacing of road gullies is determined based on rainfall intensity, which is dependent on the depth of rainfall in millimetres falling at a site for 2 minutes with an average return period of 5 years. For sites located in the ESCC, the value ranges from 3.0mm to 4.0mm. Thus, this analysis considers rainfall with an average return period of 5 years and predefined limit states for different road hierarchies. In other words, the study aims to evaluate whether the gullies meet their respective performance levels during a storm event with a 5-year return period. The probability of compliance (P_c) of one gully can be determined by the equation below:

$$P_c = 1 - \sum_{i=0}^{n_{intervals}} F_d(i \cdot t) \cdot P_{EXP}(\Delta t), \text{ with } n_{intervals} = T_c/\Delta t \quad (3)$$

where T_c is the time between cleansings, Δt is the time step considered to calculate the probability, F_d is a limit state cumulative probability function that depends on gully classification, as well as on its assigned performance level, and $P_{EXP}(\Delta t)$ is the probability of the rainfall being exceeded at least once during Δt . It is worth noting that the sum presented in equation (3) represents the probability of failure, which considers the cumulative probability function given that $P_{EXP}(\Delta t)$ is considered constant for any time interval. The latter can be obtained through the equation below:

$$P_{EXP} = 1 - e^{-\frac{\Delta t}{5.12}}, \text{ with } \Delta t = 0.1 \text{ month} \quad (4)$$

6.1 Limit states cumulative probability curves

Three limit states (LS) are defined for levels of sediment accumulation in the gully pot, which are associated with different performance levels: trapping efficiency, hydraulic efficiency, and outlet blockage. Trapping efficiency (or sediment retaining efficiency) is compromised when sediment levels range from 45% to 65% of the pot height, while hydraulic efficiency (ability to pass flow without becoming surcharged) is affected when sediment levels are between 65% and 85%. A gully is considered blocked when sediment levels exceed 85% of the pot height.

The present work exploits the exponential distributions with parameters presented in Table 3, obtained through the stochastic Petri net formalism resulting in empirical cumulative distribution functions (ECDF) for each limit state. A limit state can be defined as $LS = \{D \geq d\}$, such that sediment level (D) exceeds a specific height of the pot (d). Alternatively, these curves represent the conditional distribution function $F_d(x)$ of the capacity of a gully to remain uncleaned until reaching an undesirable limit state. The following equation represents the conditional distribution function $F_d(x)$, which can be consulted in Khetwal, Pei, and Gutierrez (2021):

$$F_d(x) = P[D \geq d | X = x] \quad (5)$$

where D is an uncertain limit state, d is a threshold of D , X is the uncertain time between cleansings, x is a particular value of X , and $F_d(x)$ represents a cumulative probability function for damage state d evaluated at x . Figure 4 presents the cumulative probability functions for the three limit states considered, as well as their respective 95% confidence intervals, which were estimated by using Greenwood's formula available in Matlab Statistic and Machine Learning Toolbox. Figure 4 also shows the lognormal cumulative probability functions that were fitted using the maximum likelihood method. Lognormal CDFs are adequate for the present analysis given that time cannot assume negative values. In addition, lognormal CDF are widely used to represent the probability of reaching a particular limit state or damage level as a function of an intensity measure, especially based on empirical data, as well as numerical model results (Nguyen and Lallemand 2022). The same principle is adopted here, however, the limit state data is obtained through LHS sampling method that uses the parameters available in Table 3.

Figure 4. Cumulative probability functions for distinct limit states.

6.2 Application of risk-based analysis for the definition of cleansings programmes

The gullies located in roads with hierarchies from (2) to (4a) must have hydraulic efficiency and trapping efficiency when the 5-year return period rainfall occurs. Consequently, the cumulative probability functions considered for those gullies refer to the Fair condition. For the gullies located on local access roads and minor roads, the objective is to guarantee hydraulic efficiency, which corresponds to the limit state Poor. The analysis presented here will compare three cleansing regimes: current; Proposal 1, improved efficiency for (2) and (3a) roads; and Proposal 2, reduced blocked outlet times. Table 4 presents their correspondent cleansings and percentage of compliances. Proposal 1 allows a reduction of 21.3% in the number of visits while reducing 6.7% the prediction of compliances. This approach can free up one weekday to perform inspections and carry out other maintenance measures. Proposal 2 results in a similar number of cleansings but reduces blocked gullies on principal roads by almost 50%, along with the time that these gullies remain full. From the cumulative probability curves corresponding to the Bad condition, one can obtain the blocked outlet times. Figure 5 provides valuable information for defining inspection strategies and planning reactive measures. Principal roads require less urgent cleaning, while roads serving limited properties are more prone to require exceptional maintenance. On the other hand, released working hours from cyclical cleansings can be used for inspections to mitigate the risk of blocked gullies.

Table 4. Total number of visits for distinct cleansing programmes (horizon of 36 months).

Road Hierarchy	Current	Proposal 1	Proposal 2
Strategic Route (2)	13112	19977	24217
Main Distributor (3a)	22246	29496	29496
Secondary Distributor (3b)	36930	28187	42278
Link Road (4a)	28909	20849	30848
Local Access Road (4b)	99604	59629	71522
Minor Road (5)	237	101	101
Total number of visits	201038	158239	198462
Percentage of compliances	(84.8%)	(79.1%)	(85.8%)

Figure 5. The blocked outlet times: (a) Current programme; (b) Proposal 1; (c) Proposal 2.

7 CONCLUSIONS

The present contribution provides a framework for the definition of gully cleansing regimes. A real case study is presented that corresponds to the definition of the cleansing regimes of East Sussex Highways, which is one of the largest Highways Authorities in the United Kingdom.

The framework utilizes Machine Learning to classify gullies based on their monthly sediment level rising rate, with key features including the average time between cleansings, flood risk zone, location at a gritting route, and zone type (urban or rural). Future improvements may involve adding data on nearby trees and hedges, as well as the gully pot depth, which affects sediment accumulation (Post et al. 2016). Stochastic Petri-nets are employed to model transition times between gully condition scores (sediment levels). Exponential distributions were used to model the timed transitions. The results demonstrate that gullies' segregation into different classes results in reduced computational effort and lower uncertainty for each class, which facilitates effective maintenance planning and decision-making for road authorities. Cumulative probability functions were derived for different service levels using simulation techniques and the Latin Hypercube Sampling. A risk analysis was conducted considering a 5-year return period rainfall and predefined service levels. The framework was tested in three scenarios, aiming to reduce the time gullies spend blocked and improve hydraulic efficiencies on principal roads, and can be widely applicable. To account for uncertainties in cleansing operations, future developments should include transitions that capture the duration that a gully remains uncleaned before being emptied.

ACKNOWLEDGEMENTS

This work had the financial support of the UK Research and Innovation through the Knowledge Transfer Partnership (KTP) programme. The authors would like to acknowledge the contribution and encouragement of East Sussex Highways. The authors would also like to express their gratitude to Lee Garrett, Barry Roughley, Peter Turland, and Daniel Palmer for the knowledge shared.

ABSTRACT: A seven span masonry bridge water channel (> 150-year-old) crossing river Cervo, as a part of “Cavour water line”, has been struck by a flood during an extreme rain event. The intermediate pier P2 has suffered a massive settlement of the foundation ($\Delta Z > 0.5$ m), with displacement and rotation components, so to induce a large damage to the masonry arched spans (near collapse) and the masonry upper water channel. A full life-cycle design approach was developed addressing historical structures studies, topographic survey, material and structural testing and laboratory campaign, detailed structure inspection, B.I.M. models, provisional structures, durability assessment, strengthening strategies, structural monitoring, bridge testing, water-proofing, seismic risk assessment, residual service life assessment. The result of many studies makes possible to increase the service life of the bridge, saving a critical water infrastructure that for more than 150 years has played a central role for the economy in northern Italy.

1 INTRODUCTION

Cavour canal bridge, which crosses the Cervo torrent in the Municipality of Formigliana (VerCELLI, Italy), has been subject to an extreme flood event of 2nd – 3rd of October 2020 and for this reason it has suffered an important damage that almost lead to the collapse of the structure. The main damage is shown by the partial collapse of pier P2. This pile is positioned in the wet bed of the Torrente Cervo together with pile P1 (Figure 1).

As shown in the satellite images of previous years, pier P3 is at the edge of the wet riverbed, while piers P4-P5-P6 are located in a part of the riverbed on the left bank characterized by a sedimentary deposit covered with vegetation (including shrubs). The following studies were developed for the damaged bridge: detailed inspection of the bridge, survey and structural monitoring, structure project and durability assessment, global seismic structural verification of the bridge, as-built BIM project, service life (residual) assessment.

2 BRIDGE HISTORICAL DATA AND PRELIMINARY DAMAGE ASSESSMENT

2.1 *Structural geometry properties of the old bridge*

The canal bridge was built between 1863 and 1866 and is of the multiple arch type in masonry and stone. The static scheme is composed of 7 continuous spans of approximately 18 m in length, with 6 intermediate piers and two end abutments.

The piers have an overall height of 4.1m and are characterized by an elongated rectangular solid blade section (L=24.2m wide) in masonry, at the ends there is a semi-circular rostrum covered in stone. The foot of the piers consists of a plinth covered in stone 4m wide, the shaft

of the pier is made of masonry with a height of 2.5m and a thickness with a truncated cone which varies from 3.2m at the base to 2.9m at the top. At the top of the pier there is a trapezoidal masonry element 0.82m high on which the base of the arches is located.

The pier foundation is of the indirect type, with a massive ribbon-like plinth $h=1.9\text{m}$ high and $b=4.5\text{m}$ wide supported by a group of wooden piles (for a total of about 42 piles). Due to the peculiarity of the canal bridge, the structure of the deck is characterized by two overlapping and collaborating parts, the arches (A) and the super-structure of the canal (B) (see Figure 2).

Figure 1. Pile numbering highlighting the P2 pile in which the failure was detected, upstream and downstream damages.

Figure 2. Bridge on torrent Cervo after construction around 1863, drawings of the original bridge project.

The arches are of the segmental arch type ($\alpha=40^\circ$, $2\alpha\leq 120^\circ$), with a clear span of 15 m and a deflection of about 2.66 m. The thickness of the arch is equal to 1.0m in the impost section and 0.7m in the key section. The “external” arch has the arrangement of the front of the bricks of the “thickness” type. The “external” arch is characterized by a stepped extrados. The “external” arch is surmounted in elevation by a “head wall” 1.5m thick which rises with a variable height from min 0.25m in key to max 2.9m in stack axis, the top of this wall is edged externally by a horizontal shutter $h=0.15\text{m}$ protruding from two bricks. This upper level coincides with the bottom level of the channel, note how this external marking had in the past the purpose of distinguishing the substructures of the arch from the wall elevations of the banks of the channel in order to understand the position of any potential water infiltrations.

The “internal” arch is hypothesized to have been built as frequently in “thickness”. The “internal” arch is on the top filled with light material with a maximum height of 0.41m in correspondence with the pier axis and a minimum of 0.1m in correspondence with the key section.

It should be noted that in these types of segmental arches ($\alpha=40^\circ$, $2\alpha\leq 120^\circ$) the horizontal line (Figure 3) passing through A and A' must always be between the two horizontal lines for points C and D. This constraint derives from one of the stability conditions of the arches, for which they need to contain in its thickness at least one thrust line (J.F. Hater, Heyman J.). The volume above the masonry thickness of the “internal” arch is characterized by fillings in lightened material. In particular, in the pier axis there is a particular elliptical lightening brick-element (elliptical internal cavity 3.5m x 1.4m). The superstructure of the canal consists of a massive “bank wall”, which stands out from the “external” arch, 1.5m thick and 3.5m constant in height, which performs the function of lateral bank. The bottom slab of the channel, for waterproofing purposes (G. Curioni), is made of a lower layer of greasy concrete 0.1m thick and a bed of bricks 0.15m thick.

In correspondence of the pier axis, the elevation made up of the “head wall” and the “bank wall” is locally reinforced by a semicircular protruding masonry stiffener with a diameter of 1.68m. The cross section of the channel is about 3.5m in height and 20.7m in width. At the time of the collapse, the water level of the canal was about 2.5m height.

Figure 3. Geometry of structural stability of the arch type and 3D view of the constitutive elements of a bridge arch and the mutual forces exchanged between the elements.

2.2 Masonry mechanical properties of the old bridge

Information has been found in the literature regarding the resistance of the masonry of the original construction of this bridge. In particular G. Curioni (G. Curioni, 1864-1884) reports the essential data to define the strength of the masonry: the tests ordered by the Civil Engineering Inspector on the bricks used for the construction of the Cavour canal (1863-1866) are reported. Regarding the strength of the mortars produced at the end of the 19th century, the same source (G. Curioni, 1864-1884) collected data on compressive strength, the density of mortars and cements and tensile strength.

According to the historical data the compressive strength of the bridge bricks was between 100 and 150 kg/cm², the compressive strength of the bridge masonry mortar was found between 70 and 140 kg/cm². As far as the “bank wall” is concerned, the literature (G. Curioni, 1864-1884) suggests to guarantee the hydraulic seal “... it is better to make them with good materials and with excellent hydraulic mortar; and the joints of the internal walls must be carefully grouted, or covered with a general plaster of good cement.”

2.3 Preliminary damage assessment of the old bridge

Just after the damage event, it was possible to make some observations regarding the general state of conservation of the bridge and a possible interpretation of the instability that occurred following the flood on 2nd-3rd October 2020. It could be observed that some extended superficial areas of the masonry of the bridge, both on the intrados of the arches and on the “head walls” and at the base of the “bank walls”, exhibit whitish spots which can be seen against the red-brown color of the masonry. These surface defects in the masonry would appear to be “efflorescence”, or infiltrations of water coming from the canal which has passed through the capillarity of the masonry bringing sulphates, carbonates or nitrates into solution. When the water reached the external surface of the masonry it evaporated, depositing the salt crystals on the surface.

The actual conservation/consistency of the base layer of the canal itself, originally envisaged in concrete and masonry, cannot be seen from the photos inside the canal. It is probable that this finish has eroded over time due to the flow of water and reduced in thickness (H bank wall 3.5m).

Pier P2 showed a subsidence of foundational origin on the upstream side (approx. 40cm) and downstream side (approx. 5cm), having occurred in river flood conditions with high material transport. It was presumed that the foundation had undergone erosion due to undermining of the basis. From the photos, the subsidence was accentuated at the upstream end of the pier, thus highlighting that the erosion phenomenon occurred in the point most subject to the hydrodynamic thrust of the river. The kinematics of the differential settlement between the upstream and downstream spurs highlights the occurred rotation of the pier/foundation along the longitudinal axis of the bridge. This configuration would in theory be congruent with two possible scenarios: either following shear damage to the pier (in an intermediate section) or with an overall rigid rotation of the pier. In this last case the average vertical settlement of the pile would be

22.5cm. This aspect can be ascertained by inspecting the masonry face of the P2 pile shaft. In both cases, the settlement resulted in a horizontal crack in the “head wall”, symmetrical with respect to the axis of pier P2 or on span P1-P2 and P2-P3, at the same height on both sides or at the top at approximately 2- 4 courses of bricks below the protruding horizontal shutter which is placed at the bottom level of the canal. The horizontal lesion on the upstream side is much more significant and denotes the lack of a portion of masonry at the kidneys of the “external” arch and the “head wall”. The following Figure 4 illustrate the instability scenario visible at both ends of pier P2.

Figure 4. Horizontal crack in the “head wall” downstream (a), and wide horizontal crack in the “head wall” and missing portion of the masonry at the kidneys of the “external” arch and the “head wall” upstream (b).

It was also observed that in the upstream elevation the lack of masonry at the kidneys of the “external” arch was probably motivated by the activation of a kinematic system linked to two concomitant unfavorable factors: the collapse of pier P2 has generated a geometry variation in the arc, this has favored the kinematic mechanisms of the arch in which it is envisaged to open a joint on the extrados, the detachment from the superstructure of the channel at pier P2 has in fact determined a change in the vertical load bearing mechanism, which is now asymmetrical on the “external” arch, which is in fact subject to the load only in the half span towards pier P1 and P3.

The sum of the two effects was unfavorable for the “external” arch, which therefore activated a kinematic mechanism with two hinges close to the kidneys. The “internal” arch behaved more favorably as it suffered the effects of only the yielding but not that of the asymmetry of the vertical load, given the distribution of the water pressures of the channel which are always uniform along the span. From the internal photos of the channel in correspondence of the bottom slab near the P2 pier, a differential settlement was detected with evident openings, such as to have captured the water inside the bridge. This flow involved the inside of the elliptical lightening present above the pier, between arch P1-P2 and P2-P3, which therefore probably resulted in being flooded (cavity) and eroded (lightening material). However, this configuration was statically balanced and this is evident from the serviceability of the channel, which remained operational for about 24 hours after the instability occurred. It was therefore necessary to define the failure mechanism that was occurred: the subsidence caused on the downstream, with length about 5m, a single horizontal crack in the “head wall”. The subsidence caused a horizontal crack of about 40cm on the upstream side in the “head wall” and loss of the portion of masonry relating to the “external” arch. It can be observed that the order of magnitude of the settlement (40cm) is equal to the thickness of the backfill on the pier axis (41cm), this produces a very critical effect on the arch because the absence of two straight lines A and A’ (see Figure 3) falling between points C and D inevitably produces the loss of the funicular of the loads. In essence, the pronounced yielding activated a direct traction in the section of the “external” arch causing a partial collapse for a stretch of about 2-3m at the kidneys, or with a kinematic mechanism that opened an arch lesion on the intrados. The width of the “external” arch that collapsed could be estimated (CNR-DT 213/2015) at about 2.9m ($b = d + 2 \times s = 1.5m + 2 \times 0.7m = 2.9m$), not more different by 1.5m that is the footprint of the load bearing wall at the top (head and bank). The subsidence caused a difference in height on the bottom of the channel, causing a local failure of the waterproof bottom layer.

Considering the failure mechanisms that have occurred and the current condition of equilibrium of the structure, the exploitation of the following currently active resistant mechanism was assumed. The “external” wall and the “bank” wall constitute a very rigid element which, given the “loss” of support on pier P2, constitutes a structural element with a high wall which develops on a double span (from P1 to P3, i.e. span $L=32m$). The effective span could be intermediate, about 25m taking into account the arc effect on pier P1 and P3. The “external” arch is partially interrupted in

correspondence with the ceded pier, however highlighting how the remaining intact stretch is joined to the “head” wall.

3 DETAILED BRIDGE INSPECTION

With reference to the recent “*Guidelines for risk classification and management, safety assessment, and monitoring of existing bridges*” (CSLP 04.17.2020) following the instability, a detailed inspection of the bridge has been carried out. This inspection had the purpose of acquiring information useful for deepening knowledge of the phenomena of deterioration and the structural condition of the work, since exceptional events such as floods have occurred and have affected the stability of the work. The detailed inspection has been developed in direct contact with the structures, and have been completed by non-destructive tests. The inspection has been carried out by certified bridge inspectors and the results of the structural inspection have been implemented in a B.I.M. model specifically set for inspection data, that could be useful to compute statistical frequency of different type of masonry structure defects.

Figure 5. B.I.M. for the detailed bridge inspection.

4 SURVEY, INVESTIGATIONS AND STRUCTURAL MONITORING

In order to implement the structural assessment of the bridge the following studied have been developed: geometric survey of the bridge, with the aim of reconstructing the current geometry of the bridge with high precision and acquiring the photographic map of the surface; structural investigation plan on the masonry, with the aim of acquiring an adequate level of knowledge on the mechanical characteristics of the masonry; structural monitoring plan, with the aim of acquiring kinematic information of the spans of the bridge in the current configuration, during the works and the reconstruction phases, up to the final operational phase.

A series of non-destructive and destructive tests had to be carried out on masonry bridge structure. These types of tests are used to obtain indications on the physical-mechanical characteristics of the materials and their state of degradation. These types of investigations have been carried out, where possible, in as many points as possible and on all the structural elements. The objective of the structural investigation plan was to obtain the following characteristics of the materials from tests in situ or in the laboratory: physical parameters of bricks and mortar (specific gravity and porosity), mechanical parameters of brick, mortar and stone (compressive strength), mechanical parameters of the masonry (compressive strength, shear strength, elastic modulus), stress and deformation state of the masonry, chemical parameters of bricks and mortar, characterization of surface degradations.

For the bridge project of rehabilitation, it was implemented a structural health monitoring system, which periodically allows the measurement of the displacements in three directions S_x - S_y - S_z of a series of significant points of the bridge in the spans subject to instability and neighboring as well as monitor the opening of cracks /main fissures. The information provided by the monitoring could be used with the following purposes: verify the trend of the global and local displacements of the structure over time in order to intercept any premonitory signal of a worsening of the deformations/damage/cracking regime; verify the stability conditions of the bridge during the safety and subsequent restoration phases; verify the final testing phases.

5 STRUCTURE REFURBISHMENT AND DURABILITY ASSESSMENT

The bridge structural project has been developed considering different steps: a first intervention will concern the safety works, to secure the bridge during the construction period (by the use of external metal structures, contrasts, wooden structures); a second intervention for the definitive restoration and reinforcement works of the structure/spans pertaining to pier P2; implementation of a real case load testing of the bridge span object of restauration works; after the dismantling of all provisional works, additional arches strengthening where finally developed.

The overall safety of the bridge was implemented through a series of interventions aimed at ensuring the local and global stability of the bridge in the affected area. In particular, since these are main vaulted masonry elements, such as arches, and wall elements, such as walls, the provisional works for safety are arranged in order to prevent any type of kinematics: for walls overturning and/or buckling, for arches loss of shape and/or detachment of ashlars.

The design for the safety of the bridge were belting with steel ropes for the walls of the elevations, with the possibility of complete winding of the cross section of the span according to a sequence of closed ropes placed at 1-1.5m center distances. This solution was expected to transversely counteract the base and the top of the bank walls inside the channel, by means of steel truss beams. In addition for both the “external” and “internal” arches: the insertion of steel ribs.

Based on the analysis of the state of stress of the structure in pre- and post-instability conditions, it was highlighted that the stress rates in the masonry were still within acceptable limits. However, the increase in the traction regime was the most critical element and the commissioning works have the purpose to mitigate the risk of activation of new potential local or global collapses.

Figure 6. Bridge safety works: belting with steel ropes and internal channel steel truss beams, internal steel ribs similar shape to the wooden type of the original arches construction period.

Thanks to the implementation of the safety measures, it was therefore possible to proceed with a reconstruction and consolidation of the bridge with the following main works:

- Consolidation of the bearing ground of the foundations, for pier P2 and then P1-P3. This intervention was also extended to all the remaining foundations in order to avoid the repetition of future similar potential settlements.
- A new connection between pier P2 and the “head wall”, by means of castings with light-weight concrete and clogging of the crack pattern. In order to pursue a monolithic nature with the existing structure, all the massive reconstruction castings of masonry volumes was provided for the creation of preventive grouting with reinforcing bars, suitably arranged on the sound portions of the masonry.
- Jetting, with ultra-light weight concrete, and reconstruction of the bottom of the channel above the “internal” arches, after checking and repairing the filler/backfill layers on the extrados of the arches. New waterproofing of the horizontal and vertical surface of the channel.
- Application of FRCM strengthening at the lower bound of the arches, to increase bending moment capacity ad the end of construction works.

Figure 7. Bridge strengthening: arches renew by cast in situ of lightweight concrete, FRCM intrados of arches, load test on the strengthened spans of the channel with water intake.

Figure 8. Bridge strengthening and renew by net of carbon bars drilled inside the masonry walls, sealing and stitching with stainless steel bars of main arch cracks (a), ultra-light weight concrete to fill and stabilize the deck slab, new waterproofing (b).

The numerical analyses carried out on global arches (internal and external), in the P1-P2-P3 spans, made it possible to evaluate the collapse modes of the same both in terms of kinematics adhering to the current conditions of instability and in terms of the value of the vertical displacement that the pier P2 can bear before inducing the collapse of the arches, i.e. the ultimate failure of the system.

The result of the collapse calculation allowed to characterize the ductility value of the vertical displacement of the pile in 1.27, a number which denotes limited plastic reserves of the structure. Considering the asymmetrical conditions of the settlement, caused by the rotation of the pile, the potential of activation of transverse collapse mechanisms was also investigated. However, this study, although approximated since it does not take into account large displacements, has shown that the activation of this mechanism was always secondary with respect to a longitudinal mechanism, therefore it would not be critical for the system (unless large displacements occur). In conclusion, having clarified the modalities of current instability and the possible modalities of progression of the mechanism up to the global collapse, it was estimated (by energy approach) the work that was necessary to be done by the reaction of the pile P2 to produce a global collapse with reference to a vertical translational kinematics. The admissible limit of the average incremental vertical settlements (therefore in the bridge axis) of the P2 pile foundation was estimated, taking into account the variability factor assumed for the materials (30%) and a safety factor (min 1.5): $\Delta Z = 4.0\text{cm} \times 0.7/1.5 = 1.8\text{cm}$

By the arch strengthening, mainly due to cracks bridging and FRCM intrados, the critical average vertical displacement was increased by almost 28%: $\Delta Z = 5.0 \text{ cm} \times 0.7/1.5 = 2.3 \text{ cm}$

All the new construction materials used for the project were subject to a detailed “durability” assessment with the objective to minimize the interaction with the old bridge structure (mainly because of the high level of humidity of the masonry due to the near river and upper channel), starting from an environmental and existing material tested performance and physical/chemical properties characterization.

6 SERVICE LIFE RESIDUAL ASSESSMENT

The service life of structures intended for civil use is influenced by the surrounding environment and consequently by various degradation phenomena which lead to a decrease in structural capacity over time. Considering the specific case of the Cavour canal bridge, through empirical observation in the field and bibliographic research relating to degradation phenomena that affect masonry structures, the following have been identified as the main degradation phenomena: degradation linked to Freeze-Thaw cycles; degradation linked to efflorescence phenomena.

Once the degradation processes and their influence on the structural capacity were characterized, it was important to evaluate the evolution of structural reliability over time and the achievement of limit levels of reliability for which the structure no longer satisfies certain requirements. The Monte Carlo simulation was used to consider and integrate the uncertainties related to the characteristic parameters of the materials, specifically the compressive strength of the masonry f_c . In the specifics of this analysis, the number of Monte Carlo simulations performed was 10^7 .

Limit states related to the operating stresses and limit states related to the ultimate flexural capacity were analyzed for the main structural elements of the bridge Cavour. In each of the cases the structure has shown good structural reliability up to the exceeding of the reliability limits proposed by various codes. In particular, the thicknesses available in the critical sections of the masonry seem to exhibit conditions of maintenance of performance in relation to the phenomena of degradation minimal for several hundred years. Therefore, it was clear that the future critical conditions of the structure will probably not depend on environmental phenomena that have been

examined. It was therefore recommended to: carry out periodic inspections of the structure, to monitor the trend of the main structural deterioration, the geotechnical conditions of the abutments, the state of integrity of the canal waterproofing; maintain constant knowledge of the hydraulic conditions of the river (Cervo turrent) in terms of geometry of the seabed, i.e. conditions of hydraulic risk with respect to all spans and related foundations; check for any damage following seismic events or extreme climatic events. It was important to highlight that the forecasts in terms of time values do not represent deterministic forecasts but are connected to a probability of exceeding the limit state and depend on multiple factors, such as the time interval considered for the analysis (in this case equal to 100 years) and the value chosen for the reliability limit.

7 CONCLUSIONS

Advanced studies and works were developed with the scope to save and quickly put in service by renew and strengthen a large damage occurred to the 150y old masonry bridge. The bridge showed an expected “robustness” structural behavior, making possible the doubling of the span of the deck masonry channel by foundation collapse in pier P2. A deep historical review of the bridge, the detailed inspection, a large material testing investigation could develop a project to put in safety the damaged structure with advanced materials thanks to the durability assessment. The service life (residual) assessment could show the importance in this massive masonry bridge of hydraulic river behavior and the exposure to extreme natural events as the most important risk exposure. The large use of BIM methodology in inspection mapping and as-built design could provide to the infrastructure owner the best opportunity to take future maintenance strategy.

SISSA, Mathematics Area, mathLab, Italy

ABSTRACT: visual inspection of highways bridges, viaducts and tunnels has nowadays a crucial role in infrastructures life-cycle management. In this paper two visual inspection numerical support methods are discussed. Both methods aim to reduce direct and indirect costs of visual inspection and to automate the inspection procedure. This is possible thanks laser scanner images of the tunnel, which are quickly acquired with remarkable decrease of money investment and with no need for *in loco* presence of engineers and then used as input for the calculations. The former method is based on Dynamic Modal Decomposition and it uses laser scanner acquisition to predict damage evolution. The latter one is based on a convolutional neural network and it aims to evaluate damage gravity according to a predefined severity scale. Both methods have been tested on Italian highways tunnels images.

1 INTRODUCTION

In order to guarantee the full functionality and safety of highway tunnels, it is necessary to carry out accurate inspections at regular intervals of time, so that to the highways manager is able to identify the structures degradations and provide for their rapid repair. The inspection process is costly and time-consuming; it requires partial or total closure of the analyzed asset, which may have a detrimental impact on the traffic flow, resulting in an increase of car accidents rate. So, it may be of interest to develop tools that make it possible to promptly and automatically identify which are the tunnels characterized by the highest risk level, in order to optimize inspections and maintenance, giving priority to these assets which present the most important safety issues.

In this context, methods capable of predicting the temporal evolution of the various defects present in a gallery can play a fundamental role. Among them, techniques such as Dynamic Mode Decomposition (DMD) and its variants are particularly promising, given their qualitative and quantitative predictive capabilities and the few necessary basic inputs.

The first aim of this paper is to carry out a preliminary study on the applicability of the DMD method to the problem under investigation; this may clarify the type of input data to be used and any problems encountered in their gathering, identify the necessary preprocessing operations and build one prototype pipeline that can be used as a starting point for more detailed future studies. The preliminary procedure is hereby applicated to three tunnels of various Italian Highways.

In the context of inspections and maintenance optimization and prioritization, it may be of interest to study and develop evaluation tools which can automatically highlight the tunnel lining critical areas. Appropriate neural networks may allow a quickly and accurately estimation of these areas, starting from a few inputs. Thus, the second objective of this paper to study prototype neural networks application to speed up and to automate the inspection process, highlighting potential limitations and fallacies of the proposed method.

2 DYNAMIC MODE DECOMPOSITION PREDICTION AND RECONSTRUCTION

2.1 *Mathematical framework*

The DMD is one of the most recent and universally applicable mathematical models and has made it possible to obtain very satisfactory results in various fields. The base idea of the DMD consists in considering a series of observations of a system at regular intervals that can be used to assemble a linear operator which approximates the time evolution between two successive observations; the modal analysis of the operator can then be used to obtain predictions of the future state of the system, or more generally, to reconstruct the state at a given instant.

To evaluate the effectiveness of the DMD method applied to the problem under investigation, various examples for the tunnels at disposal will be considered, are chosen with the aim of exploring different and complementary scenarios. The analysis was performed using the PyDMD package developed by Demo et al. (2018).

2.2 *Application of DMD*

Input data for DMD method are images derived from laser scansion of the tunnel lining. For tunnel T1 are available eight scans from 2006 to 2017 and for T2 five scans from 2012 to 2015.

The critical analysis of laser scanner images highlights many issues:

- Due to the maintenance procedures provided by the highways manager on selected lining portions, many defects may not show a general worsening year after year;
- Due to different environmental conditions or to different laser scanner used for the images acquisition, the same lining portion may be characterized by different color shades year from year. This may affect the input process of the neural network;
- For the same reasons, the same lining area or segment may be characterized by different dimensions in different scans.

The reported issues imply a partial loss of data preprocessing automation, given that only a manual selection can underline which are the not affected lining portions that can be used as input.

Four scenarios are hereby reported. The first one deals with DMD application to T1 tunnel without any preprocessing. DMD is here used with a dual purpose: reconstruction of the system state in 2009 and prediction of its state in 2011. Figure 1 shows the obtained results.

Figure 1. Lining scan: original (left), DMD reconstruction (center) in 2009 and DMD prevision for 2011.

The reported results show how DMD can replicate the state system in 2009 with high accuracy, while the obtained images are lacking in accuracy and focus for 2011. This is caused by the lining variation in dimensions and colors in the scans year from year.

In the second scenario DMD is applied with a focus on a defect located in tunnel T1 which is present in all the scan between 2006 and 2017 and which does not show a significant evolution

in the reference period. The defect shows, however, oscillation of the color shade, color brightness and relative position in the scan. These issues can cause blurring in DMD predictions and hence it is necessary to apply preprocessing techniques, which consist in i) manually isolating the region containing the defect under investigation ii) rescaling it to a reference size iii) and standardizing its brightness via standard techniques (i.e. histogram equalization).

Figure 2 shows DMD predictions after preprocessing.

Figure 2. DMD prediction for the defect under investigation: one year (left), two years (center) and three years (right).

Thanks to preprocessing, the obtained images are clearer and sharper than those shown in Figure 1. DMD prediction, besides, do not show a significant variation year from year, according to the input data. The general prediction stability can also be highlighted with reference to the modal dynamics detected by DMD, which are shown in Figure 3. Only an almost constant mode (blue line) contributes to the long-term prediction, while the contribution of the other modes tends to quickly to zero.

Figure 3. DMD images detected dynamics.

Let's now focus our attention on a significant worsening trend defect, detected in tunnel T2 and reported in five scans. Again, preprocessing is applied in order to limit the detrimental effects described before. Since the area of the defect is very limited, the image resolution will consequently be low; it is therefore not possible to evaluate the sharpness of the reconstructions (Figure 4) or of the predictions (Figure 5), but only verify that they evolve in time. It is interesting to note how in Figure 5 the DMD predictions actually change year from year, differently from what obtained in the second scenario; this evolution is also confirmed by the dynamics graph in Figure 6, where, in addition to the usual constant mode (in blue), other modes, which present a periodic dynamic, can be underline, although this dynamic is probably only partially correct (as shown by the inexact reconstruction of the year 2015 in Figure 4) given the limited number of scans.

Figure 4. Defect in tunnel T2: 2014 original and DMD reconstructed (left) and 2015 original and DMD reconstructed (right).

This third scenario therefore confirms the potential applicability of the DMD method to determine the temporal evolution of defects in tunnels, once the appropriate preprocessing interventions have been performed (when necessary), even if to reach a high likelihood of the predictions, a sufficiently high number of observations is required.

3 TOWARDS MULTI-LEVEL NEURAL NETWORK DEGRADATION IDENTIFICATION AND CLASSIFICATION

3.1 *Neural network I: Detecting lining element*

3.1.1 *Training and neural network structure*

Images derived from the scans of five tunnels, named as T4, T5, T6, T7 and T8 have been used in the neural network I training; the first four tunnels have been used for the training while the last tunnel has been used for a training quality check.

The neural network architecture is known as UNet, based on a ResNet-50 type structure. The U-Net architecture is divided in two parts: initially the input images pass through a series of so-called convolutional layers (basically a ResNet-50), that reduce their dimensions allowing, at the same time, to capture the most important characteristics for the segmentation problem; subsequently, a series of transposed convolutional layers brings back the input images to to their original size, keeping intact the information about the detected features. Therefore, the output of a U-Net will simply be the same input laser scan, accompanied by additional information useful to identify the type of defect to which a given pixel belongs. The network, implemented in Python3 through the fastai library (fastai library, Howard & Gugger (2020)) based on PyTorch (Paszke et al. (2019)) was trained for a period of twenty epochs (i.e. twenty iterations on all the data), using a learning rate parameter varying from 10^{-6} to 10^{-5} depending on the depth of the layer. As said before, at the end of the training process, the T8 scans were used to evaluate the quality of the obtained results.

3.1.2 Results

Examples extracted from the training are shown in Figure 7.

Training results are quite satisfying. Though a limited database was involved in the process, the neural network I was able to identify with a good definition the jet fans and at a sufficient level deterioration and water ingresses. Increasing the input database would consequently improve the network's prediction capability.

Figure 7. Original and neural network reconstructed images of concrete lining extracted from the training process.

3.2 Neural network II: Classifying the degradation severity

3.2.1 Training and neural network structure

A second neural network is hereby introduced with the aim of classifying the deterioration level starting from an images database. Two degradations categories are introduced: NU class, which involves 2, 2E and 3 level according to IQOA classification, and U class, which involves high risk level defects as 3U and S.

Thus, the presented procedure goal is to identify the lining degradation with a first neural network (semantic segmentation) that uses the laser scans and *classify* their severity with a second neural network that uses degradation images gathered during previous visual inspections.

3065 images from four tunnels, named as T9, T10, T11 and T12 have been used by the neural network II, 2465 during the training phase and 600 for a quality check. All the images, randomly divided for the two goals, have been scaled to the same size. These images are characterized by many critical aspects:

- the IQOA class is usually spray-marked on the lining surface and its presence in the images could negatively affect the functioning of the neural network, since it could not learn anything useful about the characteristics of the defect itself but would make its predictions by simply reading the class in the image. This problem could be solved by considering black/white images rather than color ones; an equally satisfying solution consists in transforming the images from the RGB colour representation to HBS or HLS and selecting only the B or L channel;
- defects of the same class of severity can be reconducted to different categories, such as alterations of fractures; conversely, defects of the same category can have different class of severity. Both issues affect classification process and can be solved with an appropriate cataloguing of the images, not only based on the severity but also to the type of defect.

The architecture of the neural network II is known as ResNet-152: by passing the images through a series of 152 convolutional layers, which reduce their size while highlighting their main features, this network learns to recognize the most important details for classification in a photograph, and based on these elements provides a prediction of the severity of defects. Four ResNet networks have been considered, with the aim of covering all the cases of interest: color images with U/NU classification, b/w images U/NU classification, color images with fine IQOA classification (2, 2E, 3, 3U and S) and finally b/w images with fine IQOA classification.

The same training process was performed for all the cases, again through the fastai library (fastai library, Howard & Gugger (2020), Paszke et al. (2019)) and required a period of eighty epochs (i.e. eighty iterations on the entire dataset), divided in four phases of twenty epochs each:

- In the first phase, the network is initialized with parameters obtained through a pre-training on the ImageNet dataset; during the twenty epochs of training, performed with learning rate equal to 3×10^{-4} , only the parameters of the last layer of the are changed, while those of all the previous layers are kept the same. This procedure, known as transfer learning, is usually used to reduce the training time, as it makes it possible to start from a set of parameters that are already able to recognize basic structures in the images and which only need to be adapted to the problem under investigation. In addition, during this first phase, the height and width of the images are halved, and they will therefore be 288×384 in size;
- In the second phase, known as fine-tuning, the parameters of all the layers are modified, but using a lower learning rate that varies from 3×10^{-6} to 3×10^{-5} depending on the depth of the layer, providing as input images of size 288×384 ;
- The third phase is identical to the first, but the size of the images corresponds to the original one (576×768) and the initialization parameters are those obtained at the end of the second phase;
- The fourth phase is identical to the second, except for using images of size 576×768 .

Changing the images size during training is a technique known as *progressive resizing*, and it helps to speed up learning due to the smaller data size and it induces the network to detect defect features that are not scale invariant. The simultaneous use of *transfer learning* and *progressive resizing* has produced better results for many Artificial Intelligence application and has now become a standard procedure. Finally, the so-called *data augmentation* technique was also applied: this means that during training, transformations were randomly applied to the photographs (rotations, enlargements, changes in brightness and contrast) to make sure that the network predictions are less sensitive to such variations, which are not decisive for classification purposes.

3.2.2 Results

U/NU classification is firstly considered. Starting from a database of 45% NU defects and 55% U defects, ResNet-152 networks are able to reach 93% of correct previsions for color images and 82% for b/w images. Figure 8 shows the confusion matrixes for this first classification.

Figure 8. U/NU classification results.

According to these results, it could be easily observed that the neural network gives better results when working on color rather than on b/w images but obtaining such high correct prediction rate may raise some suspicions, given the goal complexity, according to the aforementioned possibility that the network only reads the writing included in the images. With the aim of validating the procedure, it is therefore crucial to use methods, such as the so-called *heatmap*

technique which allow to highlight what the network learnt and on which elements it based its prediction. An example of heatmap application is reported in Figure 9. It is clearly shown that the network trained on color images focused mainly on these regions spray-marked, while the one trained on b/w images, focused mainly on the regions where the defect is present.

Figure 9. Heatmap for U/NU classification: color images (top) and b/w ones (bottom).

Thus, it is possible to conclude that the high correct prediction rate obtained by working on color images is simply correlated to the spray inscriptions detected by the network in the images; the network learnt to correlate the spray inscription to the degradation severity. On the other hand, working on b/w photographs provides more reasonable and reliable results since the network is less influenced by the spray writing.

As shown by the confusion matrixes in Figure 10, the network is able to reach an unrealistic 92% correct prediction rate using color images and a 69 % correct prediction rate is instead obtained by working on b/w images. Figure 11 provides for the related heatmap.

Figure 10. Confusion matrixes for fine IQOA classification.

Figure 11. Heatmap for fine IQOA classification: color images (top) and b/w ones (bottom).

4 CONCLUSIONS

In this paper, two high performance computing methods possible application for highways tunnel concrete lining damage identification, classification and prediction have been studied. DMD can be helpful in degradation evolution prediction, which is a crucial goal for the prioritization of maintenance and rehabilitation interventions. Starting from regular time-spaced observations of a system, DMD assembles the linear operator which approximates the system evolution between two successive observations. Then, by the modal analysis of this operator, it can develop prediction on the future states of the system. DMD have been applied on a set of laser scans derived from different Italian highways tunnels. It has been shown that, with a proper pre-processing of the scans, DMD is able to reconstruct and predict the lining defect evolution, even if, in order to reach a high likelihood of the predictions, a large number of observations is required.

In the second part of the paper, a system of two neural networks has been analyzed. It can help the highway manager to obtain detailed information about the lining defects, without visual inspections, but simply by the proper utilization of laser scan and defects images, with a considerable time and money saving. The first neural network detects the lining elements while the second network classifies the defects severity.

Finally, by the application of DMD and neural networks methods, starting from laser scan images and defects images gathered during the previous inspections, so with no need for further visual inspections on the highway's tunnels, it is possible to obtain satisfactory information about the lining defects severity and evolution. This process allows to obtain strategic information for the management and prioritization of maintenance and rehabilitation, with a considerable money and time saving compared with the classical visual inspection-based processes.

Experimental study on quantification of carbon dioxide adsorption by different cement types and mix proportions

Takeshi Iyoda & Erika Ishikawa
Shibaura Institute of Technology, Tokyo, Japan

Yosaku Ikeo
Takenaka Corp., Chiba, Japan

ABSTRACT: Efforts are underway in concrete to build a carbon dioxide-free society. The degree of CO₂ adsorption and fixation by hardened cement, concrete depend on the type of cement and water-binder ratio of the hardened cement. In this study, we analyzed various types of hardened cement by TG-DTA to determine the amount of CO₂ adsorbed and examined the possibility of quantifying the amount of CO₂ adsorbed by weight increase as a simple method. As a result, it was shown that the amount of adsorption differs depending on the type of cement, that water is necessary for CO₂ adsorption mechanism, and that the amount of adsorption can be determined simply by the weight change.

1 INTRODUCTION

The global effort to move away from carbon dioxide has a significant impact on the concrete industry. The manufacture of cement, one of the raw materials for concrete, emits enormous amounts of carbon dioxide, which must be curbed. Therefore, in addition to cement production using energy-saving technologies as much as possible, technologies to use large quantities of alternative cement materials with low carbon dioxide emissions are being developed worldwide. On the other hand, concrete has long been known to undergo carbonation and is said to absorb carbon dioxide during service. This is believed to lead to a decrease in the small amount of carbon dioxide in the atmosphere. For carbon dioxide to be adsorbed and immobilized as calcium carbonate, a large amount of calcium is required in the concrete. On the other hand, a factor that increases the depth of carbonation is thought to be the use of cement with more admixture or a higher water-cement ratio to penetrate carbon dioxide deeper into the concrete. Furthermore, it has been pointed out that the presence of water is important for the carbonation phenomenon.

Therefore, the purpose of this study was to compile data that would contribute to the quantification of the amount of carbon dioxide fixed by carbonation of hardened cement. Specifically, we quantified the amount of calcium carbonate produced when environmental conditions and water content were varied in order to sort out the effects of water content in the reaction field. Furthermore, the amount of calcium carbonate produced was determined by changing the total amount of calcium by varying various cement types and water-cement ratios. In addition, the amount of calcium carbonate produced was investigated by adjusting the pores so that carbon dioxide gas could enter deep into the specimens. Furthermore, we attempted to quantify the amount of calcium carbonate produced by changing the weight of the sample so that the ratio of calcium carbonate produced could be easily measured.

2 OVERVIEW OF EXPERIMENTS

2.1 Changes in hydrates and voids due to carbonation

Carbonation of cement hydrates results in carbonation of the hydrates as shown in the chemical equation below. In this process, it is considered that the increase in volume due to the binding of carbon dioxide and the dissipation of the water produced occur simultaneously.

As indicated in the literature, it is also pointed out that carbonation of calcium hydroxide may result in densification of pores due to the formation of calcite, while carbonation of CSH may result in coarsening or opening of pores with the collapse of CSH as well as the formation of vaterite. Especially in cements containing a large amount of blast furnace slag powder, the change in porosity is known to be significant, suggesting that it also affects the progression of carbonation depth.

2.2 Preparation for the test

To organize how much carbon dioxide is adsorbed and immobilized by various types of hardened cement, it can be imagined that there are influencing factors such as the test environment (temperature and humidity, carbonation gas concentration), carbonation period, carbonation in air (dry) and in water (wet) as test conditions, as shown in Figure 1. Also, the type of cement (calcium content), water-cement ratio, and specimen size (shape) can be considered as influencing factors in the mixing conditions of the hardened specimens. We quantified the amount of carbon dioxide fixation by using samples with these factors.

In preparing the specimens, the powders used were ordinary Portland cement (Density 3.16 g/cm³) and blast furnace slag fine powder (Density 2.91 g/cm³). Three types of cement were prepared: OPC, B50 (50% replacement of blast furnace slag fine powder), and B70 (70% replacement of blast furnace slag fine powder), with a water binder ratio of 0.5.

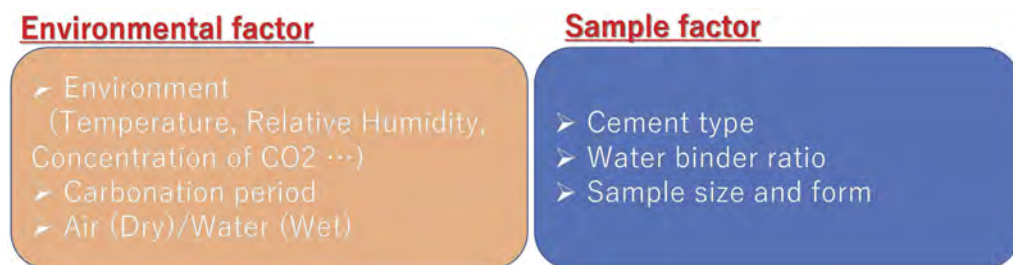

Figure 1. Influencing factor for absorption of Carbon dioxide.

For the determination of carbon dioxide adsorption, (1) the amount of calcium carbonate and calcium hydroxide were determined using TG-DTA, and (2) the amount of carbon dioxide adsorption by weight increase was determined. Because it was considered that the measurement of weight change would be difficult if affected by moisture absorption or moisture transpiration before and after carbonation, the samples were stored in a humidity-controlled environment using a desiccator so that the temperature and humidity were the same as those in the carbonated environment, as shown in Figure 2.

After 7 days of sealing and curing, the prepared specimens were placed in a humidity-controlled environment (20°C, 60% R.H.) for 21 days until there was no change in mass after the specimens were shaped. The specimens were then accelerated carbonated in a carbonation environment (20°C, 60% R.H., 5% carbon dioxide concentration) for 7, 14, 21, and 28 days, and the changes were measured by the methods described in TG-DTA and weight change.

(1) Determination of calcium hydroxide and calcium carbonate by TG-DTA

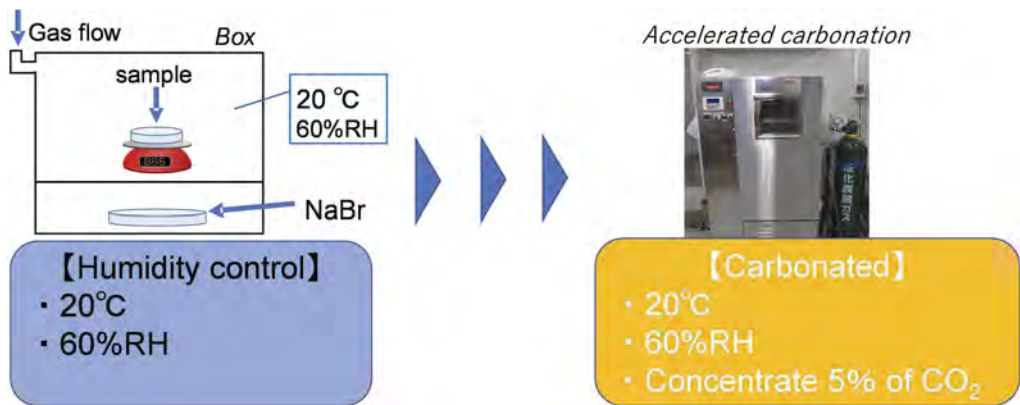

Figure 2. Weight change for determining the CO₂ absorption by easily methods.

The temperature range was 20 to 1000°C, and the rate of temperature increase was 10°C / min. The amount of dehydration of calcium hydroxide (CH) and calcium carbonate (CaCO₃) was estimated from the inflection point of the DTA curve and calculated from the decrease in weight change with endothermic peak. Tests were conducted under a nitrogen gas environment to eliminate the effects of oxidation and carbonation during the measurement.

(2) Determination of absorb carbon dioxide easily by Weight change

To quantify the amount of carbon dioxide adsorbed, the mass change was measured using an electronic balance capable of measuring down to 0.1 mg. After measuring the mass of the specimens after humidity conditioning was completed, mass measurements were taken for each carbonation material age, and the amount of carbon dioxide adsorbed was calculated from their differences.

3 RESULTS OF CARBON DIOXIDE ABSORPTION

3.1 Effects of cement type, carbonation period, and specimen shape

(1) Outline

The specific surface area of the specimen was examined for possible effects of the surface in contact with carbon dioxide and the voids in the hardened sample. As a sample, a fixed amount of cement paste was poured into a 38 x 40 x 2 mm zippered plastic bag, and the bag was sealed and cured for 7 days. After that, as shown in Figure 3, a “hardened” specimen and a “powder” specimen were prepared by grinding the specimen to less than 150 μm using a grinding mill.

Figure 3. Sample size and form.

(2) Results

Figure 4 shows the percentage of CaCO_3 content in the samples calculated by TG. The results are organized by different cement and specimen geometries. In addition, the total CaCO_3 content derived from CH were separated. Based on the amount of CH calculated from the sample prior to carbonation, the difference between the amount of CH remaining during each carbonation period was calculated as the lost CH turned into CaCO_3 . It was also assumed that the total amount of CaCO_3 minus the amount of CH-derived CaCO_3 was produced by the carbonation of CSH and aluminate hydrates.

Figure 4. Amount of CaCO_3 by different cement type and sample forms.

From these results, the first comparison of cement types shows that OPC produces the most CaCO_3 , followed by B50 and B70. This means that the amount of CO_2 absorption decreases as more blast furnace slag fine powder is substituted. In addition, the effect of each carbonation period shows that the amount of CaCO_3 gradually increases, but the increase in adsorption after 14 days is not large. The subsequent examination of the specimen forms shows that for all cement types, the “hardened” specimens have a higher amount of CaCO_3 than the “powder” specimens. Initially, it was assumed that more CO_2 adsorption would occur in the powder with a larger specific surface area, but the results were different. In addition, when the origin of CaCO_3 production was compared, the amount of CH-derived CaCO_3 production was estimated to be lower when “powder” was used. Naturally, it is understandable that the addition of blast furnace slag fine powder to the cement type reduces the amount of CH, and therefore the amount is reduced, but the following study should be conducted to determine the reason for the smaller amount of “powder”.

3.2 Moisture content during carbonation

(1) Outline

The results verified in 3.1 showed that the “powder” with a larger specific surface area produced less CaCO_3 than the “hardened” specimen. Considering that the reaction of carbonation takes place through moisture, we thought that this might be because the powder almost lost its liquid phase, whereas the “hardened” could create a liquid phase even at 60% RH in the microporosity. In other words, we think that it may be extremely difficult for CH to become CaCO_3 if the moisture content of the sample is low. Therefore, we decided to test the “powder” and

humidity-controlled samples by adding water to the samples prior to carbonation. The Figure 5 shows the amount of water added to the samples. A fixed amount of water was added to the powdered sample to create an excess of water before accelerated carbonation was performed.

Figure 5. Moisture contents during carbonation.

(2) Results

Figure 6 shows the amount of CaCO_3 after carbonation for samples with 0, 30, 50, and 70% moisture addition. The amount of CaCO_3 derived from CH and from other sources as same as Figure 4, respectively. Even though the cement types are different, the amount of CaCO_3 is higher for those with more water added. The amount of CaCO_3 derived from CH also increased significantly. On the other hand, the amount of CaCO_3 derived from other sources did not increase that much. In addition, the carbonation periods were 3, 5, and 7 days, and although the amount of CaCO_3 gradually increased, no significant changes were observed. This indicates that the larger the moisture content in the sample, the more carbonation of CH is likely to occur, indicating that the presence of moisture is important. It is also clear that the carbonation of powder does not progress most rapidly at 60% RH.

Figure 6. Amount of CaCO_3 by different of water contents.

3.3 Effect of cement type and water binder ratio

(1) Outline

To consider that the amount of CO_2 adsorption by carbonation depends on CaO , the effects of cement type and water binder ratio were varied. OPC and GGBFS cements were used, with replacement ratios of 30, 50, and 70%. Cement pastes were prepared by changing the water-binder ratio to 0.3, 0.5, and 0.7, respectively. The prepared samples were the same as those used in 3.1 and were ground before conditioning. Water was added to 70% of the sample mass just before carbonation to clarify the CO_2 adsorption potential of the hardened product, since water content has a significant effect as obtained in 3.2. The accelerated carbonation conditions were the same as in 3.1, and the number of days of carbonation was measured at 3 and 7 days. The items measured were TG-DTA and mass measurement.

(2) Results

Figure 7 shows the amount of CaCO_3 produced at each cement and water binder ratio, separated into those from CH and those from other sources. Although there was some variation in the data for each cement, it was observed that the cement with a low water-binder ratio of 0.3 tended to adsorb more CO_2 and produce more CaCO_3 . On the other hand, when looking at CH-derived CaCO_3 , the higher water-binder ratio produces more CaCO_3 . This is thought to be because of water content.

Figure 8 further shows the relationship between the amount of CaO and the amount of CaCO_3 produced. The higher the amount of CaO in the cement paste, the more CaCO_3 is produced, and the more CO_2 is adsorbed.

Figure 7. Amount of CaCO_3 by different water binder ratio.

Figure 8. Relationship between the Amount of CaO and CaCO_3 .

3.4 Relationship between weight change and the amount of CO₂ capture

Figure 9 shows the relationship between the measured weight change and the amount of CO₂ adsorption determined from TG. All results are included for cement type, carbonated periods, specimen shape, and moisture adjustment performed in 3.1,3.2 and 3.3. There is generally a positive correlation between the rate of weight change and the amount of CO₂ adsorption, and that a proportional relationship is also nominated. The higher the replacement ratio of blast furnace slag, the smaller the weight change and CO₂ adsorption, and the larger the weight change and CO₂ adsorption are for OPC alone. The effect of the addition of moisture is greater in the case of the sample with additional moisture. This indicates that the CO₂ adsorption amount of cement paste can be estimated by determining the weight change before and after carbonation, although the accuracy needs to be examined in the future.

Figure 9. Relationship between the weight change and CO₂ absorption ratio.

4 CONCLUSIONS

The results obtained from this study are summarized as follows.

- (1) The CO₂ adsorption potentials of different cement types tended to be highly dependent on the calcium content of the cement.
- (2) In carbonation, carbonation reaction proceeds at 60%RH in hardened cements because water can be retained in the capillary pores, but in powders, carbonation of CH is less likely to proceed because of the lack of water retention.
- (3) It is possible to estimate the amount of CO₂ adsorbed from the weight change of a cement paste sample under humidity-controlled conditions and a sample after carbonation.

In the future, we will investigate the relationship in the water-binder ratio and aim to quantify the amount of CO₂ adsorption by weight change in mortar and concrete blocks containing aggregate.

ACKNOWLEDGMENT

This paper is based on results of “Development of Materials, Manufacturing Methods and Quality Control System on Innovative Carbon Negative Concrete”, JPNP21014, commissioned

by the New Energy and Industrial Technology Development Organization (NEDO). Experiments were conducted by students in Iyoda Laboratory. We would like to express our gratitude.

Value of information for a rational experimental and testing budget applied to a regional old Italian bridges database

I. Vangelisti & C. Beltrami

Lombardi Ingegneria S.r.l., Milan, Italy

ABSTRACT: Experimental investigations and testing have a strategic rule in maintenance of civil structures. They allow to improve knowledge about security level, performance and maintenance of structural system. They require to be applied within a rational approach, in order to operate according to the “optimal scenario”, that is the scenario which let to gather the maximum level of useful information with the minimum money investment. The problem of allocate the optimal number of tests to each structure is here approached with the method of Value of Information, applied to an Italian regional bridge database in an ideal working scenario. It will be shown how VoI could represent a useful support to understand if testing can bring to significant information about structural maintenance, and to estimate which is the optimal number of test repetitions.

1 INTRODUCTION

In this paper an ideal scenario in which the public manager of a road network needs to decide whether to provide maintenance for a sample of bridges is proposed. In order to better orient the decisions, and limit the significative uncertainties which affect the decision, the manager requires to execute many structural tests (carbonation test, steel reinforcement tensile strength test and georadar) four times on the assets. For economic reasons, it is necessary to evaluate what could be the optimal number of each test. “Optimal” means “the minimum number of test repetition which allows to gather the maximum amount of significant information”. This is a common professional scenario, characterized by a limited amount of resources which must be spread on a certain number of operations. This “optimal” number of each test is estimated using the Value of Information, which could be assumed as a rational criterion to solve the problem. In the initial part of the elaboration, a first scenario in which the network manager requires four repetitions of each test for each structural element of each bridge (piers, pier caps, beams, decks and abutments) is presented. Ninety-nine bridges extracted from the Valle d’Aosta regional bridge database will be considered. We want to answer the following question “Is it possible to decrease the number of tests requested by the manager without losing a significant amount of the maintenance information?” In the second part of the paper, the procedure is studied and developed, modelling a complete probabilistic approach, required to face the remarkable uncertainties which characterize the working scenario. Finally, we come up with the optimal number of each typology of test, for each structural element and for each bridge.

2 BRIDGES DATABASE FEATURES

The bridge database is composed of ninety-nine bridges included in the system of State Roads in the Italian region “Valle d’Aosta”. Since very few information were initially available, it was necessary to introduce many hypotheses: i) the construction year of each bridge was assumed the same of the that of the roads (from 1928 to 1956), ii) each bridge is modelled as a simple-supported reinforced concrete beam structure, iii) beam transversal spacing is 2 m, and each carriageway is 10.5 m wide and iv) the amount of each structural element was estimated according to the span number of each bridge, which was originally known.

Figure 1 summarizes length and span number for each bridge.

Figure 1. Bridges length and span number.

3 GENERAL REVIEW OF VOI FOR PERFECT AND IMPERFECT TESTS

The Value of Information is a decision-making method that takes its origin from economical applications (Howard 1966, Miller 1975) and it has been successfully applied to civil engineering scenarios. According to Leander & Karoumi (2018), it is defined as the difference between the amount that would be spent basing test campaign planning on the structural information available in the initial scenario and the one which would be spent after the rationalization, providing only for the optimal number of tests. It allows to estimate the utility of the tests: a VoI equal or minus than zero indicates that no useful information could be obtained from its execution. It also represents the maximum amount that the rational manager should be willing to pay for the test. Finally, it quantifies the economical values of the gathered information. VoI is here applied following the procedure proposed by Pozzi & Der Kiureghian (2011) and used by Zonta et al. (2013).

3.1 *Vol of a perfect test and imperfect test*

According to Pozzi & Der Kiureghian (2011), we assume that a bridge extracted from the database can only be in one of two discrete, mutually exclusive and collectively exhaustive states: Damaged state (D), which means unsafe structural behavior or Undamaged state (U), which means a safe structural behavior. The public manager can't know which is the state of the bridge; he can simply estimate the probability of being in both D and U, $P(D)$ and $P(U)$ according to his technical experience. The possible choices are do nothing (N), with a null cost if the bridge is U but with a social and economic cost C_r if it is D, or develop a rehabilitation plan (R), with C_m cost regardless of the state of the bridge. Assuming a general minimum costs target, the decisional criterion will suggest proceeding with rehabilitation if the estimated cost C_m will be less than the quantity $C_r \cdot P(D)$. According to this criterion, the cost C_0 of the base scenario will be:

$$C_0 = \min(C_m, P(D) \cdot C_r) \quad (1)$$

We now introduce the possibility to perform a perfect test on the bridge, which allows to know which is the bridge state with no uncertainty. This is obviously just an ideal scenario. Thus, the public manager will know if the bridge is U or D and will proceed with rehabilitation only if the test will show damage on the bridge. The cost C_1 of the final scenario is:

$$C_1 = C_m \cdot P(D) \quad (2)$$

According to Leander & Karoumi (2018), Pozzi & Der Kiureghian (2011) & Zonta et al. (2013), the VoI of the perfect test is:

$$VoI_{perfect\ test} = C_0 - C_1 = \min(C_m \cdot P(U), (C_r - C_m) \cdot P(D)) \quad (3)$$

from which the cost C_1 of the test will eventually be subtracted.

An imperfect test is characterized by uncertainty and it can give false positive or false negative results. Let's consider a test able to investigate if the bridge is damaged with an alarm (A)

or undamaged with silence (S). As reported by Pozzi & Der Kiureghian (2011), it is necessary to define the probability of false positive $P(A|U)$ and the probability of false negative $P(S|D)$. Using the Total Probability Theorem, the probabilities of having an alarm $P(A)$ and a silence $P(S)$ can be easily calculated:

$$P(A) = P(A|D) \cdot P(D) + P(A|U) \cdot P(U) \quad P(S) = P(S|D) \cdot P(D) + P(S|U) \cdot P(U) \quad (4)$$

where $P(A|D) = 1 - P(S|D)$ and $P(S|U) = 1 - P(A|U)$.

Moreover, using Bayes' Theorem, probability of damage can be updated:

$$P(D|A) = P(A|D) \cdot P(D) / P(A) \quad P(D|S) = P(S|D) \cdot P(D) / P(S) \quad (5)$$

It is now possible to evaluate the expected costs when the test gives alarm or silence, using the same general minimum costs target explained at 3.2:

$$C_{2,A} = \min(C_m, P(D|A) \cdot C_r) \quad C_{2,S} = \min(C_m, P(D|S) \cdot C_r) \quad (6)$$

Finally, we can calculate the expected cost after a structural test execution and the VoI:

$$C_2 = C_{2,A} \cdot P(A) + C_{2,S} \cdot P(S) \quad VoI = C_0 - C_2 \quad (7)$$

from which the cost C_1 of the performed imperfect test will eventually be subtracted.

In this paper we only focus on the VoI for imperfect test, since it enables to obtain a more realistic simulation. VoI will be calculated for each bridge, for each test performed on each of the considered structural element.

4 MATHEMATICAL PROCEDURE

4.1 Definition of C_r , C_m and C_t

As explained at 3.2, C_r represents the total amount that the manager is forced to pay when a bridge collapses. It includes direct and indirect costs resulting from the collapse (construction of a new bridge, social and economic costs). For the sake of simplicity, it is assumed equal to the current value of the bridge, increased by 10% for a proper evaluation of indirect costs. According to these assumptions, C_r is estimated equal to 1250 €/m². Figure 2 shows the value for each bridge.

Since we want to focus on the test performed on each structural element, it is necessary to define C_r resulting from the collapse of the single structural element. Let's introduce a general criterion for the evaluation of the C_r of the i th structural element:

$$C_{r,i} = K_{tot} \cdot \alpha_i / n_i \quad (8)$$

where K_{tot} is the bridge current value, α_i considers the value of the portion of bridge lost due to the i th element collapse and n_i is related to the number of elements collapsed. Proposed values for α_i and n_i are reported in Table 1. C_m is the rehabilitation cost that the manager may decide to perform according to the decisional criterion (1). It is estimated, similarly to (8), as

$$C_{m,i} = K_{tot} \cdot \alpha_i / n_i \quad (9)$$

where K_{tot} as above, α_i is the rate cost for the rehabilitation of the i th element/cost of bridge total rehabilitation and n_i is the total number of i th elements; values for α_i and n_i are shown in Table 1.

C_t is the cost of the execution of a structural test, derived from average market prices in Italy. It must be defined for each structural test, on each structural element from one to four times.

4.2 Tests and limit states

As shown in 3.2 and 3.3, the evaluation of VoI requires the estimation of the probability of damage $P(D)$ of the bridge under consideration. The probability $P(D)$ is then estimated with reference to specific limit states, which are not to be considered as limit state for design, but simply as limit conditions against which calculate $P(D)$, with a full probabilistic approach.

Figure 2. Current value in millions of € for each bridge.

Table 1. Proposed values for the evaluation of the cost $C_{r,i}$ (top) and $C_{m,i}$ (bottom).

	Piers	Pier caps	Beams	Decks	Abutments
$\alpha_i (C_r)$	1	1	0,5 o 1	0,5 o 1	1
$\alpha_i (C_m)$	0.10	0.05	0.20	0,10	0,10
n_i	$n_{span}/2$	$n_{span}/2$	n_{span}	n_{span}	$n_{span} / n_{abutments}$

4.2.1 Limit state for concrete carbonation test

Carbonation spread in concrete can be described by Fick's first diffusion law:

$$x_c = A \cdot t^n \quad (10)$$

where x_c [mm] is concrete cover degraded by carbonation, A [mm/years^{0.5}] is the carbonation coefficient, t is the elapsed time since the triggered of carbonation and n is equal to 0.5, suggested by technical literature. For our scenario i) A is a normal random variable, with mean and standard deviation assumed according to Recanati (2011). Mean values will be lower for beams and decks because they expose a lower surface to carbon dioxide, ii) t is equal to the bridge age as it is assumed that carbonation trigger goes back to its construction. Since A is a random variable, x_c is a random variable too. The limit state can be defined with reference to the reinforcement corrosion: when carbonation layer reaches the steel bars, their corrosion begins; when corrosion have destroyed more than 66% of the single steel bar in the maximum positive bending moment section, the bridge becomes damaged. Hence, it requires two equations, the first of which is:

$$g_1 = x_{real} - x_c \quad (11)$$

where x_{real} is the cover thickness of the structural element and the probability of failure is $P(g_1 < 0)$.

Is it possible to model x_{real} as discrete random variable since it varies from bridge to bridge. (11) is a necessary but not sufficient condition to go beyond the limit state. Only when $g_1 < 0$, we introduce an analytical model for uniform steel corrosion, according to Val et al., 1998:

$$d(t) = i_{corr} \cdot t_{corr} \quad (12)$$

where $d(t)$ is corrosion depth [μm], i_{corr} is the corrosion annual rate [μm/yr] and t is time of exposure to the chemical agent [yr]. i_{corr} is assumed equal to 70 μm/yr as suggest by Pedferri, (2004) and it is modeled as a random variable with mean 70 μm/yr and standard deviation 5.34 as reported by Leander & Karoumi (2018). Assuming a safety factor equal to 1.5 for bridges design, corrosion damages the bridge if it destroys more than 66% of a steel bar or the 43% of its diameter. We can finally define the second equation of limit state as

$$g_2 = 0.43 \cdot d_0 - d(t) \quad (13)$$

where d_0 is the original diameter of the bar, modeled as a random variable according to a predetermined discrete distribution via a MCS. 10,000 simulations of (11) and 10,000 simulations of (13) when resulted $g_1 < 0$ have been performed. The probability of damage $P(D)$ for the i th bridge and for the j th element with reference to the carbonation limit state is then calculated taking into account the total number of simulations in which $g_1 < 0$ and $g_2 < 0$.

4.2.2 Limit state for steel reinforcement tensile strength test

A limit state can be formulated considering the actual and the measured yield stress of the steel. When the latter is more than 5% less than the former, the limit state is overlapped. 10,000 simulations have been performed according to the following steps: i) two steel grades, FeB44k and FeB32k, were assigned to the bridges with the same frequency ii) each grade was modeled using a normal distribution according to Verderame, et al. (2001) iii) via a MCS 10,000 samples of yield stresses have been extracted, assuming a failure when the difference between the actual and the measured values is more than 5% only by default.

4.2.3 Limit state for georadar test

With reference to i , reinforcement bars spacing, and Φ , reinforcement bars diameter, we assume that the failure occurs when, at the same time, bars spacing is more than 50% of the design spacing and bars diameter is less than 80% of the design one. The probability of failure $P(D)$ is equal to the probability of the union of the two event $P(\Phi \cup i)$, where $P(\Phi)$ is the probability of having a failure on the diameter of the bars and $P(i)$ is the probability of having a failure on the spacing. 10'000 simulations have been performed to estimate $P(D)$ according to the following steps: i) the mean value of Φ is 26 mm for piers, piers cap and abutments and 16 mm for beams and decks ii) the mean value of i is 0 iii) since is unlikely to observe diameter greater than design diameter or spacing lower than the design one, the two random variables have been modelled using skewed normal distribution iv) in each simulations, a value of Φ and i have been sampled and compared to the introduced thresholds v) $P(D)$ has been estimate taking into account the number of simulations in which thresholds have been overlapped.

4.3 False positive and false negative probabilities framework

As said at 3.3, a proper evaluation method of probabilities of false positive and false negative when tests are performed many times (type I and II errors) is required. According to Pozzi & Der Kiureghian (2011), $P(A|U)$ and $P(S|D)$ must be lower than 0.5 in order not to have a pathological test. Two methods are hereby introduced: the first one based on Bernoulli trials and the second one based on a qualitative approach. Type I and II errors are the only "degree of freedom" of the proposed procedure, since the costs shown in the past chapters are forced by economical features.

4.3.1 Bernoulli trials

The multiple execution of the structural tests can be considered as Bernoulli trials because i) the test results in only two possible outcomes (D and U) ii) type I and II probabilities are the same for each repetition iii) observations are independent from each other. Among three test samples, the probability of false positive can be defined as the probability of having two or more A when the bridge is U. There are four possible combinations for this outcome 1) AAA 2) AAS 3) ASA 4) SAA. Hence, $P(A|U)$ for three repetitions of the test, according to iii, can be calculated as $P(1)+\dots+P(4)$. For our purpose, $P(2)$, $P(3)$ and $P(4)$ are totally equal to each other since the false positive is obtained regardless of the order of the single repetitions. Thus

$$P_{fp} = P(1) + \dots + P(4) = P(A|U)^3 + (3|1) \cdot (1 - P(A|U)) \cdot P(A|U)^2 \quad (14)$$

If the number of samples is four, there will be many *pathological* combinations with two A outcomes followed by two S outcomes, that could equally be interpreted as false positive or false negative. Hence, we suppose that for 50% they are classified as false positive and for 50% are classified as false negative. Finally, we can estimate the probabilities of type I and II errors for multiple repetitions assuming the ones for the single repetition (0.20 for carbonation test, 0.15 for tensile strength test and 0.30 for georadar).

4.3.2 Qualitative approach

Type I and II probabilities have also been studied using a qualitative approach, with the aim of investigating the mathematical process stability. Starting from the general principle according to which these probabilities must decrease as the number of repetitions increases, we propose four different functions, linear, hyperbolic, parabolic and exponential rates, calibrated thanks to multiple successive iterations, considering the lack of similar data in technical literature.

5 RESULTS AND DECISIONAL CRITERION

The main results of the proposed procedure are hereby presented. For the sake of simplicity, VoI has been calculated for each bridge, for each test just for one structural element of each type.

Figure 3 shows VoI trend from one to four repetitions of carbonation test executed on a reference pier for each of the functions introduced in 4.3.2.

Figure 3. VoI plot for multiple carbonation test repetitions on a pier, using linear (1), hyperbolic (2), exponential (3) and parabolic (4) type I and II functions.

Since the test is applied on a pier, single span bridges are not included in the graphs. It is evident that i) VoI trend does not depend on the functions used to modelled type I and II occurrence probabilities and it anyway is inversely correlated to them ii) VoI increases as the number of repetitions grows up. In fact, a test becomes accurate and accurate when it is performed many and many times, with an ideal infinite VoI when it is executed infinite times (but with an ideal very high cost). For this reason, VoI can't be taken as decisional criterion, since, in this case, the manager would always plan the execution of the maximum number of tests as possible iii) the curve upon all the others represents a single pier 3-roadways bridge (ID 22), for which, at the same time, the current value is particularly high and the consequences of the collapse of the piers are dramatic (loss of the structure). With the aim of preventing the collapse of the pier and consequently of the entire structure, it is strategic for the manager to investigate and to gather information about the pier, and it is attested by the very high VoI. Similarly, curves located in the upper part of the graphs, correspond to bridges for which rate current value/n of piers is quite elevate.

Figure 4 reports VoI trend for tensile strength test applied on the reference deck obtained with Bernoulli trials formulation. All the features previously pointed out are still valid. VoI trend is inversely correlated to the one of type I and II occurrence probabilities, it swiftly increases from two to three repetitions as the probability of false positive and negative decreases in the same step and it is substantially constant from one to two and from three to four repetitions. Moreover, VoI variation is steeper and steeper as the current value of the bridge is higher and higher because it is generally economically worth to gather information for the bridges whose economic collapse consequences are remarkable.

In order to develop a decisional criterion, it is necessary to involve costs of the tests in the decisional process, for example by assuming the rate VoI/test cost as a decisional criterion. Nevertheless, this would again lead to increasing quantities as the number of repetitions grows up. For this reason, a more reliable criterion would be to link the VoI variation recorded when the number of test increases of one to the cost required to execute this specific number of tests. Thus, a new dimensionless ratio called $\Delta = \Delta \text{VoI} / \text{test cost}$ is defined. Δ generally decreases as the number of tests repetitions increase. This is an expected outcome since, after a number of test executions, the information not detected by the previous tests that could be gathered with another execution, becomes increasingly limited, facing, on the other hand, an increase in test cost.

Figure 5a shows Δ trend for carbonation test performed on a reference pier with a linear variation of false positive and negative probabilities. As expected, Δ decreases as the number of test repetitions increases. With a single execution of carbonation test, it is possible to obtain a maximum benefit of about 200 (again the top curve is related to bridge 22). Performing two tests will instead lead to a significantly more limited benefit.

Figure 5b reports Δ trend for carbonation test performed on a reference beam with an exponential variation of false positive and negative probabilities. The trend is significantly different

Figure 4. VoI for tensile strength test repetitions on a deck, using Bernoulli trials formulation.

from the previous one. Two remarkable tendencies can be underlined in the chart: the former presents its maximum for one repetition of the test, and it is related to “low” current value bridges, for which could not be convenient to allocate huge tests budget because of the limited (just in mathematical meaning) consequences of their collapse (limited VoI); the latter presents its maximum for two repetitions and it corresponds to “high” current value bridges, for which, on the other hand, it could be worth to plan extensive structural test campaigns (high VoI).

Figure 5a. (left) Δ for carbonation test on a pier and linear variation of false positive and negative, (center, 5b). Δ for carbonation test on a beam and an exponential variation of false positive and negative (right 5c) Δ for georadar on pier and Bernoulli for false positive and negative (right, 5c).

Figure 5c shows Δ for georadar performed on a reference beam using Bernoulli trials. Maximum Δ is obtained for one repetition, while Δ is null for two repetitions since the probabilities of false positive and negative according to binomial distribution are the same for one and two executions. It is possible to observe how Δ is higher for those structural elements like piers (ref. Figures 5a vs 5b) whose collapse will cause a greater damage of the bridge.

According to the decisional criterion, the optimal number of tests, associated with the maximum Δ , can now be estimated. Figure 6 reports the optimal number of steel tensile strength test on beams when the functions for false positive and false negative are used (ref 4.2.3). The bars show that the process outcomes are substantially the same regardless of the false positive and negative functions, that confirms the method stability. Again, the maximum number of repetitions occurs for those bridges whose current value is considerable high. The optimal number of tests is null for particularly recent bridges, for which the method expects good structural conditions.

An economic comparison between the starting and the optimal scenario is finally shown. In the starting scenario, the manager required to perform four tests of each category on each structural element of each bridge. According to the costs introduced at 4.1, a total of 1,284 million of € is required. The rational decisional criterion introduced in this paper, with reference to the studied qualitative functions for false positive and negative, requires the amounts reported in Table 2. For the sake of simplicity, the optimal number of tests calculated for a reference element is then taken as optimal number for all the elements of this type of this bridge.

Again, the stability of the method is proved since the expected costs variation about 16%.

The mean money saving between initial and rational scenarios is 554553.3 €, corresponding to the 43% of the total initial cost.

Figure 6. Optimal number of carbonation tests on beams for linear, hyperbolic, parabolic and exponential false positive and negative variation trends.

Table 2. Expected costs for the rational scenario.

False positive/negative function	Linear	Hyperbolic	Parabolic	Exponential
Total cost of the campaign [€]	745360	701802	789247	683198

6 CONCLUSIONS

In this paper a rational criterion based on VoI for the optimization of an experimental and testing campaign on a regional bridge database has been developed with a full probabilistic approach. Carbonation test, steel tensile strength test and georadar are asked to be performed by the manager on each structural element (abutments, piers, piers caps, beams and decks) four times. The aim of the paper was to study if it would be possible to reduce, in a rational way, the number of tests without a significant loss of information. For each test, a limit state has been introduced, according to which probabilities of failure required by the calculation of VoI of an imperfect test proposed by Pozzi & Der Kiureghian (2011), have been estimated. Probabilities of false positive and negative of the imperfect tests have been modelled both via binomial distribution (Bernoulli trials) and via a qualitative approach (linear, hyperbolic, parabolic and exponential functions).

Then, VoI has been computed for each test and for each element. The decisional criterion was based on the ratio “increase of VoI when another test is performed/cost of these tests”. According to the criterion the optimal number of tests has been estimated for each bridge, for each test and for each element. It has been shown as this rational criterion could allow to obtain a mean money saving of 43% of the budget estimated for the execution of four repetitions of each test.

Multi-risk analysis methodology for evaluating climate change impacts at different scales

F.V. De Maio, R. Valsecchi, S. Osmani, C. Solari & P. Basso
RINA Consulting SpA, Genova, Italy

ABSTRACT: The Intergovernmental Panel on Climate Change (IPCC) report on Climate Change 2021 is a “code red for humanity”. It is thus essential to work on a climate resilient society. The purpose of the paper is to present the New Enabling Visions and tools for End-useRs and stakeholders thanks to a common MOdeling fRamework towards a climatE neutral and resilient society (NEVERMORE) project. The NEVERMORE project focuses on the modelling theory to take a significant step forward to overcome the current silo approach in favour of an integrated assessment one for evaluating impacts, risks and interactions of climate change across sectors. The activity will include the analysis and modelling of extreme events in their compound attributes (magnitude, frequency, timing). For each type of extreme events identified in each case study region, the Expected Annual Loss (EAL) is provided as the relation between the probability of damage occurrence and the loss expressed.

1 INTRODUCTION

When assessing the risk posed by a certain hazard the first parameter to be qualified is its frequency of occurrence. The definition is deeply related to the relevant historical data for a given geographic reference. The definition of exposure calls into play the time and spatial correlation as some areas might be more prone to a certain hazard rather than others. Along with the determination of possible threats and relevant frequencies, the vulnerability of the asset shall be determined as well using a structural and logistics assessment. The impact could be evaluated for different assets as well as for different kinds of targets. The NEVERMORE approach integrates information from physical modelling of impacts and risk analysis methodologies and aligns them across different scales via case studies that represent various socio-ecological EU contexts.

2 HAZARD ASSESSMENT

In the proposed methodologies the Hazard is considered through the definition of the relation between the frequency of occurrence and the relative Intensity Measure (IM) of a certain hazard. The Hazards considered by this methodology are strictly related to Natural events.

Table 1. Hazards intensity measures.

Hazard	Earthquake	Wind	Flood	Wildfire	Landslide	Rockfall	Avalanche
IM	acceleration	velocity	water height	fire intensity	flow height	diameter	pressure
Unit	[g]	[m/s]	[m]	[-]	[m]	[m]	[Pa]

For the Hazard data collection, it will be possible to consider the following sources: Literature Databases, National Codes, Websites Databases, and Thematic maps on hazard distribution

produced at the national level. In the following, the hazard assessing procedure is explained. The Hazards considered are approached in different ways: Direct hazards, such as Earthquake and Wind; Indirect hazards, such as Flood, Wildfire, Landslide, Rockfall, and Avalanche. The main difference, as can be seen in the following, is related to the fact that some of them lead to a hazardous event in case of some triggering causes. One important example is the Landslide hazard that can be triggered by two direct events, the earthquake, and the rain. While the earthquake and wind are directly related to a ground shake and windy event.

2.1 State of the art on hazard curve definition

The base for the development of a multi-hazard framework for the risk assessment must be set according to a strong base. In so doing the most solid framework for the risk assessment of natural hazards is of course related to the earthquake risk assessment. Since it is one of the most relevant and most studied natural phenomena that affect negatively the infrastructure, it is also wider implement inside the Nation and International codes.

The intensity measure is usually given for 4 different percentages of exceedance in 50 years, which are commonly 2%, 10%, 50%, and 68%, common in earthquake engineering. The hazard is often expressed in terms of exceedance probability, rather than in terms of exceedance rate (number of events per unit of time). The exceedance probability is the probability that a certain intensity will occur at least once in a given period. The two can be related using a concept called a Poisson process, which is a stochastic process which counts the number of events and the number of times in which they occur. The relationship is explained in the following formula:

$$MAF = -\ln(1 - p)/t \tag{1}$$

Where MAF is the mean annual frequency, P is the percentage of exceedance, and t is the time. So, The Mean Annual Frequency (MAF) can be computed by the given percentage of exceedance, usually with t = 50 years. For each site is possible to define the hazard curve by fitting the 4 points.

Figure 1. Typical hazard curves for direct hazard.

2.2 Implementation on hazard curve definition

Here it can be highlighted, that there are two main obstacles to the definition of a homogenized procedure to assess the hazard. First, besides the case of having the whole vector of 4 exceedance and 4 intensities, it is very common to find less detailed information, such as unique intensity measures or a list of historical data from literature Database. Thus, in the case of having a limited number of IMs with the associated frequency/probability of occurrence. In this case, the few data available can be used to build up the hazard curve. This procedure can be performed through some different procedures able to give back the relationship between the frequency and intensity measure. Secondly, different natural event means different physical phenomena. These differences are mainly related to the physics of the natural elements involved; the relation triggering phenomena vs occurring events; last but not least the possible influence of the human footprint.

Before starting with the description of the hazard homogenization framework, here are described the procedure for the evaluation of the so-called indirect hazard. The Flood Hazard can be

triggered by the rainfall phenomena and the change in a generic stream flow. Starting from this definition, the inputs used in the computation are related to the average flow discharge and its variance in a certain period, that per each stream; their combination results in the definition of 4 percentage of exceedance. After that, the combination of the 4 discharges and the digital terrain model gives back water heights in the nearby asset. From these parameters is possible to draw a flood hazard curve, by an exponential fitting, in accordance to National Research Council (2015).

The Wildfire Hazard is the most complex to assess, mainly due to the different aspects that should be considered in the fire assessment. Besides that, three different aspects must be considered as input for this evaluation, as described by Scott et al. (2013): the relation between the driving wind and how the fire growth; the historical data; the relation between soil moisture and the type of vegetation. The combination of these aspects results in a wildfire hazard curve.

The Landslide/Rockfall (Soil) Hazard can be triggered mainly by different events, excessive rainfall and earthquake. Besides that, the information needed for the assessment of the hazard is of course the 4-point curve of the earthquake hazard and the rainfall event. The acceleration and the rainfall height can be easily implemented in the evaluation of the factor of safety of an inclined slope. So, the combination of them, the digital terrain model (slope evaluation), and the geological model (soil/rock physical characteristics) result in the intensity measure (flow height/block diameter), as described by Klar et al. This procedure is performed with a Monte Carlo iteration, which led to the definition of a set of Occurrence vs. Intensity values used to build the final hazard curve.

Avalanche Hazard is a complex phenomenon since its occurrence is mainly related to both human and terrain morphology, as described by Ciolli & Zatelli (2000). The approach used here is quite like the landslide case since the snow is considered a granular material, such as the soil. Besides that, three different aspects must be considered as input for this evaluation: the Boolean function related to slope triggering condition; the historical data on occurrence; the probability density function (PDF) of the avalanche pressure. The combination of all these aspects gives back the avalanche hazard curve.

This framework can assess the regional scale, by considering information in a raster format, i.e. thematical maps. In this way, all the assets that relay in a certain region can be assessed together. A schematic representation, for wildfire, of this evaluation is shown below.

Figure 2. Schematic representation of the evaluation of an indirect hazard.

2.3 Hazard harmonization

A fundamental step in the definition of this methodology consists of the harmonization of the different procedures of hazard assessment. The harmonization procedure consists of several steps, not always needed for all the hazard categories. The common procedure can be described as the selection of the Input data, MAF evaluation through the Poisson process, and evaluation of the hazard curve by fitting the results.

The input data elaboration is located between the Input Data and MAF evaluation phases. This step must be implemented in two cases. First, the data given must be elaborated to pass from single values to the 4 values needed for the relation with the probability of exceedance. Secondly, the raw input data has a period time of observation different from the selected one. This can be performed by fitting a new probability of exceedance for the different values of the time.

After the MAF evaluation is usually defined the direct hazard. This step should be defined as an intermediate one, for those hazards that are defined as indirect. Since this value represents the assessment of its triggering factor and not the hazard itself.

Therefore, for the indirect hazards, the local morphology must be considered. This step allows computing how the trigger can lead to the hazard occurrence. Must be evaluated the threshold above which the direct hazard triggers the indirect one. These steps are listed in a tabular form per hazard, to give a more understandable idea of the concept of hazard harmonization.

Table 2. Hazard harmonization scheme.

	DIRECT HAZARDS			INDIRECT HAZARDS		
	Earthquake	Wind	Flood	Soil	Avalanche	Wildfire
Input	4 IM[g] vs. P in 50y	IM_{avg} [m/s] vs. P in 15y to 50y	IM_{avg} [m ³ /s] + σ_{IM} in 15y to 50y	4 IM [g][mm/h] vs. P in 50y	-	IM_{avg} [m/s] vs. P in 15y. to 50y

3 VULNERABILITY DEFINITION

Vulnerability is a measure of asset damage/failure due to a hazardous event. As an alternative, it could be also defined as the target's inability to deter and withstand the specific disaster. The assessment can be defined considering three different factors: Geographical location; Hazard response; Target hardness. The vulnerability assessment is made by an exhaustive Database generated through the knowledge from literature, internal resources or by directly inputting the fragility curves parameters, in case of ad hoc developed fragility curves.

The definition of the vulnerability for an Asset is inhere defined according to a set of 4 fragility curves. They are set following the main studies performed in the field of risk assessment, i.e. the Federal Emergency Management Agency (FEMA). The 4 curves are defined following the 4 damage states level defined to represent the most important damage scenarios, following the Hazus Manual subdivision of damage levels. The 4 levels are used in this analysis to reach a desirable level of simplicity, without losing the minimum level of accuracy required.

The first damage state (DS1) is associated with slight damage defined as flexural or shear-type hairline cracks in some beams and columns near joints or within joints. The second one (DS2) is associated with moderate damage, corresponding to the exhibition of hairline cracks on most beams and columns; for ductile frames, some of the elements have reached yield capacity, showing larger flexural cracks and spalling, while for nonductile frames may exhibit larger shear cracks and spalling. The third one (DS3) is associated with extensive damage, corresponding to the reaching of the ultimate capacity of some elements; for ductile frames, large flexural cracks, spalled concrete and buckled reinforcement occur, while for the nonductile elements may experience shear or bond failures at reinforcement splices, or broken ties or buckled reinforcement in columns, leading to a partial collapse. The last one (DS4) is associated to complete damage, which corresponds to the structure collapse or the imminent danger of brittle failure of nonductile elements or loss of frame stability.

For the selection of the appropriate Fragility curve, many parameters are considered, such as the principal construction material, construction typology, year of construction, the type of the code

during the design phase, dimensions (e.g. footprint, ground floors, n° of stories etc.). A specific database can be built with standardized unitary values to overcome the potential lack of information. So, starting from the main characteristics of the asset, the fragility function can be defined.

4 IMPACT

The Impact is defined as the presence of people, livelihoods, species or ecosystems, environmental functions, services, resources, infrastructure, or economic, social, or cultural assets in places and settings that could be adversely affected by a hazard. Therefore, it can be seen as the scale of the consequences of a hazard, Basso et al. The impact is normally quantified in the determination of damages and losses caused to stakeholders, the environment and human life. In this study case, the analysis of the impact is based on the analysis of three different categories, according to Sousa et al.: impacts on People (fatalities/injuries); impacts on the Physical System/Infrastructure (damages on the structures); impacts on Service continuity (interruptions/downtime).

The evaluation of each component is provided in economic terms; in such a way that the combination of them provides a unique impact value following the work done by Basso et al.

4.1 Impact on people

The analysis of the impact on the people (IP_{DSi}) is based on the evaluation of the number of fatalities and injuries due to the occurrence of a certain hazard. The methodology used is based on the definition of three categories: Death, Slightly injured, and Severely injured. The evaluation is provided according to the relation carried out by Cimellaro et al., the percentage of death and injured people is related to the damage state that occurred after the hazardous event.

Table 3. Normalized human losses ratios for different damage states defined by Cimellaro et al.

	U.M.	DS1	DS2	DS3	DS4
Death _{DSi}	%	0.000	0.000	0.0015	12.500
Injury _{DSi}	%	0.000	0.030	0.1005	22.500

The number of deaths can be obtained by multiplying the death loss ratio shown above by the number of people inside the hospital, considering also a reduction coefficient δ_t that considers the effect of the asset preparedness on the people evacuation.

Furthermore, thanks to the Syner-G deliverable a further distinction could be made on the injury. They are divided into slightly and severely injured through the severity injured ratio that is typically set equal to 1/3. The total number of severe injuries can be assessed by multiplying of injury loss ratio shown above with the severity coefficient explained before, also considering a reduction through δ_p is the percentage of people evacuated within the due time. This value is also called Hospital Treatment Demand (HTD), since it must consider that some severe injury needs rapid surgical treatment, due to the threats. To do that the reduction of the treatment capacity must be assessed as the Hospital Treatment Capacity (HTC). This parameter can be assessed by multiplying the number of surgical operations that can be performed in a day with the service reduction, also considering a reduction through δ_{int} is the coefficient that considers the goodness of internal coordination among facilities and departments.

In the end, the economic loss (IP_{DSi}) can be evaluated by considering the direct death due to the event (computed by people inside the hospital), and the indirect death determined as the severely injured people that cannot have access to the surgical treatment (If $HTD > HTC$). Therefore, the number of human life losses can be multiplied by the mean value of human life.

$$IP_{DSi} = [D_{DSi} + (HTD - HTC)_{DSi}] \cdot V_L \quad (2)$$

In which D_{DSi} is the number of direct death, $[(HTD-HTC)]_{DSi}$ represent the number of indirect death, and V_L has expressed the value of life. It must be pointed out that HTD must

be reduced by considering the number of patients that can be relocated during an emergency among different hospitals, also considering a contribution of δ_{E2} which represents the coefficient related to hospital redistribution capacity during an emergency.

4.2 Impact on physical system

The impact on the physical system (ID_{DSi}) can be defined as the impact cost due to the direct damage experienced by the facility. The economic loss can be ease defined as the multiplication between two parameters: the damage value of each damage state according to the definition of Kappos et al.; the reconstruction cost expected to take back the asset to full operation.

4.3 Impact on service continuity

The impact on service continuity (IR_{DSi}) can be related to the effects of the reduction of the service due to damage. The evaluation is based on the information on the average recovery time and service reduction per each damage state, according to the relation carried out by Cimellaro et al.

The additional time that people need to get access to healthcare facilities is the base of the economic loss evaluation. As can be seen in the following formula the recovery is considered a linear function, which considers three main components:

$$IR_{DSi} = (t_{r,DSi} \cdot S_{DSi} \cdot NP) (t \cdot V_t) \delta_{rec} \quad (3)$$

Where: in the first parenthesis is shown the evaluation of the total number of people, by considering the people per day (NP), the percentage of them which are affected by the downtime (S_{DSi}), and the time of service reduction per each DS ($t_{r,DSi}$); in the second one is shown the cost per person, evaluated by taking into account additional time for accessing other healthcare facilities (t) and the value of the time per each person (V_t); at least is considered also the effect of δ_{rec} which represent the efficiency of the recovery. It must be pointed out that NP must be reduced by considering the availability of mobile healthcare posts (δ_{E1}); and of course, the number of patients that can be endorsed in it.

5 RESILIENCE

The term resilience means the ability to prepare for and adapt to changing conditions and withstand and recover rapidly from disruptions, it includes the ability to withstand and recover from occurring threats or incidents. Inside this framework, the resilience evaluation is based on the assessment of the preparation, planning capacity, internal, and external resourcefulness following what was done by Basso et al. In this methodology resilience is defined to affect the impact analysis. So, the resilience coefficients are defined to be considered into the impact analysis.

5.1 Influence on impact on people

As already described in the previous chapters, some resilience indicators influence the evaluation of the impact. In this section, the theory behind their use is described.

The evaluation of the casualties should consider the capacity of the people to evacuate in the best way. Usually, this capacity can be related to the existence or not of emergency plans, its quality, and the training frequency. In the work done by Li et al., the evacuation efficiency is assessed firstly through an exit attraction capacity factor and by a people evacuation behaviour/coordination factor. The parameter varies linearly between $\delta_t = 0.15/1.00$ from best to worst.

Another aspect of preparedness is considered, the community preparedness. This resilience coefficient is very important to fit the real number of people heated by a hazardous event. It is known from the literature that exists a relationship between warning time and people evacuated from a certain area. The two boundaries find in literature, Jonkman 2007, can be associated with one of the community experiences, namely less than 10 years and more than the 100 years.

An important aspect to consider is internal resourcefulness. The coefficient δ_{int} considers the goodness of the internal coordination among facilities and departments. It is related to the

factors that describe the organizational and the human component during emergencies, according to Syner-G. The parameter is $\delta_{int} = 0.57/1.00$, for the case of good/lack of coordination.

At last, it should be considered is external resourcefulness, especially related to the health care system efficiency, at the interhospital level. The coefficient, in this case, can be related to hospital redistribution capacity during an emergency. Therefore, the value of δ_{E2} is defined initially as a Boolean function (0/1) if the answers are all equal, while 0.5 if they are opposite.

5.2 Influence on impact on service continuity

As already described in the previous chapters, some resilience indicators influence the evaluation of the impact. In this section, the theory behind their use is described.

During the aftermath of the event, an important role is played by recovery efficiency. The recovery coefficient is set to consider the change in recovery performance. This variation is related to internal resourcefulness and preparedness, according to Cimellaro et al. The recovery of economic loss is related to the unserved goods/services in a certain period. Therefore, the coefficient is simply evaluated as the reciprocal of the area under the recovery functions. The parameter varies linearly between $\delta_{rec} = 0.19/0.50$ from best to worst.

An important aspect that should be considered is external resourcefulness, especially related to the institution efficiency. The coefficient, in this case, can be related to the accessibility to the eventual mobile healthcare post, which can ensure a certain level of treatment capacity despite the service reduction due to the damage experienced. Therefore, the value of δ_{E1} is defined initially as a Boolean function (0/1) if the answers are all equal, while 0.5 if they are opposite.

6 EXPECTED ANNUAL LOSS

The first step in the evaluation of the Expected Annual Loss (EAL) consists of the combination of the hazard and vulnerability. The results of this combination are representing the probability of damage occurrence of the impact. The Damage probability per each damage state (P_D) can be computed as the convolution integral between the Hazard curve, if available, and the fragility curves of the limit state DS. The last step of this study consists of the definition of the EAL, which is used in this methodology as the quantification of the risk level. This final value considers all the different components of the risk assessment theory, such as the probability of damage occurrence and the total impact. The EAL, can be built using the total impact and the damage.

Figure 3. Damage probability per each DS.

Figure 4. EAL evaluation.

Finally, the area under the EAL curve is computed. Therefore, the EAL is the final measure of the risk per a certain asset, subjected to a generic hazard.

7 CONCLUSIONS

In this methodology, the Expected Annual Loss (EAL) is used as the quantification of the risk level. This final value considers all the different component of the risk assessment theory, such as the probability of damage occurrence (Hazard and Vulnerability) and the total impact (Impact and Resilience). This framework is developed considering a wide range of different hazards within the NEVERMORE project. The way in which they are computed is based on the concept of hazard harmonization. This procedure permits the users to compare and sum the different risk values since the weight of the different hazards is directly calibrated in the harmonization procedure as already shown in the very beginning.

The impact is normally quantified as the consequence of damages and losses caused to stakeholders, the environment and human life. The analysis of the impact is consequently based on the definition of the impacts on People, on the Physical System/Infrastructure, and Service continuity. The consideration of all these different aspects of the impact leads to a real representation of the current value of the critical infrastructure sectors.

The already mentioned criticality level should be defined uniquely. In so doing each level, labelled DS1, DS2, DS3, and DS4, always represent the same damage state, per each asset analyzed. In this way, this methodology can be easily extended to another infrastructure category.

The losses are evaluated as a function of time as can be appreciated in the impact analysis. This is mainly related to the concept of damage and service which can be recovered in a certain time, called recovery time. The way in which the impact is assessed allows considering the resilience as a coefficient able to affect the recovery function. The result is a scalar value calculated as the area under the loss curve, that should be used to compare the risk among the different assets.

Evaluation of the safety factor in masonry buildings as acceleration varies: A quick approach

E. Garavaglia

Department of Civil and Environmental Engineering, Politecnico di Milano, Milan, Italy

ABSTRACT: The topic addressed in this paper is the search for a quick method of evaluating the seismic behaviour of masonry buildings that can be easily extended to portions of historical buildings. The proposed method is the extension to the probabilistic field of the evaluation of safety factors already present in the literature. The method applied to the proposed case study shows how the fragility curves describing the variation of the safety factors with the variation of the expected accelerations could be a useful support tool in the planning of safeguard interventions and how they are able to show, in probabilistic terms, the possible impact of seismic improvement interventions on the expected structural response.

1 INTRODUCTION

The assessment of the seismic behaviour of existing buildings undamaged by the earthquake is an important topic for the classification and subsequent safety of the historic buildings in the entire Italian territory.

The procedure that leads to the large-scale seismic performance assessment of masonry buildings must necessarily be a simple and reliable procedure. It is assumed that it should provide elements in support of a possible assessment starting from data that can be easily found in the municipal archives without necessarily requiring visits and surveys on site (which are, however, not always possible).

Approaches that address the issue of studying the seismic vulnerability and the propensity to damage of the existing buildings have been developed over the last few years by the Italian scientific community, but often the post-earthquake assessment is the starting point (Rosti, Rota & Penna 2009; Zuccaro, Perelli, De Gregorio & Cacace 2021). The models proposed are often very refined models that require an in-depth knowledge of the building and professionals qualified in the use of the calculation processes and important processing times (Saloustros, Pelà, Roca & Portal 2015).

The purpose of this research is to find a procedure to estimate the global seismic performance of existing buildings not yet damaged by an earthquake, which is reliable and easily extendable to the assessment of an entire urban area. The procedure can be useful for public administrations as a tool on which to base maintenance planning.

The approach proposed here is a probabilistic extension, of the method proposed by Borri, De Maria & Casaglia (2014) and Borri, Corradi, Castori & De Maria (2015) relating to three types of simplified verification: simplified gravity verification, simplified global horizontal loading verification and simplified local mechanism verification. The results of the three simplified checks are compared with the safety levels required by the Italian NTC2018 (NTC Italian Building Code 2018) standards for the limit state of safeguarding human life (SLV) referred to the site in question, the building type considered and the intended use class. These results are expressed in terms of conventional safety factors.

To extend this procedure to the field of probabilistic prediction in Angielu, Cardani & Garavaglia (2022) the construction of fragility curves which could describe the variation of the global safety factor, SF_G , was studied, as the expected accelerations vary in a certain seismic zone.

In this paper the method is also extended to the prediction of the variation of the local safety factor, SF_L ; this evaluation requires somewhat more detailed information than that

required by the evaluation of SF_G . The method is applied here on a case study on which the information allowed the evaluation of both factors. The SF_G evaluation was performed for the initial situation of the building; the SF_L evaluation was performed both for the initial situation of the building (pre-seismic improvement) and for the current situation (post-seismic improvement). The two probabilistic assessments were then compared.

2 THE DAMAGE PARAMETER SF

The expeditious assessment of the residual capacities of a building located in a seismic risk area requires the use of a parameter that is sufficiently reliable and quantifiable on the basis of data available from shared databases. A parameter that has these characteristics is the safety factor, SF, proposed by in Borri, De Maria & Casaglia (2014). The safety factor is a parameter capable of describing the performance of the structure when subjected to a certain acceleration. This performance is the measure of the loss in safety of the structure after the event, loss quantified through appropriate parameters.

In Borri, De Maria & Casaglia (2014) two types of safety parameters are distinguished: the global parameter, SF_G , which describes the performance of the entire building and the local parameter, SF_L , which describes the possible collapse mechanism that can locally affect some points of the building.

The global parameter SF_G can be obtained from the geometry of the structure, and from the empirical evaluation of the masonry quality, data easily available from existing databases (Cadastrale, municipal archive, vulnerability cards, etc.) The local parameter, SF_L , requires, instead, a little more detailed knowledge of the structure; in fact, its evaluation requires the estimate of the analysis of the loads and the definition of the framework of the decks (more details in section 4).

The parameters SF_G and SF_L are deterministic and associated with a specific building. In Angjeliu, Cardani & Garavaglia (2022), such approach was the basis of the study for a probabilistic application that also showed the possibility of extending the method to the evaluation of the safety of the different types of masonry buildings as the expected acceleration values varied.

3 FRAGILITY CURVES

The method consists in the construction of curves that allow a probabilistic prediction of the occurrence of a certain phenomenon when a certain condition varies, such as the probability of reaching a certain damage threshold when the level of acceleration recorded varies, as in Garavaglia et al., (2008, 2021), but also in Singhal & Kiremidjian (1996), Flora, Perrone and Cardone (2020) or Sandoli, Lignola & Calderoni (2021). The safety factors SF_G and SF_L proposed in Borri, De Maria & Casaglia (2014) are able to describe this behaviour, so they can be assumed as damage indices to be studied from a probabilistic point of view.

The construction of the curves starts from the modelling, with an appropriate probability density function (p.d.f.) of the values of the selected variable, here generally called SF, present in a certain range of the ground acceleration a^* . Therefore, in the cases studied, the fragility curve defines the probability for a system to reach the loss of a certain value of SF at a defined acceleration \bar{a} . Once the damage threshold \overline{sf} is defined, the probability of this threshold being reached at instant a^* is described by the area to the left, below the p.d.f. (dashed area).

On the opposite, the probability of exceeding this threshold is described by the area below the p.d.f. to the right in the solid area (Figure 1a).

By constructing the probability density function for the chosen random variable for each of the chosen intervals, or acceleration values, it is easy to see how it is possible to construct the fragility curve linked to the experimental evidence or, better called, the experimental fragility curve $F_{\bar{a}}(a^*)$ (Figure 1.b).

The area above the threshold \overline{sf} is calculated using the survival function reported in (1):

$$\mathfrak{S}_{sf}(SF, a^*) = \Pr\{sf > SF\} = 1 - F_{sf}(SF, a^*) \quad (1)$$

Figure 1. Probability of reaching and exceeding threshold \bar{sf} : (a) qualitative p.d.f. for a given value of a^* ; (b) p.d.f. built for different values of a^* .

where $F_{sf}(SF, a^*)$ is the cumulative distribution of sf at each acceleration a^* and describes the probability that the variable sf reaches values greater than a certain value SF , in this case $SF=sf$.

The area below the threshold \bar{sf} is given by the cumulative distribution $F_{sf}(SF, a^*) = \Pr\{sf \leq SF\}$, which describes the probability that sf can assume values not exceeding SF , in this case $SF=\bar{sf}$. The investigated variable SF shown in Figure 1a will be modelled using a Log-Normal distribution, while the experimental fragility curves will be created using the Cumulative distribution function, $F_{sf}(SF, a^*)$ and considering the dashed areas in Figure 1b.

4 THE CASE STUDY

The case study chosen for the application of the proposed method is a rural building which shows the structural typology typical of rural areas in Lombardy.

Cascina Cuccagna (Figure 2 and Figure 3) is located in Milan. The Milan area is classified as a seismic area, more precisely with a medium-low seismicity, but given that the typology is typical of the whole region, the behaviour the farmstead has been studied for a series of accelerations (PGA) foreseen for a medium-high area seismicity. Such areas are still present on the Lombard territory (eg: Salò area and Lake Garda).

As often happens, the construction of historic buildings evolves over the centuries and this induces points of vulnerability in the structures that may become real weaknesses in the event of seismic action. In a project funded by the Cariplo Foundation and conducted by ACCC (Associazione Consorzio Cantiere Cuccagna), Politecnico di Milano and Hydea (PRE.CU.R.S.OR project), the diagnostic and structural analysis of the farmstead showed points of static weakness and structural vulnerability that required both interventions of static reinforcement and of seismic improvement.

Figure 2. Cascina Cuccagna: aerial view.

4.1 The overall behaviour of the building.

As already explained, since the typological characteristics of Cascina Cuccagna are recurrent in Lombardy the evaluation of the factors SF_G and SF_L (Borri, De Maria & Casaglia 2014), is performed here for the acceleration interval (a_g) $0.15g < a_g \leq 0.25g$, typical of the Italian seismic

Figure 3. Cascina Cuccagna: a) first floor; b) ground floor. The shadow areas are involved in seismic and static improvement.

zone 2. The design spectrum was constructed for this area and the characteristic acceleration parameters (PGA) were obtained as well as the spectral amplification factor, F_0 , (Table 1).

Table 1. Seismic parameters Italian seismic zone 2 Garda Lake.

Years	PGA	F_0
30	0.042	2.551
50	0.057	2.483
475	0.158	2.483
975	0.206	2.485
2475	0.283	2.466

On the basis of some parameters, all or in part, easily available from existing databases (the number of floors above ground and their height, the covered surface, the presence in the plant of resistant walls in the x and y direction, their length and thickness, the possible characteristics of the masonry and its specific weight, the presence or absence of cracks and a plausible analysis of the loads) it is possible to measure the loss of the global safety factor as the values of accelerations imposed vary and construct the consequent curves of fragility.

The application of the method proposed in Borri, De Maria & Casaglia (2014) made it possible to quantify the experimental parameter SF_G (assumed here as random variable) as the different accelerations imposed varied in a certain interval. Such values were then normalised to the maximum value ($1-SF_{Gmax}$) obtained and a probabilistic modelling was performed on them. The purpose of this modelling was to obtain a fragility curve which, as the acceleration set varied, could describe the probability of recording a loss value ($1-SF_G$) as a percentage of the maximum expected sever value ($1-SF_{Gmax}$). Figure 4a shows the curve of fragility for the building studied relative to a value of $(1-SF_{Gmax})=58\%$.

The experimental data were then modelled with a Gamma-type probabilistic curve.

Figure 4 shows that the structural typology examined responds quite well to the accelerations expected for the seismic zone 3 ($0.05g < a_g \leq 0.15g$), that is the seismic zone to which it belongs. In fact, the probable loss of performance in the $0.05g-0.15g$ interval (typical of seismic zone 3) is to be considered between 0 and 32% of $(1-SF_{Gmax})$, while for the $0.15g-0.25g$ interval (typical of seismic zone 2) the loss of performance is certainly more consistent and it is between 32% and 94% of $(1-SF_{Gmax})$.

4.2 Fragility curves for different levels of performance loss SFG

Following the approach presented in Section 3, a further investigation to be carried out is the assessment of the loss of performance for different percentage thresholds. In this way it is

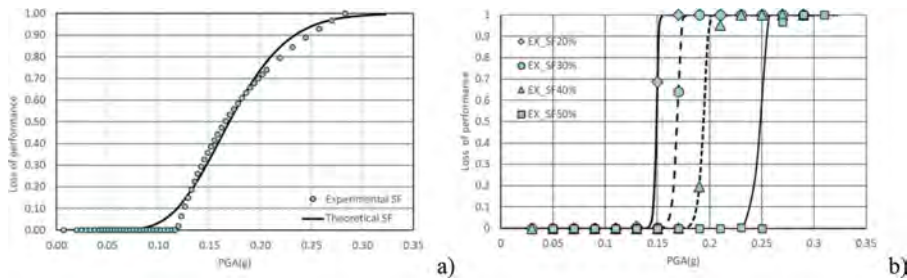

Figure 4. A) Fragility curve of the probability of reaching a value $SF \leq \overline{sf}$ ($\overline{sf} = 58\%$); b) Experimental (dots) and theoretical (lines) fragility curves describing the probability of losing for different levels of SF as acceleration varies.

possible to read the probability of reaching or exceeding a certain level of loss as the acceleration varies. In this case the experimental data are evaluated in absolute value and not normalised to the $SF_{G_{max}}$ value.

The experimental data were modelled with a Weibull-like probability function. The choice of the function is related to the behaviour of the event studied: the probability of reaching the level of maximum loss of performance increases as the acceleration value increases; such a phenomenon requires a probabilistic modelling with distributions having an increasing immediate risk function, Weibull and Gamma distributions respond well to this need. In the specific case it is believed that the Weibull distribution, with a hazard rate tending to infinity for increasing values of a_g , is the most correct distribution to describe the behaviour of the parameter $(1 - SF_G)$ as a_g varies.

For the case study of Cascina Cuccagna in Milan, Figure 4b shows the fragility curves for different loss thresholds.

Figure 4b shows the good overall behaviour of the structural typology of the farmstead. In fact, performance losses exceeding 50% are not detectable and losses of 50% seem to be predictable for accelerations around 0.20g-0.25g.

4.3 A specific vulnerability of Cascina Cuccagna

A building can show local vulnerabilities that can change the level of performance as the acceleration set varies. However, the knowledge of these vulnerabilities requires more in-depth investigations and the data necessary for it cannot be obtained from public documents, as is instead possible for the verification of overall behaviour.

In the proposed case study, during the development of the PRE.CU.R.SOR project, the survey and diagnostics carried out on the building made it possible to have sufficient elements to further investigate the local behaviour of a part of the building (Garavaglia, Anzani, Maroldi & Vanerio, 2020).

The documents collected showed a very marked flexural deformation in an inter-floor slab and the lack of clamping of the slab-perimeter walls (Figure 5). Failure to clamp the slab made the perimeter walls, subjected to the thrust of the roof, vulnerable to overturning. The evaluation of the local safety factor for the deteriorated situation, called “pre-improvement”, will then be proposed on this portion of the building.

The seismic improvement required the replacement of the main beam and the deteriorated elements of the strongly inflected floor, the stiffness of the floor was improved with the introduction of two layers of crossed boards and the masonry-floor clamping was obtained by means of inclined drills (Figure 6). The static improvement was carried out with the introduction of line break devices for the flexural improvement of the floor beams.

After the execution of work, a new evaluation of the local safety factor SF_L was carried out for the situation that we can call “post-improvement”.

Figure 5. Survey of flexural anomaly in a floor beam (a) laser scanner survey (b) section redrawing.

Figure 6. Room 33 seismic improvement actions (a) main beam replacement; (b) cross deck placement; (c) floor-wall connections with inclined drills.

4.4 The local behavior and the parameter SFL

The PRE.CU.R.SOR. project on *Cascina Cuccagna* has made it possible to have a significant and diagnostic documentation useful to formulate some hypotheses on the local behaviour of the walls and floors in the areas with the highest specific vulnerability.

Still applying the method proposed by Borri, De Maria & Casaglia (2014) for local mechanisms and considering the overturning mechanism, the database of local safety factors ($1-SF_L$) was built and the curves of fragility for the local behaviour of masonry portions were evaluated in the area subjected to static and seismic improvement. Local behaviour was assessed both in the original pre-improvement situation and in the post-improvement situation. The results are shown in the follow.

In Figure 7a it can be seen how the static improvement made to the floor of rooms 2 (ground floor) and 31 (first floor) has induced an improvement in local performance. In fact, for an acceleration of 0.15g (upper limit value and inferior respectively for the seismic zones 3 and 2 considered here) the expected loss of performance goes from 0.89 to 0.77 di ($1-SF_{Lmax}=78\%$), which is certainly still high, but the loss of performance analysed is a loss almost on the verge of collapse.

Figure 7b shows the fragility curves of the walls of rooms 5 (ground floor) e 33 (first floor) subjected to seismic improvement of the floor. In this case, the loss of performance recorded for the accelerations analysed is around 67% of the initial performance ($1-SF_{Lmax}=67\%$). The figure shows how the seismic improvement has induced a more evident performance improvement; the expected loss of performance for an acceleration of 0.15g goes from 0.8 to 0.56 ($1-SF_{Lmax}=67\%$), showing how important it is to ensure a good clamping between vertical and horizontal elements.

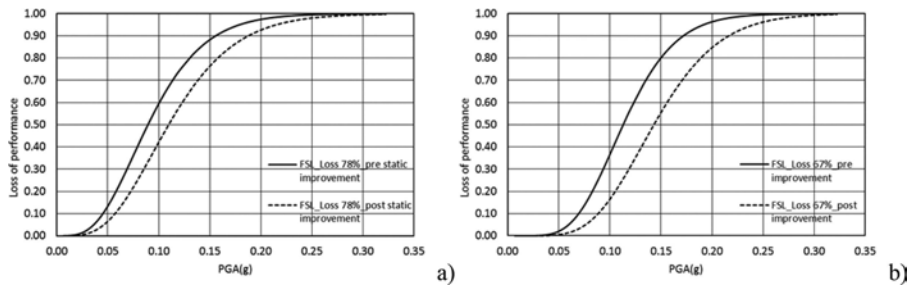

Figure 7. (a) Room 2-ground floor and 31-first floor (Figure 3 shadow area); fragility curve for pre and post static improvement; (b) Room 5-ground floor and 33-first floor (Figure 3 shadow area); fragility curves for pre - e post - seismic improvement.

4.5 Curves of fragility for different levels of performance loss SFL for rooms 5 and 33

Following the approach presented in Section 3, the fragility curves for different levels of performance loss were constructed for the rooms subjected to seismic improvement.

Figure 8 shows the results obtained for the initial situation (pre-seismic improvement) (Figure 8a) and for the current situation (post-seismic improvement) (Figure 8b).

From the two figures compared, it is possible to observe how the probability of exceeding the thresholds is translated on the acceleration axis of quantities varying from 0.019g for the curve relating to the loss of performance of 20% to 0.037g for the curve relating to the loss of performance of 50%.

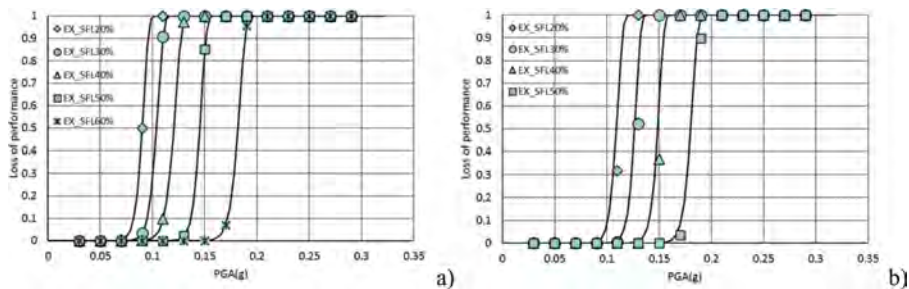

Figure 8. Fragility curves for different SF_L thresholds for rooms 5 and 33: (a) pre-seismic improvement; (b) post-seismic improvement.

Also from this analysis it is highlighted how the seismic improvement introduces an improvement of the local performances for all the investigated thresholds.

Considering that the examined structure is located in seismic zone 3, we can deduce that there have been implementation measures in the structure; the worst forecast seems to foresee a loss of local performance of no more than 40%.

5 CONCLUSIONS

The method proposed in this paper shows how the probabilistic evaluation of the global seismic performance of a historic masonry building can be carried out quickly, also on the basis of data already in the possession of public bodies, and how it can offer a first outline of priority interventions. The picture will certainly not be exhaustive, it would be important to investigate the local seismic performance as well, but these investigations require a more detailed information campaign.

The case study presented allowed us to investigate the variations of both the global and the local safety factor. The results obtained show that the improvement in the behaviour of the building obtained with local seismic improvements is difficult to detect from the analysis on the variation of the global safety factor. However, the general method can already suggest to a public body or the municipality on which buildings it would be useful to plan more detailed diagnostics.

If it were also possible to undertake an investigation on the variation of local seismic factors, this analysis would be able to predict the impact of some structural choices on the future behaviour of the building, in terms of less loss of local safety.

Attack of aggressive carbon dioxide on hardened Portland and blast furnace slag cement paste

F. Wagemann & F. Schmidt-Döhl

Institute of Materials, Physics and Chemistry of Buildings, Hamburg University of Technology, Hamburg, Germany

A. Rahimi

Federal Waterways Engineering and Research Institute, Karlsruhe, Germany

ABSTRACT: Natural groundwater and soil can contain substances which are aggressive to concrete and cement-based structures. Especially aggressive carbon dioxide occurs frequently. Chemical attack by aggressive carbon dioxide occurs in several phases in commercial cements used in foundation engineering. After a period of carbonation a leading front where calcium hydroxide is dissolved, depending on the availability in the binder matrix, is generated. As the attack progresses, the calcium carbonate formed is dissolved, leaving a layer rich in amorphous silicon dioxide, which has lower mechanical strength. This can result in problems in the long-term load-bearing behavior of more sensitive components with smaller dimensions and under tensile stress, in particular ground anchors and micro piles, which are manufactured using cement suspensions in the subsoil. This study evaluates the mechanisms induced by aggressive carbon dioxide in CEM III/A and CEM III/B compared with CEM I paste. Cement paste specimen with water-cement ratios of 0.4 and 0.5 stored in about 90 mg/l (exposure class XA2) aggressive CO_2 for 3, 6 and 12 months are investigated. The methods include X-Ray fluorescence analysis as well as polarized light microscopy on thin sections. The depth of impact is measured and evaluated in terms of durability of geotechnical elements.

1 INTRODUCTION

1.1 Sources and determination of aggressive carbon dioxide

Carbonic acid is a common part of natural groundwater. Carbon dioxide is required for its formation. Sources of carbon dioxide in subsoils and groundwater are decomposition processes of organic materials or current or recent volcanic activity in the geologic past (Terzaghi 1949; White 1957). The carbonic acid reacts to different species depending on the temperature and pH value of the water. Those species are carbonic acid H_2CO_3 , hydrogen carbonate HCO_3^- and carbonate CO_3^{2-} as shown in Equation (1).

The carbonate equilibrium describes the temperature-dependent equilibrium of carbonate dissolved in the water and the amount of carbonic acid. In case of an excess of free carbon dioxide, the water is calcite aggressive. When carbon dioxide is depleted, precipitation of calcium carbonate occurs. Figure 1 visualizes the carbonate equilibrium according to Tillmans & Heublein (1912) for a temperature of 10 °C, which corresponds to the mean value of the groundwater temperature of the isothermal zone in Germany (Hölting & Coldewey 2013). There is no free CO_2 at equilibrium. A hypothetical groundwater sample is depicted with pairs of values that lie above the equilibrium curve. Thus, this groundwater is calcite aggressive

(lime dissolving). However, only a fraction of the free CO_2 is calcite aggressive, which can be calculated by the translation to the equilibrium curve (see Figure 1). The slope of the straight line is $-1/2$ from the stoichiometric relationship that when 1 mole of calcium carbonate is dissolved, 1 mole of carbonic acid and 2 moles of hydrogen carbonate go into solution. The point of intersection with the carbonate equilibrium curve gives the corresponding y-axis intercept and thus the content of calcite aggressive CO_2 . It's worth mentioning that this amount is difficult to determine. It can be specified by the marble test for water stability or calculated from the total concentration of all species of a groundwater sample.

Figure 1. Visualization of the carbonate equilibrium with definition of the terms associated, free and calcite aggressive CO_2 ; calculation of the Tillman equation.

The degree of chemical attack on concrete structures is defined in EN 206-1 (DIN EN 206-1:2001-07) and in Germany additionally in conjunction with DIN 1045-2:2008-08. Table 1 shows the concentrations of aggressive carbon dioxide and the linked classification of aggressiveness XA from the German standards.

Table 1. Limiting values for the assessment of the rate of attack and description of aggressiveness for aggressive carbon dioxide in natural groundwater according to DIN EN 206-1:2001-07.

Exposure class	XA1	XA2	XA3
Action	weakly corrosive	moderately corrosive	strongly corrosive
$CO_{2,aggressive}$ (mg/l)	≥ 15 to ≤ 40	> 40 to ≤ 100	> 100 until saturation

1.2 Mechanism of chemical attack by aggressive carbon dioxide

Aggressive carbon dioxide in groundwater damages cement paste through reactions with calcium-containing hydrate phases. The attack proceeds in several stages. Groundwater containing aggressive carbon dioxide enters the pore volume of cement-based elements and lowers the pH value. As a result, calcium hydroxide is getting unstable and dissolves in the pore space. It reacts with the present carbonate ion CO_3^{2-} under precipitation of calcium carbonate as shown in Equation 2.

Depending on the pH value, temperature and supersaturation calcium carbonate can occur in three polymorphs: calcite, aragonite and vaterite (Stepkowska et al. 2003). This new phase formation is associated with an increase in volume, which reduces the pore space (Pham & Prince 2014). Other hydration products like C-S-H and ettringite in the binder matrix also carbonate under the effect of carbon dioxide (Borges et al. 2010; Grounds et al. 1988). Unreacted

clinker may react with CO_2 to form calcium carbonate (Rochelle & Milodowski 2013). The formation of a carbonation front is associated with an ahead area in which the portlandite content gradually decreases (Samarakoon et al. 2022).

With further ingress of carbonic acid, the calcium carbonate is converted into easily soluble calcium hydrogen carbonate as shown in Equation 3.

The dissolved calcium hydrogen carbonate is transported through the pore space out of the binder matrix. An amorphous silicon dioxide gel with high content of aluminium and iron remains as the end product of the attack (Locher et al. 1984). The amorphous gel layer is rich in water and characterised by low mechanical strength and high porosity (Koelliker 1985).

1.3 State of research on the durability of cement-based geotechnical elements

In the past, numerous laboratory studies have been carried out on the attack of lime-dissolving carbonic acid. The experimental programs differed in the boundary conditions and the sample composition, as concretes were frequently tested. Depth of material loss of after 20 years immersion in a solution with 100 mg CO_2/l was 6 mm for Portland cement and 4 mm for blast furnace slag cement with a water-cement ratio of 0.5 (Locher et al. 1984). The observations of lower material loss and the resulting corrosion depth during previous experiments led to assessment that blast furnace slag cement is beneficial regarding the resistance to aggressive carbon dioxide (Nebel et al. 2022). This is controversial though it is well known that blast furnace slag cements have a lower resistance to carbonation (exposed to the air) due to the reduced amount of portlandite (Borges et al. 2010). Nevertheless, in foundation engineering, blast furnace slag cements are preferred in order to increase the resistance of the construction material to aggressive carbon dioxide (Schäfer et al. 2007).

Portland cement paste (w/c = 0.45) had a corrosion depth, i. e. mechanically instable layer, of 1 mm after 1 year storage in aggressive carbon dioxide with 90 mg/l (Hof et al. 2004). A few laboratory tests investigated the effect of aggressive carbon dioxide on the pull-out resistance of ground anchors (Manns 1997; Hof 2004; Triantafyllidis & Schreiner 2008). After 12 months a reduction of the anchorage force of about 20 % to 75 % was observed for varying concentrations up to 100 mg CO_2/l . Due to these results and the associated uncertainties for the use of ground anchors in the presence of aggressive carbon dioxide in groundwater on construction sites, a research project was initiated at the Federal Waterways Engineering and Research Institute in Germany (BAW) to investigate the aspects action, load-bearing capacity of geotechnical elements and resistance of the building materials.

The subject of this paper are cement paste samples which were stored in water containing aggressive CO_2 connected to a large-scale experiment described in (Herten & Heidenreich 2022).

2 INVESTIGATION METHODS AND EXPERIMENTAL PROGRAMME

2.1 Materials and sample overview

The resistance of cement paste to the aggressive carbon dioxide is investigated in this study for three different cement types: CEM I 42.5 R (CEM I), CEM III/A 52.5 L-SR/HO (CEM III/A) and CEM III/B 42.5 N-LH/SR (CEM III/B). The water-cement ratios of the neat cement suspension were 0.4 and 0.5. The mixing, casting and curing was done according to DIN EN 196-1:2016-11. In order to increase the number of samples, the prisms with the dimensions of $40 \times 40 \times 160 \text{ mm}^3$ were produced and cut in half. The chemical and mineralogical composition of the used cements are given in Tables 2 and 3, respectively.

Porosity characteristics derived from mercury intrusion porosimetry (MIP) tests are shown in Table 4. The tests were performed with a Micromeritics Pore Sizer 9420 mercury porosimeter with corresponding software Auto Pore IV 9500. The pressure range was 0.005 - 400 MPa with corresponding intrudable pore radii between 151.4 μm and 1.9 nm. The sample were cured under tap water for at least 56 days and subsequently oven-dried at 70 °C until mass constancy was achieved. The compressive strength was determined according to DIN EN 196-1:2016-11.

Table 2. Chemical composition of the used cements determined with X-ray fluorescent analysis applying the NIST 1881a standard.

Cement type	Chemical composition								
	Wt.-%	CaO	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	MgO	Na ₂ O	K ₂ O	SO ₃
CEM I	63.7	20.0	5.7	2.5	1.7	0.26	0.8	3.0	2.1
CEM III/A	51.2	26.1	8.5	1.9	4.9	< 0.1	0.8	4.0	2.1
CEM III/B	46.7	29.1	10.0	1.1	6.0	0.3	0.6	3.6	1.5

Table 3. Mineralogical composition of the used cements.

Cement type	Mineralogical composition					
	Wt.-%	C ₃ S	C ₂ S	C ₃ A	C ₄ AF	C ₂ F
CEM I	54.2	17.8	10.1	7.5	0	0
CEM III/A	n.d.	n.d.	n.d.	n.d.	n.d.	55.0
CEM III/B	n.d.	n.d.	n.d.	n.d.	n.d.	69.2

Table 4. Porosity measured by mercury intrusion porosimetry (sample age: 56 days); compressive strength.

Cement type	w/c	Median pore radius	Intrudable porosity	Compressive strength
		µm	Vol.-%	N/mm ²
CEM I	0.4	0.0516	24.7	56.90
CEM I	0.5	0.0448	28.4	48.54
CEM III/A	0.4	0.0248	21.5	50.58
CEM III/A	0.5	0.0210	27.8	40.42
CEM III/B	0.4	0.0140	25.6	55.43
CEM III/B	0.5	0.0143	33.4	45.85

2.2 Exposure conditions

The cement paste samples were stored in tap water until the exposure began. Due to distortions caused by the Corona pandemic, storage was delayed so that the sample age was about 1 year instead of 56 days planned. The cement paste samples were marked with identity tags on cable ties and carefully stored in a stainless-steel tank on grids. The solution had a mean concentration of aggressive carbon dioxide of 89 ± 14 mg/l and a temperature of 14.5 ± 3.2 °C. The tanks were uniformly flown through with the attacking medium by an inlet device at a speed of 5.5 l/h.

2.3 Change in weight

The change in weight $m_{i,t}$ at time t in relation to the initial weight $m_{i,0}$ at the beginning of storage is a simple test method that provides an initial, straightforward assessment of the resistance of the cement paste samples. After 3-, 6- and 12-months storage in free solution, two samples were carefully taken out from each cement paste series. Adhering water was removed by dripping. The prisms were weighed to the accuracy of 0.1 g. The samples were then packed airtight in plastic boxes for further examination. The change in weight Δm was determined by Equation 4 and is given as the mean value of both samples. Reference storage in tap water was used to validate the weight change.

$$\Delta m = \frac{1}{n} \sum_{i=1}^n \frac{m_{i,0} - m_{i,t}}{m_{i,0}} \quad (4)$$

2.4 X-ray fluorescence analysis

X-ray fluorescence analysis (XRF) is used to determine the elemental composition of a material. During the measurement, the material is irradiated with X-rays and electron transitions are triggered in the near-nuclear region. The energised atoms emit an element-specific X-ray fluorescence radiation. The qualitative element composition is determined with the help of the respective wavelength. The intensity of the fluorescence radiation provides information on the quantitative elemental composition. (Schmidt-Döhl 2013)

The investigations were conducted with the XGT 7200 V by Horiba. This is an energy dispersive device for local μ -XRF with a resolution of up to 10 μm . To determine the depth of influence qualitative measurements were conducted. The measurements were carried out on sections of two samples per series at each time of removal from exposure. The variation of the composition of relevant elements over the depth of a sample enables statements about the degradation process. Due to the attack mechanism of aggressive carbon dioxide, mainly the element calcium was used for evaluation. Iron, aluminium and silicon served as plausibility checks. For this purpose, mappings were created over areas of min. $4 \times 4 \text{ mm}^2$. This measuring field size was determined from preliminary tests, as it was optimal in terms of resolution and measuring time and at the same time representative for the entire sample. For statistical validation, 4 measurements were carried out per sample series. The measurements were performed with an energising voltage of 50 kV, an amperage of 1.0 mA and a minimum number of accumulations of 3 with the 10 μm capillary.

2.5 Polarized light microscopy on thin section

Polarized light microscopy permits optical examination of samples down to a resolution in the micrometre scale. Both the microstructure of the specimen and the phase composition can be examined with linearly polarized light or with crossed polarizing filter (crossed polars) (Schmidt-Döhl 2013). A representative section of a sample series was selected for each time point of removal from exposure.

2.6 Definition of the term depth of impact

The term damage or corrosion depth is not generally defined for cementitious building materials under chemical attack. The *fib* Model Code 2010 (International Federation for Structural Concrete 2013) contains a model for describing the degradation of concrete by acids. This attack with decalcification results in a corrosion depth relative to the original surface which is comprised of the removal depth and the depth of the corroded material.

In principle, damage due to chemical attack includes a chemical and subsequent mechanical change in the properties of the material. Depending on the component or structure a relevant depth of impact can be defined. For several geotechnical elements the friction at the surface of the component is essential for the load-bearing capacity and the stability of the system. The attack of aggressive carbon dioxide in groundwaters results in different types of layers over the depth of the cross-section. A distinction is drawn between an amorphous layer, a carbonated layer and a layer in which portlandite is depleted. While the hardness as a benchmark for the mechanical strength of the carbonated layer of a Portland cement paste increases by about 100 % the mechanical strength of the amorphous silica layer is reduced to 39 % of the microhardness of unaltered cement paste (Kutchko et al. 2007). With regard to the durability of cement-based geotechnical elements exposed to aggressive carbon dioxide, in this study the amorphous layer with reduced mechanical strength is defined as depth of damage. However, the thickness of the preceding chemically altered layers are also reported, as they are indicators of the development of the attack and mark the depth of impact.

3 RESULTS

3.1 Change in weight

The change in weight for 3 different exposure duration is given in Figure 2. The results indicate that with increasing exposure duration, the effect of lower porosity becomes negligible

due to the lower w/c ratio. The cement type CEM III/A shows the lowest weight loss as a result of the decalcification by aggressive carbon dioxide. The attack causes a comparable loss of mass in CEM III/B and CEM I hardened cement paste specimens.

Figure 2. Change in weight of cement paste samples in relation to initial weight for different exposure duration in aggressive carbon dioxide.

3.2 Determination of depth of impact by XRF and polarized light microscopy

Figure 3 shows the determination of different layers due to the attack by aggressive carbon dioxide. The amorphous layer is recognisable in the XRF images by only a few Ca-counts. The calcium intensity increases in the carbonated layer. The preceding layer with portlandite depletion is often better visualised by using image processing tools, e.g. by segmentation with ImageJ. The carbonated layer and the decrease in calcium concentration overlap with increasing duration of attack. The thin section microscopy gives further insights of the attack. The amorphous layer was stabilized with epoxy resin before thin section preparation. In cross polarized light the porosity of the amorphous layer is significantly distinguishable by the blue impregnating resin. Relicts of clinker and small amounts of calcite are found in this layer. Unreacted slag grains are also found for the CEM III/A and CEM III/B samples.

The carbonated layer is characterized by pale high-order interference colours in cross-polarized light. Calcite is extremely birefringent. Portlandite is high birefringent in cross-polarized light and stands out against the almost isotropic binder matrix. (Ingham 2013) Portlandite depletion is evident in the increase in isotropic character of the cement paste.

In Figure 4 the measured layer thicknesses of the investigated samples are plotted. The thickness of the individual layers increases with increasing exposure duration. The lower clinker content of CEM III/A and CEM III/B cement types and the small amount of portlandite available for carbonation result in smaller carbonated, low portlandite layers and a larger amorphous layer than in the CEM I samples. Thicknesses measured by XRF and thin section microscopy usually show good correlation. The determination of the carbonated layer is more difficult to assess for the blast furnace slag cements. Figure 4 also shows good agreement between the two test methods with regard to the

Figure 3. Exemplary determination of different layers as a result of the attack of aggressive CO_2 ; left: thin section with crossed polars (scale bar corresponds to 500 μm); right: elemental distribution of Calcium by XRF (scale bar corresponds to 1 mm).

layer thicknesses for CEM I and CEM III/A specimens. Due to a major delay in the preparation of thin sections, the 12-month samples were previously measured only by XRF. The development of the layer thicknesses indicates a trend according to the square root of time law, which has been described by other authors for attack by aggressive carbon dioxide (Grube & Rechenberg 1987).

Figure 4. Thickness of layers under aggressive carbon dioxide exposure. Filled symbols: mean values of XRF method, blank symbols: mean values of thin section microscopy.

4 CONCLUSIONS

Three different cement types were investigated regarding their resistance against aggressive carbon dioxide. Though formulations containing slag are described beneficial in literature the results in this paper cannot confirm this. The results of the weight change during exposure time show hardly any difference between CEM I and CEM III/B specimens. The CEM III/A samples, however, show lower mass losses in comparison. The effect of a lower w/c ratio is less pronounced with increasing duration of exposure. The depth of impact was determined by means of XRF and thin section microscopy. The attack by aggressive carbon dioxide leads to the formation of three different layers in the corroded binder matrix: an amorphous, a carbonated and a portlandite depleted layer. Regarding the decrease in mechanical strength in the amorphous layer, its thickness becomes relevant for durability of geotechnical structures and their load-bearing capacity.

Due to their lower calcium hydroxide content, the buffer capacity of the CEM III/A and CEM III/B samples is limited. This results in the formation of a thicker amorphous and a thinner carbonated layer than with the Portland cement samples. The thickness of all layer types and thus the total depth of the chemically modified binder matrix is deeper for all cement types with higher w/c ratio. The change in weight of the samples correlates with the depth of impact. However, the distribution of the layer thicknesses and especially the formation of the mechanically less stable amorphous layer cannot be deduced from it.

For lower concentrations of aggressive carbon dioxide in groundwater in the range of XA1, Portland cement formulations seem to be favourable at least for a short service life as the investigations carried out lasted a maximum of 1 year. In this service life period CEM III/A cements can also be considered favourable. For statements about durability in the long-term further investigations are advisable. The mechanical characteristic of the amorphous layer is of major importance for the transfer of forces of geotechnical elements. The unhydrated clinker and slag grains can have a beneficial effect.

Big data in construction project management: The Colombian northeast case

S. Zabala-Vargas, M. Jiménez-Barrera & L. Vargas-Sánchez
Corporación Universitaria Minuto de Dios-UNIMINUTO, Bogotá, Colombia

M. Jaimes-Quintanilla
Fundación Universitaria Internacional de la Rioja-UNIR, Bogotá, Colombia

ABSTRACT: In recent years, the information associated with project management in organizations has grown exponentially. Delays, cost overruns, risk management problems in projects are recurrent situations. In this sense, the literature review shows that emerging technologies such as Big-Data and Data-Science have become very important for decision making. The present research is developed in the northeastern region of Colombia - South America. The proposal allowed to evaluate, with qualitative research, the state of incorporation of emerging technologies in companies of the construction sector. This was done through the focus group technique with 20 construction companies selected at convenience. A literature review was also carried out. Among the main results are: Low knowledge and appropriation of the companies of the sector on related technologies, interest in incorporating strategies that allow generating greater value to the productive chain and the intention of initiating R&D&I processes in the field of knowledge.

1 INTRODUCTION

The construction industry is one of the sectors with the greatest impact on Colombia's economy. According to the National Administrative Department of Statistics - DANE, this line of the economy in the year 2022 (third quarter of the year) contributed about 14% of the country's Gross Domestic Product; employing more than 1,700,000 people throughout the national territory (Departamento Administrativo Nacional de Estadística - DANE, 2022). Now, it is indicated in Project Management Institute (2017) that project management has multiple challenges, such as: communication problems, scope affectation, failure to meet objectives, inadequate risk management, among others. The high volume of information, and its mismanagement, especially in highly complex projects, becomes a problem and a loss of value for the project (Saltz, 2015).

These challenges in project information management, especially in the handling of large volumes of data and the strategies to make sense of them, have been addressed with emerging concepts/tools such as: A-) Big-Data, understood as the handling of large volumes of data (capture, management, storage and analysis) in order to generate relevant information and consolidate data interoperability (Chang and Grady, 2019; Gupta and Rani, 2019), B-) Data Analytics (also called Data Science), oriented to decision making from the extraction of information from large volumes of data, determining patterns and trends (Haider, 2015; Kelleher and Tierney, 2018) and C-) Artificial Intelligence (IA), as the strategy based on algorithms that allows machines (from a broad understanding of that definition) to perform processes, make decisions and in general emulate the human brain (Boden, 2017; Rouhiainen, 2018). In Colombia, some strategies have been proposed for the modernization of the construction sector, among them the National BIM Strategy 2020-2026 (Gobierno Nacional de Colombia, 2020); focusing on the use of the

Building Information Modeling (BIM) methodology as a construction management system. It is in this type of bets where the present research has enough importance and commitment, since it seeks to generate an integral model that allows the construction sector to strengthen its competitiveness. There are several references in other countries that are of interest for the research (Huang et al., 2021; Wu and AbouRizk, 2023; Zhang et al., 2017).

However, the concept of Big Data is a relatively recent idea. Cites Gupta and Rani (2019), that the concept of Big Data defines an “avalanche” of data generated from current processes, and that it has become a new scientific paradigm; understood in a broad view in data science. The most important processes associated with Big-Data are: knowledge extraction from data, knowledge discovery, information gathering, data archeology, pattern processing and exploration in data analysis; having applications in a large panorama of industries and economic sectors (Varian, 2014). From a technological point of view, the processing of this information is performed from the use of specialized software, which is considered a new generation of tools and architectures designed to extract, in the most economical and efficient way possible, relevant information from large volumes of data. This is sought to be done in the shortest possible time and with the greatest contribution to the organization (International Data Corporation, 2017).

It is at this point where these technologies connect with project management and administration. A literature review has been proposed with the following characteristics: Bibliographic index: SCOPUS; Search equation: (((“project management” OR “project administration”) AND (“big data” OR “data science”)); Revision period: 2014 – 2022 and Type of documents: Scientific articles, conference communications, literature reviews, books and book chapters.

This review shows a total of 534 records associated with the subject. In 2014 (12), in 2017 (40), in 2021 (121) and in 2023 (73). Further details are presented in the results section. In the following lines some important aspects resulting from this review are presented. Ruchi and Srinath (2018) highlight that Big Data and Machine learning (another important concept), is developed in organizations in multiple factors: product analysis, customer identification, market strategy definition, risk management and project management. In this case, they propose a framework for the analysis and processing of information associated with schedule management, project cost, risk analysis, project resources, among others. The use of these technologies allows optimizing project management by having the information processed and analyzed for decision making. The work presented by Saltz (2015) emphasizes the importance of reviewing methodologies, frameworks and tools to incorporate Big Data to the effective management of teams, as a strategy to enhance the development and monitoring of projects. This research considers that the development of technological tools, operations research and business intelligence are fields where it is possible to define the use of Big Data with an important impact.

On the other hand, Xiao et al. (2020) propose the integration between BIM technology and Big Data to optimize the way of managing business data, resulting in the improvement of the project life cycle and generating an implementation path with higher quality and efficiency. Zhu, et al (2022), presents complementary arguments of the importance of the use of intelligent technologies, such as Big-Data, for the optimization of project management in the construction area. The high levels of fragmentation, their complexity, the high turnover of the actors involved in construction management, the complex and, in many cases, hostile environments; are major challenges that hinder the proper management of projects in the construction area. It is also in this case that the proposal of Wu & AbouRizk (2023), suggests a novel route for the transformation of project management in a reliable and timely manner.

Conceptually, there are two central themes for research: Big-Data and Data Science. The concept of Big-Data has been developing for a little more than a decade. There are several meanings for this idea, according in many cases to the preceding theoretical perspective, to the conceptual and methodological application of the same, and in some cases to the associated technology. This concept refers to the set of data whose size is beyond the capacity of typical software tools for database management; oriented to capture, store, manage and analyze relevant information for decision making. The primary characteristics are high levels of: Volume (size), Velocity, variability, veracity, validity and value of information (Gupta & Rani, 2018). From this perspective, two additional concepts are presented to understand the purpose of this research: Big Data Engineering (BDE) and Big Data Analytics. The first refers to the development of the scalable technological infrastructure necessary for the capture, collection, storage and efficient

preparation of data. This proposal modifies the traditional paradigm that uses relational databases, and proposes flexible, decentralized, and highly dynamic strategies to achieve efficient information management (NIST, 2015). Now, Big Data Analytics, refers to all processes that require the use of large databases to discover and obtain meaningful knowledge for decision making.

Depending on the type of industry, the type of data analysis, the knowledge objective, Big Data Analytics requires specific and diverse skills, generating the concept of Data Science (Haider, 2015). The central objective of Data Science is to foster efficient decision making based on the extraction of information from large volumes of data. Among the elements that make up this activity are principles, context definitions, algorithms and processes to extract the not-so-obvious information from data. It seeks to establish patterns that facilitate decision making. Determining marketing trends, verifying and tracking scope, identifying segmentation and characteristics of a project's stakeholders, establishing strategies to manage risks and classifying communications are key aspects of project management that can be supported by Data Science (Kelleher & Tierney, 2018). It is important to point out that although the design and construction of architectural and civil works are consecutive and separate phases, there is an important relationship between them. Besides being mutually dependent. The constructions suffer constant modifications in the design that are informed in the execution, as well as bidirectional processes until the product is delivered to satisfaction (completion of the project). In the construction analysis phase, designers must consider all the particularities of the construction process, which is usually a type of knowledge that resides with highly experienced architects. Many researchers have proposed to "take advantage" of Big Data and Data Science, to develop knowledge in constructive design and generate rules that facilitate the development of projects (Freischlad, Schnellenbach-held, & Pullmann, 2006).

However, data collected after construction, i.e. while the building or structure is in operation, are little used in design (or redesign). Occupancy evaluation, bioclimatic characteristics, commissioning review, among others, allow to verify subsystems and make adjustment decisions. It is important then to consider comprehensive evaluations of buildings, understood as projects under development, to determine proposals for performance improvement, feedback to designers-architects, document successes and failures; and generally, increase the body of knowledge for future projects (Loyola, 2019). It is in this context and with the problems previously described, this paper presents the first results of a research whose main objective: To establish a methodological route for the incorporation of emerging technologies (Big Data and Data Science) in the management of construction projects and civil works in Colombia; in order to optimize project management and facilitate decision making. Particularly a mixed research route was selected. In this work the qualitative results are presented.

For the methodology, the focus group technique was used, applied to 20 companies of the construction sector of Northeastern Colombia. The main category was the determination of the level of appropriation of new technologies (Big-Data and Data Science) in the sector. The data were processed with the support of the Atlas.ti tool. As a result of the research, two aspects are found: 1- Low level of appropriation of emerging technologies (Big-Data and Data-Science) in the management of construction projects in Northeastern Colombia, 2- Broad interest of the sector (companies to which the focus group was applied) to appropriate new technologies, and 3- Set of guidelines and initial recommendations of the research team from the review of the state of the art of the subject. Finally, the present work has a novel factor in reviewing the incorporation of Big-Data and Data-Science in project management in the construction sector, and its articulation with BIM.

2 METHODOLOGY

The paradigm selected for the research is mixed. For the present document, the qualitative part is related to the qualitative part. A categorical analysis was developed based on the maturity level of appropriation of emerging technologies in companies of the construction sector. The focus group was the tool used (Krueger and Casey, 2014). The design did not include a control group.

2.1 *Participants*

The sample used was made up of 20 companies in the construction sector in the northeastern region of Colombia. Two focus groups were formed, each of 10 companies. There was representation from project management or the technical area. The selected companies are part of the database of the Colombian Chamber of Construction-Camacol.

2.2 *Procedure*

The research had five stages. The first step was the design of the instrument (questions) to be applied in the focus group. The questions were created from the references (Saltz, 2015; Wu and AbouRizk, 2023; Zhang et al., 2017).

The second step was the review of the scientific literature in Scopus. The main contributions specific to the topic of interest were extracted. The article quality assessment proposed by (Petticrew and Roberts, 2006), adapted by articles (Zabala-Vargas et al., 2020), was applied. The third step was the application of the interview protocol in the focus groups. This interview is presented in the Materials and Instruments section. The number of members per focus group did not exceed 12 (10) (Baumgartner et al., 2005). A single session was conducted for each focus group, lasting approximately 45 minutes. Each focus group had a moderator and an assistant. Atlas.ti was used to analyze data. The fourth step was the qualitative analysis of the data, adapting the best possible practices (Baumgartner et al., 2005; Krueger and Casey, 2014; Onwuegbuzie et al., 2011).

A deductive analysis was used. The initial category was the level of maturity in technology appropriation in companies in the construction sector. To ensure the validity of the qualitative analysis and avoid rater bias, a second rater was involved in the process. Inter-rater reliability was evaluated by comparison for the different categories, and a value (Cohen's Kappa coefficient) of 0.81 was found. Differences were resolved through dialogue and adjustments were made to the analysis. The last step was to generate an initial set of recommendations and guidelines for companies in the sector, mainly on tools and strategies that can be used as an initial phase of implementation of emerging technologies.

2.3 *Categories*

Three categories of analysis have been considered in this proposal: 1-) Maturity level of appropriation of emerging technologies (N_M), 2-) Relevance of the use of technology (I_U_TIC) and 3-) Interest in investing in emerging technologies for project management (INV). The three categories focus directly on organizations in the construction sector.

2.4 *Instruments and materials.*

For data collection, the focus group technique was implemented. The focus group was selected due to the possibility of fostering a brainstorming and discussion environment among the representatives of the constructors (Krueger and Casey, 2014). The specific Keyword in context-KWIC technique proposed by (Glaser, 1992) was considered. The source of the analysis was the verbatim transcription of each participant's contribution and each session was videotaped. An analysis of the emerging categories was conducted, also considering the opinion of both those who support the use of technology in project management and those who consider themselves dissenters (focus group members who disagree with the group in general). A set of nine questions was used: 5 for category 1 (N_M), 3 for category 2 (I_U_TIC) and 1 for category 3 (INV). The questions are presented in Table 1, being a semi-structured interview adapted for the focus group.

A second instrument allows tabulation of the main fields associated with the articles obtained from the literature review in Scopus. These fields are: Authors, Title, Year, Affiliations, Abstract, Methodology and Main results.

The quality of the articles was checked using 11 quality criteria extracted from Petticrew and Roberts (2006). Each criterion was evaluated on three scales: 1) 0, not defined, 2) 0.5, presented but not clearly, and 3) 1, presented clearly. To be included in the systematic review, the articles had to have a score of at least 6.5 for all 11 criteria, at least half of the maximum number of points possible.

Table 1. Focus group questions by category.

ID	Category	Question
N_M_1	Maturity level of appropriation of emerging technologies (N_M)	Does the organization have installed technological capabilities (hardware and software) for project management?
N_M_2		Is there clarity in the processes to develop projects with technological incorporation in the organization?
N_M_3		Does the organization have information systems for project management? If yes, which ones?
N_M_4		Does the organization identify the concepts of Big-Data and Data Science?
N_M_5		Does the organization incorporate Big-Data and Data Science concepts in project management?
I_U_TIC_1	Relevance of the use of technology (I_U_TIC)	Does the organization consider the use of technology important in the development of its processes?
I_U_TIC_2		Do the contractors of your organization use technological tools for the management of different projects and services?
I_U_TIC_3		Does technological development play an important role within the organization?
INV_1	Interest in investing in emerging technologies for project management (INV)	Is the organization interested in investing in technologies that facilitate the management of information for decision-making in project management?
INV_2		Within the annual budget planning, is there a specific item for the company's technological development?
INV_3		Is the organization interested in participating in Research-Development-Innovation processes?

3 RESULTS AND ANALYSIS

3.1 *Bibliometric analysis*

This section presents the main aspects of the bibliometric analysis performed. Figure 1 shows the number of documents per year. There is a total of 534 publications in the period 2014-2022. There is evidence of a significant increase in the last 4 years. The maximum production peak was in the year 2021. In relation to the authors with the highest level of publication, it is J. S. Saltz, from Syracuse University, who has the highest number of records in the area of knowledge. The top 6 authors, with the number of papers produced in the review window, are: Saltz, J.S (17), Shamshurin, I (8), Miller, G.J (6), Tamura, Y. (6), Yamada, S (5) and Earley, S. (4).

In the dynamics of publication by country, the Top 5 are: China (181), United States (77), Germany (30), United Kingdom (26) and Australia (20). In terms of papers by affiliation, there are: Syracuse University (18), Beijing Jiaotong University (7), Tottori University (6), Wuhan University of Technology (6), Tsinghua University (6) and Managing Consultant Maxmetrics (5).

3.2 *Categorical analysis*

For the categorical analysis, the initial categories with which the focus group instrument was created are taken as a reference. These categories are: Maturity level of appropriation of emerging technologies (N_M), Relevance of the use of technology (I_U_TIC) and Interest in investing in emerging technologies for project management (INV). The two focus groups and the subsequent analysis of the information in Atlas.ti generated the map of categories shown in Figure 2.

Figure 1. Documents vs Year (Scopus 2023).

The category with the highest density is the Maturity level of appropriation of emerging technologies (N_M). One of the first emerging categories is Infrastructure, which is made up of both software components (information systems and licenses for other applications) and hardware devices. In this last category, the importance for organizations to have servers, clustered computing equipment and devices to ensure information security is detected. Another of the initial categories (Relevance of the use of I_U_ICT technology) also appears in the focus group analysis, focusing on the existence of established processes for the incorporation of technology (which are not always found in organizations in an explicit and standardized way) and the low level of appropriation, associated with low knowledge, of the technologies that are the focus of this research (Big-Data and Data Science). It should be noted that in this case the organizations state that they are aware of the topic, but do not have a detailed level of knowledge or appropriation, at least identified, in the organization. The other key aspect is associated with the interest in investing in emerging technologies for project management (INV), of which there are two important aspects. The first is that the organizations, in general, declare broad interest in investing in technology; even considering the recognition of these in all their management. In turn, it is stated that there is annual budget planning for these investments. The other emerging category is the low or medium interest in Research, Development and Innovation processes, which is mainly associated to not clearly knowing the benefits that projects in this line can generate. In this last aspect, some organizations state that they are aware of the existence of tax benefits if they invest in research, development and innovation projects.

3.3 Summary of guidelines and recommendations

This paper briefly presents some recommendations or guidelines that can be adopted by companies in the construction sector, integrated to the development of the BIM strategy in Colombia (Gobierno Nacional de Colombia, 2020); with projection to the year 2026. In the first instance, it is key to recognize that in the world, as cited by Saltz (2015), a single methodology for the incorporation of Big-Data and Data-Science in project management is still under discussion. Therefore, it is very important to generate specific versions for each country that adapt these technologies to the context and market dynamics of the work performed. To carry out this methodology requires a pro-fund identification of the dynamics of the sector and a more effective relationship between academia, the IT industry and the construction sector itself.

Another important strategy arises from the identification of agile project management methodologies, which articulated with Big-Data and Data-Science, allow effective solutions. In this sense, it is important to define a Big-Data orientation for project or product life cycle management. As proposed by Zhang et al. (2017), a strategy mediated by: 1-) Registration and data collection; from the incorporation of sensors, embedded devices, among others; 2-) Storage and processing of information; from the integration of distributed computing using Big-Data and databases (structured, semi-structured and unstructured), 3-) Development of

data mining models; for clustering, association, classification and prediction processes; and finally 4-) the integration of Big-Data and Data-Science throughout the project life cycle. From the hardware point of view, integrate server technology (own or in the cloud), as well as IT security solutions to protect the data and finally the organizational knowledge.

The integration of specific software for the integration of BIM methodology with the management of large volumes of data is also fundamental in the incorporation process. Another important recommendation for the construction sector is the planning, execution and follow-up of training and recognition processes for the project team in the basic concepts of Big-Data and Data Science, as well as in the specific training of the technological infrastructure (hardware, software and data networks) required for the incorporation of these emerging technologies. Finally, a strategy to determine the lessons learned from the technological incorporation, which allows iterative optimization of the projects that are being developed; optimizing both the design phase and the construction phase.

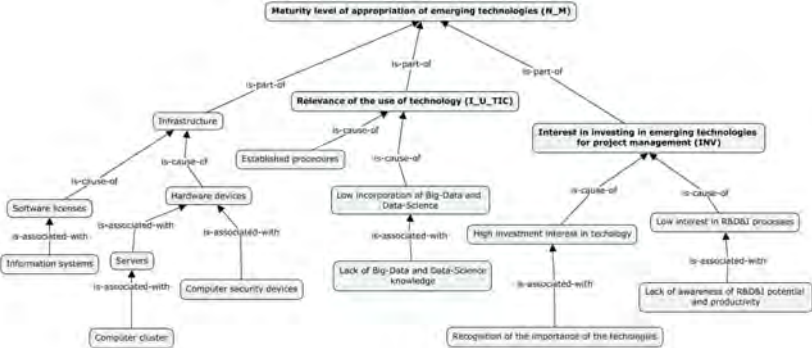

Figure 2. Map of categories resulting from the focus group.

4 DISCUSSION AND CONCLUSIONS

The development of this research shows that the construction sector in Northeastern Colombia still has a long way to go in the incorporation of emerging technologies, such as Big-Data and Data-Science. One of the important aspects is to determine its own methodologies, adapted from state-of-the-art knowledge, for the incorporation of strategies that optimize the project life cycle. These methodologies, as cited by Saltz (2015), are constantly developing and evolving. Having a specific framework for the incorporation of emerging technologies (Big-Data, Data-Science, among others) is also fundamental. These frameworks articulate so many methodological processes, incorporation of tools and technological infrastructure, development of models for data cleaning and analysis, and the application of related technologies in the project life cycle. This, in a very consistent way, with what was proposed by (Zhang et al., 2017).

On the other hand, determining new strategies for construction project management (CPM), also point to issues of project regulation and supervision. In agreement with Huang et al. (2021), many researches have focused on the construction phase, resorting to digital tools or methods; but other phases of the project life cycle do not present the same incorporation and development. In this sense, it is important not only for the case study of this paper, but in general for the construction sector; to continue strengthening the incorporation of frameworks, methodologies and models; based on Big-Data and Data-Science in the construction sector. Finally, as Wu and AbouRizk (2023) indicate, there are many fragmentation phenomena along the value chain of construction projects, high complexity and uncertainty, transience of the parties involved and hostile environments. All this generates that the data obtained in construction projects remain noisy, fragmented and very heterogeneous; generating barriers for its use. It is for this reason that it is worthwhile to continue researching on the subject and generating strategies for decision-making in projects, based on reliable real-time data.

ABSTRACT: This paper assesses the effects of expansion mechanisms in prestressed concrete sleepers. A consequence of these mechanisms in concrete is the decrease in some mechanical properties such as compressive strength, tensile strength and Young's modulus. Using the software ATENA 3D, based on the Finite Element Method, four geometrically identical sleepers were simulated with different expansion level rates. The values of the reduction of the mechanical properties were obtained through experimental tests results. From the results of the numerical analysis it was possible to correlate the maximum displacement, the states of stress-strain and the crack pattern with the loss of mechanical properties. It was observed that the shoulder region of prestressed sleepers tends to be more susceptible to the appearance of cracks, a phenomenon caused mainly as a consequence of the sleepers manufacturing process by prestressing, causing loss of bond in the regions close to the edge of the sleepers.

1 INTRODUCTION

Expansive Reactions in concrete are due to chemical processes and causes cracks and deterioration of the material during its service life cycle. According to Hasparyk & Kuperman (2021) these reactions depend on the type of causative agent, the materials involved, the dimension of the structural element and the environment exposition. These expansive mechanisms may be caused by the Alkali-Aggregate Reaction (AAR), the Sulfate Attack or both combined.

A specific case of Sulfate Attack is the Delayed Ettringite Formation (DEF). This mechanism occurs due to the high heat of hydration as a result of exothermic reactions of cement, leading to high temperatures on concrete at early ages; or thermal curing of the concrete at high temperatures. (Hasparyk & Kuperman, 2021)

Several authors have published researches correlating expansive reactions to the loss of mechanical properties of concrete. Among these authors, Nixon & Bollinghaus (1985), Hoobs (1988), Larive (1997), Marzouk & Langdon (2003), Smaoui et al. (2004), Sanchez et al. (2017) and Gorga (2018), showed that the expansive mechanisms, in fact, directly affects the compressive strength, the tensile strength and the Young's modulus of concrete.

Prestressed concrete sleepers are generally manufactured using the techniques of prestressing reinforcement and thermal curing of concrete. These techniques are essential for increasing the speed of production of these structural elements. One of the objectives of using thermal curing

in the manufacture of precast concrete elements is to increase the rate of Portland cement hydration reactions and, consequently, obtain a gain in compressive strength at early ages. The gain of compressive strength at the early ages allows the application of stress in the reinforcement, which are anchored by adhesion between steel and concrete.

Figure 1 presents the behavior of the prestressed reinforcement anchored by adherence, where l_{bp} is the anchorage length, $\varnothing 0$ is the diameter of the reinforcement without prestressing loads, $\varnothing 1$ is the diameter of the reinforcement with prestressing load and σ_{P0} is the value of the initial prestressed stress. It is possible to observe a length at the end face in which the prestressing level is not complete, decreasing the stiffness of the element in this region, leading to the appearance of cracks.

Figure 1. Adherence between steel and concrete in prestressed elements. Adapted from Pfeil (1984).

Figure 2 presents the distribution of mapped cracks on the shoulder of a prestressed concrete sleeper. The appearance of these mapped cracks may be explained by two phenomena occurring simultaneously: the occurrence of expansive mechanisms of concrete and the loss of the adherence between steel and concrete in these region, as discussed before.

Figure 2. Crack pattern in the shoulder of a prestressed concrete sleeper.

2 METHODOLOGY

Four prestressed concrete sleepers were numerically simulated, through non-linear analysis, in the software ATENA 3D, 5.9.1 version, based on the Finite Element Method. The concrete sleepers were geometrically identical, but with mechanical properties of concrete that vary with the level of expansion by 0.00%, 0.05%, 0.12% and 0.30%.

2.1 Numerical simulations

The constitutive model *CC3DNonLinearCementitious2* was implemented to simulate the concrete. According to Cervenka & Papanikolaou (2008), this material model is based in a Fracture-Plastic Constitutive Model, which allows the simulation of the behavior of the concrete associated to plastification when submitted to compressive stresses and fracture when submitted to tensile stresses. For the reinforcement steel material (wires), the discrete model *ReinforcementEC2* was implemented, presenting a Uniaxial Stress State based on the Hooke's Law and a Plastic Model based on the Von Mises Criteria. The sleeper's supports and the load application region were simulated with a set of steel plates and natural rubber. For the steel plates material it was implemented an Isotropic Model, *CC3DBiLinearSteelVonMises*, being the stress-strain relation bilinear with a yielding patamar and Von Mises Criteria. The natural rubber material was simulated through the *CC3DElastIsotropic Model*, being the stress-strain relation linear for compressive and tensile. More details about the constitutive models of materials are described in Cervenka et al. (2021).

The numerical models were submitted to the Negative Bending Moment test in the center of the sleeper based on AREMA (2020), being this test one of the prescriptions for the approval of sleepers. The test consists of applying a load in the center of the overturned sleeper with the intention to simulate the behavior of the sleeper in service, which has a centralized negative bending moment due to the elastic support of the sleeper (ballast). However, as the objective of this paper is to assess the crack pattern in the shoulder region, the analyzed models were loaded only up to the load of the opening of the first centralized crack with a width of 0.10 mm in order to prevent that these cracks which form the failure plane of the sleeper has any influence on the formation of cracks in the shoulders.

Totally, 102 load steps were applied to the models. The two first steps are related to the applying of prestress in the wires, consisting of the imposition of an initial strain in each wire, representing an initial prestressing force of 15.00 kN. The other 100 load steps are related to the application of the load to open the first crack, being applied to the upper steel plate of the models. Each load step represents 2.50 kN or totally 5.73 MPa applied in the steel plate area.

The boundary conditions (constraints) were imposed in three distinct points, restraining the translation of the model: on the bottom faces of the support plates (axis x, y and z) and on the top of the loading plate (axis x). Finally, a structured mesh of finite elements with average dimensions of 50.00 mm was applied.

Figure 3 presents the sleepers geometry, the dispose of the thirteen steel wires in the transversal section and the numerical model. The bottom of the sleepers has 291.00 mm. The top of the sleepers has 206.00 mm and 190.00 mm, in the center section and in the rail seat section, respectively.

Figure 3. Sleepers' geometry, wires dispose in the transverse section and numerical model, measurements in meters.

2.2 Mechanical properties of the materials

The proposed nomenclature for the four sleeper models is formed by the suffix PCS (Prestressed Concrete Sleeper) followed by 0.00, 0.05, 0.12 and 0.30, which represents the expansion level of each sleeper, being respectively, PCS0.00, PCS0.05, PCS0.12 e PCS0.30.

PCS0.00 model is the base for the other three models. This model was simulated with a compressive strength of 42.00 MPa and with the other mechanical properties calculated by the CEB-FIP Model Code 2010. The compressive strength, the tensile strength and the Young's modulus of the PCS0.05, PCS0.12 and PCS0.30 models were reduced according to the study by Sanchez et al. (2017) and will be presented below.

The thirteen prestressed wires has 6.00 mm diameter and are of the low relaxation steel bar type, notched, with a strength class of 1560/1750 MPa and a Young's modulus of 205 GPa, according to ASTM A421 (2021) and ASTM A881 (2017).

The supports are constituted of a set of SHORE A 50 hardness natural rubber strips with dimensions 50.80 x 25.40 x 190.00 mm in the supports and 25.40 x 12.70 x 291.00 mm in the load application point (length x thickness x width). The supports are complemented by steel plates with a yield strength of 550 MPa and Young's modulus of 205 MPa, with dimensions 150.00 x 12.70 x 291.00 mm (length x thickness x width).

Sanchez et al. (2017) performed a multi-level analysis on concrete specimens (100 mm x 200 mm) of compressive strengths of 25, 35 and 45 MPa with different types of reactive and non-reactive aggregates and twenty different types of concrete trace. Microscopic tests (SDT and DRI) and destructive mechanical tests (compressive strength, the tensile strength and the Young's modulus) were carried out in order to relate the changes in the mechanical properties of the material with the level of expansion.

Among the many traces tested by the authors, Tx + Hp 45 was chosen to implement to the numerical models. This trace is composed by High-purity fine-grained limestone from Newfoundland in Canada and Polymictic sand (granitic, mixed volcanic, quartzite, chert, quartz) from El Paso in the United States. Table 1 presents the mechanical properties loss in each expansion level studied in this research.

Table 1. Mechanical properties loss for different expansion levels according to Sanchez et al. (2017).

Exp. Level (%)	Days	Compressive Strength (%)	Tensile Strength (MPa)	Tensile Strength (%)	Young's modulus (MPa)	Young's modulus (%)	Fracture Energy* (MN/m)
0.00	28	00.0	42.00	00.0	2.54	00.0	34688.7
0.05	19	11.5	37.16	57.9	1.07	30.1	24230.8
0.12	33	12.2	36.86	60.3	1.01	28.4	24822.6
0.30	99	21.9	32.81	59.5	1.03	50.6	17118.5

3 RESULTS

The results related to the Load *versus* Displacement curves, tensile strength, opening of the first cracks and the stresses in the directions of the x and z axis will be presented. All these results will be presented for the first crack opening load at 0.10 mm.

3.1 Load versus Displacement curves, tensile strength and opening of the first cracks

Table 2 presents the values of the first crack opening load (0.10 mm) and the vertical displacements in the center section of the models (Figure 3).

According to the Table 2 the PCS0.05, PCS0.12 and PCS0.30 models reached the first crack of 0.10 mm with load at 4.07%, 3.78% and 5.73% lower when compared to the model PCS0.00. Regarding to the displacements, the models with expansion showed increases of 20.25% (PCS0.05 and PCS0.12) and 38.05% (PCS0.30) in relation to the model without expansion.

Table 2. First crack opening load and vertical displacement for the four models.

	PCS0.00	PCS0.05	PCS0.12	PCS0.30
Load (kN)	88.00	84.42	84.67	82.96
Displacement (mm)	1.63	1.96	1.96	2.25

Figure 4 presents the Load *versus* Displacement curves of the numerical models PCS0.00, PCS0.05, PCS0.12 and PCS0.30 and the graphs of Figure 5 show the relations between loss of mechanical properties *versus* load and displacement.

Analyzing the Load *versus* Displacement curves, the difference in stiffness in the models can be noted; an expected result since the models PCS0.05, PCS0.12 and PCS0.30 presents a decrease in the Young's modulus as a consequence of the expansive mechanisms.

Figure 4. Load *versus* Displacement curves of the four numerical models.

Figure 5. Mechanical properties *versus* load decrease and displacement increase.

Through the graphs shown in Figure 5, a greater influence of the Young's modulus on the behavior of models with expansion can be noted in relation to the model without expansion. This is observed by the greater variation in displacements than in crack opening load which would be affected by the tensile strength. This phenomenon can be explained by the fact that the sleeper is prestressed, delaying the opening of the cracks, even for lower tensile strengths.

Figure 6 presents the lateral and top faces of the center of the four numerically simulated sleepers in the load step of the opening of the first crack. The tension range presented on the side of each sleeper show the maximum value as the tensile strength of each model.

Figure 6. Distribution of tensile strength and cracks. (a) PCS0.00, (b) PCS0.05, (c) PCS0.12 e PCS0.30.

This behavior was already expected, since sleepers in prestressed concrete present the same behavior as prestressed beams, in which the first cracks appear centralized in the maximum moment section, whether in sections of positive or negative bending moments. Analyzing Figure 6, it is possible to note the decrease of the tensile strength in centralized regions of the sleeper, caused by the degradation of the material due to bending, leading to the opening of cracks. An important observation in the models presented in Figure 6 is the non-reduction of tensile strength in the decentralized sections, including shoulder region. This indicates that for the first crack opening load step there is no evidence of cracking in these regions.

Finally, Figure 7 presents the crack pattern of the four models, with crack range varying from zero to 0.10 mm. It is important to highlight that in the regions of the shoulders there was no cracks (already verified by the tensile strength in Figure 6), with the cracks concentrating in the central section of the sleepers. It is noteworthy that the first cracks appeared in the centralized region of the sleepers for the four sleepers, phenomenon also observed by Bastos (1999) and Neiva et al. (2020).

Figure 7. Crack pattern in models (a) PCS0.00, (b) PCS0.05, (c) PCS0.12 e PCS0.30.

3.2 Stresses in the directions of the x and z axis

Aiming to assess the possibility of the appearance of crack in the shoulders of the sleepers (Figure 2), the stresses in the directions of these cracks (axis x and z) were analyzed. Figure 8 present the stresses in x and z at the opening of the first crack with 0.10 mm, limited by the

tensile strength of each of the four models. Stresses in the x and z directions lead to cracks in the orthogonal directions to the axis, that is, y and x, respectively.

Figure 8. Stresses in the x and z directions of models (a) PCS0.00, (b) PCS0.05, (c) PCS0.12 e PCS0.30.

Observing Figure 8, it can be noticed that for the models with expansion mechanisms (PCS0.05, PCS0.12 e PCS0.30), the ends of the sleepers are on the eminence of crack opening on the front, side and upper faces (region in red, x axis), since the tensile strength was reached. It can be highlighted, as an important observation, that these regions may have been weakened by the degradation of the concrete resulting from the manufacturing process by prestressing and also by the loss of adhesion at the ends, applying an initial stress to the concrete in the first stages of the simulation.

In the case of stresses in the z axis direction, there are few observations regarding these results, since the predominant stresses are still compressive as a result of the prestressing applied to the models. As there are no loads applied in this direction, the stresses in the z axis direction are due to the state of stress to which the concrete is subjected and even for the models with lower tensile strengths, there are few possibilities of opening cracks in this direction.

4 CONCLUSIONS

In general, the numerically simulated sleepers showed expected results for the type of analysis performed, that is, they did not show major changes in structural behavior for changes made in mechanical properties.

The Load *versus* Displacement curves showed similar behavior, being influenced by the decrease in the Young's modulus of each model. As a consequence, the models with expansive mechanisms (PCS0.05, PCS0.12 e PCS0.30) presented lower stiffness when compared to the intact model (PCS0.00), greater vertical displacements and lower loads of first crack opening.

An important observation is the greater influence of the modulus of elasticity in relation to the mechanical properties of compressive and tensile strength. This fact is evidenced by the greater discrepancy between the displacements when comparing the crack opening loads, being 20.25%, 20.25%, 38.05% and 4.07%, 3.78% and 5.73% for models PCS0.05, PCS0.12

and PCS0 .30, respectively. It should be noted that the crack opening loads do not show great differences due to the fact that the sleeper is prestressed.

Regarding the opening of cracks, the models showed proximity in the results. The first cracks tend to appear in the section with the highest bending moment, that is, the central section of the sleeper. This behavior is observed in experimental tests of both sleepers and prestressed beams.

Finally, the stresses in the x axis direction show that the shoulders of sleepers with lower mechanical properties tend to present stresses closer to the tensile strength, being regions more susceptible to the opening of cracks. It can be stated that if the test were carried out at higher loads, cracks would be observed in the shoulder regions of the sleepers, presenting behavior similar to Figure 2. As for the stresses in the z axis direction, the results show that there is no tendency to opening of cracks, it is concluded that analyzes are necessary at the chemical level of the materials used or the implementation of constitutive models that simulate the degradation of concrete due to expansive mechanisms.

The probabilistic fatigue life of plain concrete under low-frequency stress reversal loading

E.C. Ferreira, P. Sotoudeh, G. Fiorillo & D. Svecova

University of Manitoba, Winnipeg, MB, Canada

ABSTRACT: There is an inherent error in selecting concrete strength for establishing maximum fatigue loads for a new experiment, due to the large variability in experimental results of compressive and split cylinder tests. Procedure presented in an earlier research was used to determine concrete strengths values with safety levels ranging between 90% to 99%. Similar process based on determining safety level is implemented in this work to determine fatigue life of concrete cylinders. Most research on fatigue of plain concrete focuses on frequencies above 1 Hz. The effects of stress reversal combined with low-frequency loading are explored in this experimental program. The program focuses on establishing the fatigue life of plain concrete cylinders subjected to cyclic tensile-compressive stresses at 0.1 Hz frequency. Concrete cylinders with 36 MPa compressive strength were studied under three high tensile stress levels, reversed fatigue loading, and a constant stress range of 11 MPa at 0.1 Hz.

1 INTRODUCTION

Infrastructures sustain different loading conditions during their lifetime. One particular loading condition that structures are prone to is fatigue loading. Fatigue is the accumulation of damage in a material due to repetitive loads, leading to cracks or complete fractures after numerous repetitions (ASTM International, 1996). It was first observed in train axles in the late 1800s and has been studied since. Concrete, among other materials, has observed its fair share of fatigue investigations by numerous researchers exploring the subject since the early 1900s (Kachkouch et al., 2022). The consensus among researchers is that there exists a large scatter in the number of cycles to failure, which is referred to as the fatigue life of concrete (Cornelissen, 1984; Tepfers, 1982; Thun et al., 2007; van Leeuwen & Siemes, 1979).

There are standard procedures to follow for the characteristic investigation of materials. However, standard procedures often disregard the fact that specimens of materials might differ in character while originating from the same batch, which is particularly true for concrete, which is heterogeneous by nature. This can be remedied by increasing the number of tested specimens and using of statistical approach rather than the use of a limited number of specimens or trivial average values of features. Therefore, the need for a statistical approach in combination with an experiment, rather than a purely experimental approach, is urged. A number of researchers addressed the challenge in different manners. For example, Khademi et al. (Khademi et al., 2015) utilized multiple linear regression and artificial neural networks to predict the compressive strength of concrete for different concrete mixtures. Although not the main focus of their study, it is interesting to know that their experimental data comprised of 2 specimens per mixture for a total amount of 90 specimens, and they used the average compressive strength value of each 2 specimens for every particular concrete mixture. This was an attempt to obtain more accurate results. To investigate the influence of the optimum number of samples for fatigue tests, Paskova and Meyer (Paskova & Meyer, 1994) ran fatigue tests on 20 cubic concrete specimens. After a statistical evaluation of their data, they

concluded that at least 5 samples and at least 3 different stress ranges are required to reach a trustworthy result on the fatigue life estimation of concrete. In another study, Nieto et al. (Nieto et al., 2006) proposed a technique to approximate the S-N curve of concrete using the fatigue results of 10 concrete specimens. They concluded that their proposed approximation method substantially reduces the amount of data required to make a prediction on S-N curves.

In designing a fatigue experiment, if the concrete strength is determined using only a limited number of tests, the inherent variability in concrete strength must be considered when selecting strength to determine stresses to be applied during the fatigue tests. If the selected strength value is too small, the specimens will experience larger fatigue life compared to those with higher strength. This is potentially the reason why many researchers agree that there is an inherent variability in the predicted fatigue life of concrete. If the strength is determined with higher accuracy, the variability may be reduced. Another approach for estimating fatigue life consists in fitting a probability distribution to a limited number of fatigue test results. If the number of specimens is limited, the distribution error may be so significant that the predictions are either over- or under-estimated. To investigate the importance of the number of specimens for the probabilistic analysis of fatigue life, Ortega et al. (Ortega et al., 2018) proposed a method to estimate the compressive fatigue life of plain concrete that accounts for the error's dispersion, and the number of tests performed. This method introduced probabilistic design curves that can be adjusted, based on a maximum tolerable error referred to as safety level.

In this study, the Ortega's method is adjusted to the case of stress-reversal fatigue analysis and the statistical approach is extended to cover characterization tests of concrete as well. To this end, a combination of experimental tests and statistical analysis was interchangeably implemented that would show the influence of sample size in either characterization tests or experimental fatigue analysis.

2 PROCEDURE AND RESULTS

Statistical analysis was used in this study to improve the efficacy of selecting concrete strength values for fatigue strength testing. First, concrete tensile and compressive strength tests were performed, and basic parameters of their statistical distributions were obtained. Then, using the aforementioned results, Ortega's approach was applied to determine the strength for the fatigue tests. In the third step, the strength values acquired in step two were used to design and perform experiments on concrete specimens under stress reversal. Finally, using these results, design curves were calibrated to estimate fatigue life and probability of failure. These steps are discussed in detail in the following sections.

3 EXPERIMENTAL PROGRAM

The total number of cylindrical specimens prepared and used for this study was 71. The cylinders are 8-in high with 4-in diameter. In order to obtain compressive strength, 23 specimens were tested in compression, while 12 specimens were tested in splitting tension to obtain tensile strength. The resulting mean compressive and tensile strengths were 36 MPa and 3 MPa, respectively. The COV of those two tests were 11.4% and 11%, respectively. For the fatigue tests, three maximum stress levels, 0.90, 0.85, and 0.80 of the tensile strength, were selected. To consider the effect of stress reversal, the stress range was kept constant at 11 MPa. Only a limited number of split tensile specimens was available in this program. Therefore, by selecting the mean value of tensile strength would overestimate the concrete strength under fatigue. In the case of compressive strength, the number of specimens was sufficient. The specific value of the stress range was obtained from an ongoing research program on an existing dam in Manitoba, Canada, that endures such stress range in a yearly cycle. A sine loading function with a frequency of 0.1 Hz was selected to test the specimens under low frequency, which is the lowest achievable frequency

with the testing equipment. A total of 36 fatigue tests were performed, 14 at the stress level of 0.90, 12 at the stress level of 0.85, and 10 at the stress level of 0.80.

4 STATISTICAL ANALYSIS

It is widely accepted that the fatigue life of concrete follows either a Lognormal or Weibull distribution (ASTM International, 2010). The larger the number of data samples from a population, the better the fit. Ortega et al. established a relationship between distribution fit error and sample size, suggesting that the appropriate sample size lies between 15 and 20 specimens (Ortega et al., 2018). Inspired by their work, the method proposed in this study is first employed to determine concrete strength value to calculate the load corresponding to each stress level and to implement conservative estimates of fatigue life of specimens subjected to stress reversal fatigue tests.

A 2-parameter Weibull distribution was fitted to each set of values obtained from compressive and splitting tensile concrete strength tests. The resulting distribution is referred to as the reference distribution. Then, 25,000 realizations were randomly sampled from the reference distribution, maintaining the same size as the original data, or 23 data points. That means that in the case of compressive strength samples, each realization contained 23 values randomly sampled from the reference distribution of compressive strength data. A 2-parameter Weibull distribution was then fitted to each randomly sampled dataset. The plot of the resulting 25,000 Weibull distributions is referred to as the scatter band, the region where any random sample of that size is likely to fall. Consequently, the bandwidth at a probability level represents the maximum variability from the reference distribution.

The observed error e_o is the relative difference between the reference distribution and each curve in the scatter band at any probability level. The error is assumed to be normally distributed with mean and standard deviation estimated from the 25,000 generated realizations. The observed error was calculated for all 25,000 curves at each of the 1000 probability levels, from 0 to 0.999 in 0.001 increments. In the distribution of the observed error, the safety level, SL, is defined as the probability that a specific error, e_p , will not be exceeded, and this value is the maximum error. Thus, for the safety level SL, the maximum error e_p is determined at each probability level as the inverse of the cumulative normal distribution function of the observed error e_o at that level.

A design curve is a correction of the reference distribution for a predetermined safety level SL. A design curve for the safety level SL is obtained by correcting the reference distribution at each probability level, according to Equation 1 below.

$$[N]_{DC} = [N]_{RD} \times \left[\frac{1}{1 + e_p} \right] \quad (1)$$

where DC and RD are indexes that refer to the design curve and reference distribution, respectively, N is the concrete strength, and e_p is the maximum error calculated at that probability level.

For each design curve, the deviation from the reference distribution is evaluated at the 5th, 50th, and 95th percentiles. The design curve for concrete strength is optional if the average deviation at those three percentiles is lower than 5%. On the other hand, a design curve for concrete strength is recommended if the average deviation is greater than 5%.

5 CONCRETE STRENGTH TESTS

Using the aforementioned method, 23 compressive strength and 12 splitting tensile strength tests were analyzed. Therefore, sample sizes of 23 and 12 were used for producing the 25,000 random realizations from the compressive and tensile reference distributions, respectively. All

reference distributions, scatter bands, and design curves were analyzed using the commercial software MATLAB vR2022a. The reference distributions were obtained using the “wblfit” built in function, and a MATLAB code was written to obtain the scatter bands and design curves according to the process described in the previous section.

The resulting scatter bands are plotted in Figure 1 for compressive strength and Figure 2 for tensile strength data. In those plots, the vertical axis is the cumulative distribution function (cdf), and the horizontal axis is the concrete strength. In both plots, the bandwidth is larger at lower probability levels indicating larger strength variability at those levels. As the probability of failure increases, the variability decreases, reaching its minimum just over 0.6 in Figure 1, and over 0.7, in Figure 2.

Figure 1. Compressive strength scatter band.

Figure 2. Tensile strength scatter band.

The scatter band limits and bandwidth for the 5th, 50th, and 95th percentiles, along with the corresponding values of the reference distributions, were calculated. Additionally, the ratio of bandwidth to reference distribution for each of the percentiles, referred to as the Normalized range of dispersion, was determined. The normalized range of dispersion in the compressive strength reduces from 40% at the 5th percentile to 16% at the 95th percentile. A higher dispersion is observed in the tensile strength, where the same percentiles show a reduction from 60% to 26%, respectively. The 12 data points in the tensile strength dataset size was much smaller than the 23 in the compressive strength dataset. The more significant variability observed in the tensile strength compared to the compressive strength is related to the smaller number of specimens tested in that case. In both cases, the same trend of reducing the variance with increasing probability level was observed, which agrees with the scatter band plots.

The design curves for concrete compressive and tensile strengths are shown in Figure 3 and Figure 4, respectively. In both figures, the vertical axis represents the cumulative distribution function (cdf), whereas the horizontal axis represents the concrete strength. Design curves in both figures are calculated for three safety levels, namely, 90%, 95%, and 99%. Both plots show the same behavior. The distance between the reference distribution and the design curves is more prominent at lower probabilities of failure and gets less significant as the probability increases. Although the observed behavior is the same in both plots, the magnitude is not. The difference between reference distribution and design curves is more prominent in the tensile tests in Figure 4 than it is for the compressive tests in Figure 3. Table 1 depicts the 5th, 50th, and 95th percentiles of concrete compressive and tensile strength for the reference distribution and the design curves at 90%, 95%, and 99% safety levels.

Table 1. Distribution of concrete strength (MPa).

Percentiles	Compressive strength				Tensile strength			
	Reference distribution	Safety levels			Reference distribution	Safety levels		
		90%	95%	99%		90%	95%	99%
5th	30.1	28.0	27.5	26.7	2.9	2.7	2.6	2.6
50th	37.4	36.4	36.2	35.7	3.1	3.0	3.0	2.9
95th	42.3	41.4	41.1	40.6	3.3	3.2	3.2	3.1

For compressive strength, as shown in Table 1, the design curve for the 99% safety level gives an 11.3%, 4.5%, and 4.0% deviation at the 5th, 50th, and 95th percentiles, respectively. The deviation is reduced for higher percentile failure probabilities and for this set of specimens, is relatively low. For the 50th percentile value, the strength changes from 37 MPa for the reference distribution to around 36 MPa for the design curves. Therefore, the use of a design curve at this level of probability of failure is not necessary. However, if the 5th percentile or lower percentile values were being considered, the conservatism of the process would be increased. Thus, the compressive strength selected for the fatigue experiment was 36 MPa, the average of the 50th percentile values for all three design curves, which coincidentally corresponds to the average of the 23 compressive strength test results.

Table 1 also shows the 5th, 50th, and 95th percentiles of the tensile strength of concrete from the reference distribution and three design curves. The design curve for the 99% safety level gives a 10.4%, 7.3, and 5.9% deviation at the 5th, 50th, and 95th percentiles, respectively. The deviation is again reduced for higher percentile failure probabilities but, for this set of specimens, is significant enough to be disregarded. For the 50th percentile value, the strength changes from 3.1 MPa for the reference distribution to 2.8 MPa for the design curves. Therefore, the use of a design curve at this level of probability of failure is necessary. Thus, the tensile strength selected for the fatigue experiment was 2.8 MPa. That value is the mean of the design curve at the 99% safety level.

Figure 3. Concrete compressive strength design curves.

Figure 4. Concrete tensile strength: design curves.

6 STRESS REVERSAL FATIGUE TESTS

The method described in the previous section can be used for fatigue tests with one slight change in the correction of the reference distribution, replacing Equation 1 with Equation 2, below. The only difference between the two is the representation of the number of cycles to

failure in a fatigue experiment, which must be presented in a log scale. Therefore, $\text{Log}(N)$ in Equation 2 represents the logarithm of the number of cycles to failure.

$$[\log(N)]_{DC} = [\log(N)]_{RD} \times \left[\frac{1}{1 + e_p} \right] \tag{2}$$

The proposed statistical analysis was carried out on fatigue test results under stress reversal and constant stress range for 3 maximum stress levels. The same safety levels used for concrete strength were used for obtaining the design curves for the fatigue tests. The sample size for the 25,000 random samples in each case was: 14 at the stress level of 0.90, 12 at the stress level of 0.85, and 8 at the stress level of 0.80. For all cases, MATLAB was used to determine the reference distributions, scatter bands, and design curves. The mean of the reference distribution and design curves are summarized in Table 2.

Table 2. Estimated number of cycles to failure.

	Stress levels*		
	0.80	0.85	0.90
Reference distribution	4868	957	762
90% Safety level	1852	468	398
95% Safety level	1471	394	340
99% Safety level	992	293	258

*Tensile stress levels

Table 2 shows a significant reduction in the predicted mean fatigue life when moving from the reference distribution to the design curves in all three cases. However, the magnitude of the reduction, predicted mean fatigue life at the reference distribution minus the design curve for the 99% safety level, is correlated to the number of tests performed in each case. At 0.80 stress level, there were only 8 specimens tested, and the predicted mean fatigue life reduction was 79.6%. At 0.85 stress level, with 12 specimens tested, the reduction was 69.4%. Lastly, at 0.90 stress level, the predicted mean fatigue life reduction was 66.1%, where 14 specimens were tested.

7 CONCLUSION

This study presented a method that accounts for the distribution fitting error when a low number of tests is available to determine the concrete strength for fatigue experiments and the analysis of fatigue test results. The method benefits from employing design curves rather than mean values from experimental results. These curves can be obtained based on predetermined safety levels. The method was applied to five datasets, including compressive and tensile strength tests and fatigue tests at three stress levels. Out of the five datasets, only one, compressive strength, had more than 15 specimens and was the only one to show no significant deviation between design curves and data means. The remaining datasets, on the other hand, showed a deviation between design curves and reference distributions, and as the number of data points reduced, the deviation increased. There was also a higher deviation from the reference curves at levels of failure below 50%. These results show that when dealing with determining concrete strength or estimating the fatigue life of concrete under stress reversal, it is advised to use design curves instead of mean values of test results when the number of tests at hand is lower than a certain limit. The fatigue life of concrete was significantly reduced when the stress level was increased from 0.8 to 0.9. For all three stress levels, the deviation from reference distribution to safety level curves increased with decreasing the number of specimens in the data set. This should be considered when designing the data set size of a fatigue experiment.

Influence of different coarse aggregate types on porosity and various properties in concrete

N. Matsuda & T. Iyoda

Shibaura Institute of Technology, Tokyo, Japan

ABSTRACT: Greater utilization of recycled aggregate concrete is desirable to realize a sustainable society. To achieve sustainable, it is necessary to clarify the factors that reduce the strength and mass transfer resistance of low-quality recycled aggregate concrete and to develop technologies to improve these factors. In this study, the porosity in the concrete and its effect on each property were identified using a variety of coarse aggregates in order to identify the porosity in recycled aggregate concrete that leads to a reduction in strength and mass transfer resistance. The results show that low-quality recycled aggregate concrete has reduced strength and mass transfer resistance due to increased porosity in the new mortar and at the interface between the aggregate and the new cement paste. A C-S-H type accelerator agent was used as a solution to this problem. Strength and mass transfer resistance of low-quality recycled aggregate concrete were improved by the use of a C-S-H type accelerator.

1 INTRODUCTION

In recent years, concrete waste has been increasing in Japan due to demolition and renewal of aging concrete structures. Figure 1 shows the projected future generation of concrete waste in Tokyo. Concrete waste will continue to increase and is projected to be approximately 1.5 times greater in 2050 than in 2022. Concrete waste is reused as aggregate for roads. However, as road construction in Japan is expected to decrease in the future, new ways of using concrete waste are needed. On the other hand, the use of natural aggregates in concrete needs to be curbed in order to reduce the environmental impact. Against this background, we believe that concrete waste should be recycled as aggregate for concrete and used as recycled aggregate concrete. To promote the use of recycled aggregate concrete, it is necessary to use low-quality recycled aggregate, which can be produced with less energy and cost than the energy and cost-intensive production of high-quality recycled aggregate. However, low-quality recycled aggregate concrete is not widely used because its strength and mass transfer resistance are lower than those of normal concrete. Therefore, it is necessary to clarify the factors that reduce the strength and mass transfer resistance of low-quality recycled aggregate concrete and to develop technologies to improve these factors. So, we thought that the strength and mass transfer resistance of concrete are related to the porosity in the concrete. In this study, the porosity of concrete made with various aggregates was compared with that of low-quality recycled aggregate concrete in order to identify the porosity that leads to reduced strength and mass transfer resistance of low-quality recycled aggregate concrete. The porosity in the concrete was classified as porosity in the aggregate, porosity in the new mortar, and porosity at the interface between the aggregate and the new cement paste. Then, we investigated the use of C-S-H type accelerator as a technique to improve the porosity in the concrete.

2 COARSE AGGREGATE AND CONCRETE OVERVIEW

2.1 *Type and characteristics of coarse aggregate*

The study used the following coarse aggregates to determine the factors that reduce the strength and mass transfer resistance of low-quality recycled aggregate concrete. Table 1 shows the characteristics

Figure 1. The projected generation of concrete waste in Tokyo.

of the coarse aggregates used. Hard sandstone was used because it has lower water absorption than low-quality recycled aggregate. Limestone was used because it has a lower water absorption rate than low-quality recycled aggregate and its main constituent is calcium carbonate. Recycled aggregate was low-quality recycled aggregate. The concrete waste used in this recycled coarse aggregate was constructed in 1966. The cement type of this concrete waste was ordinary Portland cement, and the compressive strength of the concrete was expected to be approximately 22.5 N/mm² based on the JASS 5. Artificial lightweight aggregate was used because it has a very high water absorption rate compared to low-quality recycled aggregate. RLG and LWG are assumed to have high porosity in the aggregate due to high water absorption. We believed that there is a relationship between aggregate porosity and strength, so we conducted a crush value test. The crush value test is specified in JIS A 5023. However, the load was changed from 100kN to 200kN to obtain clear results. Crushed samples passing through a 2.5mm mesh sieve were also measured. The crushing values were larger in the order of HSG < LSG < RLG < LWG. The results indicate that LWG is vulnerable due to the high porosity in the aggregate. The results indicate that LWG is more fragile than RLG due to higher porosity in the aggregate. On the other hand, it has been reported that moisture in artificial lightweight aggregates affects the internal curing effect of concrete. Therefore, we conducted a moisture loss test of RLG and LWG. This method of moisture loss testing was conducted using a drying oven to check for changes in aggregate mass. The temperature and humidity in the drying oven were 20°C and 40-50%, respectively. Since air was circulating inside the drying oven, the specimens were placed in a wire mesh basket and the surrounding area was sealed to prevent sample errors. In addition, covers were installed to prevent wind from blowing directly onto the upper and lower surfaces of the wire mesh cage. The sample was approximately 500 g, and the saturated condition was used as the base point. The moisture loss rate is calculated using Equation 1. The moisture loss rate is expressed as a percentage of the amount of moisture loss relative to the total water in the unit fine aggregate volume. Figure 2 shows the change in moisture loss rate over time. RLG increased moisture loss up to 24 hours, with 30% of the moisture in the aggregate lost at 24 hours. LWG was slower in moisture loss, and 10% of the moisture in the aggregate was lost in 24 hours. From these results, it can be inferred that LWG has a slow moisture loss from the aggregate and provides an internal curing effect in the concrete.

$$\text{moisture loss rate}(\text{vol}\%) = \frac{(\text{saturated mass} - \text{mass of each hour})}{(\text{saturated mass} - \text{oven dry mass})} / \text{unit volume} \quad (1)$$

Table 1. The characteristics of the coarse aggregate.

Type	Hard sandstone	Limestone	Low-quality Recycle aggregate	Artificial lightweight aggregate
Symbol	HSG	LSG	RLG	LWG
Appearance				
Oven dry density (g/cm^3)	2.64	2.69	2.31	1.33
Water absorption (%)	0.69	0.53	6.58	27.00
Crushing value (%)	4.1	9.7	14.0	22.9

Figure 2. Moisture loss rate.

2.2 Mix proportion of concrete

Table 2 shows the mix proportions. Ordinary Portland cement(OPC) (density: $3.15 \text{ g}/\text{cm}^3$) and blast furnace slag cement type B(BB)(density: $3.04 \text{ g}/\text{cm}^3$) were used as cement. The reason for using blast furnace slag cement was the thought that the effect on porosity in concrete depends on the type of cement. The fine aggregate consisted of crushed sand (saturated density: $2.64 \text{ g}/\text{cm}^3$) and sand (mountain sand) (saturated density: $2.58 \text{ g}/\text{cm}^3$) in a 7:3 ratio by volume. AE water reducer was used as an admixture. The amount of admixture added was set to achieve a slump of $12 \pm 2.5 \text{ cm}$ and an air of $4.5 \pm 1.5\%$.

3 OUTLINE OF EXPERIMENT

3.1 Compressive strength test

Three specimens of $\phi 100 \times 200 \text{ mm}$ were prepared for each case, and after curing in water for 28 days, a compressive strength was tested in accordance with JIS A 1108.

Table 2. The mix proportions.

Symbol	Aggregate	Cement	W/C (%)	s/a (%)	Air (%)	Unit Weight (kg/m ³)			
						W	C	S	G
NHSG	HSG								937
NLSG	LSG	OPC							951
NRLG	RLG							853	866
NLWG	LWG								595
BHSG	HSG		50.0	48.0	4.5	170	340		931
BLSG	LSG	BB							945
BRLG	RLG							847	861
BLWG	LWG								592

3.2 Air permeability test

Cylindrical specimens of $\phi 100 \times 200$ mm size were used for the test, cured in water at 20°C for 28 days, and cut into cylindrical specimens of $\phi 100 \times 50$ mm in size. The specimens were dried in a drying room at 40°C until the mass was constant. After that, air was allowed to permeate through at a pressure of 0.1 MPa, and the amount of air permeation was measured using water displacement method using cylinder, and permeability coefficient was calculated.

3.3 Porosity test

Cylindrical specimens of $\phi 100 \times 200$ mm size were used for the test, cured in water at 20°C for 28 days, and cut into cylindrical specimens of $\phi 100 \times 50$ mm in size. After that, it was the specimens were dried at 40 °C in a drying oven until the weight loss became constant and measured the mass in an absolutely dry state. The porosity was calculated by the Archimedes method using these values.

4 RESULTS AND DISCUSSION

4.1 Compressive strength test

Figure 3 shows the compressive strength. The mix proportions using OPC resulted in the lowest compressive strength of the RLG. This result was 67% of the compressive strength of HSG. On the other hand, LWG resulted in higher compressive strength than RLG. The BB mix proportions resulted in the lowest compressive strength of the RLG. This result was 82% of the compressive strength of HSG. LWG also showed greater water absorption and crushing values than RLG, but there was no relationship between these results and compressive strength.

4.2 Air permeability test

Figure 4 shows the results of the air permeability test. The permeability coefficient of RLG was large than that of HSG. Comparing OPC and BB results, the overall air permeability of BB was greater. In particular, LWG resulted in a very large air permeability when BB was used. The reason for this may be that the type of porosity affecting the air permeability coefficient is different between OPC and BB cement. These results indicate that the compressive strength and air permeability coefficient of low-quality recycled aggregate concrete are significantly lower than those of ordinary concrete. This is thought to be due to the effect of porosity in the concrete.

4.3 Effect of porosity in concrete on compressive strength and air permeability coefficient

Figure 5 shows the relationship between porosity and compressive strength in concrete. LWG had the largest porosity in the concrete, but the compressive strength results were higher than RLG. This trend was also true for BB. The reason for the increased porosity of concrete with

Figure 3. Compressive strength.

Figure 4. Air permeability coefficient.

LWG may be the high porosity in the aggregate. Therefore, the weak spots in the concrete can be considered to be the interface porosity between the new mortar or aggregate and the new paste, rather than the porosity of the aggregate. Figure 6 shows the relationship between the porosity and air permeability coefficient of concrete. The air permeability coefficient of the OPC mix proportions with the increase in the porosity in the concrete. RLG has an increased porosity and larger permeability in the concrete than HSG, suggesting that mass transfer resistance is reduced. On the other hand, the slope of the equation calculated by the method of least squares based on the relationship between the porosity and permeability in concrete is different for OPC and BB. Based on these results, we believe that the type of porosity depended on is different between OPC and BB. Therefore, we classified the porosity in concrete into aggregate porosity and other porosities and investigated the effect of porosity on the compressive strength and mass transfer resistance of low-quality recycled aggregate concrete.

Figure 5. The relationship between porosity and compressive strength in concrete.

Figure 6. The relationship between porosity and air permeability coefficient in concrete.

5 CLASSIFICATION OF POROSITY IN CONCRETE

5.1 Method for classifying porosity in concrete

The porosity in concrete was classified into aggregate porosity and other porosity, and the factors that reduce the compressive strength and mass transfer resistance of low-quality recycled aggregate concrete were examined. Therefore, the porosity in concrete was classified into aggregate porosity, new mortar porosity, and interface porosity between the aggregate and the new cement paste (aggregate interface). Aggregate porosity was calculated by multiplying the water absorption of coarse aggregate by the absolute volume of coarse aggregate. The porosity of the new mortar was calculated by the Archimedes method, and the porosity in the new mortar was multiplied by the absolute volume of the new mortar. The porosity at the interface between the aggregate and the new cement paste was defined as the porosity in the concrete minus the porosity in the aggregate and in the new mortar.

5.2 Porosity in classified concrete

Figure 7 shows the results of the classification of porosity in concrete. LWG has the largest increase in porosity in the concrete. However, the majority of the porosity in the aggregate. RLG shows an increase in porosity at the new mortar and aggregate interface. This trend is more pronounced for OPC than for BB. Therefore, low-quality recycled aggregate concrete exhibits reduced compressive strength and mass transfer resistance due to increased porosity at the interface between the new mortar and aggregate. On the other hand, the LWG also has less porosity at the new mortar and aggregate interface than the RLG. We believe the reason for this is the internal curing effect of the artificial lightweight aggregate. The high-water absorption of the artificial lightweight aggregate may have promoted hydration of the interface between the new mortar or aggregate and the paste through an internal curing effect. However, we believe that low-quality recycled aggregate has different moisture behavior in the aggregate than artificial lightweight aggregate. The reason for this is that, since low-quality recycled aggregate has no internal curing effect, we believe that moisture movement from the aggregate increased the porosity of the new mortar and the interface between the aggregate and the new cement paste. However, BB showed a slight increase in porosity in the new mortar of the LWG. This is thought to be an increase in large capillary pores, given the results of the air permeability coefficient. These results suggest that the effects of moisture and moisture movement in aggregates may differ between OPC and BB.

6 TECHNOLOGY TO IMPROVE POROSITY IN CONCRETE

The C-S-H type accelerator was used to improve the porosity in the new mortar and the interface porosity between the aggregate and the new cement paste in low-quality recycled

Figure 7. The classification of porosity in concrete.

aggregate concrete. C-S-H type accelerator are new admixtures containing CSH nanoparticles. In previous studies, it has been reported that C-S-H nanoparticles improve compressive strength and mass transfer resistance by densifying the porosity at the new mortar and aggregate interface. Therefore, we used the C-S-H type accelerators in the mix proportions of BB shown in Table 2. The reason for using C-S-H type accelerator in BB is that previous studies have reported that the reaction of blast furnace slag is accelerated by the addition of C-S-H type accelerator. Based on the above, we believe that the C-S-H type accelerator can improve the strength and mass transfer resistance of low-quality recycled aggregate concrete.

Figure 8 shows test results for compressive strength and air permeability test of concrete with C-S-H type accelerator. Compressive strength and permeability of LSG and RLG were improved by the use of C-S-H type accelerator. This is due to the improved porosity of the new mortar and aggregate interface. This image is shown in Figure 9. HSG and LWG have fewer porosity in the concrete, making it difficult for C-S-H nanoparticles to penetrate into the porosity. LSG has fewer porosity in the concrete, but the aggregate features calcium carbonate, which promotes the effect of the C-S-H type accelerator. On the other hand, RLG increases the porosity at the new mortar aggregate interface, which makes it easier for CSH nanoparticles to penetrate into the porosity. We believe that the compressive strength and air permeability coefficient were improved by the C-S-H nanoparticles densifying the porosity. The reason for using C-S-H type accelerator in BB is that previous studies have reported that the reaction of blast furnace slag is accelerated by the addition of C-S-H type accelerator. Based on the above, we believe that the C-S-H type accelerator can improve the strength and mass transfer resistance of low-quality recycled aggregate concrete.

Figure 8. Test results of concrete with C-S-H type accelerator.

Figure 9. Image of porosity improvement by C-S-H type accelerator.

7 CONCLUSION

- 1) Compressive strength and mass transfer resistance of low-quality recycled aggregate concrete were lower than those of normal concrete.
- 2) The low quality recycled aggregate concrete had increased porosity at the new mortar and aggregate interface. This would have resulted in a decrease in compressive strength and mass transfer resistance.
- 3) The compressive strength and permeability of concrete made with limestone aggregate and low-quality recycled aggregate were improved by using the C-S-H type accelerator.

In the future, we will study the moisture behavior of low-quality recycled aggregate. In addition, we would like to investigate carbonation technology as a method to control moisture movement from the aggregate.

Visual inspection of bridges and tunnels in Italy: By experience made with different owners and methods to a new proposal for a better and more efficient inspection procedures

R. Salomone, F. Damiani, M. Vittone, M. Scarsi Napolitano, I. Vangelisti, G. Giacalone, A. Bombace, M. Brescia, M. Rabbia & C. Beltrami
Lombardi Ingegneria S.r.l., Milan, Italy

ABSTRACT: In this paper principal aspects of recent years experience of visual inspection of thousands of road and highways bridges and tunnels are critically presented. Inspection activities have been carried out on bridges, viaducts, tunnels, overpasses and underpasses of different structural typologies (prestressed concrete beam, composite steel-concrete deck, cast-in-place concrete, ecc), along Italian highways and State highways. These activities allowed to pursue awareness regarding operators safety's importance, developing deep consciousness respect to proper site organization and alternative safety-enhancing procedures. Moreover, a comparison between different inspection checklist and procedures developed by the highways management company is analyzed as current Italian practice and a new proposal for a better and more efficient inspection procedures. Besides, possible application of UAS and AI as supporting tools for visual inspections are pointed out.

1 INTRODUCTION

Nowadays, visual inspections on infrastructures represent a crucial activity for the identification of structures' condition states, safety evaluation and proper allocation of economic resources. This work provides a critical review of inspection methodologies and their development over the years, deeply analyzing Italian background in terms of both structural context and national regulations. A brief overview of international methodologies and procedures is also outlined. Moreover, site organization and safety issues are critically discussed, highlighting national regulations' lack of a proper approach to the above-mentioned matter.

However, inspection of road infrastructure represents only the starting point of the management process, which is based on life cycle of structures and aims to determine structural performance, conduct surveillance activities, and implement maintenance interventions evaluating its effectiveness over time.

Therefore, in this paper, importance of monitoring and supporting technologies is also discussed, focusing on their connection with the visual inspection and their potential impact on work quality and future developments.

1.1 *Italian infrastructure background*

The first Italian highways were built starting from the 1920s, but the considerable growth of the highways network took place in the second post-war period, until the 1970s, when the highway development boom brought to an end. At that time, Italy was, for highways overall length, the third nation in the world beyond United States and Germany.

The great growth that Italian highways network, together with the German and French ones, experienced until the 1970s suffered a strong slowdown in its development already in 1980, remaining in fact unchanged from 1980 to present. Therefore, most of the Italian infrastructural heritage is reaching the end of their service life, exhibiting more than 50 years of lifetime (Beltrami & et al., 2021).

Furthermore, the worsening of environmental and climatic conditions as well as the constant increase in transport exploitation certainly had a negative influence on the current infrastructures' conditions (Beltrami C., 2020). Therefore, inspection procedures, monitoring activities, and maintenance interventions are essential to ensure adequate long-term structural performance and avoid unpleasant consequences.

2 INSPECTIONS METHODOLOGIES

In the following chapter, a general overview of infrastructures' inspection procedures is presented. Starting from first developed instructions on structural surveillance, this work outlines methodologies evolution path that led to modern inspection and safety evaluation procedures. In addition, some brief references regarding other countries methodologies are also provided.

2.1 Past methodologies

In Italy, first guidelines regarding infrastructure safety through in-situ inspections and deficiencies evaluation came with the (Circolare n° 6736/61, 1967). The *Circolare 67* claimed the need of periodical safety and stability checks (charged to the road owners) and pointed out the importance of surveillance and maintenance due to relevant problems such as: age, influence of further interventions and increase of traffic intensity.

Frequency of inspections was set to a minimum of once every three months. Activities were based on visual examination of structural surfaces and development of a brief report for each work. The three main categories of inspection were:

- *daily inspection* of the general infrastructure conditions, whose aim was notifying the competent offices of any anomalies or new occurrences
- *scheduled inspection* for the pertinent structures with also possible tests and essays
- *extraordinary inspection* "... whenever, some symptom or fact gives rise to the conviction that something is not normal"

Further instructions came with the (Circolare n°34233, 1991) which focused on the document collection for existing works and introduced main characteristics that structural ancillary parts (such as joints, flooring, etc.) must have. During those years, manuals of inspections were generally developed by the companies in charge of activities, which tended to keep them confidential and to continue updating them in-house.

Another important step in the development of inspections methodologies was the introduction of a *Management Plan*, which provides and schedules both the control and maintenance activities of a structure, in order to maintain its functionality, quality characteristics, efficiency and economic value over time.

Management Plan was first requested in (Legge Merloni, 1994) and then more detailed in its contents with the presidential decree (D.P.R n. 207, 2010). Maintenance activities include all administrative and practical operations intended to increase the useful system's life. Planning of maintenance activities is strictly linked with inspections course.

Figure 1. Relationship between inspection and maintenance policies (M. Sanchez-Silva, 2016).

For infrastructures, where often is not possible to continuously observe their conditions, pre-planned inspections aimed at determining system status at a given moment play a fundamental role and are an integral part of maintenance strategy. Figure 1 illustrates a tree structure that describes the relationship between inspection and maintenance policies and how they are deeply linked.

2.2 New procedures

In the last years in Italy, inspection methodologies have still been based on instructions from (Ministero dei Lavori Pubblici, 1967) and (Ministero dei Lavori Pubblici, 1991), but they also depended on the owner’s operating manuals and on structural typologies.

Regarding inspections frequencies, the main division between basic (every three months) and advanced (once a year) inspections have always been kept, but structure’s characteristics and conditions leading to those mentioned cases were often different from one owner to another.

IQOA CLASSIFICATION cracks / alterations		IQOA CLASSIFICATION water associated deficiencies	
1	Good conditions	1	Only moisture spots
2	Superficial deficiencies	2	Relevant water presence, possible degradation long-term evolution
2E	Evolving superficial deficiencies	2E	Relevant water presence, strenghten surveillance and take actions
3	Deep degradation with intervention need	3	Users safety
3U	Deep degradation with urgent intervention need		
5	Users safety		

Figure 2. IQOA civil (left) and water associated (right) deficiencies classification.

For tunnels, the main reference has been the CETU Guidelines (Centre D’Etudes des Tunnels, 2015). Starting from that, and with the aid of Inspection Guides (Inspection guide, 2015) the inspection activity was mainly based on the observation and description of deficiencies and deteriorations. The goal was to identify the defect, to classify it with a specific codification (CETU), to detect it within a metric reference and to give it a weight in terms of severity/dangerousness. The latter was accomplished through an alphanumeric code based on the IQOA assessment method, which also regulates interventions’ planning over time.

In some cases, those tunnels inspections have been carried out as “*Point Zero Inspection*”, whose purpose was to evaluate “*ex novo*” the structure state of consistency, defining lining thickness, reinforcement presence, location of possible voids, presence and position of superficial deficiencies and mechanical characterization of structural materials.

Dealing with bridges is instead a more heterogeneous scenario, due to the presence of many different structural typologies, in terms of both materials and static scheme. This leads to a wider range of possible deteriorations and, inherently, to a different reporting method. For each defect, generally reported data are its extension, severity, location, codification and element information.

Those modern procedures have been applied during last years, until the recent implementation of new guidelines for risk classification and management, safety assessment and monitoring.

2.2.1 UAS and supporting technologies

Historically infrastructure inspections are conducted by employing special and costly vehicles. Cranes, by-bridges, buckets mounts are all necessary to document any issues, simultaneously with roads closure and consequent traffic delays. Use of supporting technologies represents a powerful tool which can provide several advantages for the inspection activity:

- improve the efficiency of visual inspections for complex infrastructures with relevant extension and difficult accessibility
- improve the operator’ safety during the inspections
- minimize usage of traditional special site vehicles
- reduce working site’s realization and related times
- inferior inconveniences to traffic and road users
- development of 3D models and automatic structural defects detection

The Unmanned Aerial System (UAS) plays a role as a substitute of the human operator leading to a not only more efficient, safe, and detailed inspection but also less time consuming.

Despite all these advantages, actual methodologies in Italy do not include specific procedures neither recommendation about the use of UAS and UAV in visual inspections.

2.2.2 LLGG 2022 – Tunnels and bridges

Nowadays, Italy is dealing with a crucial step in the new era of infrastructures inspections and maintenance. The new *Guidelines LLGG 2022* (Linee Guida, 2022) introduce an innovative approach for the evaluation of tunnels and bridges risk and safety. This new method is based on a multi-level approach, in which the inspection activity represents what is named Level 1. The Level 0 represents instead the initial structures census and main characteristics acquisition. The core process lies in Level 2, developed for the definition and attribution of an “Attention Class”, which leads to the safety evaluation of the structure (Level 3 to 5) and to the planning of successive inspections, interventions, and monitoring plans.

Regarding inspection methodologies, main differences with past approaches is related to the different codifications for deficiencies and their severity, as well as the need of new parameters acquisition. There is indeed some information regarding road platform, mechanical systems and road signage that must be acquired in order to better determine the correct Attention Class.

The visual inspections are aimed at verifying the reliability of the data collected in Level 0, collecting further information about actual geometry, structural characteristics, surrounding environment, and assessing the structures’ conservation degree through evaluation of main degradation phenomena in specific reporting sheets, fill out in terms of intensity and extension.

Differentiated defect sheets are provided for each type of element and construction material (for bridges) or for each uniform segment (for tunnels).

Collected information on the sheets are then used to determine the *defectiveness level*, one of the main parameters acting in Level 2 classification method, based on factors of risk, vulnerability and exposure as shown in Figure 3.

Figure 3. Flow chart for attention class determination.

2.3 Other countries overview

Outside of Italy, international procedures generally have comparable approaches in terms of both inspection typologies and activities’ frequency.

In the United States of America, Federal Highway Administration encourage usage of codes and instructions in (FHWA, 1995). Maximum interval between normal inspections is set as 2 years while special non-scheduled inspections are required after unusual events. Similar example is given by (Bridge Inspection Manual, 2017), introduced in 2017 by The Department of Transportation of NY State. It outlines several types of inspection such as general, in-depth and special, whose frequency is on an annual base, and often depends on rare conditions and occurrences.

In Western Australia, according to (Australia, Main Roads Western, 2013), routine visual inspections are carried out on an annual cycle and are responsibility of the bridge owner. Where the condition of some components is not clear during the routine visual inspection, a further detailed inspection is planned.

On the same wavelength, other countries such as France (CISR, 2008) or Germany (DIN 1076, 2013) settled infrastructure inspection on annual bases and with different detailing levels, while monthly inspections are hardly ever required by authority and regulations.

Regarding the use of UAVs during inspections, specific methodologies are widely spread all over the world. Cutting edge country is France, where the IMGC (Ingénierie de la Maintenance du Génie Civil) proposed a new type of procedures for visual inspection and, in particular, recommendation for indirect observation tools, such as UAV or UAS. They defined different detail steps for different inspection levels.

3 SITE ORGANIZATION AND SAFETY ISSUES

In this chapter most relevant aspects about site organization for infrastructures' inspection are developed together with some issues related with safety on the work site, defined according to D.lgs 81/08 (D.Lgs n.81, 2008). These two aspects strongly depend on the required type of inspection, as presented in the previous chapter.

In general, all the activities must be carried out prior execution of all necessary measures for the protection and indication of the construction site equipment and operators standing in the working area, as indicated in the “New Traffic Laws” (Nuovo Codice della Strada, 1992). The latter lacks any prescription about how to proceed in case of infrastructures' inspection, which are never mentioned among all possible activities on the road area. The only developed example of guidelines is the “Road operator safety guidelines” (Linee guida ASPI, 2016), which regulate operators' behavior in order to reach an acceptable level of safety during inspections.

Due to this legislative deficiency, according to the road section along which the inspected infrastructure is located, agreement between the designed inspectors and infrastructure managers must be defined in order to organize a suitable and safe working site area.

For the basic *by-foot* inspections, the site is organized allowing the operator to proceed with a mean of protection behind him, walking inside the so-called “inspection area”, delimited with the installation of appropriate road-protective signage consisting of aligned traffic cones. This procedure has the aim to ensure operator safety against dangers coming from vehicular traffic. The operators advance in the inspection together with the delimited inspection area.

In *close-up* inspections, which involve usage of special site vehicles (i.e. by-bridge, elevating platform) the road section is partially or completely closed to traffic in order to allow their positioning and safety. At least one lane must be closed to the vehicular traffic to ensure a suitable working safety range. This has the aim of limiting the oscillation of the working machine caused by the passage of heavy vehicles and to avoid the accidental fall of material. Otherwise, it will be mandatory to proceed with the complete closure to vehicular traffic in order to guarantee safety's conditions. In both cases, definition of a working site area has a relevant impact on the vehicular traffic, especially for highway infrastructures, so that suitable advice to the road users must be provided, showing warning messages on the “variable message boards”. An example of site working areas in the case of a three lanes tunnel inspection is reported in Figure 4.

Figure 4. Example of delimited working site area for 3 lanes tunnel inspections.

It is important to underline how these safety issues together with the definition of a suitable working area have a key role in the development of infrastructures' inspection.

Differently from traditional inspection method, the development of new supporting technologies, such as UAV and UAS guarantees a significant improvement in the operator' safety together with an even better efficiency during the inspection itself.

Considering a case study of a 60 span PSC viaduct in central Italy, the use of UAVs, compared to traditional tools, allowed to reduce inspection's duration from 8 hours of traffic closure to zero (1.5 hours of flight without interaction with traffic).

4 NEW PROPOSAL AND FUTURE DEVELOPMENTS

In this chapter new proposals and possible future developments for infrastructures' inspection procedures are described in order to improve efficiency and safety with respect to traditional ones.

4.1 UAS and AI supporting tools

Within the infrastructures' inspection field, the use of supporting technologies such as UAV and UAS represents a powerful development tool. UAV systems allow to systematically collect pictures of the entire work in complete safety. The data is then combined (using the principles of photogrammetry) to build a 3D model to provide a complete and measurable overview of the structure, where engineers could pinpoint issues and highlight critical areas (Figure 5).

Figure 5. Example of a 3D bridge pile model reconstruction (by Unmanned Aerial Vehicle, UAV).

The interoperability of generated 3D models with BIM (Building Information Model) software creates an historical record of the infrastructure where each, new or existing, issue could be checked during time.

In conjunction with the acquisition realized with UAV, computer vision techniques offer promising non-contact solutions to improve infrastructure assessment. As described in (Spencer Jr, Vedhus, & Yasutaka, 2019), the most important goal of this system is to automatically convert image or video data into actionable information, identifying structural components, characterizing local and global visible damages, and detecting changes from a reference image.

All these supporting technologies represent useful and powerful tool able to improve the quality and above all the applicability of the results, differently from the traditional methods which requires more effort to make them ready for structural applications. Moreover, modern inspection's methods produce a great amount of data hard to handle with only operators' capacities. They require indeed usage of supporting systems able to quickly elaborate and store them, or even better, usage of artificial intelligence (AI) tools whose role inside the infrastructures' inspection and monitoring field is under continuous study.

Preliminary research has been carried out (Ciclo di Vita - Gallerie, 2020) about advanced numerical models as supporting tools for tunnels life-cycle assessment based on:

- Dynamic Mode Decomposition (DMD) algorithms to predict defects evolution
- definition of risk assessment indices and possibility of artificial Neural Networks usage to automate and accelerate the diagnostic procedure

4.1.1 Monitoring

In the field of structural assessment, usage of a monitoring system represents a great support for visual inspection procedures, considering also the highly increased demands in terms of traffic loads with respect to original ones. In particular, monitoring activities are generally devoted to only specific cases such as strategic infrastructures, severely damaged ones or with problems of difficult accessibility.

The modern and mostly developed structural monitoring technology is represented by the SHM (Structural Health Monitoring) which allows the detection and identification of damage that may occur in tunnel or bridges due to aging, materials' degradation, actions exceeding design values as well as natural or anthropic exceptional events, according to what prescribed in (Guidelines for structural health monitoring, 2016). Two different types of monitoring system can be applied:

- *static monitoring*: used to control structural parameters, such as cracks opening, which vary slowly during a significant observation period (chosen to catch their trend)
- *dynamic monitoring*: able to detect undergoing mechanical vibrations of infrastructures when subjected to variable actions (such as wind or vehicular traffic) over time.

In general, SMH systems are made up of four relevant components:

- sensors: instruments able to “read” structural data
- data transmission unit
- processing unit
- post-processing and interface software for read and work with monitored data

Wireless sensor chains are mostly used for infrastructures, able to transmit continuous data to a remote unit, covering also wide range distances, in the order of kilometers.

An interesting and powerful alternative in monitoring sensors is represented by the dynamic monitoring cameras I-SHM (Intelligent Structural Health Monitoring). I-SHM technology is based on usage of one or more machine vision cameras and passive measurement reflectors to be installed at the infrastructure’s location. The system allows to measure structural parameters such as deformations and displacements based on processing very high-resolution images and can perform measurements with high frequencies and at great distances, suitable for tunnel or bridges.

4.2 *Improvable aspects*

On the base of experience during recent years, considering the new *LLGG procedures* and their first on-field application, some aspects have been deeply analyzed and could be improved and optimized in order to simplify and enhance inspectors’ job, both during and after in-situ activities.

Regarding tunnels inspection, actual deficiencies detection and their in-plan localization, as well as their statistical extrapolation and information analysis, represent a crucial aspect of the entire evaluation process. In place of many paper sheets and long transcription processes, usage of tablet within a developed informatic tool/software capable of simplify deficiencies representation and data acquisition could potentially enhance quality of work results and, above all, led to a less time-consuming procedure.

Another important improvement could come from the availability of relevant information regarding as-built documentation and survey outcomes (both structural and geotechnical). Those data can be indeed directly compared with the results coming from carried out inspections and surveys during infrastructure’s life, evaluating potential deficiencies’ evolution and subsistence of design conditions.

Significant considerations could derive from those mentioned aspects, in terms of inspections and maintenance’s influence on structure’s residual life. The probability of failure determined at designed stage is susceptible of changes due to external agents related to the structure diagnostic framework. Therefore, actual likelihood of collapse would be higher than starting one, and it can be evaluated through a *Bayesian* approach, as better discussed in (M. Sanchez-Silva, 2016).

The subjectivity of infrastructures’ traditional inspections related to the operator’s point of view and the large amount of information and data hard to process and manage, represent a major problem of the current inspection procedure system. Therefore, an improvement can be achieved with usage of supporting tools able to automate the diagnostic procedure and to detect deficiencies evolution, such as Neural Networks. This procedure is still at a starting point of development, but the idea to be followed in the near future is to merge together inspection procedures with infrastructure life cycle assessment, coming up with a whole new asset governed by numerical algorithms capable of manage the entire inspection and monitoring framework and post-process all produced data.

5 CONCLUSIONS

The paper has been devoted to discuss the Italian infrastructures’ inspection procedures development over the years, with a brief overview of also international strategies. From this general overview it is possible to appreciate the strict link between inspection methodologies and infrastructures’ development and maintenance.

In the next future, practical application of new *LLGG 2022* would represent a key step for inspection methodologies evolution. For instance, the development of specific procedures and their connection with information from past inspections and surveys represent an important matter. Moreover, a national standard regarding usage of UAS as inspection supporting tools will be hopefully developed in the future, following other countries leading way.

Then, importance of other aspects regarding inspection process such as construction site organization, safety issues and artificial supporting tools, is highlighted through the aid of past experiences. Crucial issue is the use of UAS as inspection and maintenance tool, particularly for strategic or problematic structures. For those cases, consequent benefits are costs' reduction, safety enhance, faster procedures and better-quality results.

However, optimal strategy in terms of costs and benefits is generally given by a trade-off mechanism between implementation of a suitable monitoring system and execution of in-situ maintenance activities.

Finally, studies regarding usage of AI are ongoing and they are necessary to be able in the future to manage a great amount of data and to achieve an automatized diagnostic procedure. Primary aim is definition of a new global asset, accounting for all infrastructure-related aspects, starting from initial design stage, as-built information, past inspections and surveys, ending in modern maintenance and monitoring procedures linked with life-cycle assessment concept.

Inspection of highway retaining walls and geotechnical sites, state of the art in Italy and possible proposals for improving procedures and effectiveness

M. Scarsi Napolitano, D. Bonassi, R. Morè & C. Beltrami
Lombardi Engineering S.r.l., Milan, Italy

ABSTRACT: In this paper principal results of recent years' experience of inspection of hundreds of highways retaining walls and geotechnical sites are critically presented. Inspection activities have been carried out on different geotechnical works, along Italian highways. These activities allowed to build an accurate damage database whose main features and statistics are discussed below. Then, a comparison between different inspection checklist and procedures developed by the highways management company is analyzed as current Italian practice and a new proposal for a better and more efficient inspection procedures. Besides, possible application of UAS and AI as supporting tools for visual inspections are pointed out.

1 INTRODUCTION

Due to its geographical conformation, the Italian territory presents a great landscapes variety, from coast to hills, from plains to mountains. However, the mountain and hill areas cover the largest portion in terms of surfaces of the national territory. Related to the capillarity reached by the national highway system, consequently, the long sections of the network are set up in areas with irregular morphologies and, by their nature, therefore subject, above all, to a high degree of hydrogeological and seismic hazard.

In the following the geotechnical inspection activity carried out between 2021 and 2022 and regarding the state of art of the geotechnical aspects of the Italian highway network will be presented.

The Italian highway network is almost 6000 km long and counts about 705 tunnels and 1626 between bridges and viaducts. The first Italian highway dates to 1924 with the “Autostrada dei Laghi” from Milan to Varese, the second highway in the world only after the “Long Island Motor Parkway” in the New York state (USA).

Globally in recent years there has been growing attention towards the infrastructures to determine structural performance of the engineering works, through the implementation of visual inspections and maintenance surveillance; particularly, in Italy where the infrastructural network often dating back to the post-war period hence infrastructures are now of a considerable age.

After the economic boom, took place between 1958 and 1963, the construction activities of the time meant an important booster for the local economy. From now on and for the following decades, however, the aspects of aging and durability of building materials have been neglected. These, added to the fact that there was often a bad habit of building “on savings”, inevitably means that today these infrastructures present in several cases a state of degradation, that can even compromise the stability and functionality of the infrastructure itself, leading to collapse as recent news has reminded us.

Only in recent decades the importance of visual inspection, surveillance, and subsequently maintenance activities are beginning to be understood.

Above all, these activities allow the prevention of tragedies, and have a positive return from an economic point of view.

The periodic inspection activity allows to evaluate how an infrastructure, or a site, evolves over time. This evaluation returns an overview of the various points of interest. Moreover, the systematical inspection repeated over the years and the comparison of both the results of the inspections and both of several similar situations, it is possible to maintain, before the failure happens, giving tragic outcomes.

1.1 *Inspection procedure*

In Italy, according to the management procedure established by the highway managing authority, the asset of interest can be divided into geotechnical asset (i.e. road embankment, trench, natural slopes, rockfall barriers, and drapery mesh) and retaining walls.

The purpose of the asset of interest inspection is to identify anomalies already manifest or potential related to the asset.

The inspection procedure involves checking and examining previous inspections reports, after that, it provides for a purely visual type of inspection. In fact, the monitoring of asset of interest is primarily based on “visual” observation of places. The visual examination of the instability of the highway site and of the infrastructure together with the observation of the evidence present in slopes and in land near the highway site, in fact, allow a first evaluation of deformation processes and instability phenomena that may be present.

This first summary identification of the in-progress phenomena allows us to define the most appropriate corrective measures/actions to be activated (monitoring and/or maintenance interventions) and the possible need to resort to a qualified specialist technical support. The asset of interest hereinafter will be reported as “site”.

In the case of site already equipped with instrumental monitoring systems, before the visual inspection, the available monitoring data must be retrieved and examined. During the inspection, the state of conservation of the installed system must be evaluated. Based on evidence found on site and the results of previous inspections, the need to install, to update or to restore the monitoring system is evaluated.

Each asset of interest, must be fully inspected starting from highway platform to the foot of the embankment/fence, if it is an embankment highway, or up to the guard ditch at the top/fence, if you are inspecting a trench and for its entire extension in case of support or garrison work, both in the sense longitudinal and transversal and in height, including complementary structures such as ditches, gutters, channels, rockfall barriers, etc.

For each site, the anomalies must be described according to the inspection form, established by the managing authority. For the geomorphological and/or structural anomalies must be described the typology and the geometric position. To the inspection form will have to be added: *i*) photographic report of the main anomalies observed on site; *ii*) sketch in case of retaining wall with indication of anomalies (i.e. position, extension typology and photograph number); *iii*) recognition of the extent of the damage with respect to the overall state of the structure and summary evaluation of the extent of the single damage also in combination with other anomalies and indication of the potential evolution of the phenomena.

Currently, given the increased use of Unmanned Aerial Vehicles (UAV) in many activities, the employ of UAV has also been introduced for site inspection, especially for the inspections of particularly steep site (i.e. rockfall barriers or drapery mesh) and for geotechnical asset difficult to reach. For these sites (Figures 1-2) the employment of UAV allows for faster and safer inspection, with respect to a traditional one. UAV system allows to systematically collect site photos and if structural defects have been identified, suggesting a more thorough inspection, for example through specialized personnel such as rock climbers, the method and the timing of insights must be shared with the managing authority.

The last part of the inspection process is a synthetic evaluation of the preservation state of the site. This evaluation is based on all the observation done on site, the presence/absence of anomalies, their extensions, their typology, their proximity to the highway, and on the base of inspector experience. The evaluation, hence, is based on a semi-qualitative method that

may slightly change from inspector to inspector. The possible evaluation of the site, according to the maintenance procedure, are: *i*) absence of anomalies; *ii*) anomalies to monitor, *iii*) plan a restore, and *iv*) urgent restore. Neglecting the absence of anomalies whose meaning is already explained by the name; anomalies to monitor is the evaluation given to that site which present anomalies which in their state, observed during inspection, do not represent a safety problem, but which must be controlled so that they do not become one. Plan to restore is the evaluation given to that site which show anomalies that in brief time could lead to a safety problem, and urgent restore is the evaluation given to that site which show serious anomalies that already represent an incipient safety risk.

For geotechnical asset in general, is established an annual frequency of inspection. For the retaining walls, the rockfall barriers and drapery mesh on the rocky slopes, the inspection frequency is every four years. If significant anomalies are found or the monitoring inspection highlights the presence of a rapid evolution of degradation, as well as proposing (request) specialized investigations from the managing authority, the area will become a “geotechnical asset” to be inspected with annual frequency.

Figure 1. Particularly step geotechnical asset difficult to reach and close to the highway.

Figure 2. An example of geotechnical asset difficult to reach, in this case the inspection concerns the slope below the highway, that in this particular case is the riverbed.

2 INSPECTIONS RESULTS

During the period of activity, 905 inspections have been carried out. Among these, 480 have been regarded retaining walls and 425 geotechnical assets.

While retaining wall include a specific category of concrete structures and reinforced lands, geotechnical assets include various types of situations, among these we can find mountain slopes subject to geomorphological or hydrogeological instability phenomena, rockfall barriers or drapery nets, structures for the prevention and mitigation of hydrogeological risk such as weirs or selector weirs, embankments and highway trenches or areas with a high rate of erosion such as the bed of rivers on which the foundations of bridges are set.

The following tables and figures summarize the defects found during the inspections for retaining walls (Table 1, Figure 3) and geotechnical sites (Table 2, Figure 4), their frequency and degree of severity:

Table 1. Distribution of defects among retaining walls.

Retaining walls	
Defect type	%
No anomaly	6.2
Presence of lesions/cracks	27.3
Presence of deterioration of the facade	10.8
Presence of moisture stains/efflorescence	30
Armor in sight	13
Abnormal injuries /openings on joints	8.5
Rotations/dislocations	3.8
Vegetation between joints	9.3

Figure 3. The cake diagram shows the distribution (%) of each type of defect found in the retaining walls inspected.

3 HIGHWAY GEOTECHNICAL INSPECTION ABROAD

For a long time, in Italy, the geotechnical asset management have been underestimated and only in the last decades start to improve a geotechnical asset management program.

Only in recent years Italian highways authorities started a geotechnical asset inspection program, and in several case a common line, for the inspection criteria, was not followed by the different managing authorities. At the same time, many other countries worldwide started with national highway asset management program long time ago. For example, one of the most advanced countries is USA, where are already developed national asset management programs, even focus on geotechnical asset management.

Table 2. Distribution (%) of defects with evaluation of gravity among geotechnical sites.

Geotechnical sites	Absence of anomalies	Anomalies to monitor	Recovery to schedule	Urgent restoration
Widespread landslides	0	4	0.2	0
Drainage duct obstruction	0	0.2	0	0
Pavement injury	0	7.3	0	0
Diffuse erosion	0	10.4	0.2	0.2
Channelled erosion	0	3.76	0.2	0
Detachment niches	0	1.18	0.2	0
Wall injury/work in reinforced concrete	0	5.65	1	0.2
Deteriorated conteniment net	0	1.65	0	0
Dected subsidence/quay	0	4.7	0.2	0
Animal burrows in the embankment	0	0.2	0.2	0
Lanslide	0	5.4	0.5	0
No anomaly	19	0	0	0

Figure 4. The histogram shows the distribution of defects found in the geotechnical sites and the gravity of each.

3.1 USA perspective

Since 2012 with the 112th United States Congress US enacted a law for founding a reform of surface transportation called Moving Ahead for Progress in the 21st century act (MP-21). This reform changes the policy and the programmatic framework for investment for growth and development of the surface transportation infrastructure. With MP-21 the investment has been driven through a base-performance program.

Starting from that moment in USA have been developed a TAM program (AASHTO, 2011 e AASHTO, 2016) (Transport Asset Management), where was included lately GAM (Geotechnical Asset Management).

With the NCHRP Project 24-46 “Development of an implementation manual for geotechnical asset management for transportation agencies” have been collected all information, case study, to develop a Volume 1 of NCHRP Research report 903, giving a background for implementing and correct application of the GAM method.

The transportation agencies can implement a GAM program focusing on a risk-based method where all existing asset defined as: *i*) embankment; *ii*) slopes; *iii*) retaining walls; *iv*) subgrades following the principles of: *i*) do minimum; *ii*) maintain; *iii*) rehabilitate; *iv*) reconstruct; and *v*) restore. In this way it is possible to prioritize the treatment based on risk and driving the investment correctly.

The prioritize process can develop following the items: *i*) inventory and assessment; *ii*) risk management; *iii*) risk prioritization; *iv*) investment prioritization; and *v*) candidate treatment.

Same approach has been used for the implementation of GAM in Networks Rail system and England Highway in UK (Power, 2012 and Network Rail, 2017).

4 BRIEF COMPARISON AND FUTURE PERSPECTIVE

Geotechnical inspection recently has been improved in Italy, embracing the state-of-the-art method, following the path of many other countries, and focusing on semi-quantitative risk-based approach.

The preliminary application of GAM gives a successful inventory of all geotechnical assets in Italian highway network, and his own condition.

Actually ranking the risk is purely a subjective of the inspector, for this reason a further improvement of the GAM could be to introduce a risk analysis method as reported on the volume 2 of NCHRP Research report 903, where the precision of the risk analysis has been improved using two-dimensional graphic including the likelihood and consequence of two axis, or use a 3D matrix (Anderson, 2016), where the three axis of the cube report: *i*) the class of asset; *ii*) risk source;- and *iii*) the performance goals.

Other parameters to include in the ranking of the risk is the proximity to the highway (HD41/03) and the timeframe.

The experience acquired during this period could be used to update the inspection manuals issued by Italian highway authorities.

4.1 Future perspective

The achieved experience in geotechnical inspections, lead us to massively employ UAV for reaching far geotechnical asset (i.e. example rocky slope, or torrents). UAV allows to obtain fine details for single structure inspected, to obtain a better overview of the area of interest, and to repeat the same inspection over years. In particular, the UAV employment allow to reach the inspection target with a substantial saving of time and a significant increase in safety. Moreover, the inspection data has been collected in a GIS-like portal, called AGE. This GIS-like portal is also a database to report the inspection results carried out over the years.

This first technological approach demonstrates how the most advanced technology in survey and remote sensing can give huge benefit in terms of inspection efficiency and its quality. The NCHRP synthesis 582 (National Academies of Science, Engineering, and Medicine, 2022) confirm that the state of practice of the inspection use web-GIS, like AGE, GPS/GNSS positioning system, UAV, areal/terrestrial photogrammetry dominating the inspection procedure and becomes the common practice in the last years.

The challenge for the next future inspection practice will be to push over the limit of use advanced technology, like standardize the employment of photogrammetry, LIDAR, laser scanning, and thermal camera. These technologies will permit to have exactly position of structures and a precise 2D/3D model, improving the registration of the failures and its time-related evolution.

Employing UAV could upgrade geotechnical asset inspections. UAV systems allow to systematically collect pictures in complete safety. The collected data are combined (using the

principles of photogrammetry) to build a 3D model to provide a complete and measurable overview of the site. The interoperability of 3D models, generated at each periodic inspection, with BIM (Building Information Model) software creates an historical record of the infrastructure where each, new or existing, issue could be checked during time.

Furthermore, an implementation of e-ticketing system will permit to have in real-time data of failure and reduce the time gap of action for the stage of maintenance, rehabilitation, reconstruction; simultaneously the development of these kinds of systems increases dramatically the type of data registered and its amounts.

5 CONCLUSION

Geotechnical asset inspection has been started recently, implementing a GAM method for the asset management by the Italian highway authorities.

Due to the early-stage implementation of GAM many improvements must be develop, like a more precise definition of the risk management using the latest methods issued in scientific literature.

The latest technologies can be used as a booster for improving the quality of the data collection and its own management, even more speeding up the field inspections and increase the safety of the inspectors.

Using shape optimization and principal stress line based stiffness improvement of thin-shell structure and reduce construction costs

Y.X. Sun, Y.Y. Yang & L.J. Leu

Department of Civil Engineering, National Taiwan University, Taipei, R.O.C

K. Yamamoto

Faculty of Engineering, System and Information, University of Tsukuba, Ibaraki, Japan

ABSTRACT: There is a gradual rise in movements for the realization of a circular economy and the resolution of environmental issues by presenting modern architectural form that proposes new materials, constructions, and lifestyles that reduce the environmental cost. In modern architecture, thin-shell structures are widely used especially on roofs of buildings, such as the roof of Kresge Auditorium at Massachusetts Institute of Technology (MIT), because it is easy to make architectural forms look beautiful.

To uses less material to obtain the aesthetic and high stiffness roof, designing structural optimization is an easy way to reduce construction costs and improve the service life of structures. This study uses the non-uniform rational B-spline (NURBS) method and finite element method as free-form surface technology to build thin-shell structures to improve stiffness of these structures. After obtaining the optimal thin-shell structure, add the principal stress line to improve the stiffness of this thin-shell structure in the same volume. Use the principal stress lines of different layers in the flat plate to create the stiffening beams under the thin-shell structure, which adds to the stiffness of the thin-shell structure.

Applying these techniques to solve real shell structure optimization problems will be practical optimal designs. Consequently, this technique allows engineers and architects to design aesthetic shape structures with high stiffness and low cost.

1 INTRODUCTION

The design of modern architectural structures is typically streamlined or aesthetically based, where modernistic and innovative structural systems are widely implemented, introducing non-conventional beam-column-based buildings all over the world. Most roof of modernistic structures are used thin-shell structures with free-form surface designs and are gaining popularity. However, the balance between structural stiffness and aesthetics is rather tricky for these designs. In order to enhance the structural stiffness of the thin-shell, construction material used would increase dramatically and would not meet the requirement of circular economy. This study aims to investigate the volume optimization of construction materials while maintaining both their appearance and excellent structural mechanics behavior.

In the past, thin-shell structures may adopt various free-form surface designs, where most of them controlled their structural geometry through certain geometric parameters. Commonly seen design construction approaches are the Bézier curve (Bézier, 1968), uniform B-spline, and non-uniform rational B-spline (NURBS) (Versprille, 1975). Kegl & Brank (2006) opted for the Bezier curve with design optimization to construct their curved surface and implemented their method on truss structures. Espath *et al.* (2011) combined NURBS and optimization theory to optimize the design of flat plates with different shapes, using both linear and non-linear optimization algorithms to produce two different optimal design outcomes.

For design optimization of thin-shell structures, Tomàs & Matri (2010) opted a famous thin-shell structure in Spain, i.e., Universal Oceanographic Park as the initial structural model of their design optimization workflow. Whereas Kanta (2015) took a stadium-based design approach, investigating their structural mechanical behaviors with an emphasis on the linear and non-linear buckling evaluation of thin-shell structures. Marino *et al.* (2016) used the auditorium of the Massachusetts Institute of Technology (MIT) as an example, where they implemented Bézier curves in spherical coordinate system to simulate similar geometric shapes. An optimized geometric model was generated through shape optimization in their study. Veenendaal *et al.* (2017) designed the thin-shell roof of Nest Hilo in Switzerland from its initial structural design phase towards the final construction of the actual thin-shell roof. They considered various influencing factor towards the design of thin-shell structure, including various loading conditions, buckling evaluation, structural strength assessment, structural thickness, and so on. By performing design optimization with the inclusion of these factors, structural design with the best stiffness performance was selected for the building.

Apart from the implementation of free-form surfaces in thin-shell structures, Michell (1904) was amongst the earliest to study optimal mesh-based structural mechanics prior to the development of principal stress line related applications. Well-known analytical solutions of truss structures were derived, in which Michell-cantilever is the most widely known optimized structure. Rozvany (1998) further consolidated and verified that analytical solution, concluding that specific truss structure has the best structural stiffness performance for cases of light materials. This finding has in turn confirmed the tight relationship between the principal stress line and Michell-cantilever.

Halpert (2013) is one of the studies that implemented principal stress line in the stiffening of flat-slab structure. The study uses in-house principal stress line generation tool to investigate the slab structure designed by Italian structural designer Pier Luigi Nervi, confirming that the real slab system with high stiffness possess a high fitting degree to the principal stress line layout. This finding has proven the practical feasibility of principal stress line in actual engineering applications. In order to reinforce the structural stiffness of thin-shell structures, this study adopted stiffening girder for structural strengthening with principal stress line layout, which can enhance the structural stiffness of thin-shell structures effectively.

In this study, we aim to present a design concept with themes of environmental protection and circular economy, alongside aesthetic presentation. This study explores a methodology to construct a free-formed surface thin-shell structure, under a fixed volume of material, integrating the optimization theory and principal stress line in the design consideration. The outcomes of this methodology could potentially enhance the structural stiffness of the thin-shell structure while maintaining its aesthetics.

2 STRUCTURAL OPTIMIZATION

Structural optimization design can be categorized into three types based on processing approaches, namely sizing optimization, shape optimization, and topology optimization. The design workflows for these three approaches are mostly similar, from initial model definition and finite element analysis to reaching convergence in optimization process. Their key differences lie within the design parameter (variable) and the implemented algorithm. This study mainly adopted the structural optimization approach based on shape optimization in conjunction with dimension optimization, in order to optimize the design of thin-shell structures.

2.1 Shape optimization

Shape optimization achieves the best solution for its objection function by changing the geometric shape of target structure, until it reaches the minimum structural compliance. Shape optimization has been used in various structural systems. For instance, simply by changing the node coordinates of truss structure, the truss system can achieve higher structural stiffness under identical loading mode.

As aesthetic demand arises in modern engineering, many smooth streamlined parametric curves (surfaces) are developed. There are various ways to construct their geometric models. Commonly seen methods are cubic spline, Bézier curve, B-splines, non-uniform rational B-spline (NURBS), and so forth. Amongst these, NURBS has higher flexibility and accuracy in dealing with analytical functions and establishing shapes of geometric models, not to mention its faster computation speed and numerical stability.

2.2 Non-uniform rational B-spline

Non-uniform rational B-spline (NURBS) is proposed by Versprille (1975), where NURBS surface is defined as follows,

$$\mathbf{S}(u, v) = \frac{\sum_{i=0}^n \sum_{j=0}^m N_{i,p}(u) N_{j,q}(v) w_{ij} \mathbf{P}_{ij}}{\sum_{i=0}^n \sum_{j=0}^m N_{i,p}(u) N_{j,q}(v) w_{ij}}, \quad 0 \leq u, v \leq 1 \quad (1)$$

$$N_{i,p}(u) = \frac{u - u_i}{u_{i+p} - u_i} N_{i,p-1}(u) + \frac{u_{i+p+1} - u}{u_{i+p+1} - u_{i+1}} N_{i+1,p-1}(u) \quad (2)$$

$$N_{i,0} = \begin{cases} 1 & u_i \leq u < u_{i+1} \\ 0 & \text{otherwise} \end{cases}$$

where P_i is a given set of control points, i is number of control points, $N_{i,p}$ is the basis function dependent on the node vector \mathbf{U} , w_i is the weighting, p is the curve polynomial order, n is the control point amount, $m+1$ is the node amount.

The main difference between NURBS and B-spline is the inclusion of the weighting w_i . While NURBS possesses the advantages of B-spline, it forms a more accurate and smoother curve (surface) when dealing with complex geometry, reducing the formation of angular edges. This approach allows the construction of a smoother and irregular free-form surface with localized effect.

2.3 Structural compliance

In order to generate optimized outcomes, this study adopted the compliance factor derivation method from Xie *et al.* (1993), the coordinate node of variable element e is first assumed, giving a structural stiffness variation of

$$\mathbf{K}' - \mathbf{K} = -\mathbf{K}^e \quad (3)$$

where \mathbf{K} is the structural stiffness prior to changing the coordinate of e , whereas \mathbf{K}' is the new structural stiffness. Their difference is then the stiffness \mathbf{K}^e . The change in displacement can be expressed in stiffness and external force by

$$\begin{aligned} \Delta \mathbf{u} = \mathbf{u}' - \mathbf{u} &= (\mathbf{K}')^{-1} \mathbf{F} - \mathbf{K}^{-1} \mathbf{F} = [(\mathbf{K} - \mathbf{K}^e)^{-1} - \mathbf{K}^{-1}] \mathbf{F} \\ &= \mathbf{K}^{-1} [\mathbf{K} - (\mathbf{K} - \mathbf{K}^e)] (\mathbf{K} - \mathbf{K}^e)^{-1} \mathbf{F} = \mathbf{K}^{-1} \mathbf{K}^e (\mathbf{K}')^{-1} \mathbf{F} \end{aligned} \quad (4)$$

in which \mathbf{u} and \mathbf{u}' are the displacement amount prior and after the element coordinate change, respectively, $\Delta \mathbf{u}$ is the change in displacement, and \mathbf{F} is the external force. \mathbf{F} is assumed to be invariant to the change in coordinate e , a rearrangement would give

$$\Delta \mathbf{u} = \mathbf{K}^{-1} \mathbf{K}^e \mathbf{u}' \quad (5)$$

Assuming the change in displacement prior and after the element coordinate variation is infinitesimal, $\Delta \mathbf{u}$ can be expressed as

$$\Delta \mathbf{u} = \mathbf{K}^{-1} \mathbf{K}^e \mathbf{u}' \cong \mathbf{K}^{-1} \mathbf{K}^e \mathbf{u} \quad (6)$$

This gives us the structural compliance variation ΔC due to the element coordinate variation,

$$\begin{aligned}\Delta C &= C' - C \\ &= \mathbf{F}^T \mathbf{u}' - \mathbf{F}^T \mathbf{u} = \mathbf{F}^T (\mathbf{u}' - \mathbf{u}) = \mathbf{F}^T \Delta \mathbf{u}\end{aligned}\quad (7)$$

By substituting $\Delta \mathbf{u}$, we get

$$\Delta C = \mathbf{F}^T \mathbf{K}^{-1} \mathbf{k}^e \mathbf{u} = \mathbf{u}^T \mathbf{k}^e \mathbf{u} = C_e \quad (8)$$

where C_e is the structural compliance after the change in e element coordinate, which is inherent twice the element strain energy of the element e . Through derivations above, the structural compliance formula is now

$$C = \mathbf{F}^T \Delta \mathbf{u} = 2U, \quad C \propto \frac{1}{\mathbf{K}} \quad (9)$$

From the equation above, we can observe that structural compliance is twice the strain energy and is inversely proportional to the stiffness. It means the structural compliance C is larger, the stiffness is smaller, and vice versa, as shown in Figure 1.

Figure 1. Strain energy figure.

2.4 Free-form surface and shape optimization

To validate the proposed methodology in this study, an initial shape of a square flat plate with 10 m length at all sides is created. The modeled shape had Young's modulus of 30 GPa, Poisson's ratio of 0.3, density of 2500 kg/m³, flat plate thickness of 30 cm, and supports at four, where its structural schematic is as shown in Figure 2.

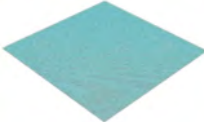

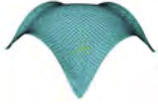

Figure 2. Flat plate model and control point and comparison diagram.

64 control points were allocated on this flat plate model, where their positions were layout continuously at the midpoints of side lengths.

Compared to the original flat plate, Table 1 shows a S4R5 element, the structural compliance decreased from 19189 N-m to 131N-m at the same volume, lead to the objective function of the optimized surface CV to be 0.007 times the initial structure. This means that the stiffness per unit volume has increased by 146 times.

Table 1. Flat plate shape and optimal shape.

3 PRINCIPAL STRESS LINE

This study implemented thin-shell structure with principal stress line approach to design a stiffening girder, in order to enhance the stiffness of the thin-shell. Finite element analysis is used to discretize series of principal stress vector fields, as the iterative source for numerical integration. The first step to obtaining the principal stress line is through the eigenvalue analysis of the element. Since shell element is a flat plate stress element, its stress magnitude and direction can be calculated through post-processing.

3.1 Principal stress line algorithm

According to the definition of Cauchy stress tensor, which is a second-order tensor,

$$\mathbf{T}^{(n)} = \mathbf{n}\boldsymbol{\sigma} \text{ or } T_i^{(n)} = \sigma_{ij}n_j \quad (10)$$

$$\boldsymbol{\sigma} = \begin{bmatrix} \sigma_{xx} & \tau_{xy} \\ \tau_{xy} & \sigma_{yy} \end{bmatrix} \quad (11)$$

where \mathbf{n} is the unit vector of an imaginary surface, $\mathbf{T}^{(n)}$ is the stress tensor passing through the imaginary surface, and σ_{ij} is the stress state at any specific points. By projecting Cauchy stress tensor onto a planar surface, it can be formulated as

$$\mathbf{T}^{(n)} = \boldsymbol{\sigma}\mathbf{n} = \lambda\mathbf{n} \text{ or } T_i^{(n)} = \sigma_{ij}n_j = \lambda n_i \quad (12)$$

The stress state of any arbitrary point can be determined through eigenvalue analysis, which gives the corresponding principal stress magnitude and direction. λ is the eigenvalue and the principal stress of the specific point, \mathbf{n} is the eigenvector and the direction of the principal stress. Since eigenvalues are in pairs, by sorting the eigenvalue in decreasing order, the maximum and the minimum magnitudes and directions of principal stresses are determined as σ_1, n_1 and σ_2, n_2 , respectively.

After determining the principal stress vector field at arbitrary point, the next step is to construct the principal stress line tangential to the principal stress direction. The streamline of the principal stress (displacement field) reveals the original streamline trajectory and generate a corresponding streamline field, as demonstrated in Figure 3.

3.2 Curved surface of the principal stress line based stiffened member

Building on the example in Section 2.4, principal stress line analysis is performed on the flat plate model, by separate analyses on upper, middle, and lower layers. This study first applied dimensional optimization on the stiffened model, involving design parameters of thickness t_s , width b and depth h . Considering the actual building mode, the three layers of principal stress line is designed to be stiffened at the bottom of the flat plate model, as shown in Table 2. It can be

Figure 3. Principal stress direction, stream line sketch diagram (Chien, 2019) and principal stress line.

observed that the stiffening performance using the principal stress line of middle layer was the best amongst the three, with an increment of 1.8 times. Table 3 shows the analysis result where the stiffness enhancement using shape optimization had the most significant improvement.

3.3 Summary

This section introduced the background of principal stress line, through the application case of the stiffened girder in Section 2.4 which included both shape optimization and principal stress line distribution. The stiffness was evaluated between the flat plate model and the optimized curved surface model. From Table 2 and Table 3, when principal stress line at the middle layer is used to stiffen internal layers, the flat plate model with both shape optimization and stiffening can achieve stiffness enhancement of around 238 times, under similar volume condition. In other words, with similar material amount as the original flat plate model, the improved design possesses significantly better structural stiffness, validating that the principal stress line stiffening approach proposed in this study is beneficial towards the enhancement of structural stiffness.

4 CASE DESIGN

In order to validate the practical feasibility of the proposed approach, this study simulated it in a case design based on the Kresge Auditorium at Massachusetts Institute of Technology (MIT). The case design needs to account for the structural strength, structural displacement, structural loading and its loading combination. Therefore, the best way to present the structural optimization of thin-shell structures is by expressing this in maximizing the stiffness per unit volume (i.e. minimizing the product of structural compliance and volume), and setting the design criteria as constraints.

4.1 Kresge Auditorium, MIT

Kresge Auditorium is constructed from one-eighth of a sphere, where its official geometrical dimensions are 15.24 m in height and 34.50m in span. However, only these two data is not enough to modeled, so this study also referred to the third paragraph of the literature reviews in Marino *et al.* (2016), where the radius of auditorium, a triangular side length, midpoint height and midpoint height of the triangular side is 34.3m, 48.5m, 14.5m and 8.1m, respectively. These dimensional data may have slight discrepancies in decimal points, they are sufficient in outlining the initial shape design for this study, and is quite accurate even when compared to the photograph of the real building, as shown in Figure 4.

Figure 4. Kresge Auditorium initial design and real building figure.

4.2 Case study analysis

The geometrical projection of the structure is an equilateral triangle, and the analysis outcomes are shown in Table 4. There has large significant variation between the optimized shape and the original structure, which highly improved the stiffness per unit volume. With shape optimization and fixed volume conditions, buckling limit is used as the constraint condition in the analysis. The stiffness enhancement using shape optimization was around 7 times, then using the principal stress line further increased this up to 50%. For joint optimization using both shape optimization and principal stress line, there were stiffness enhancement up to 10 times under similar material volume.

5 CONCLUSION

With the rise of environmental awareness, the reduction and reuse of construction materials have come into attention for engineers. This study performed a design optimization on thin-shell structure using similar material volume. Stiffness enhancement with principal stress line is implemented on thin-shell structure, which significantly increased its structural stiffness.

There are two parts to this study, namely the free-form surface and the principal stress line-based stiffening girder. The free-form surface was investigated using NURBS design, where the

Table 4. Comparison table for Kresge Auditorium.

	initial shape	initial shape with stiffening	optimal shape	optimal shape with stiffening
Shape				
t_s (cm)	50	16	50	17
V(m ³)	564			
CV(N·m ⁴)	237,242,310	145,898,691	33,740,768	23,964,751
(times)	(1.00)	(1.63)	(7.03)	(9.90)

best shape was generated using CV as the objective function, which is the product of structural compliance and material volume. Under similar material volume, the stiffness of the shape-optimized model is 146 times the original flat plate model. As for the principal stress line based stiffened girder analysis, the principal stress lines of upper, middle, lower layers for the internal of the flat plate model were evaluated in stiffness analysis. The overall stiffness enhancement of the principal stress line-based structure can reach 1.5 times the shape-optimized thin shell structure, proving its effectiveness under similar material conditions.

In order to validate the practical feasibility of the proposed approach, this study performed a case study on Kresge Auditorium at MIT. The stiffness enhancement of the thin-shell roof structure after shape optimization is 7 times, whereas the inclusion of principal stress line analysis can further improve the original stiffness up to 10 times, under similar material volume. These results have proven that the proposed methodology is effective in improving structural stiffness of thin-shell structures, through shape optimization and principal stress line approach, with similar material condition and volume. Through these optimization workflows, the overall aesthetic appearance of the thin-shell structures can be maintained while reducing the usage of construction materials.

Numerical verification of vehicle-bridge interaction system identification using a 3D models

E. Mudahemuka, S. Ryota & K. Yamamoto

University of Tsukuba, Tsukuba, Japan

ABSTRACT: Bridges are not built to last forever, and the cost to replace them is very high. To extend their service life and ensures that they continue their normal function without abrupt failure, preventive maintenance is required. Current practice of uniformly inspecting all bridges in inventory is ineffective and inefficient. For decades, estimating natural frequency and other modal parameters from vehicle vibration has been investigated. These parameters require information about the intact bridge, which is challenging to obtain. This study proposes a method to estimate system parameters of both vehicle and bridge systems, from vehicle acceleration and position data. In this study, the vehicle is modeled as a 3-D rigid body connected by springs and dashpot and the bridge system as a Kirchhoff-Love plate. Vehicle system (body mass, suspension stiffness and damping, unsprung masses and unsprung stiffness) parameters and bridge system (Rayleigh damping coefficients, and flexural rigidity) parameters are estimated.

1 INTRODUCTION

Bridges play an essential role in the transport and mobility of people and goods across the globe. The aging problem threatens these critical infrastructures on which our lives depend. In developed countries, where the bridge transport system is predominant, most of their bridges have been in service for 40 years or more. As reported in the 2021 ASCE infrastructure report card, 42% of all USA bridges were at least 50 years old in 2021, with 7.5% reported as structurally inefficient (ASCE, 2021). The biggest issue is that replacing a bridge is expensive, and governments and private bridge owners prefer repairing or preventive maintenance options.

Preventive maintenance is done after conducting a bridge health condition assessment. This is done by estimating the health condition, locating the defective section of a given bridge infrastructure, and then carrying out repair works accordingly (Malekjafarian, McGetrick and Obrien, 2015). The bridge visual checking technic plays an essential role in bridge health condition assessment and maintenance decision-making. However, its results are variable, tedious, highly dependent on the inspectors' experience, and sometimes require closing the road/bridge section. In addition, it is only possible to find a defect if it is not visible to the surface.

The analysis of the bridge's dynamic response under vehicular load started in the 90s (Olsson, 1991), (Yang, Yau and Hsu, 1997). With the development of sensing technology, the bridge's dynamic response analysis is put to another level by analyzing the data captured by sensors. This technique is realized either using bridge vibration data or vehicle vibration data. The former uses sensors mounted on a bridge in different locations, which might present installation and monitoring challenges depending on the type and location of the bridge. The latter uses sensors mounted on a moving vehicle on its body, suspension, and tire assembly, known as the "drive-by monitoring method," and it provides a way to monitor many bridges simultaneously effectively. This method was investigated for the first time by (Yang, Lin and Yau, 2004). In their method, the vehicle is modeled as a sprung mass and the bridge as a simply supported beam. Through the analysis of vehicle acceleration response by FFT (Fast Fourier Transform), they confirm that four main frequencies dominate the vehicle response: vehicle frequency, vehicle drive frequency $2\pi v/L$, and two shifted bridge's first natural frequency $f_b \pm \pi v/L$.

An experimental verification (Yang and Lin, 2005) by scanning the fundamental frequency of the bridge using a two-wheeled cart mounted on a light truck confirms the extraction of the first bridge's natural frequency from the acceleration spectrum of the cart moving at 40 km/h. The same verification has been carried out using EMD (Empirical Mode Decomposition) technique and identifying up to the seventh bridge vibration mode (Yang and Chang, 2009). These experimental verifications have recommended that natural bridge frequency be extracted using multiple passes for a heavier vehicle moving below 40km/h. The feasibility becomes much higher if prior knowledge of test vehicle properties and their calibration is available.

Extracting natural frequency from vehicle acceleration response is challenging due to the dominance of vehicle frequencies in the spectrum caused by the road surface profile. Identifying bridge frequency requires prior knowledge of frequencies and modal shapes of the intact structure. Simplified models used in previous studies do not fully capture the vehicle and bridge representation. The issue with optimization cost encountered while using methods like particle swarm optimization, and genetic algorithm (Zhao, Nagayama and Xue, 2019), is worked on by adopting the (NM) Nelder-Mead algorithm. The NM algorithm is a more suitable optimization method as it does not require a differentiable objective function and is easy to implement.

This paper proposes a method for estimating the vehicle and bridge's mechanical parameters from the vehicle's acceleration data and its position as an alternative to natural frequency estimation. The VBI (Vehicle-Bridge Interaction) mechanical system parameters and the road profile are estimated. Those parameters are continuously updated via the NM algorithm until the road profile at the front and rear axle are equal or approximately equal. The HC (Half Car) model is extended to FC (Full Car) model, and the Kirchhoff-Love theory is used to model the bridge system. Implementing this approach can help optimize maintenance schedules and allocate resources more effectively, ultimately improving the safety and longevity of bridges.

2 VEHICLE-BRIDGE INTERACTION SYSTEM MODEL

2.1 Vehicle system model

This study uses an eight-degree-of-freedom vehicle model that takes into account both pitching and rolling effects. The model includes translation, rotational motion (pitching and rolling), vertical tire motion, and rigid body equilibrium conditions, as represented in the following mathematical expressions (Jazar, 2008). The expression for the translation equation of motion of the vehicle body is given as:

$$m_s \ddot{w}_{sG} = - \left\{ \sum_{i=1}^n k_{si}(w_{si} - w_{ui}) + c_{si}(\dot{w}_{si} - \dot{w}_{ui}) \right\} \quad (1)$$

Where n indicates the number of tires considered and w_{sG} is given by the following expression.

$$w_{sG} = \frac{d_2 l_2 w_{s1} + d_1 l_2 w_{s2} + d_2 l_1 w_{s3} + d_1 l_1 w_{s4}}{(d_1 + d_2)(l_1 + l_2)} \quad (2)$$

Where w_{si} and w_{ui} represent the vertical displacement of the i th sprung mass and the i th un-sprung mass respectively, l_1 , l_2 , d_1 and d_2 represent the distance from the gravity point to the position of the left tires, to the position of the right tires, to the position of the front tire, and the position of the rear tires, respectively. The following expression gives the rolling motion expression:

$$I_x \ddot{\theta}_x = \sum_{i=1}^n a d_j \{ k_{si}(w_{si} - w_{ui}) + c_{si}(\dot{w}_{si} - \dot{w}_{ui}) \} \quad \begin{cases} a = -1, j = 1, & \text{for } i \text{ odd} \\ a = 1, j = 2, & \text{for } i \text{ even} \end{cases} \quad (3)$$

$$I_x = d_1 d_2 m_s \quad (4)$$

Where I_x is the vehicle body's inertia moment in the y -direction and θ_x is the pitch angle of the vehicle body in the x -direction.

The expression for pitching motion follows the same patterns as the expression for rolling motion and it is given below:

$$I_y \ddot{\theta}_y = \sum_{i=1}^4 a l_j \{ k_{si}(w_{si} - w_{ui}) + c_{si}(\dot{w}_{si} - \dot{w}_{ui}) \} \quad \begin{cases} a = -1, j = 1, & \text{for } i \leq 2 \\ a = 1, j = 2, & \text{for } 2 < i \end{cases} \quad (5)$$

$$I_y = l_1 l_2 m_s \quad (6)$$

Where I_y is the vehicle body's inertia moment in the x -direction and θ_y is the pitch angle of the vehicle body in the y -direction. In the same manner, the equation of motion of wheels is described.

$$m_{ui} \ddot{w}_{ui} = k_{si}(w_{si} - w_{ui}) + c_{si}(\dot{w}_{si} - \dot{w}_{ui}) - k_{ui}(w_{ui} - u_i) \quad (7)$$

In addition to the translation, rolling, and pitching equation of motion, the rigid body equilibrium conditions are considered, which helps to avoid the singular matrices.

$$\theta_x = \frac{d_1(w_{s1} - w_{s3}) + d_2(w_{s2} - w_{s4})}{(d_1 + d_2)(l_1 + l_2)} \quad \theta_y = \frac{l_2(w_{s1} - w_{s2}) + l_1(w_{s3} - w_{s4})}{(d_1 + d_2)(l_1 + l_2)} \quad (8)$$

Solving the above equalities and performing first and second derivatives with time, we can get the following three expressions for the vehicle model stability.

$$(w_{s1} - w_{s2} - w_{s3} + w_{s4}) + (\dot{w}_{s1} - \dot{w}_{s2} - \dot{w}_{s3} + \dot{w}_{s4}) + (\ddot{w}_{s1} - \ddot{w}_{s2} - \ddot{w}_{s3} + \ddot{w}_{s4}) = 0 \quad (9)$$

The above expressions are summarized into a matrix form as a general representation of the vehicle equation of motion.

$$\mathbf{M}_v \ddot{\mathbf{w}}_v(t) + \mathbf{C}_v \dot{\mathbf{w}}_v(t) + \mathbf{K}_v \mathbf{w}_v(t) = \mathbf{F}_v \mathbf{u}(t) \quad (10)$$

Where,

$$\mathbf{K}_u = \begin{bmatrix} 0 & 0 & 0 & 0 & k_{u1} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & k_{u2} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & k_{u3} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & k_{u4} \end{bmatrix}^T \quad \mathbf{F}_v = \mathbf{K}_u \mathbf{u}$$

$$\mathbf{w}_v = [w_{s1}, w_{s2}, w_{s3}, w_{s4}, w_{u1}, w_{u2}, w_{u3}, w_{u4}]^T \quad \mathbf{u} = [u_1, u_2, u_3, u_4]^T$$

2.2 Bridge system model

A simply supported 3-dimensional Kirchhoff-Love plate with length, L , width b , elastic modulus E , and material density ρ is used whose general dynamic equation is given in equation 11.

$$\rho h \ddot{y}(x, y, t) + D \left[\frac{\partial^2}{\partial x^2} \frac{\partial^2 y(x, y, t)}{\partial x^2} + 2 \frac{\partial^4 y(x, y, t)}{\partial x^2 \partial y^2} + \frac{\partial^2}{\partial y^2} \frac{\partial^2 y(x, y, t)}{\partial y^2} \right] = \mathbf{P}(t) \quad (11)$$

$$D = \frac{Eh^3}{12(1 - \nu^2)} \quad (12)$$

$$\mathbf{P}(t) = \sum_{i=1}^n \delta(y - x_k) P_i \begin{cases} k = 1, & \text{for } i \text{ is odd} \\ k = 2, & \text{for } i \text{ is even} \end{cases} \quad (13)$$

Where $\mathbf{P} = [p_1, p_2, \dots, p_n]^T$ is the contact force vector and h is the thickness of the plate respectively. The matrix form of the Kirchhoff-Love plate response to a moving time-varying contact force from the vehicle is given by the following general expression Eq.14.

$$\mathbf{M}_b \ddot{\mathbf{w}}_b + \mathbf{K}_b \mathbf{w}_b = \mathbf{F}_b \quad (14)$$

Where the matrices \mathbf{M}_b , \mathbf{K}_b , and force vector \mathbf{F}_b are given by solving the following integral expressions. Substituting the approximate solution $w_b = \mathbf{w}_b \cdot \mathbf{N}$ and $\omega = \boldsymbol{\omega}$ into Eq.14

$$\mathbf{M}_b = \int_0^L \rho h \mathbf{N} \mathbf{N}^T dx \quad \mathbf{K}_b = \int_V \mathbf{B} \mathbf{D} \mathbf{B}^T |J| dV \quad (15)$$

$$\mathbf{B} = \left\{ \frac{\partial^2 \mathbf{N}}{\partial x^2} \quad \frac{\partial^2 \mathbf{N}}{\partial y^2} \quad \frac{\partial^2 \mathbf{N}}{\partial x \partial y} \right\} \quad \mathbf{D} = \begin{bmatrix} D & \nu D & 0 \\ \nu D & D & 0 \\ 0 & 0 & \frac{(1-\nu)}{2} D \end{bmatrix} \quad (16)$$

$$\mathbf{F}_b = \sum_{i=1}^4 N(x_i) \mathbf{P}_i = [N(x_1) \quad N(x_2) \quad N(x_3) \quad N(x_4)] [P_1 \quad P_2 \quad P_3 \quad P_4]^T \quad (17)$$

Where N is the Hermite shape function, J is the Jacobian matrix. For numerical stability, the Rayleigh damping matrix is added to the bridge equation of motion and is given by the following expression.

$$\mathbf{C}_b = \alpha_c \mathbf{M}_b + \beta_c \mathbf{K}_b \quad (18)$$

Where α_c and β_c are mass and stiffness proportion coefficients for the Rayleigh damping matrix whose values are given in Table 2. For the details on how to calculate the derivative components of the stiffness \mathbf{K}_b , and mass \mathbf{M}_b matrices the reader should refer to (Ferreira, 2009).

$$P_i = -m_{si}(g + \ddot{w}_{si}) - m_{ui}(g + \ddot{w}_{ui}) \quad (19)$$

3 PROPOSED METHOD

This paper proposes a method to simultaneously estimate vehicle and bridge system parameters and road profiles from vehicle acceleration data and position. First, the vehicle model is extended to a 3-dimensional model, and the bridge is extended to the Kirchhoff-Love model. Vehicle acceleration is used as measured data. It is obtained by solving the VBI equation of motion, which requires the knowledge of VBI system parameters in this paper set with reference to (Keenahan, Ren and OBrien, 2020) and are given in Table 1 and Table 2. The vehicle is excited by the input profile $\mathbf{u}(t)$ whose value is composed of road unevenness $\mathbf{r}(t)$ referred here as road profile on one hand and the bridge vibration $\hat{\mathbf{y}}(t)$. The whole process is depicted in diagram of Figure 1.

$$\mathbf{u}(t) = \mathbf{r}(t) + \hat{\mathbf{y}}(t) \quad (20)$$

The vehicle acceleration can be used to calculate the input profile and road profile from equations 10 and 20, respectively. The objective function is formulated to minimize the error between the road profile under the front and rear axles, which is optimized using the NM algorithm described in section 5.1.

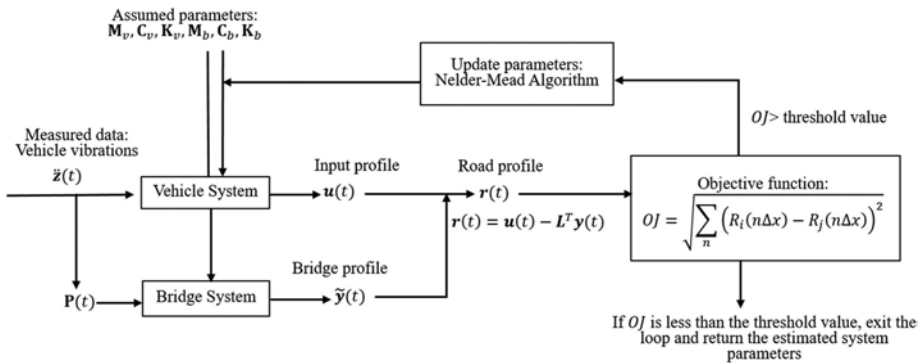

Figure 1. Process of the proposed method.

4 NUMERICAL EXPERIMENT

4.1 Input parameters

The profile over the entire road surface is not continuously the same, so it is assumed that the right and left track profiles are different in this experiment. The profile for both the right and left tracks are given in the following Figure 2. A 21tonnes full-car model with natural frequencies of 0.159Hz, 1.353Hz, 1.815Hz, 2.181Hz, 8.306Hz, 8.318Hz, 9.953Hz, and 9.989Hz, and

a 20 m long and 4m wide Kirchhoff-Love plate with natural frequencies of 0.428Hz, 1.388Hz, 2.239Hz, 2.896Hz, 4.560Hz, 4.956Hz, etc. are used. The VBI system parameters are given in Table 1 and Table 2.

4.2 Numerical experiment results

This section presents the results of a numerical experiment. First, the vehicle system is excited by an input profile that is purely a road profile, before the vehicle enters the bridge section. The input profile is updated to include the effects of the bridge response to the vehicle's vibration until the vehicle leaves the bridge section Eq.1. The vehicle acceleration response from the numerical experiment is used as measured data in the VBISI (vehicle-bridge interaction system identification).

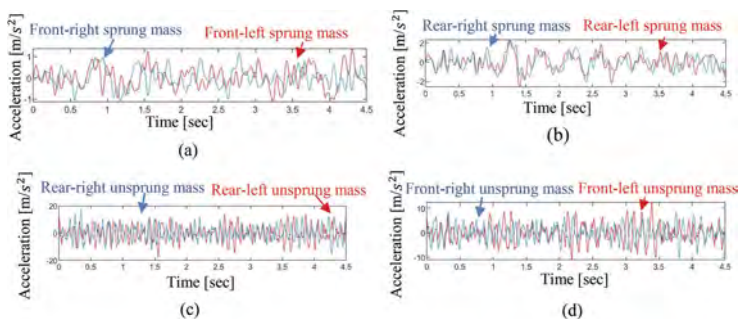

Figure 3. Measured vibration data (a) Front sprung mass (b) Rear sprung mass (c) Rear unsprung mass (d) Front unsprung mass.

5 VBI SYSTEM IDENTIFICATION METHOD

5.1 Overview of the Nelder-Mead algorithm

The Nelder-Mead (NM) algorithm finds the optimal value of an objective function in n dimensions using a simplex of $n+1$ vertices, say $\{ \mathbf{X}_1, \mathbf{X}_2, \mathbf{X}_3, \dots, \mathbf{X}_{n+1} \}$. The algorithm classifies the vertices as best, intermediate, worst, and second worst, and uses four operations (reflection, contraction, expansion, and shrink) to generate a new set of vertices by replacing the worst vertex on each iteration.

First, the worst function value is reflected through the centroid of the remaining.

$$\mathbf{X}_r = \mathbf{X}_c + \alpha(\mathbf{X}_c - \mathbf{X}_w) \quad (21)$$

Where α is the reflection coefficient whose value is greater than 0. If the reflected vertex is better than the best vertex so far, the reflected vertex is expanded.

$$\mathbf{X}_e = \mathbf{X}_c + \gamma(\mathbf{X}_r - \mathbf{X}_c) \quad (22)$$

Where γ is the expansion coefficient whose value is $\gamma > \alpha$. It can happen that the reflected vertex is not better than the second-worst vertex, in this case, the contraction step is performed.

$$\mathbf{X}_{cont} = \mathbf{X}_c + \rho(\mathbf{X}_r - \mathbf{X}_c) \quad (23)$$

With ρ being the contraction coefficient whose value is $0 < \rho \leq 0.5$. Note that coefficient ρ can be positive in case of external contraction when $f_r < f(x_{n+1})$ and negative in the case of internal expansion when $f_r > f(x_{n+1})$. If the fitness of the contracted vertex is better than the fitness of the worst vertex i.e. $f(x_{cont}) \geq f(x_{n+1})$ then the worst vertex is replaced by the contracted vertex if it is not the case, the shrinking step is performed where all vertices except the best recorded are replaced with new values.

$$\mathbf{X}_s = \mathbf{X}_1 + \sigma(\mathbf{X}_i - \mathbf{X}_1), \quad i = 2, \dots, n+1 \quad (24)$$

With σ being the shrinking coefficient whose value is $0 < \sigma \leq 0.5$. A more detailed explanation of Nelder-Mead can be found in (Nelder and Mead, 1965) and (Singer and Nelder, 2009) as explained in the original work of the original author where the above equations are referenced.

With X_r reflected vertex, X_c centroid vertex, X_w worst vertex, X_e extended vertex, and X_{cont} contracted vertex.

5.2 System parameters identification process

The vehicle and bridge system parameters are unknown, and they need to be estimated. The NM algorithm requires an initial guess of input parameters. It is possible to give a rough initial estimate of the VBI system parameters within a given range. The following table gives the range over which the initial random system parameters are chosen.

Table 3. VBI system parameters' initial range.

$C_{sis}, k_{sis}, k_{uis}, m_{uis}, \rho b, a_1, a_2$	d_i, l	D
0.8-1.2 times true values	0.1-0.9 times true values	0.8-1.2 times true values

Vehicle dimension parameters are assumed to be known since they can be measured accurately. The randomly initialized system parameters are substituted into the equation of motions to calculate input profile $\mathbf{u}(t)$ and bridge vibration response $\mathbf{y}(t)$. The objective function minimizes the error between the road profiles under the front and the rear axle.

$$\mathcal{R} = \sqrt{\frac{\sum_n (\mathbf{R}_1(n\Delta x) - \mathbf{R}_2(n\Delta x))^2}{n(\mathbf{R}_1)}} + \sqrt{\frac{\sum_n (\mathbf{R}_3(n\Delta x) - \mathbf{R}_4(n\Delta x))^2}{n(\mathbf{R}_3)}} \quad (25)$$

Where $n(\mathbf{R}_i)$ denotes the length of vector \mathbf{R} , the \mathbf{R}_i value is an estimate of the road profile under each i th tire.

6 RESULTS AND DISCUSSION

6.1 System parameters estimation

In this paper, both vehicle and bridge system parameters, as well as bridge profile, are simultaneously estimated. The results are limited to a non-damaged bridge case and vehicle data without noise.

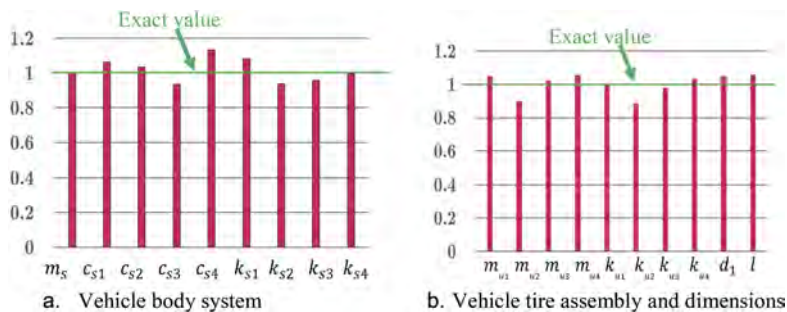

Figure 4. Estimated vehicle system parameters.

Figure 5. Estimated Bridge System Parameters.

Figure 6 shows the estimated road profile. The observation shows an estimation error observable especially on the rear axle. The previous research shows that this error is likely due to the position of the observation point to the gravity point. Even though the errors are present, the vehicle inputs can be estimated.

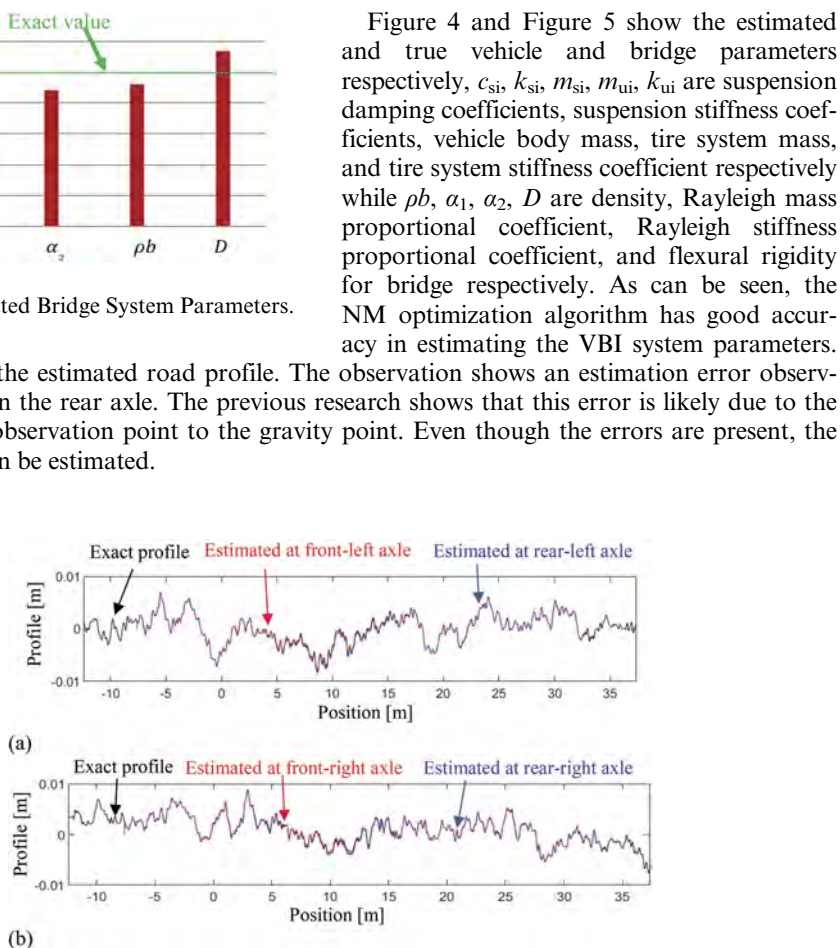

Figure 6. Road profile (a) left track (b) right track.

The estimation error in this study is small but the estimate has not improved much compared to the range of initialized parameters. The results are comparable to previous research, but some considerations are different. The study achieved comparatively accurate results compared to (Keenahan, Ren and OBrien, 2020) but comparatively low accuracy compared to (Zhao, Nagayama and Xue, 2019) due to the difference in the number of parameters estimated and the VBI model adopted.

7 CONCLUSION

In this paper, the applicability of the NM algorithm to Drive-by monitoring is investigated by estimating VBI system mechanical parameters and road profile. A 3-dimensional vehicle bridge interaction model is developed to simulate the 3-D VBI system model response. The numerical results of the model are obtained. The identification of VBI system parameters is performed using the NM algorithm by optimizing the error between the profile under the front axle and the profile under the rear axle. The results obtained by applying this algorithm are compared to the results obtained by (Zhao, Nagayama and Xue, 2019) and the results obtained by (Keenahan, Ren and OBrien, 2020), and they are found to be numerically accurate.

The accuracy of the estimated system parameters depends on the initial guess, and a poor guess can lead to longer processing times and less accurate results. The Nelder-Mead algorithm performs better than the PSO in estimating VBI system parameters, and future work includes experimental validation and extending the methodology to multiple vehicles, bridges, and runs.

ABSTRACT: Bridges have been instrumental in facilitating efficient transportation. However, bridges are prone to deterioration due to daily use and natural disasters. If left unattended, this deterioration can lead to structural damage. Monitoring is crucial because structural damage can have significant economic consequences and even be life-threatening. Therefore, we are focusing on bridge monitoring using vehicle vibration. This study clarifies the characteristics of vehicles that are effective for identifying the vehicle-bridge interaction system. This study clarified that the proposed method is affected by the damping of the vehicle and the frequency ratio between the vehicle and the bridge. The results are consistent with previous studies that have demonstrated the reduced accuracy of bridge modal parameter estimation from vehicle vibration. It is practical to design the vehicle frequency to be lower than that of the bridge when estimating the bridge's features. This paper shows that the characteristics of vehicles that are advantageous for vehicle response analysis clarified in previous studies are also important in the proposed method and show the usefulness of bridge maintenance management methods using vehicles. In the future, we will verify the feasibility of the proposed method in cases where different types of bridges and colors of noise are present.

1 INTRODUCTION

Road infrastructure is essential for efficient mobility and transportation. In particular, bridges are built to facilitate the crossing of rivers and valleys. Therefore, bridges have a significant impact on traffic. However, damage can occur due to fatigue caused by daily use and corrosion. Damage to bridges has a significant economic impact and can sometimes be fatal. Therefore, monitoring is vital to prevent structural damage to bridges. Skilled engineers support the monitoring of bridges. However, inspections of intact bridges are often wasteful. In addition, human error cannot be prevented, and there is a risk of missing damage to bridges. Bridge monitoring using sensing has therefore been proposed. Bridge inspections can be made more effective by screening bridges with a high probability of damage in advance and prioritizing inspections by skilled engineers. In addition, it is possible to conduct a practical evaluation based on the data.

Two main types of research focus on vibration as a bridge-sensing method. One is direct bridge monitoring. Direct bridge monitoring can reveal sudden structural damage to bridges caused by accidents or disasters in almost real-time. However, direct bridge monitoring is expensive because each must be equipped with multiple sensors. On the other hand, drive-by monitoring (Yang et al., 2004) has been proposed as an indirect bridge monitoring method. Drive-by monitoring is economically inexpensive because only the vehicle needs to be equipped with sensors. Drive-by monitoring is particularly effective for small and multi-span bridges in rural areas because it can easily monitor inaccessible bridges.

Drive-by monitoring uses vehicle-bridge interaction (VBI), which occurs when a vehicle travels over a bridge. One advantage of this monitoring method is that it can be used on small

and medium-span bridges. Small and medium-span bridges are rarely the target of direct bridge monitoring. In general, bridges are built individually according to construction conditions, and few bridges are the same. However, building a separate simulation model for each bridge is not realistic. Therefore, a simple mechanical model is required that can be used for a wide variety of bridges. However, it is susceptible to short VBI time, the roughness of the road surface, and environmental factors (Malekjafarian et al. 2015). Therefore, the accuracy of drive-by monitoring is generally low. Consequently, it is necessary to improve the accuracy by integrating multiple data (Malekjafarian et al. 2022).

The authors propose the VBI system identification (VBISI) method as a drive-by monitoring method that enables integrated data analysis (Yamamoto et al. 2022). The parameters estimated by the VBISI method are physical quantities based on the equations of motion and thus can use values calculated by other methods. Xue et al. (2020) use road unevenness estimated for a single vehicle to estimate vehicle mechanical parameters. Using a Kalman filter, they can estimate road surface roughness with high accuracy, even under high noise conditions. The VBISI method combines method that proposed by Xue et al. (2020) with numerical simulation of bridges to enable the estimation of mechanical parameters of bridges as well. Keenehan et al. (2020) use road unevenness estimated for multiple vehicles to estimate vehicle mechanical parameters. Most drive-by monitoring methods proposed so far focus on numerous runs of the same vehicle. However, the method proposed by Keenehan et al. (2020) allows the integrated analysis of data measured by various vehicles in the same scheme.

Since the VBISI method was proposed by Yamamoto et al. (2022), its applicability has been investigated through numerical simulations (Yamamoto et al. 2021) and field tests (Shin et al. 2023). However, these papers focus on a single bridge and do not examine the relevance of the VBISI method in multiple situations. Therefore, in this study, the applicability of the VBISI method is clarified by numerical simulations for the realization of bridge screening by drive-by monitoring. Therefore, we conducted a parametric study to show that the VBISI method is applicable to multiple bridges.

2 METHODOLOGY

This section describes the mathematical representation of VBISI. The vehicle and bridge system is shown in Figure 1. The vehicle is modeled as an RBSM (rigid-body-spring model). The bridge is based on the Euler-Bernoulli theorem. The vehicle system takes the input profile as input and outputs the vehicle vibration. The input profile is the sum of the bridge profile and road profile. A profile represents the vibration at the position of the front and rear axles. On the other hand, the bridge system takes contact force as input and outputs bridge vibration. Contact force is calculated from vehicle vibration. Therefore, the vehicle and the bridge system correspond to the input and the output, respectively (Yamamoto et al. 2021).

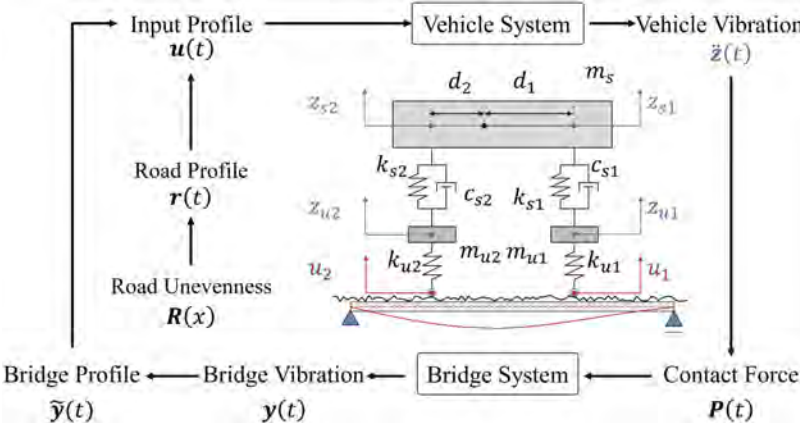

Figure 1. Conceptual diagram of VBI system.

2.1 Vehicle model

The vehicle is equipped with acceleration sensors on the vehicle body and axle. Since the acceleration sensors are installed on the front and rear wheels, there are four sensors. Body vibration and axle vibration are z_{si} and z_{ui} , respectively. The input profile is u_i . Let m_s and m_{ui} be the vehicle's body weight and tire weight, respectively. Suspension stiffness/damping and tire stiffness are k_{si} , c_{si} , and k_{ui} . The distance between the axle and the vehicle's center of gravity is d_i . The subscript i corresponds to the axle, with 1 being the front wheels and 2 being the rear wheels.

$$\mathbf{z}(t) = \{z_{s1}(t) \ z_{s2}(t) \ z_{u1}(t) \ z_{u2}(t)\}^T \quad (1)$$

$$\mathbf{M}_v = \begin{bmatrix} \frac{d_2 m_s}{d_1 + d_2} & \frac{d_1 m_s}{d_1 + d_2} & & \\ \frac{m_s d_1 d_2}{d_1 + d_2} & -\frac{m_s d_1 d_2}{d_1 + d_2} & & \\ & & m_{u1} & \\ & & & m_{u2} \end{bmatrix} \quad (2)$$

$$\mathbf{C}_v = \begin{bmatrix} c_{s1} & c_{s2} & -c_{s1} & -c_{s2} \\ d_1 c_{s1} & -d_2 c_{s2} & -d_1 c_{s1} & d_2 c_{s2} \\ -c_{s1} & 0 & c_{s1} & 0 \\ 0 & -c_{s2} & 0 & c_{s2} \end{bmatrix} \quad (3)$$

$$\mathbf{K}_v = \begin{bmatrix} k_{s1} & k_{s2} & -k_{s1} & -k_{s2} \\ d_1 k_{s1} & -d_2 k_{s2} & -d_1 k_{s1} & d_2 k_{s2} \\ -k_{s1} & 0 & k_{s1} + k_{u1} & 0 \\ 0 & -k_{s2} & 0 & k_{s2} + k_{u2} \end{bmatrix} \quad (4)$$

$$\mathbf{F}_v(t) = \{0 \ 0 \ k_{u1}u_1(t) \ k_{u2}u_2(t)\}^T \quad (5)$$

$$\mathbf{M}_v \ddot{\mathbf{z}}(t) + \mathbf{C}_v \dot{\mathbf{z}}(t) + \mathbf{K}_v \mathbf{z}(t) = \mathbf{F}_v \quad (6)$$

\mathbf{M}_v , \mathbf{C}_v and \mathbf{K}_v are the mass, damping and stiffness matrices of the vehicle (Yamamoto et al. 2021).

2.2 Bridge model

The bending stiffness and the bridge weight per unit length are $EI(x)$, $\rho A(x)$. The equations of motion of the bridge system are expressed as follows

$$\rho A(x) \ddot{y}(x, t) + \frac{\partial^2}{\partial x^2} EI(x) \left(\frac{\partial^2}{\partial x^2} y(x, t) \right) = p(x, t) \quad (7)$$

where $y(x, t)$ denotes the deflection, x represents the position. $p(x, t)$ denotes the external force distribution. $(\ddot{\ })$ denotes the second-order derivative in the time domain. The finite element method creates a global structural matrix and external force vector.

$$\mathbf{M}_b \ddot{\mathbf{y}}(t) + \mathbf{K}_b \mathbf{y}(t) = \mathbf{F}(t) \quad (8)$$

Given the Rayleigh damping,

$$\mathbf{C}_b = b_0 \mathbf{M}_b + b_1 \mathbf{K}_b. \quad (9)$$

$$b_0 = \zeta_b \frac{2\omega_{b1}\omega_{b2}}{\omega_{b1} + \omega_{b2}} \quad (10)$$

$$b_1 = \zeta_b \frac{2}{\omega_{b1} + \omega_{b2}} \quad (11)$$

\mathbf{M}_b , \mathbf{C}_b and \mathbf{K}_b are the mass, damping and stiffness matrices of the bridge. ζ_b represents the damping ratio of the bridge. ω_{b1} and ω_{b2} were obtained by eigenvalue decomposition (Yamamoto et al. 2021).

2.3 Vehicle-bridge interaction

The input profile, which is the input to the vehicle system, is expressed as follows

$$\mathbf{u}(t) = \mathbf{r}(t) + \tilde{\mathbf{y}}(t) \quad (12)$$

The input profile is the sum of the bridge profile and the road profile. bridge profile represents the bridge vibration at the moving point. bridge profile is calculated from the bridge vibration at the fixed point using the finite element method.

$$\tilde{\mathbf{y}}(t) = \mathbf{L}^T(t)\mathbf{y}(t) \quad (13)$$

$$\mathbf{L}(t) = [\mathbf{N}(x_1(t)) \quad \mathbf{N}(x_2(t))] \quad (14)$$

The road profile represents the road surface roughness at the moving point.

$$r_i(t) = \mathbf{R}(x_i(t)) \quad (15)$$

The contact force, an input to the bridge system, is calculated from the vehicle vibration and vehicle dynamics parameters (Yamamoto et al. 2021).

$$\mathbf{F}(t) = \mathbf{L}(t)[V_1(t) \quad V_2(t)] \quad (16)$$

$$V_1(t) = -\frac{d_2 m_s}{d_1 + d_2}(g + \ddot{z}_{s1}) - m_{u1}(g + \ddot{z}_{u1}) \quad (17)$$

$$V_2(t) = -\frac{d_1 m_s}{d_1 + d_2}(g + \ddot{z}_{s2}) - m_{u2}(g + \ddot{z}_{u2}) \quad (18)$$

2.4 Object function

In this study, the VBISI method is used to identify the dynamic parameters of the following VBI systems.

$$\mathbf{X} = [d_1, c_{s1}, c_{s2}, k_{s1}, k_{s2}, m_{u1}, m_{u2}, k_{u1}, k_{u2}, \rho A, EI_1, EI_2, EI_3, EI_4, EI_5, EI_6, EI_7, \zeta_b] \quad (19)$$

The input profile is inversely estimated from the measured vehicle vibration using a Kalman filter (Kalman 1965). A dynamic simulation calculates the bridge profile using the contact force as input. The road profile is obtained by subtracting the bridge profile from the input profile. The road profile and vehicle position information are used to estimate the road surface roughness at each axle. Assuming the vehicle moves straight ahead, the estimated road profile should be the same for the front and rear wheels. However, if the dynamic parameters are incorrect, the road surface roughness will not match. Therefore, the objective function is the sum of squares of the road surface roughness of the front and rear wheels. Search for a combination of parameters that minimizes the objective function using optimization techniques. In this study, the Neldermead (Nelder & Mead 1965, Gao & Han, 2012) method is used as the optimization method.

$$J(\mathbf{X}) = \sum |R_1(x) - R_2(x)|^2 \quad (20)$$

3 PARAMETRIC STUDY

Vehicle-bridge interaction occurs when a vehicle travels over a bridge. According to Yang et al. (2004), the following four vibration frequency are included in the vehicle vibration due to VBI.

- ① the vehicle frequency [w_v]
- ② driving frequency of the moving vehicle [$2\pi v/L$]
- ③ shifted frequencies of the bridge [$w_b \pm \pi v/L$]

In this study, a parametric study is conducted to investigate the feasibility of the VBISI method. Five influencing factors are considered, considering the main vibration frequencies in the vehicle.

3.1 Numerical model

Numerical simulations are carried out using the vehicle and bridge models depicted in Figure 1.

A sub-structuring method is utilized to reproduce vehicle vibration by separating the vehicle model from the bridge model. The displacement vibrations of both the vehicle and bridge are obtained through numerical integration of acceleration vibrations using the Newmark- β method (Average constant acceleration). The axial distance of the vehicle is set to 4 [m], with the distance from the center of gravity to the axle being 2 [m]. The unit mass of the bridge was assumed to be 4400 [kg/m]. The bridge length is set to 30 [m], with a 10 [m] road surface provided before and after the bridge. The time increments are set to 1.0×10^{-3} [s]. The parameters used in the numerical simulations are summarized in Table 1. Important values are bolded to make it easier to distinguish them from other cases. It is assumed that the vehicle vibration includes measurement noise. The magnitude of the added noise is estimated from the actual measured acceleration waveform (Shin et al. 2023). The bridge stiffnesses estimated for each case are summarized in Figure 3. f_b and f_v are the natural frequencies of the damped free vibration, respectively.

Table 1. Parameters used in the base case and the other 13 cases.

case	Road Level	m_s [kg]	m_{ui} [kg]	k_{si} [N/m]	c_{si} [kg/s]	k_{ui} [N/m]	f_v [Hz]	f_b [Hz]	v [m/s]	ζ_b	EI [Nm ³]

*₁: The vehicle accelerates towards the bridge center (from 9 to 11 [m/s]) and decelerates thereafter (from 11 to 9 [m/s]).

*₂: The vehicle continues to accelerate (from 8 to 12 [m/s]).

*₃: The vehicle continues to decelerate (from 12 to 8 [m/s]).

3.2 Base case

The base model was analyzed using the VBISI method as a preliminary study for the Parametric study. Table 2 summarizes the estimated parameters. All dynamic parameters were normalized to the correct values. The base statistics were generated based on 25 runs. The estimated values converge around the correct values. Figure 2 shows the estimated road surface irregularities. The estimated road unevenness for the front and rear wheels is close to the correct value.

Table 2. Estimated dynamic parameters.

Figure 2. Estimated element stiffness.

3.3 Effect of road surface roughness

When a vehicle travels on a rough road surface, the vehicle is excited by the bridge's vibration and the road's unevenness. As a result, roughness-related frequencies appear in the vehicle vibration, which may make the identification of bridge vibration difficult (Yang & He 2022). Therefore, this study examined the effect of different road surface roughnesses on the estimation accuracy of the VBISI method. The power spectral density function introduced in ISO 8608 (ISO 2016). was employed to simulate road surface roughness. In Case 1, road rank B was considered, and in Case 2, road rank C was evaluated.

The results show that the VBISI method is largely insensitive to Road roughness.

3.4 Effect of vehicle frequency

For the successful extraction of bridge frequencies from vehicle vibration, the vehicle/bridge acceleration amplitude ratio should be less than 3. It is also pointed out that i) initial vehicle/bridge acceleration amplitude, ii) vehicle speed and iii) bridge/vehicle frequency ratios are essential for the vehicle/bridge acceleration amplitude ratio (Yang & Chang 2009). Yang & Chang (2009) pointed out that bridge/vehicle frequency ratio are unimportant in estimating natural bridge frequencies because they cannot be controlled. However, the discussion of bridge and vehicle frequencies is essential to discuss what type of vehicle should be used for the VBISI method. Therefore, Case 3 was set up so that the bridge/vehicle frequency ratios are almost equal to 1. In Case 4, the bridge/vehicle frequency ratios were set to be smaller than 1.

As a result, the estimation accuracy decreased in Case 3. In addition, Case 4 demonstrated a noteworthy decline in accuracy. This implies that the VBISI method may be more effective when the bridge-to-vehicle frequency ratio is more significant than one. The natural frequency of a typical vehicle is lower than the first natural frequency of a bridge.

3.5 Effect of vehicle speed

High vehicle velocities can augment the vibration of higher-order modes on bridges. However, vehicle velocity increases and the vehicle's vibration become more contaminated by road surface roughness. Additionally, the duration of the measurement of vehicle vibration decreases, and the performance of frequency domain decomposition deteriorates (Kim et al. 2011). Therefore, in Case 5, the vehicle speed was set to 15 [m/s], and in Case 6, the vehicle speed was set to 20 [m/s]. In practical applications, it is challenging to maintain a constant vehicle speed. In Case 7, the vehicle accelerates towards the center of the bridge (from 9 to 11 [m/s]) and decelerates after that (from 11 to 9 [m/s]). In Case 8, the vehicle continues accelerating (from 8 to 12 [m/s]). In Case 9, the vehicle decelerates (from 12 to 8 [m/s]).

The findings imply that the accuracy of the VBISI method is not easily compromised by vehicle speed. This method may be suitable for use with trucks and buses in service if the bridge is adequately stimulated by the vehicles.

3.6 Effect of vehicle damping

Vehicle damping may influence the VBISI method due to its transmission of vibrations to the vehicle body. For a typical passenger vehicle, the suspension's damping ratio is frequently designed within the range of 0.2 to 0.4 for a comfortable ride (Calvo et al. 2005). Therefore, in this study, the vehicle's damping ratio in Case 10 was set to 0.2. In Case 11, the vehicle damping ratio was set to 0.4.

The findings reveal no alteration in the accuracy of the bridge stiffness estimate in Case 10. However, Case 11 showed a slight decrease in accuracy. Yang et al. (2022) observed that vehicle damping affects mode shape estimation, albeit limited. While the VBISI method is not a direct mode shape estimation technique, it is considered somewhat relevant.

3.7 Effect of bridge damping

Bridge damping ratios are generally minimal, ranging from 0.01 to 0.05 (He & Yang 2021). As the VBI system considers both steady-state and transient vibration, the duration of transient vibration is influenced by the bridge damping ratio. The smaller the bridge damping ratio, the longer the duration of transient vibration (Paz & Kim 2012). As the transient vibration dissipates, the excitation of the bridge to the measurement vehicle stabilizes, and the estimated pavement irregularity converges with the original road unevenness (He & Yang 2021). Therefore, the bridge damping ratio was set to 0.01 in Case 12 and 0.05 in Case 13.

The results show that the VBISI method is largely insensitive to bridge damping.

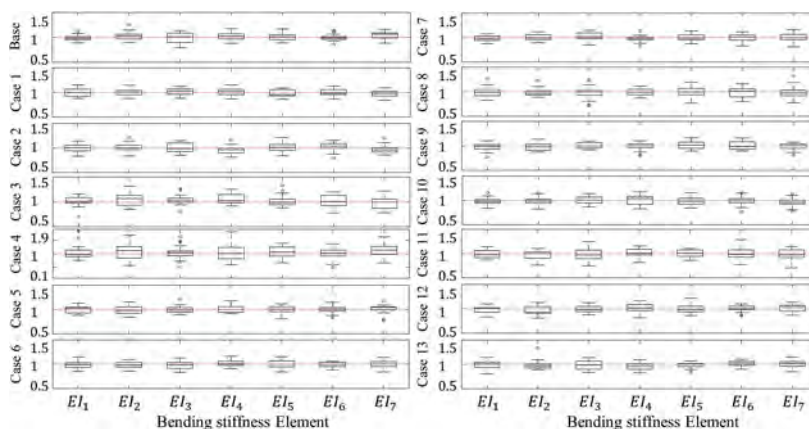

Figure 3. Estimated element stiffness.

4 CONCLUSIONS

A parametric study was conducted to assess the suitability of the VBISI method. The study focused on parameters that affect the primary vehicle vibration frequencies, specifically the roughness of the road surface, the vehicle's frequency, speed, damping ratio, and the damping ratio of the bridge. The findings suggest that the VBISI method is not sensitive to road surface roughness.

An important point revealed in this study is that the accuracy of bridge stiffness estimation is significantly degraded when the vehicle frequency is greater than the bridge frequency. Heavy vehicles, which tend to have lower frequencies, are suitable for use with the VBISI method. The accuracy is not compromised by typical vehicle speeds and is also insensitive to changes in vehicle speed. If the vehicle's damping ratio is high, the accuracy of the VBISI method is somewhat reduced. As the vehicle damping ratio diminishes the accuracy of mode

shape estimation, it is believed that this effect reduces the accuracy of the bridge stiffness estimate. The damping ratio of the bridge has a negligible impact on the VBISI method.

One constraint of this research is that only 13 cases were examined for each study subject. Each parameter should be scrutinized more thoroughly. This is because the VBISI method involves an optimization process, and accuracy verification for certain cases requires time. Consequently, implementing a technique that can expeditiously search for the optimal solution is necessary.

As a subject of investigation, it is necessary to examine the case in which the characteristics of the bridge are altered. In this study, we examined a bridge with constant stiffness throughout. In reality, there are bridges with variable stiffness, such as arch and truss bridges. Therefore, a model with different bridge structures and boundary conditions is utilized. Furthermore, only measurement noise is considered environmental noise. In the VBI research, it is noted that environmental noise is a factor that diminishes accuracy. If the noise satisfies whiteness, the Kalman filter can mitigate the impact. However, it has not yet been investigated for colored noise, such as traffic vibration. Given that the linear Kalman filter assumes white noise, it is anticipated that accuracy will be compromised with colored noise.

Influence of various admixture materials on pore structure and mass transfer characteristics

R. Yahiro & T. Iyoda

Shibaura Institute of Technology, Tokyo, Japan

ABSTRACT: Durability is important for the life cycle of reinforced concrete structures. Pore structure and mass transfer characteristics are related. Understanding the pore structure is necessary but difficult. It has been shown that gas and liquid have different mass transfer characteristics, and we thought that this difference could be express the pore structure. In this study, air permeability tests, Water penetration rate coefficient test, and porosity measurements were conducted. Various admixtures were used because the porosity is different depending on the admixture. As a result, it's clear that the mass transfer characteristics are different depending on the admixtures and amount of its content. Silica fume and blast furnace slag fine powder in high proportion showed high mass transfer resistance, and the water penetration rate coefficient was about 1/2 that of N. The difference between the air permeability and water penetration rate coefficients indicates the possibility of expressing the complexity of pores.

1 INTRODUCTION

Durability is important for the life cycle of reinforced concrete structures. Carbonation and salt damage, which are representative of the deterioration of reinforced concrete structures, cause steel corrosion and cracks in concrete. Since steel corrosion is progressed by the supply of water and oxygen, it is very important to understand the mass transfer characteristics in concrete. In Japan, steel corrosion by water penetration was added to the durability verification in the revision of the Standard Specification for Concrete Design, and a Water penetration rate coefficient test was devised in 2017. deterioration factors such as carbon dioxide, chloride ions, water, and oxygen penetrate the concrete using the pores as movement pathways. Therefore, it is often considered that pore structure and mass transfer properties are very closely related and are often discussed together with durability. Therefore, it is necessary to understand the pore structure of hardened cement in order to understand the mass transfer characteristics. In recent years, the use of various admixtures and chemical admixtures has been focusing in order to improve durability and reduce the effects on the environmental. It is known that the use of admixture materials changes the pore structure. However, it is difficult to accurately determine the pores in concrete because there are pores of different sizes and different shapes, each of which is complexly connected to the others. Thus, we considered inferring the pore structure of hardened cement when various admixtures are used, by using mass transfer characteristics and porosity. In this study, we tested hardened cement used the admixtures such as ground granulated blast-furnace slag, fly ash, silica fume, and C-S-H hardening accelerator agent. Air permeability tests, moisture penetration tests, and porosity measurements were conducted to sort out the pore structure and mass transfer characteristics formed using admixture materials. The combination of these tests was also investigated to understand the pore composition.

2 OUTLINE OF EXPERIMENT

2.1 Materials and mass ratio of cement and admixtures of mortar

In this study, mortar specimens were used to eliminate the influence of coarse aggregate. Also various admixtures were used and specimens were tested with different curing times in order to vary the diameter and distribution of pores. Ordinary Portland cement (OPC, Density 3.16 g/cm³, Blaine 3080 cm²/g) was used as cement, and blast furnace slag fine powder (BFS, Density 2.91 g/cm³, Blaine 4190 cm²/g), fly ash type II (FA, Density 2.33 g/cm³, Blaine 4460 cm²/g), and silica fume (SF, Density 0.27 g/cm³, Blaine 18.5 m²/g) were used as admixtures for the mortar. In case of using BFS, anhydrous gypsum was added to the BFS in an amount equivalent to 2% SO₃. Admixtures was replaced by mass ratio to cement. A C-S-H hardening accelerator (ACX) was used as a chemical admixture, which is thought to contribute to pore densification. Table-1 shows the mass ratio of cement and admixtures of mortar. The water-binder ratio was 50% and the binder: fine aggregate mass ratio was kept constant at 1:3.

Table 1. Mass ratio of cement and admixtures of mortar.

		Mass ratio (%)		
Admixtures	W/B (%)	OPC	Admixtures	ACX (W×%)
N	-	100	0	
B20		80	20	
B50	BFS	50	50	
B85		15	85	-
FA30	FA	70	30	
SF30	SF	70	30	
ACX	ACX	100	0	10

2.2 Porosity test

The specimen used in the water penetration test was crushed and a 25 mm square specimen was taken out. The samples were saturated with water by a vacuum desiccator. After measuring the saturated weight and the weight in water, the samples were left to dry at 40°C, RH 30% until their weights became constant, and the weight in a dry state was then measured. Porosity was calculated by Archimedes method.

2.3 Water penetration rate coefficient test

This test was conducted in accordance with JSCE-G 582-2018. Figure 1 shows an illustration of the test. Cylindrical specimens of $\phi 50 \times 100$ mm were made, and after curing, they were placed in the chamber at 40°C and RH30% until their mass became constant. After the specimens were removed from the chamber and the temperature was lowered to room temperature. The sides were sealed with aluminum tape and two sides were open. The mass of the specimen was measured, and 10mm from the bottom of the specimen was immersed in water and removed after 5, 24, and 48 hours. After the mass was measured again, the specimen was split

Figure 1. Outline of water penetration rate coefficient test.

open and sprayed with a moisture sensing agent. The range of coloration was defined as the water penetration depth, and the slope of the water penetration depth relative to the square root of the soaking time was calculated as the water penetration rate coefficient.

2.4 Air permeability test

The test was carried out using the output method with a disk-shaped specimen of $\phi 100 \times 20$ mm. In the pre-treatment, the specimens that finished the curing period were dried. The specimens were placed in an environment of 40°C , 30% RH and dried until the weight became constant. Air was injected at 0.1 MPa, and after confirming that the air flow had become constant, the permeability was measured using a graduated cylinder by water displacement method (Figure 2). The air permeability coefficient was calculated using the Darcy rule using the following equation (1).

$$K = \frac{2LP_2}{(P_1^2 - P_2^2)} \cdot \frac{Q}{A} \quad (1)$$

where K: Air permeability coefficient ($\text{cm}^4/\text{N} \cdot \text{s}$), L: Specimen thickness (cm), P_1 : Loading pressure (N/mm^2), P_2 : Outflow side pressure (N/cm^2), Q: Amount of air permeability (cm^3/s), A: permeable area (cm^2)

Figure 2. Outline of air permeability test.

3 RESULTS OF TESTS

3.1 Porosity

Figure 3 shows the results of porosity calculated by Archimedes' method for each mix proportion. The porosity showed a decreasing trend as the curing period was extended. This may be because of the hydration reaction of the cement, or the reaction caused by the admixture material. It was also clarified that even with the same number of curing days, the porosity was different depending on the type of admixture and the replacement ratio. The porosity is largest in B85, suggesting that the hydration reaction may not be sufficiently complete.

3.2 Water penetration characteristics

Figure 4 shows a specimen that had been cured for 28 days and was sprayed with a water sensing agent on the split surface of the specimen after 48 hours of immersion. It was confirmed that the use of admixture materials suppressed water penetration. B50 and SF30 showed smaller depths of water penetration than N, and SF30 showed higher resistance to water penetration, less than 1/2 that of N. On the other hand, the water penetration characteristics were different depending on the admixture and its amount of content. Especially, it was observed that the higher the BFS replacement ratio, such as B85, the more water was penetration at the sides of the cylindrical specimen and the greater the water penetration depth compared to the

Figure 3. Results of porosity test.

center of the specimen. This was reported in previous studies to be caused by changes in the pore composition affected by drying in the case of high BFS replacement. This result may have been obtained in B85 because drying was performed as a pretreatment. While the effect of drying was small for N, however, B85 was greatly affected by drying before the test was conducted, and the water penetration behavior was different between the center and the sides of the specimen. Therefore, it is clear that the water penetration behavior is different depending on the mixed material and its content.

Figure 4. Results of water penetration characteristics.

3.3 Air permeability coefficient

Figure 5 shows the air permeability of each mix proportions calculated from the results of the pressure air permeability test. As a general trend, the permeability decreased as the number of curing days increased. FA30 shows a significant decrease at 28 days of curing compared to 7 days of curing. It is considered that this is because of the densification of the pores due to the long-term occurrence of the pozzolanic reaction of FA in addition to the hydration reaction of cement. In addition, regardless of the number of curing days, B85 and FA30 showed significantly higher values of permeability than the other mix proportions. On the other hand, B20, B50, SF30, and ACX showed similar or slightly smaller values than N. Thus, it can be seen that the use of admixtures improves the mass transfer resistance.

4 DISCUSSION AS EXPRESSION OF PORE COMPOSITION BY MASS TRANSFER TEST

4.1 Relationship between water penetration rate coefficient and air permeability coefficient

Figure 6 shows the relationship between the water penetration rate coefficient and the air permeability. No correlation was observed between them. This may be because the water penetration rate coefficient test and the air permeability test are affected by different factors. Group

Figure 5. Results of air permeability coefficient.

A and Group B in Table 2 show some mix proportions with similar porosity. The relationship between the water penetration rate coefficient and the air permeability coefficient in these mix proportions shows that some hardened materials with the same porosity show similar values in group A but group B shows different values. In other words, even hardened materials that have the same porosity, but they are expected to show different trends depending on the pore composition, the material used in the mass transfer test, and the driving force of the test.

Figure 6. Relationship between water penetration rate coefficient and air permeability coefficient.

4.2 Relationship between porosity and mass transfer tests

Figure 7 shows the relationship between porosity and air permeability coefficient, and Figure 8 shows the relationship between porosity and water penetration rate coefficient. Figure 7 shows a positive correlation between porosity and permeability coefficient, with a decrease in permeability coefficient with decreasing porosity. On the other hand, Figure 8 shows a slightly negative correlation between porosity and water penetration rate coefficient. This relationship was different from that of the water penetration rate coefficient.

This result suggests that both of the water penetration rate coefficient test and the air permeability test evaluated the mass transfer in the hardened cement in the same way, but the results were affected by different factors, which may have caused the differences in the air

Table 2. The mix proportions with similar porosity.

Group	Mix proportion	Curing days	Porosity(%)	Marks
A	N	7	14.81	●
	B20	28	14.84	■
	ACX	28	15.00	■
B	SF30	7	17.89	●
	B50	7	18.26	●
	FA30	7	18.43	●

Figure 7. Relationship between porosity and air permeability coefficient.

Figure 8. Relationship between porosity and water penetration rate coefficient.

permeability test, a correlation was observed between them, suggesting that the pore volume in the hardened cement affects the air permeability. However, a different trend was observed in the water penetration rate coefficient test, which suggests that other factors besides pore volume, such as the complexity of the pore composition, may have an effect on water penetration. In Figure 7 and Figure 8, the two groups shown in Table3 are N, ACX, FA30, and B20 (Group I) and B50, B85, and SF30 (Group II).

In Group I, it can be seen that both the water penetration rate coefficient and air permeability coefficient decrease with decreasing porosity. On the other hand, in Group II, the air permeability

Table 3. Groupings in Figures 7 and 8.

group	Mix proportion	Color of the mark
I	N	○ □
	ACX	● ■
	FA30	○ □
	B20	○ □
II	B50	○ □
	B85	○ □
	SF30	● ■

coefficient decreases with decreasing porosity as in Group I. However, the water permeability rate coefficient does not change so much with decreasing porosity. From these results, it was considered that B50, B85, and SF30, which were classified as Group II, had complex porosity. The complexity of the porosity composition may have affected the water permeability rate coefficient, resulting in a smaller water penetration rate coefficient, even with a large porosity. In addition, even if the porosity is the same, the air permeability coefficient of Group II shows a slightly smaller value than that of Group I. The relationship between porosity and air permeability coefficient also suggests that Group II has a complex pore composition. Therefore, it is suggested that the complexity of the pore composition can be expressed by combining the results of the water penetration rate coefficient test with the porosity and air permeability coefficient.

5 CONCLUSION

- (1) The mass transfer characteristics and porosity showed different trends depending on the admixture material and its content. In particular, the mix proportion with a high replacement of blast furnace slag fine powder showed large water penetration at the side of specimen and that is significantly different from that of other mix proportion.
- (2) It was found that even hardened cements having similar porosity showed different tendency in several mass tests depending on the test method transfer such as air and water.
- (3) The water penetration rate coefficient may be affected by the complexity of the pore composition, suggesting that the complexity of the pore composition may be expressed by evaluating the combination of the air permeability coefficient and porosity.
- (4) Since the size and diameter of each pore in this study were not measured, in the future a mercury intrusion porosimeter will be used to measure the porosity in detail.
- (5) Only gas pressure injection and water permeation have been conducted, so we hope to understand the pore structure more clearly by conducting mass transfer tests using different materials and driving power.

ABSTRACT: The anti-sliding performance of the cable clamp is significant to the safety of the suspend-dome structure, the anti-sliding test was designed and the results showed that the anti-sliding bearing capacity of the cable clamp is greater than double the internal force difference between the two ends of the cable clamp under the most unfavorable working conditions of the design, and the FEM analysis of the cable clamp showed that the error between the anti-sliding bearing capacity of simulation and the test value is within 10%, indicating that the length and structure of the designed cable clamp met the design requirements.

1 INSTRUCTIONS

The suspend-dome structure has become the preferred structural form for the roof of the gymnasium because of its light structure, clear force transmission route, simple node structure and convenient construction. The anti-sliding performance of the cable clamp has a great influence on the mechanical performance of the suspend-dome structure. The lack of anti-sliding capacity of the cable clamp will lead to the slip of the cable, even change the stress state and structural form of the cable net structure, which may result in the instability and collapse of the structure.

In view of the force analysis of the anti-sliding performance of the cable clamp, a series of studies have also been carried out by relevant scholars. Luo *et al.* 2012. Proposed the concept of slip force density to describe the anti-sliding performance of such nodes through experiments and simulations of chord-supported dome cable clamp joints, and found that ribbing in the nodal groove can effectively improve the anti-sliding ability of the joint. Tian.2015. and Li *et al.* 2017. Found that cable tension and radial creep after compression were the main causes of bolt preload loss by experimentally analyzing the cable clamp slip process, and on this basis, the influence of bolt pretension, friction coefficient and other factors on the anti-sliding performance of the cable clamp was analyzed by finite element means. Ali *et al.* 2019. Combined the linear complementarity method in finite element analysis and dynamic relaxation method to study the mechanical behavior of the tension structure system that generated slip, which provided ideas for the analysis and calculation of similar structures. Ruan *et al.* 2019. Revealed the anti-sliding mechanism of cable clamps by presenting a theoretical model considering the effects of long-term creep and cable tension, and carried out the anti-sliding tests to verify the theoretical model. Wang *et al.* 2022. Further found that the bolt preload, the cable tension, the sequence of screwing bolts and stretching the cable and the diameter of the bolt would affect the anti-slip performance of the cable clamp by changing the normal pressure of the cable-clamp interface.

Considering the diversity of cable clamp joints in the actual engineering suspend-dome roof structure, the combination of component test and finite element simulation is still a reliable research method when conducting anti-sliding research on such components. This paper aims to study whether the cable clamp at the abrupt change of cable line type meets its required anti-slip force through experiments and finite element analysis, and provide data and method basis for subsequent research.

1.1 Engineering background

Located in Chibi City, Hubei Province, China, the Chibi Sports Center project has a total land area of about 543 acres, including a 15,000-person stadium and a 5,000-person gymnasium and a national fitness park. The main structure of the sports center is a concrete frame structure, and the roof is a suspend-dome structure (outer field) and single-layer grid shell and local tension string beam structure (infield). The model of the roof of the gymnasium is shown in Figure 1 and the ring cable and radial cable are all made of GALFAN plated steel strand clues.

Figure 1. Axonometric drawing of the stadium roof model.

Due to the different architectural functions of the gymnasium, the infield roof is divided into a suspend-dome part and a string beam part, which causes the roof of the suspend-dome part to be extremely irregular. The regular chord branch dome structure will show overall downward deflection under the action of vertical load and live load, and the roof dome structure of this project due to its irregularity, resulting in deformation under vertical load presents a special phenomenon of local downward flexural and local upturning. This phenomenon was mainly caused by the irregularity of the roof, and there was a sudden change in the internal force of the ring cable at the junction of the radial and circumferential directions. The maximum internal force difference between the two ends of the cable clamp reached 92kN and 196kN respectively under the combination of the most unfavorable load conditions, so it is necessary to verify the anti-sliding capacity of which by tests and FEM analysis.

2 INTRODUCTION OF THE EXPERIMENT

The main purpose of the test is to measure the anti-sliding capacity of the cable clamp. Compared with the specimen used in the sports center, the test specimen was simplified: the cable-way in the test specimen is straight rather than arc-shaped.

The test specimen is two D70 central ring cables and D110 outer ring cables, the test cables are all GALFAN plated steel strand clues, the diameter is 70mm and 110mm respectively and the corresponding test cable clamps are configured, the test cable clamps are G20Mn5QT steel casting cable clamps, the specific material properties are shown in the "Cast Steel Joint Application Technical Regulations" (CECS235:2008), the structure and specifications of the test cables are consistent with the engineering cables. Before the test, the cable clamp is preloaded with high-strength bolts before the cable tensioning. The specific specifications of the cable body are shown in Table 1, and the detailed drawings of the dimensions of the corresponding cable clamps are shown in Figure 2 and Figure 3.

Table 1. Test cable specification sheet.

Structural parameters				
specimen	material	diameter /mm	Effective cross-sectional area /mm ²	Minimum breaking force /kN
D70	1670 grade high vanadium	70	2840	4310
D110	Coated steel strands	110	7020	10560

Figure 2. Detailed view of the D70 test cable clamp.

Figure 3. Detailed view of the D110 test cable clamp.

3 EXPERIMENTAL RESULTS

According to the measured data, the tightening force attenuation curve of each high-strength bolt after the initial tightening with time is shown in Figure 4. The average initial tightening force, final tightening force and relaxation rate of the bolts on each cable clamp calculated by the tightening force curve was shown in Table 2. The test shown that the tightening force attenuation rate of the high-strength bolt is basically about 38%.

Figure 4. Attenuation curve of the bolt force.

Table 2. Bolt force on each cable clamp.

Specimen	Average initial force /kN	Average final force /kN	Average decay rate
D70-1	173.13	106.75	38.34%
D70-2	172.40	105.37	38.88%
D110-1	204.43	125.39	38.66%
D110-2	202.49	125.28	38.13%

Figure 5 shows the sliding curve between the cable and cable clamp which was calculated according to the measurement index. The anti-sliding test results are shown in Table 3, where the anti-sliding friction coefficient was calculated according to Equation (1). The friction coefficients of cable clamps are all greater than 0.15 specified in Specification for Design of Highway Suspension Bridges (JTG/TD65-05-2015).

$$\mu = \frac{F}{m \sum P_e} \quad (1)$$

In Equation (1), μ represents the friction coefficient of cable clamp; F is anti-sliding bearing capacity of cable clamp; m represents the number of friction surfaces between the cable clamp and the cable, which is 2.0, $\sum P_e$ represents the sum of the tightening forces of all bolts when the cable clamp slips (also the effective tightening forces of bolts). The anti-sliding bearing capacity of D70 and D110 cables is taken as the minimum of the two groups of data, which are 220kN and 520kN respectively. Under the combination of the maximum load conditions, the maximum internal force difference between the two ends of the cable clamp is 92kN and 196kN respectively. The anti-sliding safety factor of the cable clamp is 2.4 and 2.7 respectively, both greater than 2.0 which shown that the anti-sliding ability of the cable clamp meets the design requirements.

Table 3. Results of cable clamp anti-sliding test.

specimen	Effective bolt force /kN	Anti-sliding capacity /kN	Composite friction factor	Average comprehensive friction coefficient
D70-1	427.00	235.00	0.27	0.26
D70-2	421.48	220.00	0.26	
D110-1	752.34	560.00	0.37	0.35
D110-2	751.68	520.00	0.34	

Figure 5. Thrust - slip curve of cable clamps.

4 NUMERICAL SIMULATION

In order to verify the anti-sliding test results, the finite element analysis software ABAQUS was used to simulate the cable clamp test process, and the test results were compared with the finite element analysis results to verify the rationality of parameters setting of the nonlinear finite element model, which could be used as the basis for the further analysis of the applied engineering specimens.

4.1 Model

The high-strength bolts connecting the cable clamp were simplified in FEM model, the gasket and thread details of the bolt connection pair were omitted, and the cable twisted by multiple steel wires was simplified into a uniform solid cylinder of equal diameter. Appropriate material properties and cell types was chosen to assign to the model components, and the face-to-face contacting was defined. Finally, the finite element model is solved under reasonable boundary and loading constraints.

Figure 6. FEM models of cable clamp.

4.2 Material

To simplify the calculation, the stress-strain curves of various materials in the model are modeled by bilinear hardening model, the elastic modulus of the strengthening stage is αE , the coefficient α is 3%, and the strength of the material wouldn't increase after reaching the ultimate tensile strength. The D70 and D110 ring cables are made of steel wire twisting, and the sections were simplified to attain the deformation consistency of the two cables, the axial and the radial elastic modulus of the cable reduced according to Equation (2). The parameters are shown in Table 4.

$$E_e = \frac{EA_e}{A} \quad (2)$$

In Equation (2), E_e represents the radial and transverse equivalent elastic modulus of cable body; E is elastic modulus of cable, which is $2.06 \times 10^5 \text{MPa}$, $1.60 \times 10^5 \text{MPa}$; A_e is equivalent cross section area of the cable; A represents the nominal section area of cable, which is also the section area of cable in the FEM.

Table 4. Material parameters of each part in the FEM.

Part Name	Material	f_y/MPa	Axial modulus of elasticity E/GPa	Radial modulus of elasticity E_r/GPa	Poisson's ratio
Cable clamp plate	G20Mn5	385	206	160	0.3
High-strength bolt	20MnTiB	640	206	160	0.3
D70 Cable	Zinc-coated wire	1670	152.10	118.13	0.3
D110 Cable	Zinc-coated wire	1670	152.25	118.25	0.3

4.3 Assembly and mesh

Every part of the model was established and assembled respectively according to the test conditions. Considering that some parts in the model were irregular in shape and various parts were segmented to different degrees in the modeling and assembly process, all parts were automatically meshed through tetrahedral elements. In terms of the element selection, considering the large number of contact surfaces in the model, a modified second-order tetrahedral solid element (C3D10M) is selected, which is designed to be applied to complex contact simulation problems. The mesh partition is shown in Figure 6. The contacting surfaces of the model includes bolts and the cable clamps as well as the cable and the cable clamps. Considering that the main function of bolts is tightening the cable clamps, the vertical contact surface between screw and cable clamps was set smooth, and the horizontal contact surface was set bound and restrained. Coulomb friction was used for the contact surface between the cable and the cable clamps, and the friction coefficient was the average friction coefficient obtained by the test. Finally, the axial temperature expansion coefficient is set in the material part of the bolt to apply the bolt preload.

4.4 Boundary condition

The pre-tightening force of bolts was applied by the virtual temperature method according to the Specification for Design of Highway Suspension Bridges (JTJ/TD65-05-2015). In order to prevent the calculation from not converging due to small rigid displacement of the structure, displacement loads are applied to the top and bottom of the bolts. Firstly, all the degrees of freedom at both ends of the cable were fixed, and then the axial degrees of freedom at one end of the cable were released for the hierarchical tension of the cable after the contact between all the components is complete. In addition to the constraint on the end face of the cable, the coupling of the top and bottom surfaces of the cable clamps and the top and bottom surfaces of the bolt was also carried out through the reference points to apply the load and control the degree of freedom of the component surface in the process.

4.5 Numerical analysis results

The sliding curves of D70 and D110 cable clamps got by the FEM analysis are shown in Figure 7, and the anti-sliding bearing capacity is compared in Table 5. It can be seen that: the error of the calculated anti-sliding bearing capacity of D70 cable clamp is within $\pm 5\%$, and that of D110 cable clamp is within $\pm 10\%$. Compared with the test, the thrust force of the model remains basically unchanged after the slip occurs. The reason is that the body and the cover of the cable clamps remained horizontal during the loading process and slid at the same time.

Figure 8 shows the variation curve of tightening force of high-strength bolts in the two types of cable clamps along with the tension of the cable during the test process. The tightening force attenuation of high-strength bolts showed two stages: before the tension of the cable, the tensile force of bolts decays with the stress adjustment between the cable clamp and the cable. During the tension of the cable, the bolt tightening force decreases linearly with the extension of the cable. Based on the simulation results, the tightening force relaxation rate of high-strength bolts of D70 cable clamp during the process is 31.16%, and that of D110 cable clamp high-strength bolt is 31.49%, which is less than the test value, because the isotropic materials used in the FEM was simplified on the basis of the actual material, and the radial elastic modulus of the model is larger than the actual modulus. Therefore, the tightening force relaxation rate of the high-strength bolt was less at the stress adjustment stage of the cable clamp, which led to a final less relaxation rate.

Table 5. Comparison of the anti-sliding bearing capacity.

Specimen	Capacity of test/kN	Capacity of the FEM /kN	Error
D70-1	235.00	226.54	-3.60%
D70-2	220.00	226.54	2.97%
D110-1	560.00	517.10	-7.66%
D110-2	520.00	517.10	-0.56%

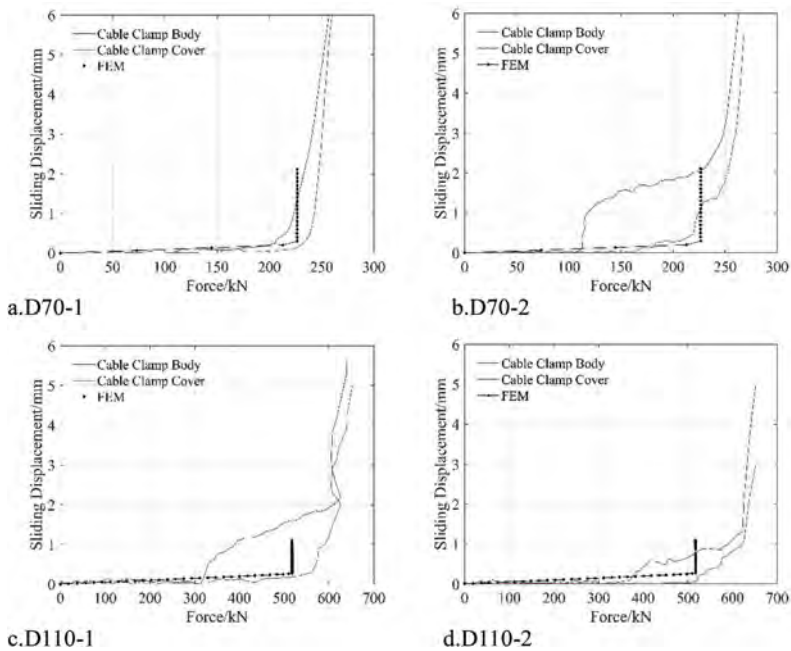

Figure 7. Comparison of simulation and anti-sliding test.

Figure 8. High-strength bolt fastening force-cable tension curve.

5 CONCLUSION

In this study, the anti-sliding tests and the FEM analysis of two kinds of cable clamps were designed and carried out, the observations and conclusions of the study were summarized as follows:

- (1) The test results showed that the cable clamps D70 and D110 at the position of the unbalanced maximum force had the anti-slip bearing capacity of 220 kN and 520 kN respectively. The maximum internal force difference between the two ends of the cable clamp is 92kN and 196kN, and the anti-sliding safety factor of the cable clamp is 2.4 and 2.7 respectively, indicating that the anti-sliding ability of the cable clamp meet the design requirements and has a certain degree of safety.
- (2) The results of the FEM analysis and anti-sliding tests were compared, which showed that the error between the test and the finite element analysis of anti-sliding bearing capacity of cable clamps is within 8.0%. The decline of bolts tightening force in the FEM and the tests

were basically consistent with each other, and the former is about 7% less. The comparison results indicated that the numerical simulation is basically consistent with the test results, and these two methods confirmed each other, which can ensure the anti-sliding ability of the cable clamps and the safety of the main structure of the project.

- (3) In order to facilitate the test, the cable clamps in the test and FEM were simplified, resulting that there were some differences in the stress state between the cable clamps of the test (also the FEM) and the actual project. In the further research, the arc-shaped cable clamps can be tested and simulated to get the corresponding relationship between the anti-slip bearing capacity of the arc-shaped cable clamp and the straight cable clamp of the same length, which is convenient for engineering design.

Lessons learned from highway tunnels inspection, analysis, assessment and refurbishment works

A. Damiani, E. Crippa & M. Rabbia
Lombardi Ingegneria s.r.l., Milan, Italy

ABSTRACT: Civil engineering infrastructures in Italy were intensively developed since the 1960s and now-adays most of existing tunnels is affected by aging and deterioration processes. To face this challenge, the main Italian motorway agency has adopted a sound approach for the assessment of more than 350 km of tunnels and for the definition of specific interventions, conceived for the defects detected during inspections. It is important to emphasize that the fact-finding phase is fundamental to identify the best solution to repair the defects. This paper illustrates the effectiveness of the adopted methodology aimed at identifying defects, considering their nature, location, extension and origins, based on visual inspections and instrumental diagnostic methods. Great efforts have been devoted to defining and developing proper interventions in order to solve critical situations, reduce impacts of deterioration, prevent the evolution of defects and fulfill functionality and safety requirements. Several repair techniques and rehabilitation schemes are presented in this paper.

1 INTRODUCTION

Starting from 2020, there has been an intensification of inspection activities in existing tunnels in Italy. The performance of the inspection of tunnels and of structural elements in general, although already envisaged by current legislation, however, was mostly delegated to the single Concessionaire who acted by adopting his own criteria and analysis, according to the law interpretation; in recent years it can be said that inspections has begun to be addressed systematically according to shared procedures and methods defined by Decrees or Standards that had the merit of better focusing and framing this activity.

In the context of this situation, it should be noted that in recent years in Italy there have unfortunately been some important collapses of structures belonging to both national roads and motorways, which in some cases have caused victims. This chain of events, if there were still any need, has led to the awareness of how much the national heritage of galleries, among other things very heterogeneous and extensive if compared to the situation in other European countries, is characterized by an average age in many cases higher than 50 years, usually considered for this type of construction. Furthermore, this figure is often accompanied by a less than optimal state of conservation exacerbated by the fact that the older tunnels do not present waterproofing systems.

This article aims at providing an examination of the activities connected to the inspections of the motorway tunnels in which Lombardi Ingegneria has taken part in the last 3 years; the main objective is to create the so-called “Zero Point” of the state of conservation of the tunnels, in order to define any interventions to make the structure safe, dictating the various priorities for action.

2 THE HIGHWAY TUNNELS INSPECTION IN ITALY

2.1 *Reference legislation*

The inspection of motorway tunnels in Italy in particular, as well as for other types of structures, is envisaged in the National Decree no. 6736-61-A1 of 19 July 1967, which foresees periodic checks as regards stability conditions of the various structures and the state of conservation in order to maintain constant efficiency. The Decree defines the characteristics of the inspection (thorough technical checks or minor inspections) and their frequency (annual or quarterly). It represents the first attempt aimed at introducing and making systematic the controls on structures and their connected elements (including foundations, slopes, etc. . .). The Decree also establishes the minimum frequency of inspections, starting with in-depth inspections to be performed at least once a year, up to not in-depth inspections to be scheduled at least quarterly. For several decades, this regulatory reference represented the only one to provide the minimum guidelines for the surveillance of road infrastructure.

In recent years, however, other Decrees and Guidelines has been issued focusing on the supervision of tunnels and related activities, as briefly summarized below. The Manual issued by Ministry of Transportation on 05/26/2020, identifies and clarifies the key points of the visual inspection, in particular, with regard to the so-called “Point Zero” inspection. The Supplementary Decree issued on 07/07/2020, has introduced the possibility of investigating the condition of the tunnel linings using methods other than direct vision, provided that the methods and technologies used prove effective.

Furthermore, the Decree no. 152 of 04/09/2021, provides guidelines for the preparation of the “surveillance plan” for tunnels that have already been inspected. This plan must take into account the results of the inspections and the interventions carried out. Lastly, the new ministerial guidelines for existing road and motorway tunnels were approved, in August 2022. These guidelines are a tool for classifying existing tunnels according to “attention classes”, on the basis of which investigations, inspections, monitoring activities and interventions can be planned. Their purpose is in fact to ensure homogeneity of risk classification and in the management, assessment and monitoring of existing tunnels along the road and motorway network.

3 INVESTIGATING THE LINING CONDITION

Lombardi Ingegneria was commissioned to carry out detailed inspections of the final lining of all the tunnels of one of the main motorway concessionaires operating in Italy.

The main objective of the activity is to create the so-called “Point Zero” of the state of conservation of the tunnels, in order to define interventions, dictating the different priorities for action.

Following the Client’s request to propose a new inspection method compared to what had been done so far, the adoption of the inspection manual approved by the “Center d’Etude des Tunnels” (CETU) in 2005, already applied in Italy for the Mont Blanc tunnel section, was proposed. The manual represents a consolidated reference because it has been used for years abroad and complies with the requirements of the Italian Standards n. 6736/61 of 19.7.1967 and n. 34233 of 25.02.1991.

The proposed system considers the deterioration related to both the structure and the presence of water and is based on two documents published in the last revision in 2015, which constitute the Guidelines (Book 1: from disorder to analysis, from analysis to rating and Book 2: Catalogue of deteriorations).

The CETU guidelines propose a catalogue of 47 defects, divided into 12 types. All defects found during an inspection are traced back to these types and are classified according to their nature (structural or water presence) and their severity, in accordance with the “IQA” scheme, “Image qualité des ouvrages d’art”, which, as defined in the name, provides an insight into the health of the structure. With reference to the civil part, the IQOA Classification takes into consideration cracking defects, damage and alteration in general, identifying them with

an alphanumeric code that describes the severity/dangerousness, in relation to which the rehabilitation can be planned over time, as far as the safety of users is concerned. The same approach is followed for water-related defects.

The activity mainly concerned the tunnels built between 1930 and 1979, characterized by the absence of waterproofing behind the final lining. The aims are:

- to define the inspection methods for the tunnels and the classification of their defects;
- to define the types of intervention for the most frequent maintenance work;
- to analyze the results of the georadar surveys, in order to obtain the thickness of the concrete, the presence of voids behind the lining, the presence of rebars and defects; these results will form the database, together with the design and construction documentation available in the client's archives;
- to carry out inspection after dismantling of the corrugated sheets present in the crowning and on the walls, thorough visual inspection of the lining, carrying out instrumental and diagnostic investigations deemed necessary (georadar and video endoscopies; tests on concrete samples; flat jacks testing; ultrasonic tomography; doorstopper tests. . .) and coordinating the execution of the surface demolition of unstable concrete;
- to define the types of rehabilitation works for the defects detected.

The working methodology is composed in detail of the following phases:

- general knowledge phase: retrieval and analysis of available historical documentation (executive project, as-built, results of previous inspections);
- instrumental diagnostic phase, georadar execution; Phase I: 3 or 5 longitudinal profiles depending on the section of the tunnel (2-lane or 3-lane respectively) and Phase II: in-depth analysis with localized georadar profiles on the basis of the results of visual and sound inspections (with hammer percussion), on the first phase georadar, direct checks and calibrations with video endoscopies and concrete sampling (n° 3 samples every 50m);
- inspection phase with visual and sound inspection (with hammer percussion), detection of defects (with relative definition of the class/grade) and detection of any deterioration of previous refurbishment;
- intervention phase with definition of the typological interventions to be implemented and definition of any areas to be monitored.

Figure 1. Inspection of the tunnel lining with MEWP.

The first essential step of the activity is to fully know the consistency of the existing tunnel. It is therefore essential to proceed first with the recovery of all available historical documentation. This may consist of design documentations and final accounting of the original works, including reports and drawings, as well as projects and accounting of rehabilitation carried out during the tunnel's operating life. To this documentation it is useful to add, if available, the historical archive of inspections carried out to date, which, containing the identification of defects, represents an important indication of the evolution that they have undergone over time.

All the information collected during this phase must then be verified in terms of truthfulness and completeness during the subsequent inspection phase and must finally form a specific set up by the Italian Ministry of Transport.

The inspection of “Point Zero”, as previously mentioned, is detailed with reference to the final lining (walls, crown) and includes: a) visual and auditory inspection of critical areas of the surface of the lining, with particular attention to areas that show alterations or cracks that could cause concrete surface detach; b) identification of cracks on the lining with vertical, horizontal, diagonal direction, with indication of their width; c) traces of salts, encrustations or deposits; d) identification of efflorescence; e) identification of water leaks; f) detection of surface detachments and their dimensions; g) detection of the presence of cortical voids and their dimensions; h) detection of visible local reinforcement; etc.

At the end of the inspection, the tunnel is open to traffic, except in case of defects that compromise the safety of users, classified with the letter “S” in accordance with the CETU Guidelines. If there is an “S” defect, a technical design team will determine the type of temporary intervention to be implemented so that the tunnel opened to traffic as soon as possible, compatibly with the rehabilitation measures to be implemented.

This is followed by a “back office”, during which the investigation will be reproduced in a graphic document and in a report, in order to present, as accurately as possible, the state of the structure at the time of the inspection. All data is then collected in tabular form, so as to constitute a “database” that summarizes the state of conservation of each tunnel and that will represent the knowledge base for future inspections and maintenance.

4 REFURBISHMENT WORKS

The activity involved more than 90 tunnels. The maintenance work are identified according to the type of defect to be worked on. The range of maintenance work can vary from simple steel mesh fixed with dowels to the tunnel lining to contain the detachment of the concrete aggregates to bolting. Maintenance works are also foreseen in the presence of water infiltrations inside the tunnel, for the treatment of cracks in the thickness of the final concrete lining and for the filling of cavities. For particularly severe conditions, in the presence of diffuse and open cracks, with pushing masses and where the bolts did not guarantee adequate performance in the geomechanical context, under-arch interventions with ribs and shotcrete were foreseen. Where, on the other hand, the concrete of the lining was particularly poor, in terms of mechanical characteristics, and with unsuitable residual thicknesses, the refurbishment of the lining was carried out by using self-supporting prefabricated formworks integrated in the new lining, after controlled demolition of the existing one. All maintenance works are subjected to a validation process by the Politecnico di Torino, identified as external reviewers.

An examination of the main types of maintenance works is given in the following paragraphs. For their execution, a discriminating factor to be taken into account is the possibility of carrying out the works in the absence or in the presence of traffic; this aspect is very delicate due to the considerable impact that any type of intervention to be carried out may have on vehicular traffic, especially if inside a tunnel.

The execution of the maintenance works in the absence of traffic represents the most desirable solution as it allows the workers to have no particular constraints on site operations, for example, the possibility of using the “jumbo” for the installation of bolts otherwise not be possible with vehicular traffic. On the other hand, the closure of one carriageway leads to traffic being diverted onto the opposite carriageway, with inevitable traffic delays and queues of vehicles. Depending on the section of motorway affected by the works, the closure times were in any case a constraint that the workers had to take into account. Given the wide variety of types of defects found, it is necessary to define the appropriate type of maintenance works for the resolution of each defect. Clearly these are the culmination of the entire activity. Furthermore, in order to make the intervention more targeted and effective, the root causes of the defect itself should be identified. In fact, the defect can also be classified according to the dominant cause that generated it with reference to fundamental influencing factors (defects) such as: Site and Construction. As regards the

Site, the causes of defects are: water action, environment (freeze-thaw, water chemistry, etc). Regarding the Construction factors, these are: design, execution and material. Site-related defects are those that affect an element or part of the structure and that occur gradually or rapidly, denoting a change. Construction defects, on the other hand, are the result of faulty workmanship.

The following table shows the main investigation techniques for achieving the above goals.

Table 1. Instrumental diagnostic methods and their aims.

AIMS		LASER SCANNER	GEORADAR	VIDEO- ENDOSCOPY	CONCRETE SAMPLING	PULL-OUT	FLAT-JACKS SIMPLE	SEISMIC TOMOGRAPHY
Geometrical and constructional characteristics of the lining	a) <i>Geometry</i>	X		X				
	b) <i>Lining thickness</i>			X	X			
	c) <i>Presence of reinforcement and evaluation of the concrete cover</i>			X				
	d) <i>Presence and position of steel supporting beams (single and/or double)</i>			X				
	e) <i>Cracks</i>	X						
Criticality in the lining	f) <i>Water and humidity zones</i>	X						
	g)			X	X			
	h)			X				X
	i)			X	X			X
	j)			X	X			
	Determine/verify the concrete mechanical characteristics of the full thickness of the lining					X		
Determine/verify the mechanical characteristics of the concrete in the surface part of the lining for the verification of the superstructure foundations (plants, protective nets, etc.)						X		
Define the stress state of the lining and possibly monitor critical situations							X	
Verify the state of consistency of the lining covered by protective nets			X	X		X		

4.1 *Shallow interventions*

4.1.1 *Steel and FRP nets*

This solution is typically applied on surface deteriorations up to 5 cm of thickness, on concrete lining, with or without waterproofing, and can also be applied in presence of cracks. After any preliminary scarification of the surface, light protective nets (e.g. welded stainless steel mesh ϕ 1.6 mm, 12.7x12.7 mm) are applied with overlapping heavy protective nets (e.g. welded stainless steel mesh ϕ 5 mm, 50x50 mm). These nets are fixed to the tunnel intrados by means of steel dowels. The steel mesh can be replaced by fiberglass mesh.

4.1.2 *Treatment of shallow cavities*

It is applied on deteriorations in the absence of water on concrete coverings, with/without waterproofing, both in rock and soils. The work involves the preliminary removal of any unstable portions, followed by restoration of the thickness with high-strength gunite reinforced with electrowelded mesh. After the final smoothing, protective stainless-steel mesh is laid. The joint between the gunite and the existing cladding is made by laying steel dowels. In presence of water, radial drains must be provided in order to set up a water collection system. These drains, made of PVC pipes, must have a blind section and a windowed section in order to intercept the water at the top of the tunnel without the risk of dispersing it inside any discontinuity in the thickness of the concrete.

4.1.3 Replacement of reinforcement bars

In case of deterioration of the reinforcement and concrete up to 20 cm depth and in the absence of water, with/without waterproofing, with prior scarification of the concrete, the interventions can be provided where the reinforcement is in good condition and only superficially rusted, removal of the superficial rust layer from the iron and application of protective products based on two-component anti-corrosive cement mortar and in areas where the reinforcement is intensely degraded, the steel bars must be replaced. The degraded concrete area will be replaced with reinforced gunite. The final phase involves the application of stainless-steel mesh and anchors. As an alternative to stainless steel mesh, a panel system composed of layers of high-strength GFRB grid may be used.

Figure 2. Example of treatment of shallow cavities.

4.1.4 Leakage collection

The collection of diffuse or concentrated water from the concrete lining, in the absence of surface deterioration, can be achieved by the installation of stainless steel corrugated sheets. The plates are fixed to the tunnel intrados by means of steel dowels. They are typically interrupted at the footings and convey water to drainage gutters. The drains normally consist of micro-slotted PVC pipes covered with non-woven fabric; the drains have both a blind and a windowed cross section in order to intercept the water at the tunnel top without the risk of dispersing it within the discontinuities in the thickness of the concrete.

4.2 Deep interventions

4.2.1 Interventions in presence of deep detachments (20-40 cm)

The intervention is applied in the presence of deep detachments (between 20-40 cm) in the absence of water, on concrete linings, without waterproofing, and in rock masses. Initially, the potentially unstable portions are removed, and the surface regularized; then connectors are installed and anchored into the lining. The missing thickness is then restored with high-strength gunite, reinforced with electrowelded mesh. A stainless-steel mesh will then be applied, joined to the lining by means of self-drilling radial bolts. The bolting operation thus makes it possible to ensure complete cooperation between the existing lining and the supplementary casting. If, during the drilling of the radial bolting, significant water leaks are found, the intervention must include the installation of the corrugated sheets described above.

4.2.2 Treatment of cavities at the ground-lining interface

In presence of significant voids within the linings (min. residual thickness > 30 cm) due to lack of filling during casting and possible deep cavities in absence of diffuse or concentrated water, the following intervention can be envisaged. Initially, the unstable portions are removed, followed by radial bolting with Swellex type bolts, length to be defined according to the geometry of the cavity at the contour, arranged with mesh according to the specific case. In the presence of a cavity at the boundary, a pumping phase will be carried out with material such as cemented expanded clay, until the cavity above is completely filled. A final bolting mesh will be created executing self-drilling bolts and drilling radial drains made in order to intercept the

water at the top of the tunnel. Finally, stainless steel corrugated sheets will be laid on the peripheral sections where the drains are located.

Figure 3. Example of treatment of cavities at the ground-lining interface.

4.2.3 Structural arches at the intrados

This consists of protection in the presence of open and persistent cracks on concrete linings, including those associated with significant stress level, both in rock and soft soil, in the presence of diffuse or concentrated water. The specifications, such as the type of profile, the spacing and the construction details will have to be defined on a case-by-case basis during the design of the intervention, according to the context found in the tunnel. The intervention, in general, is made of positioning of the steel supporting beams and execution of the redirective profile. The absence of interference between the dimensions of the new intervention and the space-proofing must first be verified by means of detailed topographical surveys along the stretch concerned.

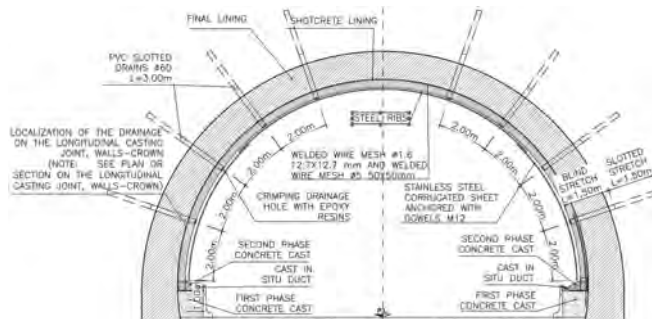

Figure 4. Structural arches at the intrados.

4.2.4 Lining demolition and reconstruction

The intervention consists in the demolition, in sections, and reconstruction of the arch of the lining or of the entire lining. The intervention, in relation to the geological, geomechanical and hydrogeological conditions, requires a preliminary phase of consolidation of the cavity, carried out from inside the tunnel. Once the consolidation phase has been completed, demolition must proceed according to precise design geometries, which will have to be detailed on a case-by-case basis in relation to the number of lanes, geological boundaries conditions and defects in the concrete. If local instability is found during horizontal cutting operations, work must be stopped and all safety procedures implemented. Once the milling phase has been completed, it may be necessary to even out the surface with a layer of shotcrete before laying the waterproofing. This is followed by the laying of the reinforcements, the precast elements (or the formwork) and the concrete casting.

Figure 5. Examples of lining reconstruction.

4.3 Rehabilitation works in presence of traffic

In order to carry out the reconstruction or the repair of the lining in presence of traffic and at the same time reduce the inconvenience of a long closure of the tunnel, a reinforced concrete protection shield is used in some cases, to keep the tunnel in operation. The shield allows the normal flow of motorway traffic from the construction site in conditions of maximum safety, separating and protecting it from falling material during the various phases of execution. The reinforced concrete protective shield has the purposes to support for the passage of construction site vehicles over the shield, to protect for the vehicles on the road during repair work, to delimit the roadway and to guarantee the workers safety in the personnel paths adjacent to the roadway.

Figure 6. Concrete protection shield layout.

5 CONCLUSIONS

The tunnel assessment experience described in this paper was a national novelty in terms of inspections. Over the months, it has undergone refinements in the procedures for carrying out inspections, also in definition the types of intervention to be adopted on the various types of defects. Other improvements will emerge in the future, e.g. with reference to the adoption of tablets during the inspection phase, connected to the cloud and with pre-loaded information already available, lightening the amount of work related to the extrapolation of statistical data (types, dimensions, location, etc. . .). This will also allow a better understand the evolution of defects over time and the identification of the need for the refurbishment of the tunnels.

Other improvements already underway concern the use of Artificial Intelligence for defect recognition and evaluation over time. Lombardi Ingegneria, already in 2020, started specific research and studies with some leading University Centres for its application in road infrastructure.

Deterministic and probabilistic damage calculation of offshore wind turbines considering the low-frequency fatigue dynamics

N. Sadeghi, P. D'Antuono, K. Robbelein, N. Noppe, W. Weijtjens & C. Devriendt
Offshore Wind Infrastructure-lab (OWI-lab) | Vrije Universiteit Brussel (VUB), Brussels, Belgium

ABSTRACT: With the ultimate goal of extending the lifetime of offshore wind turbines, applying monitoring data to develop fatigue damage calculations is of great interest. However, uncertainty in recorded loads and potential underestimation must be considered. This study analyzed the interface loads of a wind turbine in the North Sea using three years of strain and SCADA (Supervisory Control And Data Acquisition) data to predict lifetimes deterministically and probabilistically. The deterministic method calculated short-term damages through Rainflow cycle-counting and Palmgren-Miner rule. While the first probabilistic method additionally used bootstrapping to obtain confidence intervals, the second, binned short-term damages in wind speed groups. As the chronological order of load cycles is lost by constructing datasets from bootstrapping or binning, to account for the effect of Low-Frequency Fatigue Dynamics (LFFD), an amplifier factor from (Sadeghi et al., 2022) was applied to the total damage. Finally, the deterministic/probabilistic methods with/without LFFD impact were compared.

1 INTRODUCTION

Offshore wind turbines are fatigue-driven assets that are aging and beginning to reach their design lifetime. To make decisions regarding a future lifetime extension of the turbine and its foundation, a precise assessment of fatigue damage and lifetime is desired for each wind turbine. During design, each wind turbine's fatigue is calculated using numerical simulations. (Ziegler & Muskulus, 2016) and (Bouty et al., 2017), for instance, examined these simulation-based fatigue assessments for OWT substructures. However, the outcomes of these simulations are subject to uncertainty due to the limited number of simulations conducted and the modeling errors. Therefore, there may be a significant discrepancy between the conservative design assumptions and the actual performance of that turbine, allowing us to extend the lifetime (Byrne et al., 2015) (Ziegler, et al., 2019).

The new recommendation (DNVGL-RP-C203, 2019) advises using measured data when available since it is an essential complement to simulation-based assessments, diminishes numerical simulation uncertainty, and provides a more accurate damage calculation that is turbine-specific. In the current data-based practices, the Rainflow cycle counting (ASTM, 2017) and the Palmgren-Miner rule (Palmgren, 1924) (Miner, 1945) are utilized to estimate the damage. However, applying the data-based approach also has inherent uncertainties (Zwick & Muskulus, 2015) (Hafele et al., 2018). Therefore, the long-term extrapolated damages can vary depending on different assumptions that we make (e.g., uncertainty in the recorded loads or the limited measurements).

Recently, several researchers tried to use different sampling techniques, such as Monte Carlo (Hübler et al., 2019) or bootstrapping (Hübler et al., 2018) to consider the uncertainty of damage calculations caused by insufficient data. Using probabilistic methodologies, we can consider some uncertainties in our data-based evaluation and provide a Confidence Interval for the lifetime we ultimately compute. (Petrovska et al., 2020) and (Marsh, 2016) estimated the uncertainty of the extrapolation by bootstrapping, a statistical resampling method. In this study, sample-based bootstrapping with replacements is also introduced to the current

measurement-based process to augment the limited recorded damages and decrease the results' degree of uncertainty.

In a higher step, binning the data can also improve the lifetime estimation. For extrapolation in time, (Hübler & Rolfes, 2022) compared different approaches and concluded that binning extrapolation has the lowest percentage errors of predicted damage values compared to actual damage values among all extrapolation methods. It also showed that using environmental and operational conditions (EOCs), i.e., SCADA (Supervisory Control And Data Acquisition) data, is beneficial compared to a deterministic extrapolation based on pure strain data. Some researchers focused on the correlations of the uncertainty of the fatigue damage calculation with EOCs by applying binning (Petrovska et al., 2020) (Marsh, 2016), and usually, bootstrapping is used to calculate the uncertainty. Some possible parameters for binning the damages are wind speed, turbulence intensity, wind direction, or wave height (Hübler et al., 2018) (Noppe et al., 2020) (Pacheco et al., 2022). According to (Hübler et al., 2018), if the recorded damages are divided up into wind speed bins for their data type, the most accurate lifespan estimates are feasible. Therefore, in this study, we solely concentrate on wind speed binning as a starting point. The probability of occurrence of each bin can be either from the turbine's recorded wind speeds (Mai et al., 2019) or the theoretical or design wind speed distributions.

The binning method is founded on the concept that varying environmental and operational circumstances are the primary cause of variances in fatigue damage. Therefore, it is not required to have lifelong recorded fatigue damage. It is sufficient to be aware of the EOCs over a lifetime after the relationship between EOCs and fatigue damage has been established. The probability of EOCs is typically known for the turbine's life, which is the basis for fatigue design. Moreover, they can be easily validated, even in the absence of fatigue data, as relevant parameters are included in the SCADA data, e.g., wind speed. Therefore, the main problem is determining how fatigue damage and EOCs relate. Techniques like statistical analysis or machine learning (Santos et al., 2022) (Dimitrov & Natarajan, 2019) can be used to determine this correlation (Hübler & Rolfes, 2022). Binning is the simplest choice that can consider this correlation. Based on (Hübler et al., 2018), for each wind speed bin, the occurrence probability should be based on data rather than design or theoretical documents. Based on (Hübler & Rolfes, 2022), since the enhancements of grouping data into operational cases are not significant, it is adequate for many purposes to omit clustering the data based on operating circumstances. In this study, we followed the approach applied by (Noppe et al., 2020) to consider the uncertainties of our extrapolation, based on bootstrapping and binning on wind speeds from as-measured distribution.

On the other hand, another point that should be considered is the full effect of loads. The short recorded strain measurements in ten-minute windows cannot capture all physical processes occurring at very low frequencies, which may have periods of several days, e.g., the slow variation of windspeed over several days. These incomplete cycles are represented as so-called residual or half-cycles. As the half-cycles do not fully reflect the total size of a sizeable slow-varying cycle, the use of half-cycles does result in non-conservative life estimates. Concatenating the segmented time series in the time window of interest, e.g., joining 52596 10-minute measurements into a single dataset of one year before cycle-counting, is the most obvious way to address this problem. But this choice requires much calculation time, memory, and preferably uninterrupted measurements. To resolve, (Pacheco et al., 2022) considered 24-h long strain time series and found an 11% increase in damage compared to when they used 10-min long strain windows. (Marsh et al., 2016) proposed a technique that considerably saves calculation time without sacrificing accuracy in the final result, and we implemented it in our recent work (Sadeghi et al., 2022). But this method requires the cycle-counted histograms to remain chronologically stored. However, during binning or bootstrapping, this chronological order of stress cycles (cycle count histograms) is lost, so this technique cannot be used in this work to resolve the low-frequency cycles. Therefore, we followed the outcomes of our earlier research to account for the Low-Frequency Fatigue Dynamics (LFFD) effect (Sadeghi et al., 2022) by applying an amplifier factor to the final calculated damage without the need to restart our analysis from the histograms.

This work aims to add more confidence to our analysis, for which we should consider the uncertainties and the full effect of loads. We study the common (deterministic) method's confidence level to predict the lifetime and check the refinements to that by applying binning. We

select different data window sizes to verify if the methods give trustable results from short measurement durations. The LFFD factor would be applied in each method to observe the effect of low-frequency cycles.

2 MEASUREMENT SETUP

OWI-lab received a dataset with three years' worth of data, including the strain and SCADA 10-min subsets from an offshore wind turbine (<5MW installed on a monopile) located in the North Sea. The turbine is equipped with six strain gauges at the tower-transition piece interface. These sensors are utilized to determine bending moments in the fore-aft (FA) and side-side (SS) directions using the nacelle orientation of the turbine from the SCADA data (The mean yaw angle and mean wind speed are among the SCADA parameters provided). (Sadeghi et al., 2022) explains how sensors' strain measurements are converted to the FA and SS bending moments.

For each 10-min interval, the accumulated short-term damage was calculated based on the classical approach using rainflow counting and Miner's rule, as given by (1), where D is the accumulated fatigue damage, n_i is the occurred number of cycles, and N_i is the number of cycles to failure, given for every stress range by the chosen S-N curve.

$$D = \sum_{i=1}^k \frac{n_i}{N_i} \leq 1 \tag{1}$$

Therefore, a dataset of about 157000 (3 years) 10-min FA bending moments is used in this study to compare different methods. The same approach can be applied to any other parameter (e.g., SS bending moment or heading strain).

3 LONG-TERM DAMAGE METHODOLOGIES

Short-term (10 min) damages must be calculated in the first step to analyze the damage extrapolation in time. As the short-term damage calculation is a relatively standardized procedure and is not the focus of this work, it is not explained in detail. A thorough explanation of the standard short-term damage calculation procedure is given by (Hübler et al., 2018). We

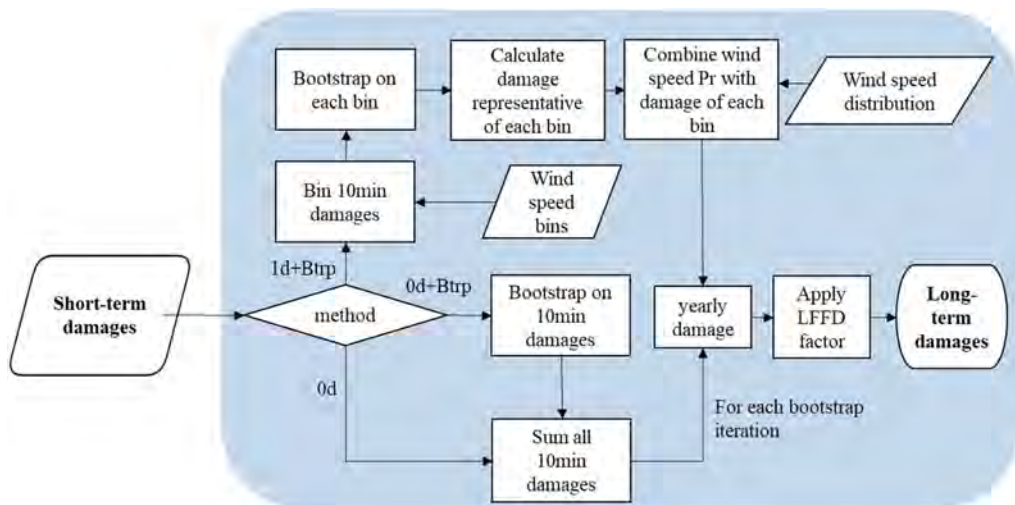

Figure 1. Flowchart of the long-term damage calculation methodologies.

could have several options to reach the yearly damages from these short-term damages. All short-term damages could be used as one pool (as done for 0d) or can be sorted into one or more environmental and operational conditions (EOCs) bins (xd). The number and type of considered EOCs and the sizes of the bins can differ.

In the following flowchart of Figure 1, three different methods to reach long-term damage are mentioned. Among these methods, 0d is deterministic, and the other two methods (0d+Btrp and 1d+Btrp) are probabilistic. In the following subsections, each method is explained in detail.

3.1 *Deterministic approach (0d)*

In this method, we directly sum the short-term damages of three years and apply a data completeness factor to compensate for the missing short-term damages (calculated based on the number of missing points of the three years). From this sum, the average yearly damage is obtained without considering the uncertainties of the limited damages or the EOCs.

3.2 *Probabilistic approaches*

To consider the uncertainties of the limited recorded damages, by using the bootstrapping sampling method, we have two options: bootstrapping on the damage pool (0d+Btrp) or the binned damages (1d+Btrp). In these methods, we apply proper factors to reach the equivalent annual damage. These factors will be explained for each method in the following subsections.

In statistics, bootstrapping (Efron, 1992) is frequently used to estimate an unknown distribution based on limited known samples. In the context of wind energy, bootstrapping was already applied, for example, in the presence of limited wind data (Gass et al., 2011). The general concept of bootstrapping relies on random sampling with replacement, i.e., the same measurement can be picked more than once. For this study, bootstrapping is used to estimate the unknown empirical damage distribution in the collected damage data, and the resampling is repeated multiple times to give an estimate of the damage distribution. In the following, the two probabilistic approaches are explained.

3.2.1 *Bootstrapping method without binning (0d+Btrp)*

In this method, we randomly select with replacement (a datapoint can be selected more than once) a sample with the sample size of the measurement length (the number of recorded damages in that window) from the 10min damage pool. The size of the damage pool is selected as one year and three years to find the effect of increasing the data size on the lifetime uncertainty. The methods are named '0d+Btrp 1y', and '0d+Btrp 3y', respectively. For Bootstrapping, the resample size should be similar to the sample size. Otherwise, the distribution that the Bootstrapping gives for the sample mean, is not the true distribution. So, for example, for '0d+Btrp 1y' method, the bootstrap resample size is less than the number of 10min intervals in a year, since there is data gap in the measurement. We sum all the selected damages in the bootstrap sample. To convert the '0d+Btrp 1y' sum to a 'complete' yearly damage, we use the data completeness factor of the first year, while for '0d+Btrp 3y', we follow the same factor as the (0d) approach. This process is repeated 10000 times to reach an acceptable spread in the final calculated annual damages. Then for each yearly damage, we extrapolate in time to find the lifetime. The lifetime is calculated by linear extrapolation, which is the inverse of the annual damage.

3.2.2 *Binning and bootstrapping method (1d+Btrp)*

For this method, binning is used to consider the environmental uncertainties, and bootstrapping is applied to each bin to estimate the unknown empirical damage distribution by only using the available damage values. For this study, we only focused on the wind speed because, as explained by (Hübler et al., 2018), if the damage data is divided into wind speed bins, the most accurate lifetime estimates for the current data are made possible. The bin size is selected as two m/s to comply with the design. The binning and bootstrapping procedure results in damage scatter in each bin. This spread will be reduced to one value based on the chosen metric. The choice of the statistical damage parameter is quite essential. E.g., for each bin, the

mean value of all bootstrapped damage values can be calculated. However, a high percentile (e.g., the 90th) can be used to be more conservative. The mean (as advised in (Hübler et al., 2018)) values are selected for this study. The bootstrap resampling size for each bin equals the number of measurements in that bin. Then from each bootstrap iteration, we choose the mean damage of the resampled bin.

Bins for which the specific combination of EOCs might not occur during the monitoring campaign (empty bins), especially bins of higher dimension, need to be filled with well-considered values. For instance, each empty bin can be filled with the maximum value found in the neighboring bins. Because we had a relatively long measurement, we had no empty bins, although some bins with high speeds had few numbers of data points (around 3-4). So for this work, we did not apply a bin-filling method. In case it is needed, (Hübler et al., 2018) and (Pacheco et al., 2022) compared different ways of bin filling. The filling might be data-driven or based on design documents, according to the availability of the necessary information (Noppe et al., 2020).

Finally, each bin has a certain occurrence probability ($Pr(j)$). $Pr(j)$ can either be determined using measurement data (e.g., several years of SCADA data) or given in design documents or theoretical relations. On the one hand, probabilities given in theoretical documents are typically based on long-term data (20 years and more), making them more reliable. On the other hand, even if a site-specific OWT design is conducted, the EOC's distributions are typically not derived for the particular site of the considered turbine, which might lead to biased results. In this work, we use the three-year measured wind speed distributions. The measured distributions can be either the as-measured probabilities or the fitted distribution to the as-measured wind speeds. We used the as-measured histograms. Then with Equation 2, we can apply the wind speed probability of occurrence to the damage of bins ($D(j)$). This analysis repeats this procedure 10000 times for every bin, resulting in 10000 values for the estimated yearly damage.

$$yearly\ damage = \sum_{j=0}^{bin\ number} Pr(j) \times D(j), \quad (2)$$

where $Pr(j)$ is the probability of occurrence of bin j , and $D(j)$ is the representative year-size damage of bin j . Year-size damage means if we consider the average value of each bin, we multiply it by 52596 (number of 10-min damages in a year) to have the damage in a yearly order of magnitude and not in the 10-min scale.

Applying the LFFD factor and the damage linear extrapolation in time are the last steps shared between all the previously mentioned methods. We used the LFFD factor of 1.09 for FA considering the SN curve of 'DNV-D-W' with the slope of $m=3$ and in free corrosion condition. This factor was obtained by accumulating three years of FA damage with and without considering the LFFD effect (Sadeghi et al., 2022). The predicted lifetime L (in years) is the inverse of the yearly damage ($L = 1/yearly\ damage$). The resulting distributions from the bootstrapping can then be plotted for each method, giving a histogram of the resulting extrapolated lifetime's mean.

4 CASE STUDY

We applied different methods to our measurements, starting from the standard deterministic approach to the binning process to increase our confidence in the predicted lifetime. As mentioned in the previous section, in the 1d binning method, the short-term damages are spread in each wind speed bin. Figure 2 shows boxplots of the FA binned damages before bootstrapping and the mean of each bin (blue markers). For confidentiality, binned damages (pink dots) are normalized to the maximum 10min damage. By comparing the average and the 75p (the top end of boxplots), we see that although the 75p damage is more conservative for the middle bins, there is no significant difference between the average and 75p values for the lowest and highest bins. As the mean and median do not align, the spread in each bin is not gaussian. Based on the central limit theorem, regardless of the distribution of damages in each bin, after enough bootstrap iterations, the distribution of the mean of each bin would be

gaussian and enables having the desired statistics. Therefore to have the confidence intervals of the selected parameter (mean), for this study, we achieve the distribution of the mean in each bin by performing bootstrapping. This plot shows that despite the spread in the bins, there is a clear relationship between wind speed and damage. So, grouping damages into wind speed bins should at least consider part of the EC uncertainties.

Figure 2. Boxplots show normalized FA damages from a three-year damage pool before bootstrapping on each bin. Blue markers are the average of each bin.

Figure 3 shows the result of the first method (deterministic, 0d, after LFFD) (in black) as the reference. We considered the three-year deterministic lifetime as “reality” because that is the closest available value to reality. The results from all processes are normalized to the lifetime from 0d after LFFD. The deterministic lifetimes of the 0d approach before and after applying the LFFD factor are compared with the distribution of the lifetimes’ mean from 10000 iterations of bootstrapping for each probabilistic method.

The red vertical line indicates the lifetime from 0d before LFFD. The LFFD effect decreases the deterministically predicted lifetime by 8%, which is still quite limited because of the choice of the SN curve (Sadeghi et al., 2022). The two blue histograms show the 0d approaches with bootstrapping after LFFD. From right to left, the data size was increased from one year to three years. It shows that increasing the data size changes the average value of 0d+btrp methods by 15%. So, if we only had one year of available measurement, we would predict a lifetime that its distribution does not even include the deterministic value. The problem with the 0d approach with a limited dataset is that we do not have control over the conditions seen during that period and, thus, the conditions used to extrapolate. The fact that the predicted lifetime decreased by adding more data is somehow a coincidence, as the third year had harsh EOCs, but if the order of the first and third years was reversed, then the result would increase with the more data we added. Although 0d+bootstrapping gives probabilistic insights, it does not provide the desired precision in case of limited data.

The close result of 0d and 0d+3y bootstrapping shows that bootstrapping does not change the final result if the damage pool is similar to the deterministic pool. It gives the 95% confidence interval of the deterministic mean, which means we are 95% sure that the average life would be in the range (0.995-1.005), 0.5% off the deterministic lifetime. We used binning to address the issue of the 0d method regarding the limited data. So, in such cases, using longer available SCADA data will yield a better lifetime prediction. The green histograms show the 1d method from one and three-year damage pools. The comparison of ‘0d+Btrp 1y’ and ‘1d 1y’ shows that binning improves the results by almost 7% (closer to the deterministic value) because in the 1d approach, we also consider wind speed distribution. Although the error of the lifetime prediction based on the limited measurement is better when we use binning, we still have a significant error (The “1d 1y” method is around 7% far from the 0d from three years), which means that the binning should be improved to consider other EOC uncertainties as well.

Regarding the distributions, the 0d+Btrp histograms are wider than the 1d results. The reason is that 1d binning also considers the uncertainty of the wind speed, so the result is less scattered due to the omitted uncertainty from wind speed. In both 0d and 1d methods, when we increase the damage pool size from one year to three years, the distributions become narrower because by increasing the measurement data, we decrease the uncertainty from the limited measurement, and therefore, we have less spread in the distribution.

Figure 3. Histograms of the means of 10000 (bootstrap iterations) lifetimes for each probabilistic method with LFFD + deterministic (0d) value (before and after LFFD).

5 CONCLUSIONS AND FUTURE WORK

In this contribution, we used different deterministic and probabilistic approaches to compare their long-term extrapolation to a lifetime and their corresponding uncertainty. In the deterministic method (0d), we summed the damages. In the probabilistic approaches, we used bootstrapping (0d+btrp) or binning and bootstrapping (1d). Comparing the results of 0d from three years of data without and with bootstrapping shows the distribution of the 0d mean lifetime. By selecting different data sizes (1 and 3 years) for the 0d+btrp method, we showed that increasing the data size affects the results of this method, which is not desirable, as one year of data should be enough to have a reliable long-term prediction (Hübler & Rolfes, 2022). 1d binning using the wind speed bins results in a better extrapolation in case of limited measurements, compared to bootstrapping without binning, and in general, 1d gives a narrower bound compared with 0d+Btrp. The improvement is that 1d binning also considers the wind speed’s uncertainty. When we increase the damage pool size in either the 0d or 1d methods from one year to three years, the distributions in both cases become narrower because the increased measurement data reduces the uncertainty resulting from the limited measurement, which results in a smaller spread in the distribution. Although 1d binning seems a better method than 0d+Btrp, it still can be improved.

Comparing the deterministic lifetimes before and after applying the LFFD factor, a difference of 8% of the lifetime was observed for the under-study turbine, under the corrosion-free condition (SN curve with m=3), and for a critical weld.

All turbine operational cases (producing, non-operating, and events) were considered together in one group for this work. So in future studies, to obtain the full effect of EOCs, in addition to wind speed, other environmental and operational conditions will be used as binning dimensions. A series of statistical criteria will be introduced to determine the required minimum number of data points in each bin and evaluate the binning quality and the binned data. We only considered FA damages to compare the methodologies, but we can use the damages in the critical heading for a realistic lifetime calculation.

ABSTRACT: Construction is often solely associated with the Permanent Works (PW) that need to be constructed, leaving behind all those activities that are necessary to support the construction of PW. These activities fall into the definition of Temporary Works (TW), representing a significant part of any construction project, sometimes 50% or more of the construction's cost. Because of its significant impact on the construction process, we think that TW could be a particularly valuable use case to study the implementation of Circular Construction (CC) approaches related to designing and reusing materials and components in the TW process. Reuse practices may already take place on many construction sites, but currently, there are no standard or Circular-Economy-centric approaches. As a first exploration of the suitability of TW as a starting point to implement CC approaches, this paper introduces a high-level framework defining a system of three core tasks and technologies central to enabling Temporary Works' Circular-ity: data collection standards, data capturing methods, and a digital TW trading platform.

1 INTRODUCTION

1.1 *Scarcity of materials in the construction sector*

The construction industry is the largest consumer of raw materials, with civil construction responsible for 60% of the raw materials extracted from our planet (Zabalza Bribián et al., 2011). In the next decades, the demand for natural resources will increasingly rise due to the expected population growth, leading to increasing resource extraction and waste production. Therefore the main challenge in future will be to deal with the upcoming waste, as well as the supply of sufficient land, material and natural resources. To tackle this upcoming global problem, a growing consensus among policymakers, industry stakeholders, and researchers from academia is promoting Circular Construction (CC) approaches to maximise reuse and recycling rates and consequently minimise the consumption of raw materials and decrease the production of waste and its impact on the environment. CC aims to establish a resource-efficient economy where materials and higher-level construction products can be reused so that what previously would have become waste is now a valuable resource to start the next production cycle (Kovacic et al., 2020) and maintain their value in the economy as long as possible (eur, 2015). Most of the CC research in the built environment focuses on recycling and reusing building materials; as a result, assessment tools to support circular buildings and material flow analyses typically focus on a long life-cycle of 50 years or more (Khasreen et al., 2009).

1.2 A focus on shorter life-cycle systems

As the industry increasingly focuses on applying CC principles, one should remember that the construction industry is concerned with more than just the final assets it delivers but also with the construction processes and methodologies applied during the construction phase, including Temporary Works (TW) built to support these processes. There is a need to validate CC approaches in the built environment on a shorter life-cycle ecosystem. Because the “mini-system” of TW has a shorter life-cycle, and is typically governed by fewer stakeholders and decision-makers, we argue that it would be easier to apply and monitor recycling/reusing practices, assessment tools and material flow analyses, which in turn could result in clear insights with tangible results to enable further progress and refinement on their more extended applications.

2 BACKGROUND

2.1 Working with temporary works

Given any construction site, the core focus for a construction operation team is to plan, manage and execute all necessary activities to enable and support the construction of Permanent Works (PW). These activities represent a significant part of any construction project, sometimes 50% or more of the construction’s cost (Hewlett et al., 2014). Although the terminology used to define such activities varies across the world, in many countries, especially where there is a significant application of British standards, these are defined as TW. On every construction project, contractors deal with the safe implementation of TW design to enable the construction of PW. There are many definitions of TW, with differing emphases; this paper follows the definition of the BS 5975: 2019 (bsi, 2019), which defines TW as “*all those activities that provide an engineered solution that is used to support or protect either an existing structure or the permanent works during construction or to support an item of plant or equipment, or the vertical sides or side-slopes of an excavation during construction operations on site or to provide access. It is used to control stability, strength deflection, fatigue, geotechnical effects and hydraulic effect within defined limits*”.

Figure 1. This flowchart of Leighton Asia’s procedure for the design and control of temporary works illustrates how TW processes are structured in large construction firms.

TW structures are designed to support the construction of the PW in their temporary state. Examples are scaffolds, working platforms, falseworks and excavation-lateral-supports (ELS). Every construction project, to a greater or lesser degree, will involve the need for TW, which are usually removed during or at the end of construction. The main reasons why TW is a critical part of any construction site and a necessity to deliver PW are:

- Safety provided to the workforce involved in construction;
- Support provided to structural members to achieve adequate strength while under construction;
- Access provided to areas where construction is ongoing and direct access is not possible or unsafe.

TW can impact construction projects in many ways. However, just as successful TW can enhance project outcomes, inadequate, poorly planned or poorly executed TW can have significant negative consequences. Hence, many organisations have developed and implemented “Design and Control of TW” procedures, often following the principles promulgated by the Temporary Works forum (TWf), one of the most important associations in the industry based in the UK. These procedures are maintained to standardise and monitor the safe implementation of the TW activities on site and usually describe the processes to design, manage, control, erect, maintain and dismantle TW. The primary aim of these processes is to ensure that TW

are implemented to allow the construction of the PW safely, economically, and efficiently considering all constraints and risks intrinsic to the construction site. Construction organisations develop and apply these procedures with different levels of sophistication, but they follow the same general principles as illustrated in Figure 1.

The nature of TW results in several characteristics that arguably make these types of construction works an interesting case study and application domain for studying and implementing CC approaches:

- Short lifespan: TW have a relatively short lifespan, typically ranging from a few weeks to a few years. This means that they go through a complete life cycle in a much shorter period of time than PW, making them an ideal “mini cycle” to study and test CC approaches in a short period of time;
- Single handler: it is considered common practice for PW designers not to consider TW in their design/submission, and it is the industry practice to leave this entire activity to the contractors, which makes them the only handler of the whole TW life-cycle;
- Modular and compatible: some TW are designed in a modular fashion and can be easily disassembled and reassembled in different configurations. This makes them more versatile and suitable for reuse in different projects;
- Changes in ownership: some commonly used types of TW (e.g. scaffolding) can change ownership multiple times during their lifespan, as they are often rented or leased rather than purchased outright. This means that they may be used by multiple parties over their lifespan, which can affect their potential for reuse and the feasibility of implementing circularity approaches.

We argue these properties make TW an interesting ground to study and test circularity approaches, at the end of “a package Life Cycle” some TW can be disassembled and reused on other packages/projects, giving researchers the possibility to verify and test CC approaches more easily, which could help to set the direction for a more comprehensive implementation of CC throughout the life-cycle of PW.

Figure 2. This BAMB diagram identifies the four building composition levels and their hierarchy levels covered in materials passport (Matthias Heinrich, 2019).

2.2 *Introducing the concept of materials passport*

Materials Passports (MP) are one of the critical tools to support the implementation of CC approaches (Eichstädt, 1982), bringing benefits (Luscuere, 2017) to the industry such as:

- Maintain a database to identify materials that can be reused;
- Provide relevant data for impact assessments; and
- Monitor the material’s change in value over time.

In the built environment sector, an MP is a qualitative and quantitative documentation of the materials composition of a building or an asset, displaying materials embedded in buildings as well as showing their recycling potential and environmental impact, providing accurate information for reuse and recovery (Debacker and Manshoven, 2016). Most of the work on MPs in the Built Environment focuses on their development at the building level, as exemplified by the work of the European project “Buildings As Material Banks” (BAMB). Within BAMB, an MP is defined as “a digital set of data describing defined characteristics of materials and components in products and systems that give them value for present use, recovery, and reuse”. BAMB describes relevant MP data categories such as physical, chemical, and production data to be collected for different composition levels as in Figure 2 (Mulhall et al., 2017):

- A System refers to a product in its complex form, including a product that constitutes multiple components and parts from different manufacturers;
- A Product represents an item that is manufactured and sold, and it generally constitutes a commercial name, a serial number and a producer ID;
- A Component is one of the parts that make a product (raw materials such as timber, clay and stone are also considered at this level); and
- A Material includes the chemical properties that make up a component.

3 METHODOLOGY

3.1 *The aim of the framework*

The proposed framework aims to facilitate and support the analysis of a standardised dataset collected among a large number of TW packages scattered around one or multiple construction sites, to identify the material becoming available and inform the Designer for consideration in his design. It is essential to have a standard to capture the data homogeneously so that data collected by different people on different packages and possibly on different construction sites can be analysed together and compared.

Figure 3. Schematic of the proposed high-level framework and the key actions to enable temporary works' circularity.

3.2 *Enabling circularity in temporary works: A framework and key innovations*

As a first step, this paper proposes a high-level framework mapping key innovations required to enable Temporary Works' Circularity, consisting of three key actions and three key technologies. The three key actions, showcased in Figure 3 are:

1. Identify key TW component properties and the potential applicability of MP to track information, such as the type and quantity of materials used, their sourcing and manufacturing processes, history and current status/location.
2. Develop a collecting and reporting system, possibly through an existing process. For instance the temporary works procedure could include a step for identifying and tracking the materials used in the temporary works, and for recording this information in the MP.
3. Establish a TW reuse network of stakeholders who are interested in using these components. This can include construction companies, suppliers, and other organisations that have a need for TW components. By establishing this network, one could create a marketplace for the trade of TW components, which could help to reduce waste and extend the life cycle of these components.

Three core technologies that can benefit the implementation of this framework are:

1. A Digital Twin to create virtual models of temporary works to store data, enhance design performances and increase collaboration across projects.
2. Asset and Data management to track the life-cycle of temporary works, including information about their design, construction, and use, and identify opportunities for reuse.
3. Integration of distributed ledger technologies (e.g. Blockchain) or other technologies to improve transparency and traceability in the supply chain by introducing trust between different parties that need to rely on the history, certifications and quality assurance of the materials.

3.3 *How to use the framework and the necessity for a temporary works materials passport*

Current practices focus on material information at the building scale with little attention to the micro-scale, like in our case with TW design packages. This requires integrating information from the construction project systems and at the site level. The value of an MP increases when it is created and updated during the asset's Life Cycle. Therefore, this paper proposes a direction to extrapolate MP data from current industry, practices and procedures set to automate the updating process in the background. Under these considerations, a Temporary Works Materials Passport (TWMP) to support TW Circularity should:

- Describe TW using composition levels;
- Collect properties in parallel with the TW procedure; and
- Associate properties and TW steps to create a historical log.

In construction, as a general framework for planning and organizing tasks and resources, there are four “Ws” consistently asked before every activity commences: “Who does What, When and Where?”. Following this principle, the critical information that needs to be collected to temporarily and economically quantify TW are:

- The actors that generate and consume data across the TW Life Cycle (Who);
- The material information, including the certificates, the lab tests, the quantities, their cost, and the history of the usage of each structural element, including the aggressiveness of the environment of erection: corrosive, marine, tunnel, adverse chemical, etc. (What);
- The planned time of erection and dismantling (When);
- The planned location of the erection (Where).

The information listed above can be considered part of the TWMP. Linking the data of the TWMP to a project timeline would allow for a contract-based trading platform that informs TW designers on what is available, when and where and influence their design based on resource availability. In the beginning, this platform can be substituted by simple access to the TWMP as a starting point and developed into a more visual environment to enhance clarity and usability. A blockchain trading module can also be developed based on the TWMP data and the unique identification of each component.

4 CASE STUDY FROM THE INDUSTRY

The first author of this paper is an employee of Leighton Asia, an international contractor in the construction, civil engineering and offshore oil and gas sectors headquartered in Hong Kong and part of the CIMIC Group. The following review of Leighton Asia Temporary Works procedure is based on the author's first-hand experience on the topic and the training material available at the company level, of which a few copies exist in the public domain thanks to webinars and sessions organised with the Construction Industry Council Hong Kong (Sein, 2022). In Leighton Asia, the design and control of TW is a high-level framework (Figure 1) that specifies a series of steps that need to be followed to ensure TW are appropriately managed and controlled; these are:

- Planning and risk allocation;
- Designing and checking;
- Procuring and constructing;
- Verifying as-built and safe removal; and
- All steps are running while considering and managing changes to the design.

The core objective of this procedure is to provide a framework to ensure TW are appropriately managed and controlled. Although this procedure may look quite simple to implement, divergence arise during the TW life-cycle due to day-to-day construction activities or due to the dynamic nature of TW involving multiple stakeholders, staff turnover, competing concurrent site activities, resource demands, and ever-changing constraints over time often add unforeseen complexity to what should otherwise be a straightforward process.

Figure 4. This flowchart identifies a specific temporary works form for each stage of Leighton Asia’s procedure for the design and control of temporary works.

4.1 *The design and control of temporary works procedure*

This high-level procedure (Figure 1) develops in a series of forms, as outlined in Figure 4, to be filled and signed to certify the completion of a particular step.

4.1.1 *The TW0 Form and the appointment of qualified person*

The first step of the procedure is planning and risk allocation, initiated with the “Appointment of Qualified Persons”, which records the nomination and appointment by the Project Director of persons with commensurate qualifications and competency to take responsibility for their respective roles under the TW procedure. Subsequently, the planning of TW activities can start. The correct planning of the TW design and activities generates a Temporary Works Master Schedule (TWMS) that collects these essential records:

- The TW Design Package Number;
- The TW Design Package Description;
- The Risk Categories associated with each package;
- The allocation of all Stakeholders based on the TW0;
- The required approval date with adequate provision for design, approval, procurement and construction; and
- The Estimated Date of dismantling.

[Relation to the framework]: The difficulty of this step is to envisage and foresee the complete set of TW designs required to enable the construction of the PW. The redaction of the TWMS is particularly critical because it becomes the baseline that would trigger the Responsible Site Person (RSP) to initiate the next step.

4.1.2 *The TW1 Form and the design brief*

The second stage of the TW procedure is the design and checking based on the design brief initiated by the RSP and issued to the Temporary Works Coordinator (TWC), which reviews the design request and coordinates with a Temporary Works Designer (TWD) the design process. During this process, the TW1 Form collects information into two categories: technical and commercial. The technical part is filled by the TWD and collects information ranging from:

- The TW Design Brief Number;
- The TW Design Package Number;
- The TW Design Documentation;
- The Loading Criteria;
- The Survey information regarding the area of erection;
- The Material Requirements; and
- The TW Installation and the Removal Methodologies.

[Relation to the framework]: It is at this stage when it would be useful to have a TW database of available material of reuse to match the requirements outlined in the TW1 Form.

The commercial part is filled by the quantity surveyor assigned to the design package and identifies:

- The Estimated quantities of the design materials;
- The Estimated cost of the design;
- The Estimated cost of the construction;
- The Procurement Reference;
- The Comparison against the budget of the works;

- The cost code reference for the material; and
- The estimated construction date (to complete the procurement on time).

4.1.3 The TW3 Form and the independent checking

Once the design review has been completed and approved (after multiple rounds of proposals for discussion with the extended project team), the selected design option is ready to be issued of endorsement to the Independent Checking Engineer (ICE) prior to construction. A TW3 Form is created and issued to the ICE for review and endorsement. The TW3 Form is generally solely related to a design check and does not carry any particular or relevant information other than the approval date and signature. Once endorsed, the TW package will move to the site for construction.

[Relation to the framework]: This is when actual planned materials need to be measured and checked for availability in the reusable TW market database.

4.1.4 The TW4 Form and the permit to load and remove

When the construction is completed, an inspection is to be carried out to verify the compliance of the site construction with the approved design and a new TW4 Form is generated by the RSP for the TWC to inspect the works and issue the approved “Permit to Load” which allows the RSP to load the TW and start the construction of the PW. Similarly, when the construction of the PW is completed, the TW are ready to be dismantled, and a new TW4 Form needs to be raised by the RSP to verify that the TW structures take no more loads and can be removed. The TWC carries out another inspection, and a “Permit to Remove” is issued to the RSP to start the safe removal and dismantling of the TW.

[Relation to the framework]: At this stage, the MP needs to classify the current condition of the material and verify that it was never overstressed during its use. If it was, this must be recorded into the MP to clearly mark it as not suitable for further use.

Both TW4 Forms carry valuable information like:

- The location of the inspections;
- The TWC checking remarks;
- The ICE checking remarks; and
- The dates of each inspection, including any remark regarding the deviation of the initially assumed loads and the effects of the actual loads on the structures.

[Relation to the framework]: These are historical insights that can help evaluate and assess a particular component or element of the TW structure before being reused.

4.1.5 The TW2 Form and the managing of the changes

Whenever a design change occurs during the process just described, a TW2 Form needs to be raised by the RSP to initiate a TW design change. The TWC reviews it and issue it to the TWD to update the design. Once the design update is completed, the TW2 Form needs to be reviewed and approved by the TWC, the RSP and the ICE, similarly to what happened with the original TW1 Form. The TW2 Form also outlines the design changes in quantities, including all the commercial changes identified by the quantity surveyor, the new estimated construction date and the approval date of the new design.

[Relation to the framework]: The issuing of a TW2 should, in fact, refresh and update all TW properties stored in the MP to capture the latest changes.

5 CONCLUSIONS

The main contribution of this paper is to identify Temporary Works as a miniature Life Cycle system to experiment and validate the application of Circular Construction approaches and to enable circularity at the construction site scale. It identifies the requirements for a specific TWMP, designed around the data collected while applying the Design and Control of Temporary Works procedure. The TWMP could even replace the TW Forms and become the central repository for storing the TW procedure data. Mapping (Figure 5) TW properties to generate a TWMP can significantly improve the construction industry by providing a comprehensive and accurate record of all materials used in the TW process and to track the life cycle of all materials used in the project. The proposed TWMP can be implemented on many construction sites with an existing TW procedure, enhancing the application of CC and potentially creating a new material/component market between construction sites that can reduce waste and generate savings for the main contractors.

Life-cycle assessment of buried water-transmission concrete mains

H. Yáñez-Godoy & S.M. Elachachi

Institut de Mécanique et d'Ingénierie (I2M), Université de Bordeaux, Talence, France

ABSTRACT: The progressive decline in performance of aged pipes is not always evident in practice, particularly for buried water-transmission mains. A geomechanical approach can provide interesting elements to assess and/or predict their integrity. Simplified Winkler-type models can effectively represent the complexity of soil-pipe interaction. The spatial variability of the soil is necessary to understand how this variability can be used to study the structural behaviour of the buried pipe. The numerical modelling of the soil-pipe system adopted in this study combines different strategies and steps in order to speed up and optimise the computation in an uncertain context that involves the execution of several simulations. The quantification of criticality indicators, in a context of asset management, allows to evaluate the performance of a pipe, according to a reliability approach, with respect to limit states defined in the framework of inspection, maintenance or renewal strategies of the pipelines.

1 INTRODUCTION

The renewal of drinking water buried pipes is necessary because of their “natural” and/or anthropogenic ageing, which leads to a progressive decrease in their performance level. Monitoring, during the implementation of the worksite as well as during the operation of new portions of a linear to be renewed, is an important issue in order to constitute an experimental record of the work. Indeed, this is a way of acquiring a better knowledge of the mechanical behaviour and mechanisms of the soil-pipe system. The acquisition of data through the instrumentation of the renewed pipes brings on the one hand, information which is not contained in the data bases or exploitation and on the other hand, allows to validate and to qualify the mechanical/numerical models adopted to study the short- and long-term behaviour of the pipe.

Reinforced concrete pipes consist of a steel cylinder positioned between two layers of concrete (Figure 1). The concrete not only acts as a passive layer on the steel cylinder core but also serves as a bending reinforcement. The outer concrete cover is reinforced with steel wire coils. These pipes are also known in France as Bonna pipes and are designed and manufactured according to the recommendations of French standards (Afnor 1995).

Figure 1. Diagram of a Bonna type pipe.

2 METHODOLOGY FOR LIFE-CYCLE ANALYSIS OF A BURIED PIPELINE

The proposed methodology for buried drinking water pipes aims at optimizing resources for maintenance (Yáñez-Godoy et al. 2017). It is about implementing an efficient risk management during the whole life cycle of the network which leads to associate diagnosis, prognosis and decision making concerning the desired performance (the structural integrity of the pipes, the need to ensure the continuity of the service, etc.). This methodology is based on:

- The acquisition of interesting parameters (e.g. embedded defects generated during pipe laying; long-term defects as corrosion of wires, steel joints or steel cylinder) that are relevant for aging and degradation assessment of concrete pipes
- The use of some of the identified parameters in the previous item as input to geomechanical models to study the behaviour of concrete pipes
- The use of other pipe degradation monitoring parameters (e.g. detection of broken wires; condition of joints) to validate the numerical models and readjust them to improve their predictive function
- The integration of geomechanical models, used in a probabilistic context, in an inspection and maintenance optimization approach

The first three items mentioned above imply a precise follow-up during the installation of the pipes as well as a long-term monitoring of the degradation mechanisms of the pipe materials. These points are outside the scope of this study. The last item (geomechanical models) can be considered in a geomechanical approach and is explained in the following section.

3 GEOMECHANICAL APPROACH

3.1 *Input data*

For the modelling of the geomechanical behaviour of Bonna pipes, it is necessary to build a numerical model which represents the pipe laid in a heterogeneous medium. The input data required for this model include:

- The geometric characteristics of the pipe section: most of these data are the easiest to obtain as there are generic documents from the supplier
- The mechanical characteristics of the pipe section: if the data are not available, the assumptions that can be made will be the most appropriate ones based on the characteristics of typical materials such as steel and concrete
- The geomechanical properties of the surrounding soil: the uncertainties of these data are more easily identified and their treatment is more efficient when geotechnical data are available; pressuremeter tests should be considered for example to determine the Young's modulus of the soil
- The spatial structure of the soil: data from instrumented sites (Yáñez-Godoy et al. 2019) makes it possible to simulate a random field to model the spatial variability of the soil along the axis of the pipe; this random field would make it possible to deduce the response of the structure under certain loading conditions and to observe its sensitivity to differential settling
- The vehicle loading: this data has some sensitivity due to its variability
- The temporal variability of the properties of the soil-pipe system: on the one hand, access to information from databases (e.g. <http://www.ad.es.eaufrance.fr>) that record the monitoring of groundwater management for a specific area and for several years seems very relevant in order to assess possible seasonal stresses on the pipe; on the other hand, non-destructive testing techniques (e.g. geophysical measurements with geological radar), would allow the study of natural seasonal fluctuations of the site (soil moisture) and look at their effect on the mechanical behaviour of the structure; this point is outside the scope of this study

3.2 *Geomechanical model*

In order to ensure a safer design of a new pipe or to assess the residual life of an existing buried pipe, a reliable assessment of the soil stresses applied on the pipe due to soil and pipe

movement is required. The design of longitudinal pipes in the literature is approached by models which consider pipes as articulated elastic beams laying on an elastic continuum (Yu et al. 2013). These models are grouped in two categories: the local continuous medium models (the soil is represented by a linear or non-linear medium with a mechanical behaviour described by stress-strain relationships) or the global simplified models (the local behaviour of soil is replaced by a simplified mechanical model; the most used common model to represent soil-structure interaction is the unidimensional Winkler model). The rigid or flexible pipes are vulnerable due to generated stresses due to soil displacements. Some studies addressing the influence of settlements on the behaviour of pipes and particularly on the behaviour of joints exist (Buco et al. 2008). The rigidity of joints depends on the used technology and their geometry (flexible joints, welded joints). In order to represent the non-linear and non-homogeneous soil characteristics, spatial variability and uncertainties have to be taken into account.

The pipeline model used in this study consists of a set of pipe segments. Each pipe segment of finite length is decomposed into a number of beams connected to each other by nodes. At the ends of segments, a pair of two independent nodes is used to represent the joints. Each beam element is subjected to a uniformly distributed loading, q , and rests on a soil modeled, according to the Winkler model, by a set of independent springs with a coefficient of subgrade reaction or soil reaction coefficient, k_s , in order to take into account the soil-structure interaction. This model is described by a uniaxial distribution of the form:

$$p(x) = k_s \cdot w(x) \quad (1)$$

with $p(x)$ the pressure applied to the abscissa x , $w(x)$ the displacement in the direction transverse to the abscissa x . The soil reaction coefficient, k_s is not a measurable physical quantity and depends on the properties of the pipe, in addition to those of the soil it is supposed to represent. The determination of its value has been the subject of many studies and several semi-empirical relationships have been proposed (Elachachi et al. 2004). These formulas involve geometric and mechanical characteristics of the pipes as well as mechanical properties of the soil, including the soil modulus, E_s and the soil Poisson's ratio, ν_s . The values derived from these models are not only quite different but also result in values that are widely dispersed. Here, k_s is related to the mean soil modulus, E_s by Vesic model (Vesic 1961):

$$k_s = \frac{0.65}{d} \sqrt[12]{\frac{E_s d^4}{E_p I_p}} \cdot \frac{E_s}{1 - \nu^2} \quad (2)$$

with E_p the modulus of elasticity of the pipe, I_p the moment of inertia of the pipe, ν the soil Poisson coefficient and d the diameter of the pipe.

The pipe sections and the soil are considered to have a linear behaviour. The main limitation of this longitudinal model is that it is unable to take into account the effects in the cross-section, such as the effect of the internal hydraulic pressure and the effect of the lateral soil, hence the interest in thinking about the coupling of longitudinal and transverse effects, which we have translated into a hybrid model with a transverse model of the pipe cross-section, called 2.5D model.

3.2.1 2.5D hybrid model

The model used to represent the studied soil-pipe system was based on 1D (Euler-Bernoulli beam model) and 2D (plane stress model) models. The 1D model allows to obtain the settlement profile of the pipe, as well as the stresses coming from the bending effects. The 2D model allows the evaluation of the various circumferential stresses developing in the cross-section of the pipe, taking into account the transverse effects of the soil and the effect of the internal pressure. The combination of the two models has been named "2.5D hybrid model" (Darwich 2019) as a coupling is taken into account. Placing the pipeline in a frame of reference where the x-axis is the axis passing through the left and right ends of the pipe, the y-axis is the vertical axis, and the z-axis is the longitudinal axis of the pipe (Figure 2), the assumptions made for this 2.5D modelling result in the combination of two stress systems, based on different assumptions in the state of planar stresses. In the 1D model, the stresses in the cross-section, σ_{xx} , σ_{yy} , and σ_{xy} are assumed to

be zero and the axial stress σ_{zz} can vary longitudinally. Whereas in the 2D model, non-zero stresses σ_{rr} , $\sigma_{\theta\theta}$, and $\sigma_{r\theta}$ are sought to be calculated, with the axial stress σ_{zz} assumed to be constant along the pipe. Three points in the thickness of the pipe cross-section are considered at four critical locations: left and right ends and top (crown) and bottom (invert) ends. As the left and right ends are symmetrical, only one end is retained. The combination of stresses for the proposed 2.5D model is based on the following assumption:

$$\sigma_{2.5D} = \sigma_{1D} + \sigma_{2D} \quad (3)$$

Figure 2. Assumptions for stresses in 1D and 2D models and critical locations in the pipe cross-section.

3.2.2 Uncertainties and random variability of soil properties

The variability and/or uncertainty related to soil characteristics and therefore to the soil response coefficient comes from: the soil which is in fact a material with spatial heterogeneity resulting from its deposition and aggregation process; the inaccuracy of measurements; the model's uncertainty. The soil modulus, E_s , is assumed to characterize the spatial randomness of the soil as it is a geomechanical property which is indirectly dependent on soil density and soil moisture. A cross section of a pipe is shown in Figure 3 where the interaction with the soil is done by springs of stiffness k_{sh} for springs not belonging to the support arc of angle α of the pipe and of stiffness k_{sb} for springs belonging to it. k_{sb} parameter is associated with the pipe laying bed supposed to be compacted. This modelling allows to take into account the different horizontal and vertical loads on the pipeline, q_h and q_v respectively, but also the reaction of the laying bed. It should be noted that the vertical loads are mainly due to the weight of the soil and surface overloads due to road traffic or to overlying buildings and structures.

The role of longitudinal variability can be studied by considering random fields (Vanmarcke 1977). Random fields let to model the spatial variability characteristics of k_s through some parameters as the mean value m_{k_s} , the variance $\sigma_{k_s}^2$ and the correlation length l_c . This last parameter is linked to autocorrelation function, $\rho(\tau)$, where τ indicates the distance between two points and describes the spatial structure of the correlation of soil properties. Both parameters, l_c and E_s are important factors for understanding the spatial behaviour of the soil-pipe system (Elachachi et al. 2012, Onyejekwe et al. 2016).

Figure 3. 2D model representing soil-pipe interaction and applied loads, q_b and q_v and internal hydraulic pressure P_i .

3.2.3 Criticality indicators or performance criteria

Three main potential failure modes for a buried pipe are identified: an excessive displacement of the pipe; an excessively high stress on the pipe, thus compromising the structural integrity of the pipe; and an excessively high joint opening (which could compromise the tightness of the pipes and result in a drop in pressure, unserved users, etc). These failure modes are linked through three different criticality indicators, I_{cri} ($i = 1,2,3$), which will help to understand which phenomenon or potential event has the highest occurrence. Indeed, the models developed are used in a probabilistic context and allow the formation of a set of performance criteria that are defined from the definition of limit states. The criticality indicators help to optimize pipeline renewal strategies, e.g., through a proactive approach, by identifying alert thresholds, etc. The probabilistic approach makes it possible to identify the areas that are likely to deteriorate in a pipe and to forecast the evolution of the indicators in the long term.

For each of the failure modes, two reliability indices β will be calculated for two distinct limit states:

- The serviceability limit state (SLS), the exceeding of which compromises normal service conditions (induces minor effects)
- The ultimate limit state (ULS), corresponding to the state which, if reached, could lead to damaging consequences at the level of a portion of the pipe or in its totality.

The expression for the reliability index β is given by:

$$\beta = \frac{\ln\left\{\frac{R}{S} \left[\frac{(1 + COV_S^2)}{(1 + COV_R^2)} \right]^{1/2}\right\}}{\left\{ \ln\left[(1 + COV_S^2)(1 + COV_R^2) \right] \right\}^{1/2}} \quad (4)$$

with R the value of the acceptable stress, S the mean maximum stress, COV_R the coefficient of variation of the acceptable stress (here taken to be zero, as R is supposed to be deterministic) and COV_S the coefficient of variation of the maximum stress, assuming that both R and S follow a lognormal distribution. The values of β for the ULS and SLS can be specified by the user according to the standards or the desired performance levels. For example, Eurocode 0 (Afnor 1990) recommends a value of 1.5 for the SLS, which corresponds to a probability of failure of 6.7×10^{-2} , and a value of 3.8 for the ULS, which corresponds to a probability of failure of 7×10^{-5} .

For buried pipes, 3 levels of performance or criticality indicators, I_{cri} , can be considered:

- Safe pipe: no intervention by the manager is necessary; all calculated β values are higher than the value indicated as acceptable, that is to say $I_{cri} = 0$
- Pipe to be inspected: the manager must carry out a follow-up in terms of inspection for the pipe studied; there is at least one computed β value (not several) that is lower than the value indicated as acceptable, that is to say $I_{cri} = 1$
- Pipe to be maintained or renewed: there is a high probability that a failure of the pipe would have occurred; maintenance or renewal is then necessary because several calculated β values are lower than the value indicated as acceptable, that is to say $I_{cri} = 2$

4 CASE STUDY

The case study presented in this section concerns the renewal of a Bonna type pipe of 1100 mm inner diameter in an urban municipality. The pipeline consists of 15 individual segments, each 6 m long, for a total length of 90 m. The pipe is laid at a mean depth of 2 m in a sandy clay soil. The laying quality is assumed to be good. The pipe operating pressure is 6 bar. The static load due to road traffic is considered to be 67 kN/m^2 (mean value). In order to arrange the large amount of input data and outputs, the following sections present the organization process.

4.1 IT tool for decision-support

The computer tool developed in Matlab is an autonomous set of scripts allowing to execute, through a graphic interface, a geomechanical computation (in an uncertain context) of

a buried pipe. It allows, according to parameters given by the user such as the geometrical, mechanical or geotechnical characteristics, to obtain as output of a probabilistic computation:

- The values of maximal displacements, stresses and joint opening angles
- Then, by post-processing, quantify and display on a window, criticality indicators that will indicate to the user the global state of the pipe and thus know, thanks to the model, where the pipe is in terms of structural integrity and tightness (these are the two monitored performances)

4.2 Data acquisition from available databases

The characteristics of the concrete pipe, the geomechanical properties and the loads and boundary conditions are shown in Table 1.

Table 1. Characteristics of the soil-pipe system.

Geometrical characteristics	Mechanical characteristics
Inner diameter: 1100 mm	Young's modulus of concrete: 30 GPa
Number of pipe segments: 15	Young's modulus of steel: 210 GPa
Pipeline length: 90 m	Diameter of steel wire: 10 mm
Thickness: 88 mm	Number of steel wires per meter: 25
Burial depth: 2 m	
Type of joint gasket: welded	
Geomechanical properties	
Type of soil: sandy clay	
Volume weight of the backfill: 20 kN/m ³	
Soil modulus: 125 MPa	
Poisson coefficient: 0.4	
Modulus of subgrade reaction: 58.78 MN/m ³ (calculated by Vesic model)	
Quality of the pipe laying bed: good	
Loads and boundary conditions	
Internal pipe pressure: 6 bar	
Intensity of rolling surface loads: 67 kN/m ²	
Ratio of horizontal to vertical stresses in the pipe (this parameter depends on both the quality of the pipe laying bed and the type of soil): 1	
Threshold values for the limit states	
Circumferential pipe stresses: SLS: 5 MPa; ULS: 8 MPa	
Pipe displacement: SLS: 30 mm; ULS: 60 mm	
Pipe joint opening: SLS: 0.01°; ULS: 0.02°	

4.3 Data acquisition by instrumentation of a pipe: Correlation length of soil modulus

The experimental acquisition of quantities of interest such as the correlation length, l_c , of soil properties was presented in (Yáñez-Godoy et al. 2019). Results in (Yáñez-Godoy et al. 2017) showed that for horizontal l_c values between 6 and 18 m, the increase in the probability of failure of the pipeline (i.e., the reliability index decreases) is greater than for smaller values. A forthcoming study by the authors suggests that the horizontal l_c of the soil below the pipeline could have a more important effect on the structural integrity of the pipe. The spatial variability below the pipeline was assumed to correspond to the soil modulus parameter, E_s , in the model.

From these studies we know that for the correlation length of E_s a mean value of 6 m is a good choice for assessing the effects of spatial variability. A coefficient of variation, COV, of the order of 0.5 (relationship between the standard deviation and the mean value of E_s) is taken into account, it will define the variability of this parameter. Although naturally the variability of E_s can be very large, in the case of non-linear soil behaviour problems, very high values of COV (higher than 0.5) tend to a numerical non-convergence of the result.

4.4 Tool outputs: Geomechanical responses of the pipe

The values of the calculated stresses, displacements and joint openings are shown in Figure 4. For all N simulations ($N = 1 \times 10^4$), the mean and standard deviation of the maximum values of the three relevant outputs and the 5% and 95% fractiles of the maximum displacements and pipe joint openings are calculated (top of Figure 4a). It is possible to display for each of the simulations performed (here, simulation number 7 at the bottom of Figure 4a) the spatial variability of the modulus of subgrade reaction in parallel with the displacement of the pipe. In particular, Figure 4b shows the cumulative distribution function of the circumferential stress at the point BE1 of the pipe where the mean maximum value occurs.

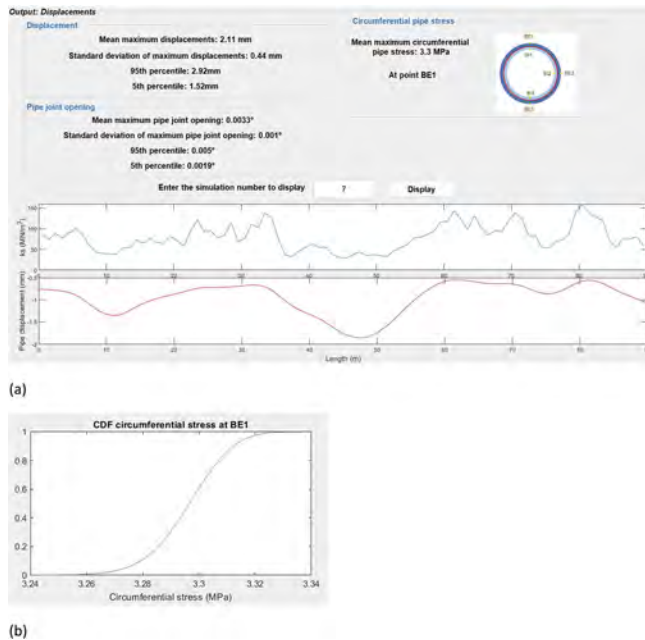

Figure 4. (a) Values of the calculated stresses, displacements and joint openings; (b) Cumulative distribution function of the mean maximum circumferential stress at the point BE1 of the pipe.

4.5 Tool outputs: Criticality indicators of the pipe

In the IT tool, three criticality indicators are present. They are calculated by the method described in 3.2.3 and allow a quick understanding of whether or not an intervention should be considered

Figure 5. Criticality indicators of the pipe.

on the studied pipeline. Figure 5, shows that the three indicators are green, which means that for the three main failure modes, the study has not revealed any particular risk.

5 CONCLUSIONS

This study presented the different steps of a geomechanical approach to allow a drinking water network manager, thanks to an IT tool, to evaluate its performance with regard to the different performance criteria. These steps aim to optimise the resources allocated to asset management through an effective life cycle risk management process. The experimental campaigns provide access to key elements for the understanding of the soil-pipe behaviour. Indeed, these elements provide a good knowledge of aspects that are not sufficiently known, such as soil variability, on real sites with pipelines in operation. The coupling of the geomechanical approach with durability aspects, which take into account degradation kinetics, is feasible and constitutes a very complete analysis tool. This IT tool can provide experts with decision elements for better safety calibration in soil-pipe interaction problems where soil variability is an influential parameter.

ACKNOWLEDGMENTS

The authors would like to thank Syndicat des eaux d'Ile de France (SEDIF) for its involvement in this project. Created in 1923, SEDIF is a public utility that is responsible for supplying drinking water to subscriber towns and municipalities in the Greater Paris area. SEDIF is the leading public drinking water utility in France and is one of the largest in Europe. Producing 765000 m³ of water every day, SEDIF delivered 254 billion liters to users in 2019 through a network of pipes stretching 8767 km. The authors also thank G. Darwich and A. Darolles for their contributions to the development of the IT tool.

Shear strength investigation of carbon fiber reinforced polymer strips-wrapped concrete beams with regression analysis and experiments

P. Fan, H.F. He & S.S. Cheng

Research Institute of Highway Ministry of Transport, Beijing, China

S.S. Guo & C. Liu

Tongji University, Shanghai, China

ABSTRACT: With the increase of the service time of concrete structure, the bearing capacity of the structure will decrease to a certain extent. In order to ensure that the structure meets the needs of serviceability state, the structure needs to be reinforced and transformed to improve the bearing capacity. In this paper, the method of carbon fiber reinforced polymer strips-wrapped concrete beams is used to strengthen the concrete beam, and the calculation method of the shear bearing capacity is studied and analyzed. However, the shear behavior of reinforced concrete beams (RC) is complex. To analyze the shear capacity of RC beams strengthened with carbon fiber reinforced polymer (CFRP) strips, the main factors affecting the shear performance are summarized and analyzed based on existing literature firstly. Then, the calculation formula of shear capacity of CFRP is determined by regression analysis of test data and is verified with model tests. Finally, the applicability of the calculation model proposed by author is analyzed and compared with previous shear models. The results show that: (1) the main factors affecting the shear performance include the effective height of CFRP strips, the spacing of CFRP strips, the width and thickness of CFRP strips, the axial compressive strength of concrete, the inclination angle of crack of reinforced concrete beams and CFRP strips; (2) the shear capacity of RC beams strengthened with CFRP with previous calculation models are conservative, and the maximum error is 29.47%; (3) The calculation results of the model proposed by author are consistent with the test results of side obliquely pasted CFRP, and the error is 6.21%. But there is a large error with the test results of U-shaped pasted CFRP strips.

1 INTRODUCTION

The shear behavior of reinforced concrete beams remains a significant subject of research. The shear theories still need modification with regard to reinforced concrete members. It is important to note that shear failure of concrete structures is exceedingly hazardous because it is rarely expected and usually occurs explosively. Therefore, improving the properties of concrete has become imperative. The use of Fiber-Reinforced Polymer (FRP) to enhance the shear behavior by strengthening, repairing, and rehabilitating RC elements has significantly increased. Fiber reinforced polymer has the advantages of light weight, high strength, corrosion resistance and fatigue resistance. It has been gradually used in civil engineering structures since the 1980s. Currently, fiber reinforced polymer has become a mainstream composite material in bridge reinforcement. Carbon fiber reinforcement technology is convenient and efficient and has broad development prospects in the field of structural reinforcement (Dittrich et al., 2014, Kim and Harries, 2011, El-Saikaly and Chaallal, 2015). Research (Li and Gu, 2012, Zhang et al., 2010) shows that FRP reinforcement can not only improve the flexural

capacity of the bridge, but also effectively improve the shear capacity. It plays a significant role in improving the stiffness of the structure, reducing the deflection, and delaying the emergence and development of cracks. For reinforced concrete beams strengthened with FRP, the shear capacity gradually improves with the increase of the effective height of CFRP and the decrease of the spacing. Daniel Baggio(Baggio et al., 2014) et al. conducted the research on the method of improving the shear capacity of concrete beams with FRP. They pointed out that fiber reinforced polymer composites can significantly improve the shear capacity of reinforced concrete beams through the change of FRP type and anchorage mode. Moreover, the anchoring method will not change the failure mode, but only improve the shear capacity of reinforced concrete beams. Based on the shear tests of concrete beams strengthened with CFRP, scholars put forward the calculation methods of shear capacity through the research and analysis of the shear mechanism of concrete beams. J. F. Chen, J.G. Teng(Chen and Teng, 2003a, Chen and Teng, 2003b) put forward the calculation theory of shear capacity of reinforced concrete beams strengthened with CFRP. They analyzed the factors affecting the shear strengthening effects of CFRP combined with the failure mode of concrete beams - peeling failure or tensile failure. A. Bukhari(Bukhari et al., 2010) gave the calculation formula of shear capacity of reinforced concrete beams in the form of power function based on a large number of test results of reinforced concrete beams with small shear span-depth ratio. During the process, they considered the relationship between effective strain and ultimate strain of CFRP and adopted the method of regression analysis.

At present, the reinforcement technology with carbon fiber sheets is relatively mature in the world. There are several codes for fiber composite reinforcement and prestressed carbon fiber-reinforced polymer plate reinforcement. Many experiments have been conducted to analyze the shear capacity of reinforced concrete beams strengthened with CFRP. However, the test results are discrete due to the complexity of the shear behavior of concrete beams. Many experiments will greatly increase the cost, which is more troublesome and uneconomical.

The regression analysis method based on previous test results can become easier to give the prediction on the shear capacity of reinforced concrete beams strengthened with CFRP compared with the experiments. In the paper, the shear calculation model of CFRP is determined with the regression analysis of test data in the existing literature. Then, the theoretical model is verified by experiment. Finally, the accuracy of the calculation method is compared and analyzed.

2 EXISTING CALCULATION METHODS OF SHEAR CAPACITY OF CONCRETE BEAMS REINFORCED WITH CFRP

Scholars in the world have carried out a large number of researches on the shear reinforcement effects of concrete beam bridges with FRP. Through theoretical derivation, numerical analysis and regression analysis, some calculation methods of the shear capacity of reinforced concrete beams strengthened with FRP have been obtained. Here, a part of calculation methods have been collected and sorted out through literature research.

(1) Triantafilou 1998(Triantafillou, 1998)

$$V_f = \frac{0.9}{\gamma_f} \rho_f E_f b_w \varepsilon_{fe} d (1 + \cot \alpha) \sin \alpha \quad (1)$$

(2) Triantafilou and Antonopoulos 2000(Yost et al., 2001)

$$V_f = \frac{2 w_f t_f E_f \varepsilon_{fe} d_f}{s_f} \quad (2)$$

(3) Matthys and Triantafillou 2001(Matthys and Triantafillou, 2001)

$$V_f = \frac{2 w_f t_f E_f \varepsilon_{fe} d_f}{s_f} \quad (3)$$

(4) Pellegrino and Modena 2002(Pellegrino and Modena, 2002)

$$V_f = (A_f / s_f) 0.9 d f_{fe} (1 + \cot \beta) \sin \beta = \rho_f b_w 0.9 d R f_{fu} (\sin \beta + \cos \beta) \quad (4)$$

(5) Khalifa and Nanni 2002(Khalifa and Nanni, 2002)

The calculation model adopts the correction coefficient “R” to reduce the effective strain of FRP, and the calculation model is as follows:

$$V_f = \frac{A_f f_{fe} (\sin \beta + \cos \beta) d_f}{s_f} \quad (5)$$

(6) Taljsten 2003(Taljsten, 2003)

$$V_f = 2 t_f \varepsilon_f E_f 0.9 d (\cot \alpha + \cot \beta) \sin^2 \beta \cos^2 \beta \quad (6)$$

(7) Chen and Teng 2003(Chen and Teng, 2003b)

$$V_f = 2 f_{fe} t_f w_f \frac{h_{fe} (\cot \theta + \cot \alpha) \sin \alpha}{s_f} \quad (7)$$

(8) Wang Suyan et al. 2007(Suyan and Yingwu, 2007)

Wang Suyan et al. obtained the calculation expression of equivalent effective strain through regression analysis of the test data and put forward corresponding calculation model considering the influence of the ultimate strain of FRP, the non-uniformity of strain distribution along the crack, the inclination angle of crack and other factors.

$$V_f = \rho_f E_f \varepsilon_{f,ee} b d (1 + 0.835 \cot \alpha) \sin \alpha \quad (8)$$

$$\varepsilon_{f,ee} = 0.005229 (\rho_f E_f^{1.23})^{-0.6152} \quad (9)$$

(9) Mofidi and chaallal2011(Mofidi and Chaallal, 2011)

$$V_f = \frac{2 t_f \varepsilon_{fe} E_f w_f (\cot \theta + \cot \alpha) \sin \alpha \alpha_f}{s_f} = \rho_f E_f \varepsilon_{fe} b d_f (\cot \theta + \cot \alpha) \sin \alpha \quad (10)$$

$$\varepsilon_{fe} = \frac{\beta_c \beta_L \beta_w \tau_{eff} L_e}{t_f E_f} = 0.31 \beta_c \beta_L \beta_w \sqrt{\frac{f'_c}{t_f E_f}} \leq \varepsilon_{uf} \quad (11)$$

(10) Bukhari et al. 2013 (Bukhari et al., 2013)

Based on the test results of reinforced concrete beams with small shear span-depth ratio, the proposed calculation model is as follows:

$$V_{Rd,f} = 0.9 \rho_f b_w \varepsilon_{fe} E_f d (\cot \theta + \cot \alpha) \sin \alpha \quad (12)$$

$$\varepsilon_{fe} = \varepsilon_{fu} [0.0812 (\rho_f E_f)^{-0.9434}] \quad (13)$$

3 CALCULATION METHOD OF SHEAR CAPACITY OF REINFORCED CONCRETE BEAMS STRENGTHENED WITH CFRP

Regression analysis is the basic method of prediction. It is a statistical analysis method to determine the interdependence between two or more variables. A functional equation approximately expressing the quantitative relationship between variables is established by analyzing the relationship between dependent variables and independent variables. The regression equation is used to predict the numerical change of dependent variables. A reasonable calculation

formula of shear capacity of concrete beams strengthened with FRP is obtained through regression analysis based on the research results in the previous literature. During the process, the existing calculation methods of the shear capacity in the literature are referred. The main factors considered during the regression analysis include the effective height of CFRP strips, the spacing of CFRP strips, the width and thickness of CFRP strips, the axial compressive strength of concrete, the inclination angle of crack of reinforced concrete beams and CFRP strips.

Figure 1. Calculation model.

In Figure 1: w_f is the width of CFRP strips; s_f is the distance of two adjacent CFRP strips; θ is the angle between oblique cracks and the longitudinal axis of the beam; α is the angle between the CFRP strips and the longitudinal axis of the test beams; d is the depth of the test beam; h_{fe} is the effective height of CFRP strips; b_w is the width of the cross section; n is the number of layers of CFRP strips; t_f is the thickness of CFRP strips; E_f is the elastic modulus of CFRP strips; f_{fu} is the ultimate tensile stress of CFRP strips; ε_{fu} is the ultimate tensile strain of CFRP strips; ε_{fe} represents the effective strain of CFRP strips; f_c is the axial compressive strength of concrete; $f_{cu,k}$ is the cube compressive strength of concrete; f_{ck} is the prismatic compressive strength of concrete; f_t is the tensile strength of concrete. Where, A_f represents the area of CFRP strips, ρ_f is the distribution rate.

(1) Theoretical calculation method

Different relationships between the ultimate tensile strain and effective tensile strain of carbon fiber cloths are given based on the consideration of the compressive strength of concrete. The theoretical formulas are listed, and the unknown parameters are determined by regression analysis using the existing test data. The derivation of the theoretical formulas is as follows.

$$V_f = 2 \varepsilon_{fe} E_{fe} t_f w_f \frac{h_{fe} (\cot \theta + \cot \alpha) \sin \alpha}{s_f} \quad (14)$$

$$\varepsilon_{fe} = \varepsilon_{fu} [\alpha_1 (\rho_f E_f)^{-\alpha_2}] f_c^{\alpha_3} \quad (15)$$

Among them, α_1 , α_2 and α_3 is unknown.

Through regression analysis, the theoretical formula is obtained.

$$V_f = 2 \varepsilon_{fe} E_{fe} t_f w_f \frac{h_{fe} (\cot \theta + \cot \alpha) \sin \alpha}{s_f} \quad (16)$$

$$\varepsilon_{fe} = \varepsilon_{fu} [1.4378 (\rho_f E_f)^{-0.6301}] f_c^{0.6382} \quad (17)$$

4 EXPERIMENTS

(1) Experimental design

The rectangular concrete beams with the length, height and width of 3600 mm, 500 mm, and 200 mm with simply supported ends were manufactured and tested. The strength grade of

concrete was C40. The longitudinal tensile reinforcement adopted HRB400 steel, the compressive steel reinforcement and stirrup adopted HPB300 steel. The longitudinal tensile and compressive reinforcing bars with nominal diameters of 25 mm, 12mm were used in the specimens. Besides, the transverse reinforcements were made of two stirrups (8 mm in diameter) and the spacing between stirrups was 200mm. A reinforced stirrup was added at the beam end, 50mm away from the beam end. The reinforcing details of the test beam are shown in Figure 2.

Figure 2. Sectional diagram of reinforced concrete beam.

(2) Reinforcement

① Reinforcement type

In this test, the oblique and U-shaped bonded carbon fiber sheets were used to strengthen concrete beams to verify the theoretical model of shear capacity of reinforced concrete beams strengthened with carbon fiber sheets. The reinforcement methods are shown in Figure 3.

Figure 3. Obliquely and U-shaped pasted carbon fiber cloths.

② Loading test

In the experiment, each beam was simply supported and loaded monotonically at four-points to failure. 4000kN hydraulic testing machine was used during the loading. By distributing steel beam, two synchronous and equivalent concentrated forces were symmetrically applied on the test beams, and the concentrated forces were transmitted to the test beams through rubber bearing.

(3) Materials

① Concrete

The beams were made of normal concrete, and the strength grade of concrete was C40. Nine cubes whose dimensions of $150 \times 150 \times 150 \text{ mm}^3$ were poured on site. After 28 days of curing under the same conditions, material properties of concrete cubes were measured in the laboratory. The test results were as follows: the cube compressive strength is 41.1MPa, the axial compressive strength is 31.24MPa, and the axial tensile strength is 3.05MPa.

② Reinforcement

The longitudinal reinforcement used in the tests was HRB400, and the stirrup was HPB300. The material properties are shown in Table 1.

Table 1. Material properties of reinforcement (unit: MPa).

Reinforcement model	Reinforcement grade	Yield strength (MPa)	Ultimate tensile strength (MPa)
B25	HRB400	440	615
A12	HPB300	–	520
A8	HPB300	–	565

(4) Test results

① The test beam strengthened with obliquely pasted carbon fiber strips

The test beam was strengthened by obliquely pasted carbon fiber strips. It was difficult to observe the initial cracks in the middle span and bending shear section because of the application of longitudinal strips. When the test beam was loaded to 60kN, cracks began to appear in the mid span; When the load increased to 180kN, oblique cracks in the shear zone began to appear; After 220kN, the inclined cracks in the shear zone became wider obviously; When the load reached 410kN, the width of inclined cracks reached 0.45mm. Finally, the carbon fiber strips of the test beam were torn. The ultimate load was 530kN, as shown in Figure 4.

Figure 4. Experimental phenomena of concrete beams strengthened with obliquely bonded carbon fiber strips.

② The test beam strengthened with U-type pasted carbon fiber strips

When the test beam strengthened with U-shaped carbon fiber strips was loaded to 60kN, the cracks in the mid span first appeared; loaded to 120kN, oblique cracks in the shear zone began to appear; When the load reached 190kN, the inclined cracks in the bending shear zone became wider obviously; When the load was up to 280kN, the width of inclined cracks reached 0.4mm. Finally, the carbon fiber strips in the test beam showed peeling failure, as shown in Figure 5.

Figure 5. Experimental phenomena of concrete beams strengthened with U-shaped bonded carbon fiber strips.

5 COMPARATIVE ANALYSIS OF SHEAR CAPACITY OF REINFORCED CONCRETE BEAMS STRENGTHENED WITH CARBON FIBER STRIPS

The calculation method of shear capacity of reinforced concrete beams strengthened with CFRP was determined by regression analysis method in the paper. Combined with the existing calculation methods of shear capacity of concrete beams strengthened with CFRP, the shear capacity of the test beams was calculated and compared. The calculation results are shown in Table 2.

Table 2. Summary of calculation results of shear capacity of concrete beams strengthened with obliquely pasted carbon fiber strips.

Serial number	Calculation model	Theoretical value(A) (kN)	Test value(A) (kN)	Error(A) (%)	Theoretical value(B) (kN)	Test value(B) (kN)	Error(B) (%)
1	Triantafillou 1998	214.77	265	18.96	210.63	255	17.40
2	Triantafillou and Antonopoulos2000	244.81	265	7.62	233.86	255	8.29
3	Matthys and Triantafillou 2001	208.09	265	21.48	208.09	255	18.40
4	Pellegrino and Modena 2002 (Crack width)	186.91	265	29.47	186.91	255	26.70
5	Pellegrino and Modena 2002 (Effective stress model)	225.82	265	14.78	221.22	255	13.25
6	Khalifa and Nanni2002	226.07	265	14.69	221.46	255	13.15
7	Taljsten 2003	279.63	265	-5.52	206.78	255	18.91
8	Chen and Teng 2003	342.06	265	-29.08	281.10	255	-10.23
9	Wang Suyan et al. 2007	246.17	265	7.11	232.77	255	8.72
10	Mofidi and Chaallal2011	281.10	265	-6.08	281.10	255	-10.23
11	Bukhari et al.2013	266.38	265	-0.52	230.05	255	9.78
12	Regression analysis(author)	248.54	265	6.21	215.45	255	15.51

Where, A: shear capacity of concrete beams strengthened with obliquely pasted carbon fiber strips; B: shear bearing capacity of concrete beams strengthened with U-shaped pasted carbon fiber strips

It can be seen from Table 2 that the calculation results of previous calculation models are quite different from the experimental values, and most theoretical calculation results are conservative compared with the experimental values. For the test beam strengthened with obliquely pasted CFRP, the error of theoretical model proposed by author is 6.21%, and the calculation accuracy is higher. However, for the test beam strengthened with U-shaped pasted CFRP, the theoretical model given in this paper has an error of 15.51%, which is rather conservative. Therefore, the theoretical calculation model determined by regression analysis is properly used to calculate the shear capacity of concrete beams strengthened by obliquely pasted carbon fiber cloths. The accuracy of theoretical calculation method for U-shaped reinforcement still needs to be improved.

6 CONCLUSIONS

CFRP is a widely used material in civil engineering. The calculation method of shear capacity of RC beams strengthened with CFRP should be studied more clearly to promote its application. In the paper, regression analysis method is used to calculate the shear capacity of reinforced concrete beams strengthened with CFRP. At the same time, model tests are used to verify the prediction results. The study indicates that:

- (1) Carbon fiber cloths can significantly improve the shear capacity of reinforced concrete beams, and limit or even prevent the development of cracks efficiently;
- (2) Based on the existing test data, the theoretical calculation results determined by regression analysis of the shear capacity of concrete beams strengthened by obliquely pasted CFRP strips have smaller errors compared with the test results, and the error is 6.21%. The calculation method can be used in actual projects. However, the difference of theoretical results and test values is relatively large for RC beams strengthened with U-shaped pasted CFRP;
- (3) The calculation results of the existing theoretical models for the shear capacity of reinforced concrete beams strengthened with carbon fiber cloths are conservative, and the maximum error is 29.47%. Based on experimental data obtained through literature, the theoretical model by regress analysis is proposed in the paper. The theoretical calculation results of the shear capacity of reinforced concrete beams strengthened with obliquely pasted CFRP are more consistent with the experimental results, which can significantly improve the efficiency of CFRP.

ABSTRACT: Given the established incentive to produce more sustainable concrete, the application of alternative and environmentally preferential materials, such as limestone (LS) powder, as partial cement (OPC) replacement, can make a significant global contribution toward sustainability. This paper presents the sustainability aspect of this green concrete through its potential application in reinforced concrete slabs and columns. For that purpose, 26 experimentally verified, concrete mixtures with and without LS powder were evaluated using the multi-criteria decision analysis framework ECO_2 . The conducted analyses show the significant potential and competitiveness of concrete with reduced cement and high LS powder content and their potential application in all types of reinforced concrete structures. In the case of slabs, the best ECO_2 score was obtained for concrete containing LS powder. In the second case, due to the nature of the structural performance requirements in columns, approximately equal sustainability potential of OPC and LS concretes was observed.

1 INTRODUCTION

Decarbonization of the construction sector could play an essential role in achieving a carbon neutral future. In the whole sector, the concrete industry is recognized as the largest emitter of CO_2 , principally because of the cement production phase (Working group UNEP-SBCI, 2015). It is estimated that about 90% of greenhouse gas in concrete are attributable to ordinary Portland cement (OPC), (Marinković et al., 2010). Moreover, 7–8% of total anthropogenic CO_2 emissions are a consequence of cement production with a tendency to grow up to 10% by 2030 (Miller et al., 2016). With this in mind, the application of locally available and environmentally preferential supplementary cementitious materials (SCMs), such as limestone (LS) powder, to partially replace OPC can make a significant global contribution toward sustainability.

Although numerous tests of the physical and mechanical properties of concrete have been successfully conducted in which more than 50% of cement has been replaced by LS powder, the average LS powder content in cement is only 6–7% globally (Working group UNEP-SBCI, 2015). These results show that adequate mechanical (Chen et al., 2014; Proske et al.,

2014), durability (Palm et al., 2016), as well rheological properties (Kwan et al., 2015; Rezvani et al., 2019) and workability (Proske et al., 2014) were achieved, even at high percentages (50%) of cement replacement. This makes LS concrete an attractive and potentially more sustainable alternative, which is crucial for its wide practical structural application.

Unfortunately, previous investigations were not followed by the appropriate economic and environmental assessments, and these are still missing. However, some studies in which the global warming potential (GWP) of LS concrete is analyzed were found (Celik et al., 2015). These studies show a potential reduction in GWP by up to 50% (Palm et al., 2016; Proske et al., 2014). The percentage of GWP reduction is usually closely related to cement reduction.

To fill the knowledge gap, the paper provides a holistic assessment of the suitability of structural application of concrete with a high LS powder content, by combining the environmental, economic, and structural performances. This could be a significant contribution to the research community as well as the construction sector. For that purpose, a multi-criteria decision analysis (MCDA) methodology is required. Evaluations of alternatives and determination of the optimal choice were done by using the MCDA framework ECO₂ method. The ECO₂ combines ECOlogical and ECONomic assessment (Hafez et al., 2021). Finally, the structural performances are taken into account by the appropriate adoption of functional units (FU).

2 MATERIALS AND METHODS

2.1 Materials

To ensure the structural applications, all concretes must meet certain conditions and the set criteria. The most important conditions include satisfactory workability, appropriate compressive strength as well as durability, i.e. service life. Besides that, as the main goal of this paper is the sustainability assessment of structural concrete with a high LS powder content, only concretes with partial replacement of cement by LS powder ($\geq 15\%$) including their control OPC concretes were considered. All selected conditions and criteria are listed in Table 1.

Table 1. Conditions and the set criteria that concrete must fulfill.

Criteria	Condition	Targets
1. Mix compositions	cement replacement	$\geq 15\%$
2. Workability*	slump/flow class	S2 ($\geq 50\text{mm}$)/F2 ($\geq 350\text{mm}$)
3. Compressive strength**	class	C20/25 ÷ C45-55
4. Durability/service life**	exposure class XC3	50 years

*(EN 12350-2, 2010; EN 12350-5, 2010); **(EN 1992-1-1, 2015).

The listed criteria were used during the literature search which was conducted in relevant databases such as Science Direct and Scopus. After applying the first criterion, over 150 tested concrete mixtures were selected from 10 studies (Radović et al., 2022). Finally, it was determined that 26 concrete mixtures, including 4 of our own, fulfill all the prescribed criteria. Nine mixes were control (OPC only) and 17 mixes included different ranges of partial

Table 2. Number of concrete mixtures in terms of cement content.

Number of mixtures	Cement content [kg/m^3]			
	>300	250–300	200–250	<200
Total	22	20	21	23
Selected	9	9	5	3

replacement by LS powder (nine with 15% LS, five with a 25–30% replacement range, and three mixtures in which 45–55% of cement is replaced by LS powder). For further analyses, mixes were grouped according to the total amount of cement (per m³), as follows: >300 kg (G1); 250–300 kg (G2); 200–250 kg (G3); <200 kg (G4) as shown in Table 2.

The composition of the selected concrete mixtures is shown in the database compiled by (Radović et al., 2022), which is available online. Mixtures have the following designations: XX-Y%-Z, where X is the symbol for the country of origin of the study, Y represents the percentage of cement replacement and Z is the mass per unit volume of the CEM I component in the concrete mix.

2.2 Applying the ECO₂ framework

2.2.1 LCA: Scope, Alternatives, and Scenarios definition

The first step of the ECO₂ analysis involves defining the scope of the LCA study, the scenarios, and the alternatives. A possible Cradle-to-Grave scope includes three main phases: “Production”, “Use” and “End-of-Life”. End-of-life phase activities such as the demolition, landfilling, or recycling of concrete into aggregates are omitted due to high future uncertainties. Similarly, in a lack of a reliable model to predict the CO₂ uptake of LS powder concrete, it was decided to exclude the “Use” phase too. The concrete production, transportation, and casting phases are the same for all alternatives and these were neglected, without affecting the comparisons. Finally, in this study, the Cradle-to-Gate scope which includes only the production and transportation of concrete mix constituents to the concrete batching plant was accepted, Figure 1.

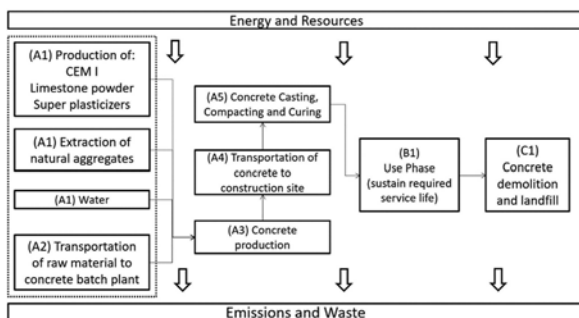

Figure 1. LCA boundary and the scope (Radović et al., 2022).

The alternatives under comparison in LCA are all the concrete mixes that passed the criteria specified in Table 1, and these are listed in the online database (Radović et al., 2022).

To perform a comprehensive analysis and include a sufficient number of parameters, two possible scenarios which include two types of structural elements were formed. In the first, the horizontal elements loaded in bending and shear, such as slabs, were analyzed. The second one included typical vertical elements - columns, dominated by the axial load.

2.2.2 LCA: Functional unit calculations

The functional unit (FU) is responsible for the quantification of the environmental and economic impact indicators. To allow proper evaluation and comparison of alternatives, FU has to include strength, durability, as well as serviceability (Marinković et al., 2021). Hence, the volume of concrete per 1 m² of the surface area of an RC slab and 1 m³ of the height of an RC column, required for the same strength, service life, and serviceability, was adopted for the FU.

For each scenario of structural element and loading, the minimum concrete cover that fulfills the required service life of 50 years was calculated. Concrete elements inside buildings with moderate humidity (exposure class XC3) were chosen. In the absence of a model for assessing the

durability of concrete with a high LS powder content, the proposal given in the draft of the new version of Eurocode 2 (prEN 1992-1-1, 2021) was used. Based on the measured carbonation depth, the carbonation rate $k_{(i)}$ is determined in accordance with (EN 12390-10, 2018) and compared to exposure resistance classes XRC, (CEN/TC 250/SC 2/WG 1/TG 10, 2021). Finally, the value of XRC was converted to a minimum concrete cover (Radović et al., 2022), by reading corresponding values from the table given in (CEN/TC 250/SC 2/WG 1/TG 10, 2021).

In the next step, the FU was corrected for strength and serviceability. A reduced amount of cement paste generally leads to reduced shrinkage and creep of LS concrete (Kwan et al., 2015; Rezvani et al., 2019), so similar serviceability (slab deflections, column displacement) was assumed for all alternatives in both scenarios. Therefore, there is no need for serviceability adjustment of the FU, only for strength.

In the case of the RC slab, scenario 1, the compressive strength of concrete has little influence on the load-bearing capacity, so it is neglected. This property is only indirectly (through carbonation resistance) included in FU, by the size of the concrete cover (c_{nom}). Assuming the same amount of reinforcement in the slabs, their flexural strength depends only on the effective depth d . Thus, the influence of reinforcement is the same for all alternatives and is also excluded from further analysis. Finally, in scenario 1, RC slabs with $d = 200$ mm, were adopted.

In scenario 2, RC columns on the ground floor of a 10-story building with the estimated ultimate axial load of $N_{Ed} = 4,000$ kN were analyzed. The design axial strength of column N_{Rd} can be expressed as:

$$N_{Rd} = N_{Ed} = A_c \cdot f_{cd} + A_s \cdot \sigma_s \quad (1)$$

where A_c = cross-sectional area of concrete; σ_s = compressive stress in the reinforcement.

The influence of reinforcement amount (A_s) on the resistance of the cross-section, since the same (minimum) area resulted the same in all alternatives, was neglected in the analysis. The required cross-sectional area can be determined from Equation 1, and thus the FU for each alternative in scenario 2.

Calculated FUs for all alternatives in both scenarios are available in the database (Radović et al., 2022).

2.2.3 LCA: Inventory data and impact assessment

Collecting the necessary inventory data is the last step before the impact assessment. It implies sourcing data on the energy and emissions associated with all materials and activities. Because of the dispersion of the experimental data sources and to increase the reliability of the assessments, a combining of databases such as Ecoinvent and data from previously published papers (Chen et al., 2010; Habert et al., 2012; Kurda et al., 2019; Tošić et al., 2015) was done by averaging the values.

The environmental impact was shown through six mid-point indicators: Global Warming Potential (GWP), Acidification Potential (AP), Eutrophication Potential (EP), Abiotic Depletion Potential (ADPE), Photochemical ozone creation potential (POCP), and Cumulative Energy Demand (CED).

The economic impact is encompassed through the market price, which includes all constituent materials and transportation costs.

The inventory database of the average values for each ingredient and the selected indicators is available online as well, (Radović et al., 2022).

For all alternatives, impacts per unit volume are calculated by multiplying the inventory of producing and transporting impacts of each constituent by its quantity. Variations in concrete performances across the different mixtures are taken into account by multiplying the total impact per unit volume and the functional unit of each alternative. Finally, all indicators are then normalized, according to Equation 2:

$$GWP_n = \frac{1.1 \cdot \max(GWP_i) - (GWP_i)}{1.1 \cdot \max(GWP_i) - 0.9 \cdot \min(GWP_i)} \quad (2)$$

In this way, the maximum values of indicators were enlarged and the minimum ones were diminished by 10% (Josa et al., 2021). Therefore, the alternative with the lowest impact gets a maximum value (< 1) and the one with the highest impact has a minimum value (> 0).

2.2.4 ECO_2 score calculations

Averaging all normalized environmental impact indicators, a single environmental impact indicator V is obtained. Finally, by weighting the normalized single environmental score V and the normalized market price X for each alternative, the ECO_2 score is calculated, Equation 3:

$$ECO_{2,i} = V_i \cdot W_1 + X_i \cdot W_2 \quad (3)$$

In this study, for each scenario and alternative, ECO_2 scores were calculated for 3 weight distributions, namely: the equal weights distribution ($W_1 = W_2$), the environmental advantage distribution ($W_1 = 2W_2$), and the economic advantage distribution ($W_2 = 2W_1$).

3 RESULTS AND DISCUSSION

The calculated sustainability (ECO_2) scores, for each alternative, regarding the cement content (for scenario 1) and concrete compressive strength (for scenario 2) are shown in Figure 2.

Figure 2. ECO_2 scores vs. cement content for scenario 1 (a) and compressive strength for scenario 2 (b).

Comparing ECO_2 scores and cement content (scenario 1), there are no reliably determined relations, but the trendlines appear to follow a bilinear relationship, with practically no dependence of the ECO_2 score on the cement content up to 250 kg and a somewhat inverse linear relationship afterwards ($R^2 = 0.0; 0.47$).

The main reason for this is the increased content of quite expensive plasticizers in some low-cement mixtures (< 250 kg), which impairs economic and consequently sustainability scores. Therefore, the sustainability benefit brought by lower cement content is not always guaranteed.

In scenario 2, a good positive correlation ($R^2 = 0.87$) between ECO_2 scores and compressive strength is clear. Due to the different structural performance requirements for vertical (versus horizontal) elements, this property is the most important. Every 10 MPa increase in compressive strength is followed by an average increase in the ECO_2 score of approximately 0.2, indicating its importance.

Figure 3 presents the calculated ECO_2 scores for the three best alternatives (with the highest ECO_2 scores) from each G1–G4 group in both scenarios. It seems that higher variations are observed in groups with lower cement content (particularly G4). In scenario 1, groups G1 and G2 showed the smallest score value variation of 0.02–0.06. The group G3 had slightly more (0.09), but G4 had the largest variation within the top three alternatives in each group, as much as 0.31. In scenario 2, the results of the top three alternatives within the groups are additionally influenced by the concrete compressive strength, so the variations are greater. Here, one should bear in mind the different numbers of mixtures in each group (only 3 mixtures in G3).

ECO_2 scores with a different distribution of weight coefficients (equal importance, the environmental advantage 2:1, and the economic advantage 1:2) for the best three concrete mixtures in both scenarios are shown in Figure 4.

For scenario 1, all these mixtures contain LS: IT-15%-212 (G3); CH-15%-264 (G2); RS-55%-150 (G4). As can be seen, groups G3 (200–250 kg), G2 (250–300 kg), and G4 (<200 kg) participate with one mixture each, i.e. there is no OPC (G1) concrete. The differences in ECO_2 scores between these mixtures are small enough (0.03), that none can be declared the best. In other words, all three should be considered potentially optimal solutions. Almost the same values of the ECO_2 scores (0.69–0.72) of the three best alternatives in this scenario, together with a high difference (0.22–0.26) in individual (environmental and economic) scores make alternatives sensitive to changing weight coefficients. This is especially pronounced for the mixtures which have a large deviation of the economic and environment scores, such as RS-55%-150 (0.56–0.83) and CH-15%-264 (0.61–0.82). Thus, in the case of environmental advantage, RS-55%-150 became the mixture with the highest score and CH-15%-264 with the lowest ones and vice versa, when criteria weights are changed in favor of the economy.

Figure 3. ECO_2 scores for the best three alternatives from each group: a) Scenario 1; b) Scenario 2.

Figure 4. ECO_2 scores for the best three mixtures with different weight distributions: a) Scenario 1; b) Scenario 2.

The results obtained for scenario 2 showed a different order of alternatives. The three concrete mixtures with the highest ECO_2 score were: DE-0%-320 (G1), IT-30%-210 (G3), and DE-50%-190 (G4). One of the top three mixtures is from the G1 (>300 kg) group and two others contain LS (G3 and G4). The differences between the first and third mixture in the ECO_2 scores are about 0.09, three times higher than in the previous scenario. Due to the best economic (0.92) and good environmental (0.84) score, mixture DE-0%-320 with the ECO_2 score of 0.88 in scenario 2, followed by IT-30%-210 with a score of 0.82 represent potentially the most sustainable choice. Smaller differences between the environmental (0.04) and cost (0.21) criteria in scenario 2 make alternatives almost insensitive regardless of the value of the weights (the order of alternatives is unchanged).

4 SENSITIVITY ANALYSIS

The impact of critical variables (variation of concrete cover depth, costs of OPC, LS powder and superplasticizer, as indicated in Figure 4) on the sustainability scores was tested by sensitivity

analysis, Figure 5. The results showed that there is no effect of the tested variables on the ranking of best alternatives in scenario 2 (only a change in relative differences), but it has in scenario 1. This is due to negligible differences between the overall ECO_2 scores of the alternatives in scenario 1, as well as the large differences in individual indicator scores within certain alternatives. Accordingly, the variation in the input data does not cause excessive changes in the final sustainability scores, but relatively small changes are sufficient to affect the ranking.

Figure 5. ECO_2 scores regarding sensitivity analysis for the best 3 mixtures: a) Scenario 1; b) Scenario 2.

5 CONCLUSIONS

In this paper, a multi-criteria analysis framework ECO_2 was used to assess the sustainability potential of reinforced LS powder and comparable OPC concrete slabs and columns. For this purpose, 26 experimentally verified concrete mixtures were evaluated through economic, environmental, as well as performance-based criteria. Mixtures were grouped according to the amount of cement in four groups: >300 kg (G1); 250–300 kg (G2); 200–250 kg (G3); <200 kg (G4).

Based on the conducted research, the following conclusions can be drawn:

- Concrete compressive strength has an indirect effect (through the concrete cover depth) on FU for flexural elements (slabs), while it is crucial for axially loaded elements (columns). When it comes to columns, increasing the concrete compressive strength by every 10 MPa brings a high average increase in ECO_2 scores of about 0.2.
- In the case of RC slabs (scenario 1), the best five mixtures with almost equal ECO_2 scores (0.67-0.72) represent potentially optimal solutions. All these mixtures belong to LS concretes: CH-15%-264, IT-15%-255, GB-25%-266 (G2); IT-15%-212 (G3); RS-55%-150 (G4).
- In the case of RC columns (scenario 2), there are only two potentially optimal solutions: DE-0%-320 (G1), and IT-30%-210 (G3). Due to the higher compressive strength of OPC concrete, and its decisive influence, an equal presence of LS and OPC concretes was observed.
- Large deviations between environmental and economic scores within some mixtures in scenario 1, coupled with the close overall scores, make these sensitive to eventual changes in input parameters or weights.
- At the same time, the results showed that the inputs or weights changes have influence only in relative differences of alternatives in scenario 2; therefore, the order is unchanged.

The results of this study depend on numerous assumptions and should not be generalized when interpreting conclusions until further research is conducted with a large number of alternatives and a wider range of input parameters.

Development of life-cycle inventory for timber products to support the circular economy in construction

S. Ge, P.J. McGetrick, C. O’Ceallaigh & A.M. Harte

Timber Engineering Research Group, Ryan Institute, University of Galway, Galway, Ireland

ABSTRACT: The supply of raw materials from Irish forests is forecasted to double between 2017-2035, creating opportunities to increase the output of timber products for construction. Furthermore, residential building construction in Ireland needs to achieve an average annual rate of completion of up 35,000 within the next decade to meet housing demands and population growth. A significant challenge for sustainable construction globally is materials with high embodied carbon, like steel and concrete, remain the primary structural material choices. Although the potential increase in carbon emissions from future construction can be minimised through substitution using timber products, full lifecycle assessment and comparison of such structural solutions to quantify the climate mitigation benefits can be limited by a lack of detailed lifecycle data. Therefore, this paper summarises the development of a national reference database for this lifecycle information and presents a quantification of the lifecycle impacts of Irish timber solutions for sustainable construction.

1 INTRODUCTION

The latest assessment report launched by the IPCC showed we are currently at 1.5 times the greenhouse gas (GHG) concentrations compared with the 1850 level (IPCC, 2014). In Ireland, the total GHG emissions (excluding LULUCF) in 2021 were 61.53 Mt CO₂ eq (EPA, 2022), with agriculture, transport, and energy industries being the first three influential sectors, accounting for 71.9%; still, the contribution of the building sector is not clearly stated in this report. A recent study outlined that the Irish built environment is responsible for 37% of Irish GHG emissions in a standard year (i.e., 2018), containing operational (23%) and embodied carbon (14%) (IGBC, 2022). To mitigate the pressure of climate change, Ireland has committed to reducing GHG emissions to half of the 2018 level by 2030 and reaching net zero by 2050. In the total emissions reduction, the building sector is allocated to a challenging 44-56% burden within executive measures, such as retrofitting houses and introducing renewable energy heating systems for both existing and new dwellings (Government of Ireland, 2021). Moreover, similar to global trends, the Central Statistics Office (CSO) reported that Ireland’s population is forecasted to increase to between 5.6 and 6.7 million by 2051, bringing more housing demand simultaneously. The National Development Plan 2021-2023 predicts that 600,000 new homes will be required by 2040, meaning roughly 33,000 new residential buildings are needed each year. Considering the rising housing demand and the significant load the building industry takes to mitigate GHG emissions, timber is an excellent structural material option for building construction.

Unlike traditional building materials like concrete and steel, timber is a low embodied carbon material; its use in place of concrete and steel can considerably reduce the embodied carbon emissions in building projects. Operational carbon emissions (OCE) and embodied carbon emissions (ECE) are two leading indicators to assess a building’s atmospheric impact. OCE indicates the emissions caused by energy consumption during the building’s use stage, while ECE is mainly related to the emissions from materials and other stages like construction,

transportation, deconstruction, etc. Many studies have substantiated the excellent performance of timber in decreasing carbon emissions. Skullestad et al. (2016) studied timber and reinforced concrete structures under different building heights, finding that the former caused 34-84% less climate change impact than the latter. Assuming natural gas heating is replaced by the incineration of recovery wood residues, the climate change impact saving by timber structures can be increased to 220% approximately (Skullestad et al., 2016). Laurent et al. (2018) studied an existing arena in North America that integrated glued laminated timber beams with steel. They found that the hybrid structure reduced the total emissions by 83 tonnes of CO₂ eq compared to the whole steel structure. Moreover, Murphy et al. (2015) localised LCA research on Irish timber products in seven manufacturing scenarios. They found that GHG emissions can be further reduced by integrating combined heat and power (CHP) plants with sawmills, as CHP plants can transform the co-products during production (e.g., sawdust) into energy and feed it back for production (Murphy et al. 2015).

Considering the great potential of wood in GHG emissions reduction, this paper focuses on timber construction products and subsequent contexts are organised as follows: Section 2 analyses the Irish timber products and gives some reasons for low timber frame application in Ireland. Section 3 introduces the lifecycle assessment (LCA) and compares Irish and international LCA practices in timber construction. Section 4 presents a general lifecycle inventory (LCI) model for Irish timber products. After a simple application of EPD, Section 5 discusses several controversial points in timber's lifecycle assessment.

2 IRISH TIMBER PRODUCTS ANALYSIS

Timber products used in Ireland can be broadly classified into structural and non-structural use. Sawn timber and wood-based panels (WBP) are the most representative products in the former category, and the latter includes wood used for energy generation, paper production, horticulture, etc. Sawn timber indicates products made from large diameter logs, which can provide excellent performance for structural use. WBP commonly refers to the panels comprising compressed layers of wood, typically combined through adhesives or fasteners. Based on the wood size used in panels, this paper divides WBP into four levels, shown in Figure 1. The smallest wood size level is the fibre level, of which medium-density fibreboard (MDF) is a typical representative. Strand level products include oriented strand board (OSB), laminated strand lumber (LSL) and parallel strand lumber (PSL); PSL organises wood strands in parallel - OSB and LSL are layered in perpendicular directions. At the veneer level, normal plywood laminates wood sheets with adhesives in a direction where the grain of adjacent layers is perpendicular to each other. In laminated veneer lumber (LVL), the grain of all layers is oriented in the same direction; laminated veneer board (LVB) organises internal layers in a grain-parallel way, with outer layers perpendicular to the inner direction. The last level is the semi-manufactured level, meaning the wood used in these products has already been processed. Cross-laminated timber (CLT) and glue-laminated timber (GluLam) are both manufactured by gluing layers of sawn lumber together, but the grain in adjacent CLT layers is cross-oriented and GluLam layers are in parallel. Unlike CLT and GluLam, dowel laminated timber (DLT) and nail laminated timber (NLT) use wood dowels and metal nails, respectively, to fasten multiple boards to make larger panels.

Ireland is export-oriented in the forest products sector, and over 80% of WBP is exported overseas, where the UK, Germany, and Benelux countries are the primary markets. However, the application rate of timber frames in Ireland is much lower than in many other European countries. The Timber Frame Housing Report 2002 estimated that timber frame housing accounted for up to 15% of the total output in 2001 and 2002 (Government of Ireland, 2002). The Irish Timber Frame Manufacturers Association (ITFMA) also pointed out that about 30% of new dwellings are timber frame (IFFPA, 2016), and as of 2022, this figure could be as high as 50% for low rise residential buildings. However, these figures are far lower than Finland's at 80%, Scotland's at 83%, and Sweden's at 90% (Kitekuzman et al., 2017). In addition, annual wood-flow reports by COFORD from 2010 to 2018 show that the average proportion of timber products used in construction is 26%. However, Ireland's total roundwood harvest (including

firewood) keeps increasing from 2.9 million cubic meters in 2010 to 3.7 million cubic meters in 2018 and is forecasted to double to 7.9 million cubic meters in 2035 (IFFPA, 2016). In summary, there is significant potential to increase the use of Irish wood for construction applications.

The reasons for Ireland’s low timber frame application rate can be boiled down to two points. First, Ireland has the lowest forest area (%of land area) in EU countries, excluding Malta and the Netherlands. Although Ireland has extended its forest area from 6.7% in 1990 to 11.4% in 2020, it is still lower than the average value (i.e., 34.1% in 2020) of EU countries (The World Bank Group, 2020). Secondly, there is no significant culture of building with wood in Ireland, and there are many misconceptions about how timber frame construction will behave in Ireland’s climate. Finally, there is a lack of lifecycle assessment data on Irish timber products which would give the general public and building specifiers confidence when specifying environmentally sustainable solutions such as wood for buildings. Addressing this final point is the focus of the paper, and the next section will specifically analyse the gaps between Irish and international LCA practices in timber construction.

Figure 1. Classification of the wood-based panel (WBP).

3 COMPARISON OF LCA PRACTICES IN TIMBER CONSTRUCTION

Lifecycle assessment (LCA) in the construction industry indicates the environmental impact estimation of building projects within a defined system boundary. A typical LCA starts with the goal and scope definition, then followed by inventory analysis and impact assessment, and ends with specific interpretations (ISO 14040:2006). For particular projects, LCA is flexible in the research object and system boundary definition. The studied target can be the whole building or a single product, and the system boundary can be cradle-to-gate, cradle-to-grave, and cradle-to-cradle. I.S. EN 15978:2011 defines the system boundary for the building’s lifecycle assessment, composed of four stages: (i) the product stage, (ii) the construction stage, (iii) the use stage, and (iv) the end-of-life stage (Figure 2). The cradle-to-gate system refers to the first stage (i.e., A1-A3), and the cradle-to-grave system indicates the whole building life (i.e., A1-C4). After considering materials recovery and reuse within the boundary, it can be called the cradle-to-cradle system or circular economy (i.e., A1-D). If categorised by the type of carbon emissions, B6 and B7 phases are related to OCE, and ECE happens in the rest phases, of which A1-A3 contribute the most. This paper focuses on the embodied sector of Irish and international LCA practices for four timber products frequently used in construction: sawn timber, OSB, MDF, and CLT.

3.1 Overview of Irish and international LCA practices

Environmental product declarations (EPDs) provide a universal approach to comparing and evaluating the environmental performances of a product. The international EPD system is now the oldest operational EPD programme in the world and the reference of many national programmes. In March 2018, the Irish Green Building Council (IGBC) activated a localised EPD programme, EPD Ireland, enabling Irish manufacturers to develop EPDs for their products. However, there are no mandatory regulations or laws for their use in Ireland, which limits their use. By contrast, MPG (Milieu Prestatie Berekening) is already in force in the Netherlands for every environmental permit concerning all new-built residential and office buildings over 100 m², whether public or private. The MPG combines all environmental indicators into the shadow cost of materials applied in the building with the unit of Euro per square meter GFA (gross floor area) per year. France also issued a decree (No. 2021-1104) in

July 2021 on energy and environmental performance requirements for all new buildings, including residential, office, and primary or secondary educational buildings. The climate impact indicators include two categories, one for materials and site impact (similar to OCE) and another for energy consumption (similar to ECE).

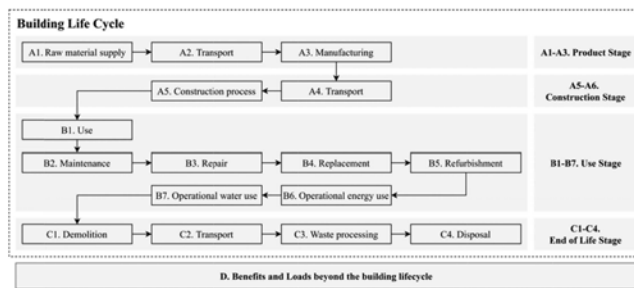

Figure 2. System boundary definition.

In addition to the absence of mandatory regulations, Ireland falls behind many nations in the amount of declared EPDs, particularly for wooden products. Several EPD websites were searched using the following keywords: timber, lumber, wood, CLT, MDF, and OSB. At the time of writing, the EPDs published by EPD Ireland have just exceeded 80 EPDs, with about 11 linked to wood products. In comparison, the IBU of Germany has collected 1734 published EPDs, of which 50 EPDs are related to wood products. The INIES of France contains approximately 150 EPDs about wood products of 6977 environmental data in total. The following section discusses the differences between the EPDs of selected timber products between Ireland and other countries.

3.2 EPD comparison

The comparison examines five EPDs from different countries (including Ireland) for four timber products, as outlined in Table 1. All selected EPDs comply with ISO 14025 and I.S. EN 15804, so they are comparable with each other. The UK or European level is chosen as a reference where an EPD from Ireland is unavailable, and only three EPDs are collected and compared for OSB.

Tables 1 and 2 highlight that Ireland only has EPDs for MDF and OSB. The International EPD System is the most frequently used programme among the 18 studied EPDs, e.g. EPD Turkey and EPD Australasia are aligned as regional members of this system. Following the global standard, the IBU of Germany is the second programme with high adoption, covering all four products. Although EPD Ireland is independent of the International EPD System, IGBC has joined the Eco Platform, an organisation of European EPD programme operators, ensuring that all the EPDs published by EPD Ireland can be visible across Europe.

Furthermore, differences can be found in some specific EPD items between Irish and international LCA practices. First, nearly 80% of the studied EPDs select 1 m³ as the declared unit, and some use 1 m² with a defined thickness for WBPs, while Ireland uses 1 tonne to calculate the environmental impact of MDF and OSB. Second, I.S. EN 15804 was revised in July 2019 (i.e., I.S. EN 15804+A2), increasing the required indicators to nineteen from eleven. In the latest version, the global warming potential (GWP) is divided into three sub-indicators: GWP-F, GWP-B, and GWP-Luluc, accounting for GWP related to fossil fuels, biogenic carbon and land use and land use change, respectively. In Table 1, nearly half of EPDs contain all three categories, and some only include the total GWP value due to their early issue time. The EPDs published by EPD Ireland have not incorporated the GWP-Luluc.

Finally, I.S. EN 15804+A2 states that modules A1-A3, C1-C4, and D must be declared in all construction products unless the conditions to exclude modules C1-C4 and D are met. The declared modules of EPDs are shown in Table 2, where 50% of them cover all the required

stages, and 80% incorporate environmental impacts from the wood waste treatment (i.e., modules C3-C4) and corresponding benefits and burdens beyond the building life (i.e., module D). However, the EPD for MDF from MEDITE omits the D stage, and the EPD for OSB from SMARTPLY only declares the A1-A3 stages. Therefore, Ireland still has a long way to go compared with other countries in LCA practices for timber products.

Table 1. EPDs used in comparison.

Category	Declared unit	EPD owner	Validity	Scope	Programme
Sawn timber	1 m ³ kiln dried planed or machined sawn timber used as structural timber ¹	Wood for Good	10/04/17-09/04/22	UK	BRE
	1 m ³ sawn kiln-dried softwood	Wood Solutions	14/02/22-14/02/27	Australia	EPD Australasia
	1 m ³ kiln dried, rough sawn and planed EGGER timber	Fritz EGGER GmbH	29/07/21-09/05/26	Germany	IBU

4 THE LIFECYCLE INVENTORY FOR IRISH TIMBER PRODUCTS

In terms of the gaps identified during the comparison, this sector develops a general lifecycle inventory (LCI) for lifecycle analysis of Irish timber products. Before the LCI analysis, the studied system boundary needs to be defined; modules A1-A3, C1-C4, and D are mandatory stages (I.S. EN 15804+A2). In addition, as the contribution of GWP-Luluc in different stages for the eight EPDs is less than 1%, this indicator is excluded from the following discussion.

4.1 Modules A1-A3

Modules A1-A3 refer to the production stage, from the raw materials supply to the packaging of finished products, also called the cradle-to-gate system. For timber products, this stage should include all steps from tree seeding to the completed products leaving the factory. During the production phase, the sources of GHG emissions and removals are from three sectors: (i) energy consumption, (ii) materials, and (iii) waste treatment.

Energy consumption to produce timber products must consider electricity and thermal energy, as almost all the manufacturing of timber products requires the drying process to reduce the moisture content. In 2020, the energy input to Ireland's electricity generation was still dominated by natural gas (i.e., 52%), although the contribution of renewable energy has increased to 42% from 6% in 2005. Thanks to the greener energy mix, the CO₂ intensity of Ireland's electricity grid has decreased to 296 g CO₂/kWh in 2020 from 636 g CO₂/kWh in 2005 (SEAI, 2020). As for emissions from thermal energy, it depends on how much carbon is stored in the wood waste used as biomass fuel. Thus, factory-specific data needs to be recorded during the manufacturing process.

Different from conventional construction materials, such as concrete and steel, timber contributes carbon removals due to CO₂ sequestration during its growth. The stored, or biogenic, carbon relates to the GWP-B indicator. I.S. EN 16449 provides a formula to calculate CO₂ from the biogenic carbon in wood, and all studied EPDs comply with this method.

$$P_{CO_2} = \frac{44}{12} \times cf \times \frac{\rho_w \times V_w}{1 + \frac{w}{100}} \quad (1)$$

where 44/12 indicates 1 kg biogenic carbon equals 44/12 kg CO₂; cf = carbon fraction of woody biomass (default value is 0.5); ω = moisture content of the product (%); ρ_ω = density of woody biomass of the product at that moisture content (kg/m³); V_ω = volume of the wood material in the product at that moisture content (m³).

Other materials required in timber products, such as glue for the lamination of wood boards, should also be considered. The EPD owner should ask for the original data from material suppliers to calculate corresponding GHG emissions if the materials are not produced in the same factory. Finally, the processing up to the end-of-waste state should be included for all wastes in this stage, like wood and packaging materials.

4.2 Modules C1-C4 & D

Modules C1-C4 (i.e., end-of-life stage) start from building dismantling to transportation of wastes and end with waste treatments. As module D needs to declare the benefits and burdens related to waste treatments, it is also discussed in this sector. Furthermore, modules C1-C2 are excluded because the product market might be worldwide, and four end-of-life scenarios are listed below.

Table 3. GHG emissions in four end-of-life scenarios for wood material.

Scenarios	C3	C4	D
Reuse	BR	ND	Benefits of avoiding producing the same amount of new products
Recycling	BR + emissions from processing wood waste to a ready-for-recycling state	ND	Benefits of avoiding producing the same amount of new materials
Incineration	BR	ND	Energy recovery
Landfill	ND	ND	ND

BR: biogenic carbon release. ND: not declared.

In all studied EPDs that cover modules C3 and C4, 33% use mix scenarios for the wood waste treatment and 26% calculate the ECE separately in different scenario assumptions. Only one scenario is taken into account for the remainder, with 5 EPDs considering incineration and 1 EPD considering landfill. As shown in Table 3, each scenario can get corresponding benefits declared in module D except for landfill. However, the landfill gas generated from degrading organic carbon in the wood waste can also be combusted for energy recovery, and EPD Australasia has already applied this. In terms of Ireland, the EPD for MEDITE MDF defines a 50/50 allocation for incineration and landfill. However, research showed that about 96% of the wood waste in Ireland is used as biomass fuel; only 4% goes to landfill (Cristescu et al., 2020). The differences between product EPDs and the national market highlight that as much data as possible should be collected and analysed for precise end-of-life scenario allocations.

In addition to applying reasonable end-of-life assumptions, other data should be considered. For example, most EPDs assume wood properties will not change during usage, but the density and moisture content in the wood waste should be remeasured for a more accurate biogenic carbon estimation. Moreover, it still requires data related to energy consumption in waste processing and facility efficiency in energy recovery for GHG emissions calculation.

4.3 A simple EPD application in Ireland

An EPD application on a typical Irish timber frame house with 2 storeys (Table 4) reveals more issues waiting to be solved. It can be seen that modules A4-A5 and C1-C2, omitted in the LCI analysis, contribute 40% of the total GWP when applying the EPD owned by Wood for Good. These components are too significant to be excluded. Moreover, the EPDs of EGGER and Swedish Wood both assume 100% incineration at the end-of-life, but the figures vary significantly (i.e., -4941 and -1415 kg CO₂ eq, respectively) for adopting different incineration efficiency and energy types for recovery.

Table 4. Application of EPD for Irish sawn timber (12.2 m³).

EPD owner	GWP-T (kg CO ₂ eq)								
	A1-A3	A4	A5	C1	C2	C3	C4	D	Total
Wood for Good	-8686	95	506	155	90	9455	112	-3062	-1336
Wood Solutions	-9321	-	-	-	-	0	706	-3	-8618
Fritz EGGER GmbH	-8491	-	-	0	18	9833	0	-4941	-3581
Swedish Wood	-9077	-	-	3	81	9443	0	-1415	-965
Baskegur	-8320	-	-	-	-	-	-	-	-8320

5 CONCLUSION

Based on the EPDs reviewed in this paper, modules A1-A3, C3-C4, and D are expected to be included in the LCA for Irish timber products. Considering that the UK is the primary market for Irish timber, modules A4-A5 and C1-C2 should also be added according to typical transit modes and construction styles in the UK. To build a precise Irish LCI for timber products, further research will be oriented towards (i) obtaining more specific details on Irish wood products to make suitable assumptions in filling the gaps in required modules and (ii) determining a realistic end-of-life scenario for Irish wood waste.

Life-cycle assessment and sensitivity analysis of a clayey sediment-based geopolymer concrete

L. Monteiro, H. Yáñez-Godoy, J. Saliba & N. Saiyouri

Institut de Mécanique et d'Ingénierie (I2M), Université de Bordeaux, Talence, France

ABSTRACT: This article evaluates, through a life cycle assessment (LCA), the environmental impacts of a sediment-based geopolymer mortar mixed with alkaline reagents. The obtained results were compared to the use of classic Ordinary Portland Cement (OPC) for treating dredged sediment with similar compressive strength. Dredging methods as well as transport were taken into account in addition to the mix-design and fabrication methods. In order to quantify the sensibility of the chosen hypothesis, a sensitivity analysis was also conducted to make the methodology more robust. Throughout the analysis, it could be concluded that the use of alkaline reagent reduces the impact on climate change but does not lead to better impact results than OPC for all other categories considered. Therefore, the use of alternative local precursors is not sufficient and market potential of geopolymer mortars will depend on an alternative to the alkaline reagents currently used for geopolymerization.

1 INTRODUCTION

In 1978, the French chemist Davidovits (2005) coined the term geopolymer to describe a class of aluminosilicate inorganic materials obtained by reaction between a precursor, aluminosilicate material, and alkaline reagents. Considered as mineral binders due to their properties similar to OPC, geopolymers represent a potential replacement for cement. For this reason, their low carbon impact is an important leitmotif in the studies published to date. Davidovits (2013) estimates that the manufacturing process of geopolymers requires 9 times less energy than the production of Portland cement and emits 8 to 10 times less greenhouse gases. Indeed, the materials used for geopolymerization do not require a calcination process, contrary to clinker production. In the most favourable case, when the manufacture of the precursors is not taken into account, it achieves an 80% reduction in CO₂ emissions compared to Portland cement. These results, although similar to other studies (Robayo-Salazar et al., 2018; Salas et al., 2018), are highly dependent on the assumptions made in LCA. In the literature, CO₂ emission reduction values ranging from 9% to 80% are observed. The factors responsible for these variations are: the variability of the precursors used, the different transport distances considered, the high alkali content, whether or not the solid fraction of the silicate is taken into account, and the requirement for high-temperature processing. Despite diverging results, there is a general consensus towards the same conclusion: geopolymer production produces less CO₂ than cement production.

One of the strategies identified as essential to the competitiveness of geopolymers on the market, is the use of local resources that allow to decrease the costs related to the manufacture of materials and their transport. Among the identifiable local resources, dredged sediments are a source of interest due to their adequate mineralogical composition and their significant quantity. Annually in Bordeaux, 9 million m³ of sediments are dredged. Several studies have successfully evaluated the potential of dredged sediments for use in geopolymer matrices (Ferone et al., 2013; Komnitsas, 2016; Lirer, 2017). Using sodium silicate (Na₂SiO₃), Ferone et al. (2013) obtain a value of 3.44 MPa at 28 days for a mortar with calcined sediments. Similarly, Mograhbi et al.

(2018) obtained at the age of 28 days 0.2 MPa for untreated sediments from the Grand Port Maritime of Dunkerque. However, despite the technical viability, to the authors' knowledge, there is no study on the LCA of such process. Furthermore, existing studies on the ecological impact of geopolymer applications focus on the impact regarding climate change, but the true environmental profile of these materials goes far beyond that and will define the true limits for the development of this technology in a sustainable construction industry.

Through a LCA, this paper fills a knowledge gap by presenting the impacts of the full LCA of a geopolymer mortar formulated from untreated dredged sediments taking into account the activities associated with the extraction of raw materials, transport and the manufacture of 1 m³ of mortar. In addition, in order to minimise the uncertainties associated with the assumptions and choices made in the study, a Monte-Carlo sensitivity analysis was performed. Three different scenarios were considered for two different mortars based on untreated dredged sediments: a reference cement-based mortar and a geopolymer-based mortar. The impact of mortars was evaluated based on four environmental indicators: climate change, acidification, eutrophication and water pollution.

2 SCOPE DEFINITION AND METHODOLOGY

2.1 *Goal, scope definition and life cycle assessment*

The objective of this study is to compare the ecological performance of two different treatments to formulate a mortar from untreated dredged sediments from the Garonne. The functional unit retained in this study is the production of 1 m³ of mortar with cement or alkaline reagents with equivalent mechanical resistance. It was decided in this study to focus on the early parts of the life cycle with a “cradle to gate” approach. The boundaries of the system are therefore the extraction and production of materials, the dredging and processing of sediments in addition to the transport and manufacturing energy required to produce 1 m³ of mortar. Other processes related to on-site implementation, sustainability, end-of-life and recycling were not considered in this study. Sensitivity analyses were performed to take into account market developments in geopolymerization and circumstantial changes in transport distances of activators.

The scenarios of the different mortars were established according to ISO 14 040 and ISO 14 044 and were modelled in SimaPro using the EcoInvent 3.2 database. The calculations were then carried out according to the NF EN 15804+A1/CN (2014) and CML-IA method (2016).

2.2 *Mix design*

The geopolymerized mortars were obtained from untreated dredged sediments from the Garonne River as a precursor. The sediments are used at a water content of 30% to limit the additional external water input and to facilitate the treatment by eliminating additional operations such as screening and crushing. The production of geopolymerized mortar from dredged sediments is based on the alkaline activation of 70% sediment with 30% activator by mass. The activator mixture is a combination of a 4M solution of NaOH and Na₂SiO₃ with an optimum weight ratio of SiO₂/Na₂O solution of 1.2. Sodium hydroxide (NaOH) was used in the form of pellets (99% purity) which were dissolved in a ready-to-use silicate solution (Na₂SiO₃) supplied by Xatico. The choice of these activators is motivated by their classical use in most studies, allowing the results obtained to be compared with those known in the literature. A first formulation of geopolymer-based sediments (GBS) was established using this methodology. The reference formulation with OPC is a mixture of 80% sediment and 20% conventional Portland cement. The formulations and mechanical strengths of the two solutions are detailed in Table 1. The volume and the water/solid ratio are kept constant at 1 m³ and 0.40 respectively.

2.3 *Life cycle assessment*

The data for cement and alkaline reagents (NaOH, Na₂SiO₃) are taken from the EcoInvent database. The data for OPC in EcoInvent corresponds to the production of cement consisting

Table 1. Mix design and compressive strength of the studied mortars.

Mix	Mix proportions for 1m ³				Mechanical Strength [MPa]
	Sediment	OPC	NaOH	Na ₂ SiO ₃	
OPC	1319.00	172.70	-	-	1.67
GBS	1138.18	-	14.43	153.10	4.78

of 0.9 kg of clinker for one kg of cement. The molarity of the NaOH solution was taken into account according to the mass of pellet added. For sodium silicate (Na₂SiO₃), only the solid fraction of the silicate is considered in this study. There is no dredging process for sediments on EcoInvent so the impact of dredging was modelled as follows:

- Moving the dredger in the estuary to the dredging area in Pauillac, Gironde (*transport, freight, inland waterways, barge*)
- Hydraulic suction dredging operation (*sand quarry operation, sediment extraction from river bed*)
- Dumping of sediments with shovels and skips (*excavation, hydraulic digger + transport, freight, lorry 3.5-7.5 metric ton*)
- Natural dewatering of the sediments in landfills (*process-specific burdens, inert material landfill*).

For transport, it is assumed that the concrete production plant is located in Bassens next to the Port of Bordeaux, while the dredging of the sediments is located in the Pauillac area upstream of the estuary. The material suppliers were chosen as close as possible to the concrete production plant. The distance assumptions are presented in Table 2.

Table 2. Transport inventory.

Materials/Process	Supplier	Distance from supplier	Mode
Portland cement	Lafarge (France-Bassens)	1.4km	Road
NaOH	Sigma Aldrich (Germany)	1146km	Road
Na ₂ SiO ₃	Xatico (Spain – Saint Gugat del Vallès)	638km	Road
Sediment	-	-	-
Round trip	-	75km	Estuary
Unloading platform	-	0.2km	Road
Landfill deposit	-	48.8km	Road

3 RESULTS AND DISCUSSIONS

3.1 Global impacts

Table 3 presents the calculated impact values for each category related to the production of 1m³ of the formulations compared in this study. Figure 1 shows the comparison of the values in relative terms for each impact category. Considering the Climate Change impact, which represents the CO₂ emissions emitted per 1 kg of mortar produced, a clear decrease is observed for geopolymerized solutions. OPC emits 227.54 kg.CO₂.eq against 180.1 kg.CO₂.eq for GBS. The use of a geopolymer binder relative to the use of OPC, allows a reduction of carbon emissions by 21%. Although the GBS shows a lower performance for the climate change category than OPC, results shows that geopolymer treatment has a higher environmental score regarding the other impact categories such as Acidification (A), Eutrophication (E) and Water Pollution (WP) which increases by 47%, 68% and 56% respectively. Thus, this questions the ecological benefit of using alkaline reagent in order to develop the mechanical strength. The use of local sources of materials has been identified as one of the major keys to reduce the environmental impact of geopolymer (Turner & Collins, 2013) yet, despite the use of local and

alternative precursors such as dredged sediments, high impact in A, E and WP were observed. Alkaline reagents are often targeted when questioning the environmental potential of geopolymer. Indeed, sodium silicate (Na_2SiO_3) process, through the electrolysis, is responsible for the high value in those categories. The reduction of environmental scores for geopolymers will require the search for new, more environmentally friendly activators which are often identified as the major source of contribution.

Table 3. Results for each impact category.

Impact category	Unit	OPC	GBS
Acidification (A)	kg. SO_2 .eq.	0.57	1.06
Eutrophication (E)	kg. PO_4 .eq.	0.14	0.44
Water Pollution (WP)	m^3	2.39	5.50
Climate Change (CC)	kg. CO_2 .eq.	227.53	180.06

Figure 1. Global impacts of each mortar calculated with the EN 15-806 and CML-IA.

3.2 Sensitivity analysis

3.2.1 Deterministic model

In order to test the robustness of the results and their sensitivity to the chosen initial hypotheses, a deterministic sensitivity analysis was carried out. The objective is to define the limit values of the study in order to be able to study the sensitivity of the results related to the input parameters. Among the hypotheses defined in the study, the transport distances and the extraction of the sediments are considered. As Davidovits (2013) pointed out, it is difficult to compare the cement industry, implemented in France for several years now with hundred cement factories which implies an easy proximity supply in France, with the importation of alkaline reagent. For the sake of comparison and in anticipation of market forces, the new impacts of geopolymer mortars should be calculated assuming nearby suppliers. Concerning sediments, it can be assumed that, as sediments are considered as waste and because their extraction is linked to port activities, the consideration of this process can be neglected in the sensitivity analysis. Table 4 shows the results for OPC and GBS impact categories when transport distances for GBS are considered similar as cement and when sediment extraction is not taken into account for both mixtures.

Table 4. Results for each impact categories after sensibility analysis.

Impact category	Unit	OPC	GBS
Acidification (A)	kg.SO ₂ .eq.	0.43	0.88
Eutrophication (E)	kg.PO ₄ .eq.	0.13	0.38
Water Pollution (WP)	m ³	0.45	3.94
Climate Change (CC)	kg.CO ₂ .eq.	202.35	138.95

The reduction of transport distances and the non-inclusion of sediment extraction lead to an environmental gain for every impact category. Transport and sediment extraction are identified as key parameters in this first analysis. A study including uncertainties for these parameters is carried out to analyse their impact in the following section.

3.2.2 Stochastic model

In order to observe the sensitivity of the emissions for the different impact categories in Table 3, three scenarios, y_{sci} , are considered. Each scenario is defined by Equation 1 below:

$$y_{sci} = \sum_1^k F_j \cdot X_j \quad (1)$$

where F_j is the emission factor (defined in EcoInvent 3.2 database) for each input parameter X_j , that are stated for OPC mortar as follows:

- X_{OPC1} : amount of cement (kg)
- X_{OPC2} : amount of electricity (kWh)
- X_{OPC3} : amount of excavation (m³)
- X_{OPC4} : amount of landfill of inert material (kg)
- X_{OPC5} : amount of sediment extraction (kg)
- X_{OPC6} : transport, freight, inland waterways, barge (t.km)
- X_{OPC7} : transport, freight, lorry 16-32 metric ton (t.km)
- X_{OPC8} : transport, freight, lorry 3.5-7.5 metric ton (t.km)

and for GBS mortar:

- X_{GBS1} : amount of electricity (kWh)
- X_{GBS2} : amount of excavation (m³)
- X_{GBS3} : amount of landfill of inert material (kg)
- X_{GBS4} : amount of sediment extraction (kg)
- X_{GBS5} : amount of NaOH (kg)
- X_{GBS6} : amount of Na₂ SiO₃ (kg)
- X_{GBS7} : transport, freight, inland waterways, barge (t.km)
- X_{GBS8} : transport, freight, lorry 16-32 metric ton (t.km)
- X_{GBS9} : transport, freight, lorry 3.5-7.5 metric ton (t.km)

The three scenarios, y_{sci} , that have been identified are listed below:

- y_{sc1} : this scenario is considered the baseline scenario with all the input parameter X_i where current distance from raw material suppliers for activators (Table 2) are taken into account
- y_{sc2} : this scenario is similar to y_{sc1} for OPC mortar but for GBS mortar we consider a market of raw material suppliers located in the region, the impact of transport (X_{GBS8}) being therefore minimal
- y_{sc3} : this scenario considers that the extraction of sediments is a necessary action for the maintenance of the waterways and is therefore not a source of emission allocated to the production of mortars from the dredged sediments (X_{OPC5} and X_{OPC6} , for OPC mortar, and X_{GBS4} and X_{GBS7} , for GBS mortar, are not considered in Equation 1).

For the following input parameters, X_i , an uncertainty range was identified which allowed us to define them as random variables: X_{OPC5} , X_{OPC6} , X_{OPC7} , X_{GBS4} , X_{GBS7} and X_{GBS8} . Indeed, using the Monte-Carlo method, we perform a sensitivity analysis to measure their impact on the calculation of different scenarios defined above. Having identified three values characterizing the uncertainty: a minimum, a most likely and a maximum value, as shown in Table 5, we have modeled these variables with Beta probability distributions. For example, Figure 2 shows the probability distributions for the variables X_{OPC5} and X_{OPC6} by considering a coefficient of variation (ratio between standard deviation and mean value), $COV = 10\%$. The interval values correspond, for transport (t.km), to the minimum and maximum distances that lorry must travel to transport the materials. For X_{OPC5} and X_{GBS4} , the minimum corresponds to the non-consideration of sediments in the analysis, the most likely interval represents the minimum to be dredged for $1m^3$ of the defined formulation and the maximum value corresponds to the total quantity of sediment dredged per operation.

Table 5. Uncertain input parameters with their value intervals.

Random variable	Value intervals		
	Minimum	Most likely	Maximum
X_{OPC5} (kg)	0.00	1319.00	4350.00
X_{OPC6} (t.km)	0.00	98.93	172.60
X_{OPC7} (t.km)	0.12	64.69	83.97
X_{GBS4} (kg)	0.00	1138.18	4350.00
X_{GBS7} (t.km)	0.00	85.36	149.01
X_{GBS8}^* (t.km)	55.79	169.76	225.79

*For y_{sc2} this variable is not random but deterministic with the minimum value

Figure 2. Beta probability distributions for the variables X_{OPC5} and X_{OPC6} , $COV = 10\%$.

3.2.3 Results of sensitivity analysis

1000 Monte Carlo simulations were performed to assess the sensitivity of each scenario, using the model in Equation 1, for each mortar and for the different impact categories. An uncertainty of $\pm 5\%$ was assumed for the emission factor, F_i . A uniform probability distribution was used to model this uncertainty. Table 6 ($COV = 10\%$) and Table 7 ($COV = 30\%$), present the overall results obtained, where μ and σ are the mean and standard deviation values respectively, and the values in square brackets is the 95% confidence interval.

Table 6. Results of the sensitivity analysis for each impact category, $COV = 10\%$.

3.2.4 Discussion

With regard to the above sensitivity analysis, the obtained results shows that a strong dependence exist between the final impact category score and the subjective choice of input parameters. Furthermore, results found for both sensitivity analyses are similar to the one calculated with a deterministic approach even more when the coefficient of variation is set to 30%. It can be estimated that for OPC, Climate change is the less sensitive category with a variation range of -11% to 6% from the referring value of 227.535 kg.CO₂.eq, followed by Acidification that can vary from -16% to 7% compared to an initial value of 0.569 kg.SO₂.eq. Eutrophication present similar range value as a variation of -21% to 8% has been observed. However a relevant variation from -80% to 52% is observed for the Water Pollution impact. As for GBS, results shows that Eutrophication is characterized by low variation (-9% to 5%) followed by Acidification (-12% to 6%) and Climate Change (-15% to 8%). Water Pollution for GBS also presents the highest variations ranging from -31% to 19% from the referring value of 5.500 m³. Despite the variations observed in the final life cycle analysis results, conclusions remain the same. In all three of the scenarios, GBS presents a lower impact in Climate Change and higher impact on Acidification, Eutrophication and Water Pollution.

4 CONCLUSION

Throughout this study, life cycle analysis score of a geopolymer-based sediments mortar has been compared with an OPC-based sediments mortar. In accordance with the results obtained for the climate change impact category, this article argues that geopolymer can be a better option for reducing CO₂ emissions in comparison with the traditional use of OPC. However, the highest score for this article argues that geopolymer can be a better option for reducing CO₂ emissions in comparison with the traditional use of OPC the Acidification, Eutrophication and Water Pollution impact categories were observed for GBS due to the use of alkaline reagent. In order to analyze the sensibility of the results toward the chosen scenarios, a sensitivity analysis was performed on the input parameters. High range of variation were observed for Water Pollution when transport and sediment extraction were taken into account however conclusion toward the environmental score of GBS compared to OPC remains unchanged.

If climate change scores could make geopolymers viable competitors to cement, it is appropriate, in perspective, to study the use of alternative alkaline reagent in order to improve the environmental scores of geopolymerized mortars from dredged sediments.

Tongji University, Shanghai, China

ABSTRACT: Creep and shrinkage effects of concrete plays an important role in the design of composite bridge. In the past, many analysis on the creep and shrinkage effects of concrete and other materials has been carried out based on experiments, and a general theoretical calculation method has been formed, which makes the calculation of creep and shrinkage effects in the design of concrete bridges and steel-concrete composite bridges more accurate. However, it is only used in concrete bridges and ordinary steel-concrete composite bridges currently. For steel-concrete-UHPC composite bridges, no calculation and analysis has been carried out yet. The steel-concrete-UHPC composite bridge involves the creep and shrinkage effects of concrete and UHPC, and the influence of age and external load simultaneously needs to be considered. The performance of steel-concrete-UHPC composite bridges under the creep and shrinkage effects of concrete and UHPC is different from that of ordinary concrete bridges and steel-concrete composite bridges. In this paper, based on the previous theoretical calculation methods of creep and shrinkage effects of concrete and UHPC, the equivalent cooling method and metal creep theory are used to simulate the creep and shrinkage effects of concrete and UHPC for steel-concrete-UHPC composite bridges. Then, the stress and deformation of steel-concrete-UHPC composite bridges under the creep and shrinkage effects are analyzed and studied with calculation results, which provides a reference for subsequent calculation and analysis of the creep and shrinkage performance of composite bridges.

1 ENGINEERING BACKGROUND

The bridge is a three-span continuous steel-concrete composite girder bridge. The span is $40+60+40=140\text{m}$, and the width is 16.5m . The layout of the bridge deck is: 0.5m (anti-collision guardrail) $+7.5\text{m}$ (motor vehicle lane) $+0.5\text{m}$ (central separation pier) $+7.5\text{m}$ (motor vehicle lane) $+0.5\text{m}$ (anti-collision guardrail). Bridge deck pavement is made with 2mm waterproof layer and 100mm asphalt mix.

Bridge deck is a composite bridge deck, in which the inner thickness is 270mm , the thickness of the root of the cantilever slab is 370mm . The thickness of bottom steel plate is 8mm . Steel plate and concrete are connected with T-type steel ribs and studs. The cross section is shown as follows.

2 RESEARCH SIGNIFICANCE

Due to the difference of the properties of steel and concrete in steel-concrete composite bridges, the shrinkage and creep of concrete will have a significant impact on the force

Figure 1. Cross section of main bridge.

distribution of entire structure. In previous studies, scholars have calculated and analyzed this effect. However, the structure proposed in this paper involves three materials—steel, normal concrete and UHPC, and the concrete and UHPC are constructed in batches. There are certain differences in the shrinkage and creep properties of the two types of materials, which should be considered in the design. This paper conducts calculation analysis and research on the shrinkage and creep effects of composite bridge under the influence of concrete and UHPC and provides a reference for bridge design.

3 CALCULATION METHOD

The shrinkage and creep effects of concrete and UHPC are relatively complex, mainly affected by the construction age, humidity and size effects. The shrinkage effect is similar to the temperature effect, and the cooling method is used for analysis here given the provisions of the specification.

3.1 Concrete shrinkage

Concrete shrinkage coefficient is determined according to Specifications for Design of Highway Reinforced Concrete and Prestressed Concrete Bridges and Culverts (JTG-3362-2018). The calculation method is shown as follows.

$$\varepsilon_{cs}(t, t_s) = \varepsilon_{cs0} \cdot \beta_s(t - t_s) \quad (1)$$

$$\varepsilon_{cs0} = \varepsilon_s(f_{cm}) \cdot \beta_{RH} \quad (2)$$

$$\varepsilon_s(f_{cm}) = [160 + 10\beta_{sc}(9 - f_{cm}/f_{cm0})] \cdot 10^{-6} \quad (3)$$

$$\beta_{RH} = 1.55 \left[1 - (RH/RH_0)^3 \right] \quad (4)$$

$$\beta_s(t - t_s) = \left[\frac{(t - t_s)/t_1}{350(h/h_0)^2 + (t - t_s)/t_1} \right]^{0.5} \quad (5)$$

Where:

t - Calculation age of concrete (d);

t_s -Concrete age at the beginning of shrinkage can be assumed to be 3~7d;

$\varepsilon_{cs}(t, t_s)$ - the contraction strain corresponding to considered concrete age (t);

ε_{cs0} - nominal shrinkage factor;

β - coefficient of shrinkage over time;

f_{cm} - Average cylindrical compressive strength (MPa) of concrete at the age of 28 days,

$f_{cm} = 0.8 f_{cu,k} + 8\text{MPa}$;

$f_{cu,k}$ -concrete cube compressive strength standard value (MPa) with a guaranteed rate of 95%;

β_{RH} - The coefficient related to the annual average relative humidity, applicable to $40\% \leq RH < 99\%$;

RH -Environmental average relative humidity (%);

β_{sc} - The coefficient depends on the type of cement; for normal Portland cement or rapid hardening cement, $\beta_{sc} = 5.0$;

h -Theoretical thickness of the member (mm), $h = 2A/u$, A is the cross-sectional area of the member, u is the perimeter of the component in contact with the atmosphere;

$RH = 100\%$; $h_0 = 100mm$; $t = 1d$; $f_{cm0} = 10MPa$.

In addition, the nominal shrinkage coefficient of concrete ϵ_{cs0} can be determined according to annual average relative humidity (%) of the environment. The relation between nominal shrinkage factor and Environmental annual average relative humidity RH (%) is shown in Table 1.

Table 1. The relation between nominal shrinkage factor and Environmental annual average relative humidity RH (%).

Environmental annual average relative humidity RH (%)	[40,70)	[70,99)
ϵ_{cs0}	$0.529 \cdot 10^{-3}$	$0.310 \cdot 10^{-3}$

3.2 UHPC shrinkage

The shrinkage coefficient of UHPC is determined according to the specification for the application of Ultra High-Performance Concrete for highway bridges and culverts (the draft for comments).

In this project, UHPC is cured at normal temperature. For standard cured UHPC, the shrinkage strain can be calculated according to the following formula:

$$\epsilon_{cs}(t) = \epsilon_{cs,0} \cdot e^{\frac{c}{\sqrt{t+d}}} \quad (6)$$

Where:

$\epsilon_{cs}(t)$ - the shrinkage strain at the considered age t ;

$\epsilon_{cs,0}$ - nominal ultimate shrinkage strain ($700\mu\epsilon$);

t - UHPC age(d);

c, d - fitting coefficient, for low shrinkage cement, $c = -2.48$, $d = -0.86$.

Shrinkage curve of UHPC with time is shown in the Figure 2.

Figure 2. Shrinkage curve of UHPC with time.

Figure 3. Comparison of shrinkage curve of UHPC and concrete with time.

The calculation here is based on the shrinkage and creep of the material within 10 years. There are certain differences in the shrinkage process of UHPC and normal concrete, as shown in Figure 3. UHPC shrinks faster in the early stage and slower in the later stage, while normal concrete shrinks more gently. The feature results in the difference of shrinkage effects compared with that of steel concrete composite bridges.

Among them, the shrinkage curve of UHPC is a dotted line, and the shrinkage curve of normal concrete is a solid line.

3.3 Creep effect of concrete

The calculation method of creep effect of concrete is considered with reference to the specification, and the calculation method is as follows.

$$\phi(t, t_0) = \phi_0 \cdot \beta_c(t - t_0) \quad (7)$$

$$\phi_0 = \phi_{RH} \cdot \beta(f_{cm}) \cdot \beta(t_0) \quad (8)$$

$$\phi_{RH} = 1 + \frac{1 - RH/RH_0}{0.46(h/h_0)} \quad (9)$$

$$\beta(f_{cm}) = \frac{5.3}{(f_{cm}/f_{cm0})^{0.5}} \quad (10)$$

$$\beta(t_0) = \frac{1}{0.1(t_0/t_1)^{0.2}} \quad (11)$$

$$\beta_c(t - t_0) = \left[\frac{t-t_0}{\beta_H + \frac{t-t_0}{t_1}} \right]^{0.3} \quad (12)$$

$$\beta_H = 150 \left[1 + \left(1.2 \frac{RH}{RH_0} \right)^{18} \right] \frac{h}{h_0} \quad (13)$$

Where:

t_0 - concrete age at loading (d);

t - concrete age (d) at the moment of consideration;

$\phi(t, t_0)$ - concrete creep coefficient considering the age (t);

ϕ_0 - nominal creep coefficient;

β_c - development coefficient of creep with time after loading.

In the formula, f_{cm} , f_{cm0} , RH , RH_0 , h , h_0 , t_1 is the same as other formulas.

3.4 UHPC creep effect

As a new type of material, UHPC has relatively complex components, and the research on durability is still incomplete. Here, the provisions in the current specifications are used for calculation and analysis. The code stipulates that when the compressive stress borne by UHPC is less than 0.4 times the UHPC compressive strength, UHPC manifested as the linear creep, and the creep coefficient can be calculated according to the following formula:

$$\phi(t, t_0) = \phi_0(t_\infty, t_0) \frac{(t - t_0)^a}{(t - t_0)^a + b} \quad (14)$$

Where, $\phi(t, t_0)$ - UHPC creep coefficient considering the age (t);

$\phi_0(t_\infty, t_0)$ - ultimate UHPC creep coefficient at the loading age;

t - UHPC age(d);

t_0 - UHPC age when firstly loaded (d);

a, b - Fitting coefficient, the value can be taken from the table below.

Table 2. Ultimate creep coefficient and coefficient a, b of UHPC.

Loading age $t_0(d)$	Conservation system	Ultimate Creep coefficient $\phi t_0(t_\infty, t_0)$	Coefficient a	Coefficient b
4	standard maintenance	1.2	0.6	3.2
7	standard maintenance	1.0	0.6	4.5
28	standard maintenance	0.8	0.6	10
	90°C steam curing for 2 days or 80°C steam curing for 3 days	0.2	0.6	10

4 CONSTRUCTION PROCESS

There are many construction methods to choose for bridge construction. Since the overpass bridge is located in the urban area, the impact on the surrounding area should be minimized. This bridge adopts the formwork of steel structure for bridge deck construction, which can reduce the impact on the surrounding environment and improve performance of the overall structure in the meanwhile.

After comprehensive consideration, the construction process of the bridge is as follows:

- (1) The steel structure is carried out on the bracket first, and the bracket is removed after the splicing is completed;
- (2) For the concrete pouring of the bridge deck, the steel structure that has been processed bears the concrete self-weight load (shrinkage of the concrete starts to be considered at the time);
- (3) UHPC is poured 1 to 4 days after concrete pouring. At this time, the self-weight of UHPC is borne by the steel-concrete composite section (UHPC shrinkage and concrete creep starts to be considered), forming an overall structure and bearing the second-phase load.

5 COMPUTATIONAL ANALYSIS

According to the bridge construction method, the bridge adopts the staged construction method. And there is a problem of structural system conversion during the construction process. The initial load of the steel structure is borne by the lower bracket. After the construction of the steel structure is completed, the bracket is removed and the concrete is poured. The self-weight of the concrete is borne by the steel structure; similarly, when concrete reaches a certain strength to pour UHPC, the self-weight of UHPC is borne by composite beams formed of steel and concrete.

The realization of general construction process is relatively easy to realize in special bridge software, such as Midas, Bridge Doctor, etc., but it is difficult to realize in 3D general software such as Ansys and Abaqus. The Ansys software provides the function of unit life and death, that is, during the construction process of this stage, the components of the next stage are passivated and activated in the next stage. Through this function, the staged construction of the bridge can be realized.

Shell181 element is used to simulate the steel beam, and the solid185 element is used to simulate concrete and UHPC. Nodes are connected. Reinforcement bars and internal stiffeners are connected to concrete and UHPC units by coupling elements. Constraints are used to constrain the lower nodes of the steel main girder according to the constraints of the three-span continuous beam.

5.1 Shrinkage calculation method

Since concrete shrinkage has nothing to do with structural stress, the calculation of concrete shrinkage is relatively simple, and it is realized by cooling in Ansys. The basic condition for the calculation of concrete bridges is an average humidity of 70%.

5.2 Creep calculation method

Using the metal creep function in ANSYS, the concrete creep calculation is realized by specifying the creep strain increment in the unit time interval. Creep is a rate-dependent material non-linearity, that is, the characteristic of continuous deformation of materials under constant load. Conversely, if the displacement is fixed, the reaction force or stress will decrease with time.

Creep can be divided into three stages. In the initial creep stage, the strain rate decreases with time, and this stage generally occurs in a relatively short period. In the second creep stage, there is a constant strain rate, so the strain develops at a constant rate, and in the third creep stage, the strain rate increases rapidly until the material fails. Implicit and explicit integration methods are used to analyze creep analysis in ANSYS, both of which can be applied to static and transient analysis. The implicit creep analysis method is more powerful, faster, and more accurate, and it is generally recommended to use the implicit creep analysis. It can handle temperature-dependent creep constants and simultaneously simulate creep and isotropic hardening plasticity models. The calculation and analysis in this paper adopt the implicit integral method for calculation and analysis of creep effects.

6 CALCULATION RESULT ANALYSIS

Ansys is used to calculate and analyze the shrinkage and creep effects of composite bridges. Considering the shrinkage and creep effects of construction stages and different materials, the calculation is carried out according to the age of 10 years. The calculation results are shown below.

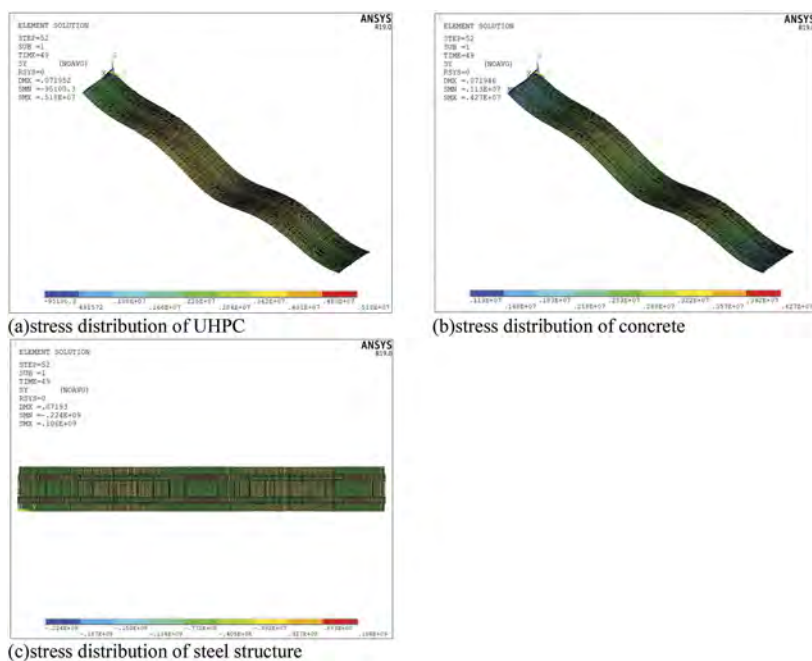

Figure 4. Stress distribution along bridge direction of composite bridge.

For three-span continuous girder bridges, the bridge deck over the support along the bridge direction is under tension and is easy to crack, so force control should be carried out; the stress at the root of the cantilever slabs is mainly considered in the transverse bridge direction, and it is clarified that under the applied load. The stress of specific key parts under the action of shrinkage, creep and construction self-weight is shown in the Table 3.

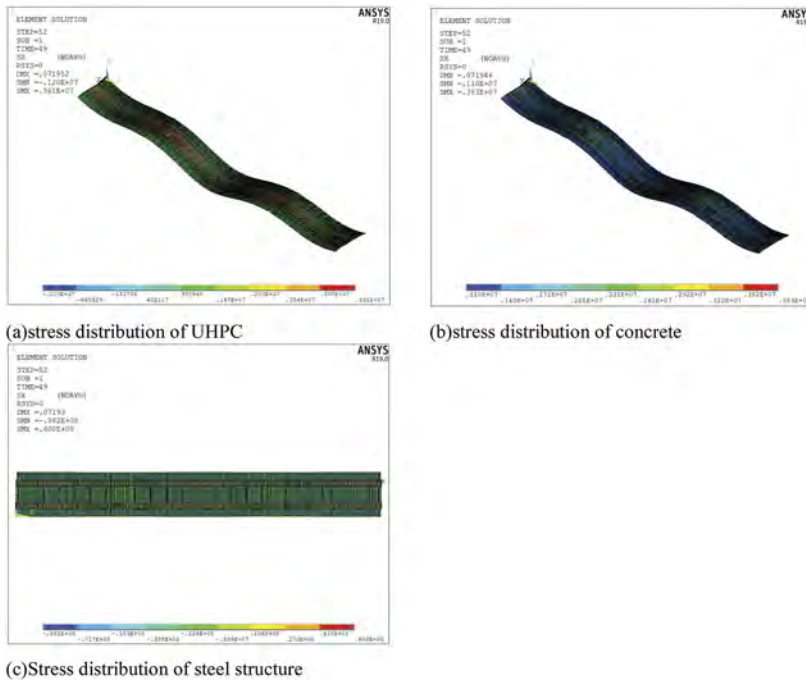

Figure 5. Stress distribution in transverse bridge direction of composite bridge.

Table 3. The stress of critical position.

Serial number	Location	Direction	Stress (MPa)
1	UHPC of negative bending moment area over the support	along the bridge	4.01
2	Concrete of negative moment zone over the support	along the bridge	3.57
3	Steel plate of negative moment zone over the support	along the bridge	13.2
4	UHPC at the root of the cantilever slabs	cross bridge direction	1.39
5	Concrete at the root of the cantilever slabs	cross bridge direction	1.33
6	Steel plate at the root of the cantilever slabs	cross bridge direction	-48.4

7 CONCLUSION

Shrinkage and creep effect is an extremely complex effect, which is affected by various factors in the environment. This paper combines the existing calculation methods and applies the finite element calculation method to calculate the shrinkage and creep effect of steel-concrete-UHPC composite bridge deck based on the provisions on the shrinkage and creep effects of materials in the latest codes. It can be seen that,

- (1) The shrinkage and creep are long-term effects, and the shrinkage of UHPC develops more rapidly in the early stage. So, the construction process should be considered in the calculation analysis;

- (2) By comparing the calculation results, it can be seen that the shrinkage and creep effects of concrete and UHPC have more influence in the negative bending moment area over the bearing along the bridge than on the transverse effect of the composite bridge. But for the lower steel plate, the creep and shrinkage effects have a higher influence on the bottom plate in transverse directions.
- (3) The shrinkage and creep effect has an adverse effect on the force in the negative moment zone of the bridge. In order to make full use of the excellent performance of UHPC, part of the effect of shrinkage and creep can be eliminated by high temperature steam curing, thereby improving the performance.

Interactive visualization of uncertain embodied GHG emissions for design decision support in early stages using open BIM

K. Forth & A. Borrmann

Technical University of Munich, Munich, Germany

A. Hollberg

Chalmers University of Technology, Gothenburg, Sweden

ABSTRACT: To meet the European climate goals in the building sector, a holistic calculation and optimization of embodied greenhouse gas (GHG) emissions using the method of life cycle assessment (LCA) in early design stages are necessary. Hence, this paper presents a comprehensive and transparent design-decision-making approach for reducing embodied GHG emissions in early design stages by interactive, model-based visualizations of uncertain results. The proposed approach is based on a previously developed Natural Language Processing (NLP) based methodology of matching elements of a Building Information Model (BIM) to those of an LCA database. With the help of a prototypical implementation and a case study, the uncertainties of the derived LCA results are visualized using different levels of transparencies. This paper shows that open BIM models and the proposed 3D color coding support the hotspot analysis in combination with box plot diagrams for visualizing uncertain GWP results for decision-making in early design stages.

1 INTRODUCTION & MOTIVATION

In order to reach the international climate goals, the AEC sector with its impact of 40% of the global Greenhouse gas (GHG) has a significant impact (UN 2021). Currently, the embodied GHG emissions, meaning those from material extraction, manufacturing of construction products, etc., are responsible for up to 12% of the GHG emissions (EU Commission 2022a). Life cycle assessment (LCA) has been an established method to evaluate these embodied GHG emissions in the design phase of new buildings. Several national and international frameworks are currently including LCA in their assessments for comparing sustainability of building designs, for example LEVEL(s), which is also used for ensuring current EU Taxonomy classification system (EU Commission 2022b).

In a market survey with 161 participants from Germany, Schumacher et al. (2022) identified significant potential of using Building Information Models (BIM) for a loss-free data-exchange, as well for understandable and user-friendly communication of LCA results. This also means that in future, non-LCA-experts should be able to understand LCA results and make design decisions based on these results.

Nevertheless, most of the existing tools and methods in the field of BIM-based LCA focus either on closed BIM approaches, developed for architects, designers or BIM modellers, or require a high level of LCA expertise to conduct and interpret LCA results. Building owners or clients, who are usually making design decisions, often have not the required expertise in LCA and are increasingly using open BIM models. Therefore, in this paper we propose an interactive and comprehensive approach of visualizing uncertain embodied GHG emissions for design decision making by non-LCA-experts using open BIM models in early design stages.

2 BACKGROUND & RELATED WORKS

Several related publications were investigated with regards to variant selection and visualization. Wiberg et al. (2019a) presented in their publication a chronology of the development of a visual, dynamic and integrated approach of LCA of building. Regarding the dynamic aspect, they identified several approaches of integration using Visual Programming Language, such as Dynamo and Revit or Rhino and Grasshopper. Furthermore, they classified other approaches of parametric approaches as well as dashboards using Revit models or district models, where generally only the models were shown, but not used to highlight or visualize results. As a next step, they propose a visualization approach using Virtual Reality for improved stakeholder participation (Wiberg et al. 2019b). For this, they used Revit models to color the models with the LCA results and used the VR to interact with the model, which was concluded as a “good platform for communicating and visualising complex data [...] not only for researchers but also for the general public” (Wiberg et al. 2019b).

The recent review of Hollberg et al. (2021) regarding visualizing LCA results describes current practice and presents a systematic overview of different strategies and potentials. The methodology using BIM models to visualize LCA has shown great potential for synergies (Röck et al. 2018a, b, Mousa et al. 2016). In these approaches, color coding was mainly used to visualize final LCA results in authoring tools. In another visual method for detailed analysis of LCA results by Kiss and Szalay (2019), this model-based color coding was used to highlight certain aspects of the results in combination with a sunburst diagram. For implementation, Kiss & Szalay used Rhino and Grasshopper.

Miyamoto et al. (2022) proposed an approach for integrating LCA and LCC results as a basis for design decision-making. Although they did not use BIM models, they discussed the growing importance of integrating a spreadsheet approach with BIM workflows, however focusing on architects and not other stakeholders. Hollberg et al. put target users in the focus of their user-centric LCA tool development for early planning stages (Hollberg et al. 2022). Different stakeholders such as architects, sustainability engineers and consultants as well as real-estate developers were involved in the process. However, only fixed results were visualized, and no active interaction with the model was envisioned. Also, uncertainties and different levels of development have not been considered. To visualize these aspects, Abualdenien & Borrmann (2020) present several approaches of visualizing geometric and semantic uncertainties of building elements in early design stages. As one main conclusion of several approaches, “the combination of color value and transparency for quantifying the reliability of the semantics resulted in relatively high intuitiveness and acceptance” (Abualdenien & Borrmann 2020).

Furthermore, Ströbele (2022) introduced an approach of fuzzy life cycle assessments (fLCA) considering vaguenesses by distribution curves instead of single results. Schneider-Marín et al. (2022) established an EarlyData knowledge database for deciding material choices in a design stage, where no detailed information about specific materials is available. In this methodology, the semantic uncertainty is also visualized by assessing “a vast number of possible material combinations at once” using boxplot diagrams that visualize the ranges of the Global Warming Potential (GWP) (Schneider-Marín et al. 2022).

Petrova et al. (2019) propose a methodology for decision support for sustainable design based on knowledge discovery in disparate building data. They are using different matching mechanisms between project data repositories and Common Data Environments (CDE), such as data mining, direct semantic queries and geometric feature matching. The direct semantic queries are based on different ontologies, such as Building Topology Ontology (BOT) (Rasmussen et al. 2017) or product specific ontologies.

In summary, the discussed publications show the relevance of using BIM models to visualize LCA results and describe first approaches. However, an integration in an open BIM workflow was not investigated and also the interactive exploration of the results was not presented. This documents the gap existing regarding an interactive, design-decision tool for non-LCA-experts based on open BIM methodology in early design stages. The main focus of this publication is how to visualize uncertainties of the rough model semantics and vague results in a comprehensive way.

3 INTERACTIVE VISUALIZATION OF UNCERTAIN LCA RESULTS USING BIM

3.1 General workflow

As shown in Figure 1, the general methodology consists of the LCA knowledge database and four main steps. Overall, the methodology bases on a LCA knowledge database (LKdb), which consists of conventional elements and all information for calculating a holistic LCA, such as layer-specific replacement rates, LCI datasets using Ökobaudat, missing End-of-Life scenarios, etc. Details about the LKdb can be found in (Forth et al. 2021, 2022).

Figure 1. General workflow for visualizing uncertain embodied GHG emissions for design decision support in early design phases using open BIM.

The first step of the general method comprises the creation of the BIM model in an authoring software (step 1.a) and the subsequent IFC model export, which is performed by the BIM modeler (step 1.b). The next step consists of deriving the quantity take-off and element matching. The quantity take-off parses all geometric and semantic information of the IFC model for the calculation of the LCA, including base quantities, such as area, amount, layer thicknesses or length, as well as density, materials and the name of the element, its GUIDs and classification (step 2.a). The expressions of the materials and element are used in the next step for the matching of the IFC elements to the LKdb (step 2.b). This step has been previously introduced and validated (Forth et al. 2022, 2023). This matching is based on an existing NLP network, and compares cosine similarities of the element and material expressions in the IFC model and all elements and material categories and material options of the corresponding classification group in the LKdb. The most similar element of the LKdb is being matched to each IFC element.

After completing the element matching step, all missing information about LCA datasets, life spans or missing layers are filled by the datasets of the matched LKdb element. Afterwards, the results of the LCA are calculated taking into account the uncertainty of the element matching (step 3.a). Depending on the level of matching (see Section 3.3), a range of material options for each element's layer is taken into account and leads to a range of LCA results for each element and the whole building.

In this paper, the focus is on the concept for the final step of the general methodology, the design decision process (step 4.a-e).

3.2 Design decision support concept

The goal of the proposed workflow is to support non-LCA-experts in the decision making of construction-element and material-related variants. For supporting the decision maker in the early design stages, several hierarchical visualization goals are proposed, based on Hollberg et al. (2021). To identify hotspots for the design optimization, the 3D color code is recommended as an intuitive visualization type, which can be implemented using open BIM models (Figure 2). For comparing different design options, box plot diagrams are the only type which also include uncertainties in its visualization. Additionally, the selection boxes of each element variant or material option can be also color coded, normalised to benchmarks. As LCA benchmarks on element level are still missing according to the German classification systems used in this approach, the colors are normalised relatively to all potential design alternatives within one classification group. Once

benchmarks will be available also on the third level of cost groups according to DIN 276, the colors can be normalised according to these benchmarks.

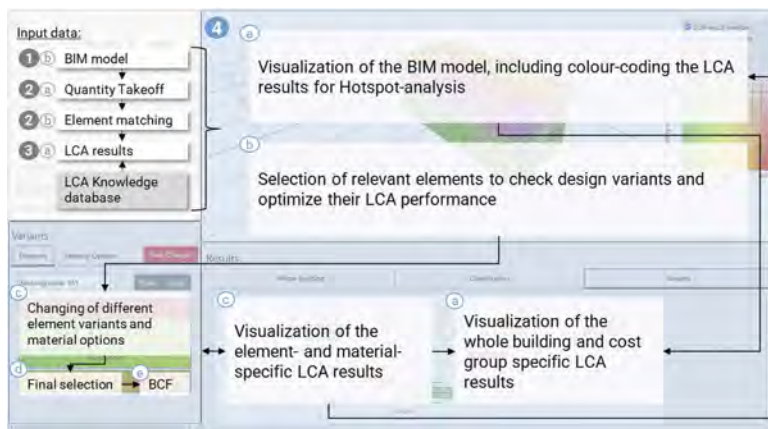

Figure 2. Concept of frontend visualization and interaction workflow for LCA-optimized design decision making.

This design decision process is based on the previous calculation and matching results including its uncertainties and is generally divided into five steps, as shown in Figure 2. First, the LCA results are visualized using a model viewer and conventional criterion-specific charts (4.a). When summing up the LCA results for each cost group and the whole building, Boxplot diagrams are suitable to visualize the ranges of possible results (bottom right). Furthermore, the element-specific results will be color coded on the BIM viewer to highlight the performance hotspots (top right). As a next step (4.b), the worst performing elements can be selected in the model viewer for design optimization (top left).

In the following step (4.c), variant results are visualized for the element selected in the model viewer, and different element variants of the same classification group can be selected (bottom left). Variants are derived on element and on material level according to the existing alternatives of each classification group in the LKdb. For every element in the BIM model, the LCA results of all design variants are previously calculated (step 3.a), independently of the matched element (bottom middle). In the last two steps, the final changes of variants are saved (4.d), and communicated back to the BIM modeler using the BIM Collaboration Format (BCF) as an open BIM standard (4.e).

3.3 Visualization of matching-related uncertainties

There are important features which are taken into account, based on the previous findings. On the one hand, the cosine similarity of the matching performance is an indicator for the degree of similarity the matching is based on. On the other hand, there are different cases how the elements are matched from the IFC model to the LKdb, as described in the following list.

IFC elements are matched to:

1. default element of the classification group in the LKdb (worst case)
2. most similar element expression, as there are no materials available
3. most similar element expression, as the material matching performs worse
4. element with the most similar material category
5. element with the most similar material option

These different cases lead to different levels of reliability of the resulting LCA results. Therefore, this information needs to be considered when visualizing the semantic-related uncertainties.

As previously mentioned, Abualdenien et al. already concluded that the combination of color value and transparency of an element is highly intuitive and accepted for visualizing the

reliability of semantics (Abualdenien & Borrmann 2020). Therefore, the transparency value for each element t_e is derived by the following equation:

$$t_e = \frac{\sum_{l=1}^m c_e * \cos(\theta)_{e,l}}{m} \quad (1)$$

where l = layer number; m = maximum layer number; c_e = matching case of each element; and $\cos(\theta)_{e,l}$ = cosine similarity of each element's layer (according to (Forth et al. 2022)). The values of the above mentioned five matching cases for each element c_e are distributed as followed: case 1 = 20%; case 2 = 40%; case 3 = 60%; case 4 = 80%; and case 5 = 100%.

Figure 3. Color coding scheme for visualizing relative & uncertain GWP results.

To combine both information of semantic-related uncertainties and the relative performance of GWP results in the hot spot analysis, a color scheme matrix is established in Figure 3. On the x -axis, the relative GWP results according to the normalisation in each classification group is plotted. Generally, the legend of the relative colours ranges from green, representing the best performing variant, to red for the worst performing variant.

On the y -axis, the transparency value for each element t_e is visualized derived by equation 1. For the selection boxes of the element variants and material options, the same color range is used using 0% as transparency.

For the visualisation of the pre-calculated GWP results (according to (Forth et al. 2022)) on whole building and classification group level, box plot benchmarks of a study of 50 buildings by the German Sustainable Building Council (DGNB) are used to compare the correlating box plot GWP results (Braune et al. 2021).

4 CASE STUDY & IMPLEMENTATION

4.1 Case study project

To validate the approach using a prototypical implementation, an IFC model of a real-world office building with 1950 m² is used as a case study. The matching results and the LCA results have been previously validated (Forth et al. 2023). As the project is located in Germany, the classification follows the standard of German cost groups according to DIN 276 (DIN276 2018). The German database Ökobaudat was used as the materials and elements are named in German language (BBSR 2021). For the element matching the best performing NLP network BERT is used, as previously evaluated in (Forth et al. 2022). The case study model consists of 307 individual elements, which are from 16 different object types. The total surface area of all elements sums up to ca. 5824 m².

4.2 Prototypical implementation

The prototypical implementation is based on conventional web development tools using HTML, JavaScript and CSS. The web-ifc-viewer library of IFC.JS (Gonzalez Viegas 2022) is used as model viewer, which is a state-of-the-art the open-source toolkit based on JavaScript library three.js for 3D scenes in web browsers (Mrdoob 2022). For the hotspot analysis, every element surface is colored according to its performance relative to the classification group and the mentioned color scheme of Section 3.3.

Figure 4. Prototypical implementation of the hot spot analysis using the case study (step 4.a-b).

Figure 4 illustrates the first part of the prototypical implementation using the case study. On the left side, all relevant quantities and semantical information of the selected element are shown (step 1-3), such as classification group (KG), element name, amount of elements of this object type, material name, layer thicknesses, the matched element variant and the matching case. On the right side, the 3D color coded hot spot analysis is applied on the uploaded IFC model using the color scheme and transparency values for showing the matching-related uncertainties (step 4.a). In the following step 4.b, one highlighted element with bad performance is selected to check design variants and optimize its GWP performance.

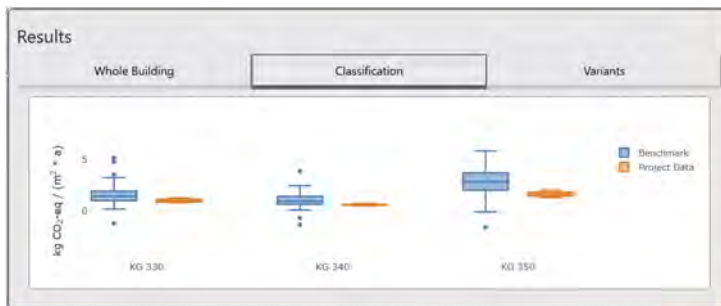

Figure 5. Prototypical implementation of the result on classification group level for comparing to benchmarks (step 4.a).

Figure 5 visualizes the GWP results in [kg CO₂-eq./ (m²*a)] of each classification group compared to the DGNB benchmark results ranges (step 4.a). For comparing the GWP results to the DGNB benchmarks, the results are normalized using the net floor area and the reference study period of 50 years. As the DGNB benchmarks include 50 different case studies, the resulting range is wider than the ones of the case study. Nevertheless, a general performance trend of the designed model can be identified intuitively for non-LCA-experts.

In the next step 4.c according to the proposed visualization approach, different element variants (Figure 6) and material options (Figure 7) are visualized. On the left sides, the name of each element variant or material option is color-coded according to its normalized GWP range compared to the other selectable alternatives. On the right side of Figure 6, the box plot diagrams of all element variants are shown. As every material option is connected to one pre-calculated LCA result, it is visualized as a differently colored dot mapped on top the box plot diagram of the selected element variant (Figure 7).

Figure 6. Prototypical implementation of the element variant comparison comparing variants of cost group 342 Non-load-bearing interior walls (step 4.c).

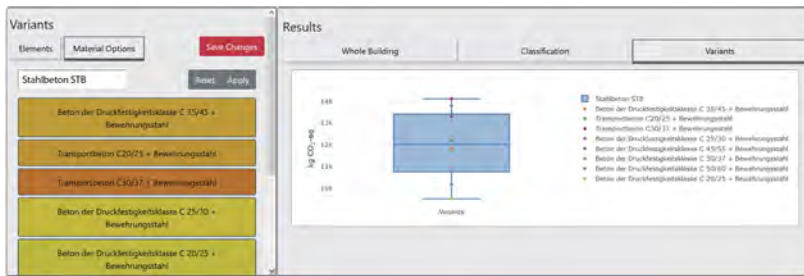

Figure 7. Prototypical implementation of the material option comparison of reinforced concrete (step 4.c).

5 CONCLUSIONS

This paper proposes a comprehensive and transparent approach for design decision making in early design stages in order to optimize embodied GHG emissions of new buildings. With the help of open BIM models and its 3D color coding for the hotspot analysis in combination with box plot diagrams for visualizing uncertain GWP results, an interactive process for non-LCA-experts is introduced.

Based on a previously validated method of NLP-based similarity assessment, this publication uses the results of the automatic element matching, where those elements of the IFC model are matched to the most similar ones in an LCA knowledge databases. The level of element matching and similarity analysis are taken into account for visualizing the uncertainty and reliability of the derived LCA results. Due to missing benchmarks on a level of elements and classification groups, the results are normalized based on the relative performance in each classification group and implemented for the 3D color coding as well as for the element variant and material option selection.

In the future, the proposed methodology will be evaluated by user testing and online surveys. Test users will be asked to assess different features in terms of intuitiveness, acceptance and applicability. The test users will be non-LCA-experts with different professional backgrounds.

To finalize the implementation of the proposed methodology, all relevant information of the Quantity Take-Off, Element Matching and LCA calculation will be stored and archived. Furthermore, the last step of the proposed methodology will be implemented using the BIM Collaboration Format (BCF) based on a server solution in order to communicate the feedback of the decision making back to the BIM modeller using authoring software. Thereby, an approach of archiving the design decision including the LCA results and further project information, such as the results of the element matching, needs to be considered.

The proposed methods is a first approach of supporting design decision making in early stages using BIM models and different visualizations, considering uncertainties of LCA results. In a next step, this prototype will be evaluated by non-LCA-experts from practice.

Port facilities asset management: Coping with aging infrastructure and constrained budgets on the long term

H. Voogt

Port of Rotterdam, Rotterdam, Zuid-Holland, The Netherlands

ABSTRACT: With the aging port infrastructure around the world, it is crucial to understand the current condition state of these structures and adopt cost effective and sustainable strategies to repair and maintain these assets. Over the past decade, considerable work was conducted on the mechanisms responsible for the deterioration of structures exposed to harsh environments and how to report condition and performance. Recently, a new generation of deterioration models and risk based management approaches combined with state-of-the-art geographical and sensor data technology have seen the day and are used to assist port owners and engineers in optimizing the use of funds in keeping their ports as safe and competitive as possible. This presentation covers the asset management approach and its underlying principals in one of the world's largest port to build a long term asset planning that is able to visualize the consequences of constraints in available budget.

1 INTRODUCTION

The Port of Rotterdam is after being the world's largest port for many years in terms of handled goods, still the major port in Europe. On a yearly bases the Port handles a total of approximately 470 million tons of goods. Only 27 percent of this amount is filled in by in a total of 14,5 million TEU's, the major part is dominated by liquid and dry bulk. Furthermore the Port of Rotterdam accommodates ships up to a water depth of 75 feet (24 meters) and is visited by approximately 30.000 sea-going vessels and 120.000 inland ships per year. As the Port of Rotterdam is a landlord port, the asset management department is responsible for a wide set of assets, amongst others over 50 miles of waterfront structures (quay walls and jetties) with a total replacement value estimated at \$2 billion USD. More than two-third of these quay walls are exposed to varying salinity seawater which causes degradation in the form of corrosion for the substructures constructed of steel sheet piling or steel combi walls (combination of tubular piles and sheet piles) and chloride ingress followed by rebar corrosion of the concrete elements. Almost 50 % is older than the design lifetime but still in good condition, even though the Port of Rotterdam is facing these challenging conditions.

With the typical service life of their waterfront structures around 50 years and the port in constant expansion, the Port of Rotterdam needed to implement a rigorous approach and protocols to efficiently track required annual maintenance as well as forecast the short- and long-term costs of keeping their structures in service for their tenants.

Upon completion of the first phase of implementation, the Port of Rotterdam's resulting system accurately provides current condition state, simulates various maintenance strategies on the basis of the inspection results so that the most efficient and cost-effective inspection regime and maintenance scenario for the structures in question can be selected and applied, provides insight on the consequences – such as reduction in remaining service life or availability of the structure – of postponing specific maintenance measurements, and determines the consequences of different alternative maintenance measures.

The approach considers the possible risks and causes that endanger the structures (or parts of it) relating to availability, structural safety, sustainability and aesthetics and it ranks the risks associated with retaining the desired functionality, then presents the financial consequences of postponing required maintenance for budgetary or economic reasons.

Based on the predictive deterioration models and risks, a multi-criteria approach, called business value is used to prioritize the maintenance tasks to be carried out. Required maintenance tasks are ranked based on – commercial importance, availability requirements, and end of contract date.

This prioritization approach of maintenance tasks, based on a multi-criteria analysis, ensures that expenditure and maintenance are performed on the structures that are most economically important to the Port of Rotterdam Authority and where the safety risks are the highest. Not for the next year, but also long term over a period of 30-50 years.

2 DETERIORATION OF WATERFRONT INFRASTRUCTURE ASSETS

The maritime assets of ports add enormous value to the business of the port and are a facilitator of added value to several regions and countries, but due to the function these structures serve and the maritime environment, these assets are relatively costly to construct and maintain. When not looked properly after, the harsh conditions of the maritime environment will cause major deteriorations of the assets. But not only the circumstances can cause problems with the structural integrity of the assets. Also the management strategies or the company policy can make things worse than needed. Here is a list of some examples:

- Deferred maintenance costs: is often seen in organizations where the budgets are cut due to several reasons. Despite the saying that the most expensive maintenance is deferred maintenance, this strategy is not completely banned.
- Inadequate capital allocation: is often seen in organizations where there are constraints on the available budget for asset management, which leads to not being able to do the full set of maintenance measurements
- Run-to-failure repair & maintenance programs: is sometimes called the fire fighter approach and is often seen in organizations that do not have achieved a certain maturity level in order to be able to implement preventive maintenance plans.
- Inspections based on random observations: is often seen in organizations where there is no insight in where the vulnerable structures are that are under high risk of deterioration. A risk based approach can help identify these structures.

All these forementioned examples will lead to a loss of competitive edge and productivity or even worse safety and security concerns for the port and need full attention of not only the asset management staff. A well-performing asset management system for waterfront infrastructure is very important.

3 CHALLENGES OF THE ASSET MANAGER

For Port Authorities, waterfront assets like quay walls, wharves and jetties are the pivot of their business cases. The Port's income will depend on whether the asset is capable of performing adequately during the lease period of the tenant. Of course, when there is no availability for the tenant to load and unload goods, he will certainly not pay the lease fee for the use of these assets. In the short term, this will mean a loss of profit for the port, but in the long term, it will mean that there will be a decrease in cash flow and no potential opportunities for future developments or rebuilds. Finally, as a landlord port, disrupting the business of the tenant with unexpected big repairs or with notifications that part of these assets no longer meet the agreed program of requirements in terms of load or safety, is the most unwanted situation.

Apart from the need to accommodate the tenant in a proper way, there are more challenges for the asset manager. The more intensive use of the assets due the growing amount of calls of

ships because they are handled more efficiently, will have an effect on the condition of the quay walls and jetties. Not to mention the ever increasing size of the vessels, in a very short period for instance container vessels have grown from 8.000 TEU to a nowadays standard of 22-24.000 TEU, while the assets are still the same and have a design based on the a program of requirements that describes the mooring of 8.000 TEU ships. Compared with the standard design lifetime of a waterfront asset, which is typically 50 years, there is a huge mismatch in keeping up with the speed of growth. The ships are far bigger than calculated in the design. This means that the program of requirements and thus the quay wall or jetty is stretched to the maximum.

On top of that the internal organization of the Port Authority also rises some challenges for the asset manager, first he will have to explain (sometimes justify) to the board the needed budget in order to prevent the budget from being cut. The board might have some questions about the budget, such as: “what will happen if next year’s budget is not granted, or if it has to be cut in half?” Or, the wish of the financial director to level out the peaks in the long-term budget for the coming years. These are tricky questions because typical deterioration of assets usually takes much longer than just one year, so the answer will often be that next year will be fine, but nevertheless the problems are “postponed” to the upcoming years. An insight on the effect on the long term asset planning is needed to come to the right decision. Secondly there is the commercial desire to extend the tenant’s contract for a longer period preferably with a commitment of the asset manager that major investments are not needed to extend the useful lifetime of the assets involved. Thus, the “end of contract” becomes an important date.

Within the organization therefore, asset management, including an understanding of the life-cycle position of their broad portfolio of assets and a risk-based approach to the allocation of the capital resources, becomes a strategic imperative for every port in the world.

Therefore the asset management within a organization must have a minimum level of maturity. In the beginning all asset management will be reactive, with projects based on the available budget, that itself is based on the budget of last year and less reduction of risk by the invested budget. The aim is to be proactive instead of reactive where budgets are based on future needs, high risk assets are replaced before the moment they fail and the focus is on a high benefit to cost ratio. As the maturity level grows, the attitude will shift from “cost focus” to “value focus”. Consequently, costs will go down, and value and performance will increase.

4 STEPSTONES IN ASSET MANAGEMENT

In order to reach a higher level of maturity in asset management and so being able to be proactive and focus on value and performance there is a roadmap with 7 stepstones available that can be followed.

1. Document the assets owned and managed, Ask yourself: “How many assets do I have to take care of?” and subsequently “Are all dimensions known, and /or are drawings and specs available?” These are very simple questions, but not always so easy to answer. It takes time and effort to sort this out, but it is a necessary first step.
2. Understand the current condition of the asset in respect to the useful lifetime. Once you have an overview of all the assets, the next step is to inspect the current condition of every single asset. The way that this is done, depends on the structure and the material and can vary from a simple visual inspection to an extended life time inspections with a subsequent predicting model.
3. Understand what budget is needed to catch up, keep up and move forward. With the result of the previous step, it is now possible to examine whether the condition of an asset is meeting the required standard or needs extra attention. The required actions can then be identified and followed by a maintenance plan and a needed budget for the coming years.
4. Understand what endangers the functionality: risk analysis. You do not want to spend your available budget on assets of which the functionality is not at risk. To obtain this insight a in-depth risk analysis needs to be done. The basic question in the risk analysis is:

“What phenomena can endanger the asset’s functionality?” “What are the effects and what is the probability of occurrence. Once these risks are known and identified, preventive maintenance measures can be listed to mitigate these risks. If maintenance measures are not executed, then this will inevitably lead to the risks to occur. Several proven methods are available for risk analysis, so use one that fits your assets the most.

5. Understand the business value, the business value is a multi-criteria calculated figure that represents how much an asset contributes to the goals of the organization. In other words, in the case of an port authority, a frequently used quay walls need more attention and higher prioritization than a quay wall that is rarely used.
6. Establish the level of service for an asset and calculate the cost of service Not all the assets need the same level of service, for instance highly visible assets will often have a higher level of service. Or some tenants have based on their SLA agreed a higher level of service than others. This will lead to an extra effort in asset management and thus to extra needed budget that must be calculated and incorporated in the (long term) financial asset planning.
7. Prioritize the needed budget based on risk and business value: required maintenance tasks are ranked by the business value: a quality mark which is made up of various factors – commercial importance, availability requirement and end of contract term. By using this quality marking system in conjunction with the level of risk to be covered, it’s possible to create a prioritized list of all maintenance measures, a high quality mark combined with a top-ranked risk gives a maintenance action the highest priority. A low quality mark with a bottom-ranked risk gives it the lowest priority.

5 DEVELOPING AND USING AN EXPERT SYSTEM

Port of Rotterdam has been investing in a tool that is able to support the asset manager in doing the tasks as explained in the seven stepstones above. Most organizations and also Port of Rotterdam will have a triangular shaped IT backbone in place that comprises of an ERP system (Port of Rotterdam uses SAP), a document management system like Sharepoint or an equally qualified system and a geographic information system (GIS). When it comes to documenting all the assets, the functionalities of these IT systems will be sufficient to create a register and breakdown structure of all the assets, store the drawings and other documents and produce a map with the exact location of your assets.

To support the other stepstones you will need expert systems that do a specific task and that get their master data from the forementioned main IT systems. Port of Rotterdam developed an asset management tool that compares the results of deterioration models with the “end of contract” date to identify if and when the functionalities of the structure are endangered and uses the risk analysis and business value of a quay wall to clarify its maintenance priorities. A screenshot is presented in Figure 1. It provides the asset owner and asset manager with a LTAP (long term asset planning) tool to efficiently manage a portfolio of quay walls or other maritime civil engineering structures. Different scenarios can be evaluated, in the case of underspending risks of loss of functionality will arise over the years, in the case of overspending budget is spent too early. In current times with constraints on the budget, this will help to find the optimum scenario.

6 PREDICTIVE ASSET MANAGEMENT: REMAINING USEFUL LIFETIME

The typical service life for the port and maritime structures is approximately 50-75 years. A large proportion of these assets in the Port of Rotterdam will be nearing the end of their service life in the coming decades. In order to effectively and efficiently manage these assets, it is critical to have a system in place to track the yearly required maintenance as well as forecast the short and long-term costs of keeping these structures in service.

Figure 1. Screenshot of the landing page of Port of Rotterdam's expert system.

A quay wall's remaining lifetime and system integrity is mainly determined by the quality of the substructure and the superstructure. Other components of a quay wall are most of the time replaceable and do not influence the strength of the structure. When the quay wall's integrity is in danger, it's often due to two aspects: namely accelerated low water corrosion occurring at the substructure or concrete deterioration in the superstructure.

More than two-thirds of the quay walls in Port of Rotterdam are deteriorating from accelerated low water corrosion because the substructure is made of steel sheet piling or steel combi walls (combination of tubular piles and sheet piles). The concrete top structures are also degrading due to the chloride ingress from the salt water and carbonization due to CO₂ in the air.

Port of Rotterdam drew up and validated a steel deterioration model based on corrosion rates that is capable of predicting the safety factor on both the strength of the structure and soil retention over the remaining lifetime of a quay wall, and if needed, to present the ultimate moment to start maintenance. a similar method is being used to predict the aging of concrete. Both models need input from field inspections. In the case of the steel substructure this done by doing ultrasonic thickness measurements or check the effectiveness of the cathodic protection system. For the concrete model prediction cores are drilled from the quay wall and tested in the laboratory. These results in combination with GPR measurements on the concrete cover and HCP measurement to locate initiated corrosion of the rebar are input for the model to calculate the remaining useful life. Figure 2 shows a screenshot of the outcome of the life-time calculations.

With the aid of its highly advanced deterioration models, the expert system can predict when the lower safety limit for a quay wall will be reached, how the inspection regime must then be detailed and what maintenance measures must be done in order to meet the asset owner's required functionalities (such as availability for use, or asset lifetime).

7 THE EFFECT OF MAINTENANCE STRATEGIES ON THE LIFETIME

The model is capable of simulating various maintenance strategies, So it gives insight on the effect of the applied strategy. The strategy can consist of several measures with an in between

Figure 2. Screenshot of the progress of chloride content at rebar over time.

period of several years. So the most efficient and cost-effective maintenance scenario for the quay wall in question can be selected and applied.

It will also provide insight into the consequences – such as a reduction in the remaining service life or availability of the structure – of postponing specific maintenance measures or the effects of a do nothing scenario.

The results of these simulations, what maintenance measures in what year are used in the Port of Rotterdam’s expert system to draw up the LTAP (Long Term Asset Planning). Putting all assets in the planning and combining this with the regular O & M costs of the assets, will give insight in the needed budget over the coming years and can be used to make the most optimized financial investment plan.

8 RISC MANAGEMENT IN MAINTENANCE STRATEGIES

One of the best methods to make the most out of the constraint budgets, is to apply risk management on the activities.

Not all risks that endanger the functionality of the quay wall (or parts of it) will lead to a highly unwanted situation. The risk figure is calculated by multiplying the probability of failure by the consequence of failure. The consequence of failure (CoF) of (the part of) an asset can be calculated by ranking the effects on the business in terms of financial, image, safety, availability etc, by using the redundancy and by using the measures taken to reduce the CoF. The CoF can be seen as a more or less constant figure that will not change radically over time, when an asset fails these are the consequences. On the other hand the probability of failure (PoF) will change over time in a more or less same speed as the deterioration. If the condition of an asset goes down, the PoF will grow. With that in mind, the assets that have a low CoF will in case of failure have acceptable consequences and thus will have a different maintenance strategy (run to failure) than an asset with a high and unacceptable CoF, where an intensive monitoring can be the preferred maintenance strategy. So even in the case of constrained budget, there is still a way to make choices that do not affect the business in an unacceptable way and lead to more damage for the company than needed.

9 LONG TERM ASSET PLANNING

Once the asset manager finalizes prioritizing the required maintenance on each structure, the sum of the individual identified maintenance actions, whether they are CAPEX or OPEX, over a period time will give a long term asset planning for that asset. The Long Term Asset Planning will provide the asset manager on overview of the needed budget over the next 50 years. This will give the financial department the possibility to make a financial planning and if needed the effects of peak shaving can be made visible and the plan can be adjusted.

Compiling work packages for multiple structures containing similar tasks means these packages can then be procured under one contract in order to reduce installation time and cut costs. The prioritization of maintenance tasks, based on a multi-criteria analysis, ensures that expenditure and maintenance is performed on those structures that are the most economically important to the Port of Rotterdam Authority – and where the safety risks are highest.

If necessary, when maintenance work is postponed to the next calendar year, (for example, due to budgetary constraints), the system will then translate the consequences of this directly into the maintenance budget for subsequent years. In effect, it translates the risks of not performing a certain maintenance task into a higher priority for the coming years.

10 CONCLUSIONS

The Port of Rotterdam succeeded in developing an asset management tool based on a simple but effective method that can help the asset manager to make the right decision in regards to the (constrained) maintenance budget. Not only based on lifetime prediction of the most vulnerable parts, but also on business value of the asset and the risks involved.

It will allow the Port of Rotterdam to predict the degradation of quay walls, whether they are built of concrete, steel or a combination of both. It will also provide a good indication about when preventive maintenance should be done, the costs that are involved and the safety of the structure for its tenants. When Port of Rotterdam faces the need to constrain the available budget to whatever reason, the consequences of different scenarios in terms of budget, condition and risk can be calculated and the optimum scenario for the given situation can be chosen.

The method that was developed in the Port of Rotterdam is based on a simple stepstone method that is applicable in any other port in the world. Whereas Port of Rotterdam has put extensive effort in developing state of the art degradation models, the use of more simple methods can also lead to acceptable results to give insights in the different scenarios.

Modeling and characterization strategy as a basis for improved prediction of concrete fatigue degradation in wind power plants

A. Baktheer, M. Aguilar, H. Becks, M. Classen, J. Hegger & R. Chudoba
Institute of Structural Concrete, RWTH Aachen University, Aachen, Germany

ABSTRACT: The fatigue behavior of concrete has been usually investigated experimentally for loading scenarios with constant amplitudes. However, in reality, concrete components and structures such as wind turbine towers are subjected to loading scenarios with variable amplitudes. Current design rules insufficiently capture the effect of amplitude changes and loading sequence within load scenarios on the fatigue behavior of concrete and can lead to both uncertain and uneconomic design. A purely experimental investigation of the sequence effects in cyclic loading of concrete is not feasible due to the large number of possible combinations of experimental parameters. In this paper, the concept of a combined numerical-experimental methodology is presented with the aim to develop an engineering model that will deliver more realistic predictions of the fatigue life of concrete towers, thus increasing the reliability and economic viability of wind turbines. A microplane fatigue model recently developed by the authors is used to study and analyze the fatigue behavior of concrete covering a wide range of applications, accounting for any kind of loading scenario. The paper presents recent advances in modeling and characterization of fatigue behavior of concrete, considering the effect of loading sequence and provides an outlook of the prospective methodology for deriving design rules for fatigue life prediction in wind power plants.

1 INTRODUCTION

A realistic prediction of the fatigue life of concrete under high-cycle loading scenarios with variable amplitudes is of utmost importance for a reliable and economically efficient design of structural infrastructure for energy supply such as wind power plants. In modern high-performance RC structures, the compressive fatigue of concrete gains crucial importance due to the high material utilization (Schmidt, Schneider, and Marx 2019). This is especially important for prestressed slender structures, such as the concrete towers of wind turbines, where cyclic loading leads to stress fluctuations around considerably high permanent compressive stresses. The fatigue behavior of concrete has been mainly studied experimentally under constant amplitudes in the last decades, e.g. (Kim and Kim 1996; Schneider, Humme, Marx, and Lohaus 2018). Based on these studies, the fatigue life of concrete is typically characterized by the Wöhler/S-N curves (fib Model Code 2010). However, in reality, concrete members and structures are subjected to complex loading scenarios with variable amplitudes such as the stochastic wind actions in the onshore and offshore wind power plants (Lenschow 1980).

Since the experimentally determined Wöhler curves characterize only uniform fatigue loading, more refined methods are needed to evaluate fatigue damage due to fatigue loading with variable amplitude. In current design codes, e.g. (fib Model Code 2010; EN-1992-2 2005), the widely used Palmgren-Miner P-M (Palmgren 1924; Miner et al. 1945) rule is considered. This rule assumes that the cumulative fatigue life for a loading scenario consisting of n loading ranges is estimated by linear interpolation of the fatigue life for each loading range individually. The fatigue failure is assumed when

$$\eta = \sum_{i=1}^n \frac{N_i}{N_i^f} = 1, \quad (1)$$

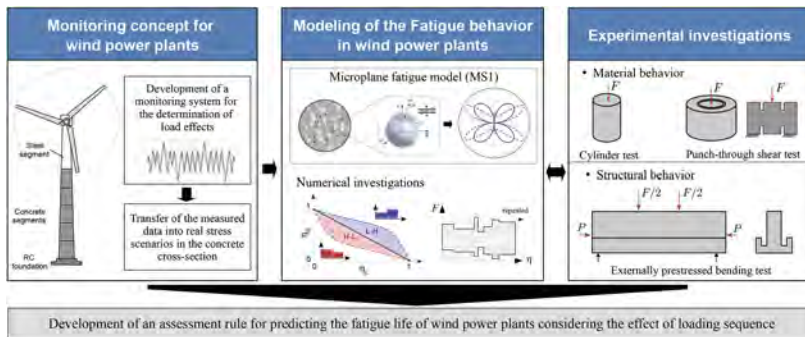

Figure 1. Summary of the planned methodology for characterizing the fatigue loading sequence effect in wind power plants.

where N_i^f is the number of cycles to failure achieved under a constant amplitude loading corresponding to the level i and N_i is the number of applied cycles at the load level i during a multi-level loading scenario. Although this hypothesis is widely used, experimental evidence is so far lacking. On the contrary, the few available published experimental results show that the P-M rule can lead to a very unsafe lifetime prediction (Holmen 1979; Baktheer and Chudoba 2021). Therefore, it is necessary to derive engineering models that allow a more realistic prediction of concrete fatigue lifetime in wind power plants.

A purely experimental investigation of the sequence effects during cyclic loading of concrete is not feasible due to the large number of possible combinations of loading parameters. Within a joint research project named (WinConFat-Structure) funded by the German Federal Ministry of Economic Affairs and Climate Action (BMWi), the main goal is to characterize the concrete fatigue behavior in wind power plants considering the effects of loading sequence as a basis for an improved engineering model.

For a more realistic prediction of the fatigue life of concrete, the support of advanced numerical and theoretical models that describe the fatigue damage process in a thermodynamically consistent way is urgently needed. A physically based microplane fatigue model MS1 developed recently by the authors (Baktheer, Aguilar, and Chudoba 2021) will be used for an efficient simulation of the fatigue damage development in the critical concrete cross-sections and zones of wind power plants over the entire lifetime in combination with the development of a monitoring system to determine load effects and load sequences in wind power plants. The modeling approach will be calibrated and validated with recently developed experimental setups at both the material and structural levels (Becks and Classen 2021; Becks, Baktheer, Marx, Classen, Hegger, and Chudoba 2022) as shown in Figure 1.

The overall view of the research project is summarized in Figure 1. The current paper highlights the main concept of the research project (WinConFat-Structure) with the intended combined numerical-experimental methodology for characterizing the effect of loading sequence on the fatigue lifetime of concrete, and presents recent advances in modeling and characterizing the fatigue behavior of concrete considering the effects of the loading sequence.

2 MODELING OF CONCRETE FATIGUE RESPONSE

2.1 Microplane fatigue model MS1

A recently developed microplane material model for concrete fatigue MS1 (Baktheer, Aguilar, and Chudoba 2021), that introduces the cumulative shear fatigue hypothesis (Baktheer and Chudoba 2018; Chudoba, Vořechovský, Aguilar, and Baktheer 2022) at the microplane level, will be used in the combined numerical-experimental methodology for characterizing the concrete fatigue behavior considering the effect of loading sequence (Aguilar, Baktheer, and Chudoba 2021). By linking fatigue damage evolution to a cumulative measure of inelastic shear

strain, the triaxial stress redistribution within the concrete material structure in response to subcritical fatigue loading can be captured (Figure 2). The model was formulated within the microplane framework using the kinematic constraint to project the macroscopic strain tensor to the microplanes and the principle of virtual work and energy equivalence to obtain the macroscopic stress tensor.

In the following sections, examples of fatigue simulation of concrete using the described model are presented, showing the ability of the model to capture the main phenomena of concrete fatigue.

2.2 Fatigue under uniaxial compression

To study the feasibility of the model to simulate the concrete fatigue behavior, simulations of a single material point behavior are considered in this section. Assuming that the dissipative effects governing the compressive fatigue behavior of concrete within a cylindrical specimen are uniform within its volume, the state evolution of the specimen can be idealized as uniform uniaxial stress and strain over its fatigue life.

A recently performed experimental program on cylinder specimens with a compressive strength of 60 MPa under uniaxial compression including several loading scenarios is used to identify the model parameters. The calibration of the model was achieved by simultaneously considering the monotonic scenario and the fatigue loading scenarios with several upper load levels. The experimentally obtained curves for monotonic and fatigue loading and the simulated curves reproduced by the calibrated model are depicted in Figures 3a-c. To study the applicability of the calibrated model to any loading scenario, its predictions for a pre-peak cyclic loading with step-wise increasing upper load level are compared with the obtained experimental results as shown in Figures 3d-f.

The model shows the ability to simulate the monotonic and fatigue behavior of concrete under compression with a consistent set of material parameters. Furthermore, the numerically predicted fatigue creep curve for the step-wise loading scenario in Figure 3f shows a realistic prediction, indicating a promising capability of the model to simulate the concrete behavior under more complex loading scenarios.

Figure 2. Interaggregate dissipative mechanisms included in the developed microplane fatigue model MS1 and illustration of the microstructure containing a system of dissipative microplanes that are integrated within 3D hemisphere idealization.

2.3 Fatigue under combined shear-compression loading

The developed thermodynamic-based microplane model MS1 described in Sec. 2.1, hypothesized that fatigue evolution in the concrete material structure can be realistically modeled by defining a cumulative measure of inelastic shear strain as the fatigue driving mechanism. The standard method of fatigue characterization using cylinder specimens induces shear only as a secondary effect within the volume of the specimen. To validate the hypothesis, experimental methods with dominant shear strain appear more appropriate. A recently developed Punch-

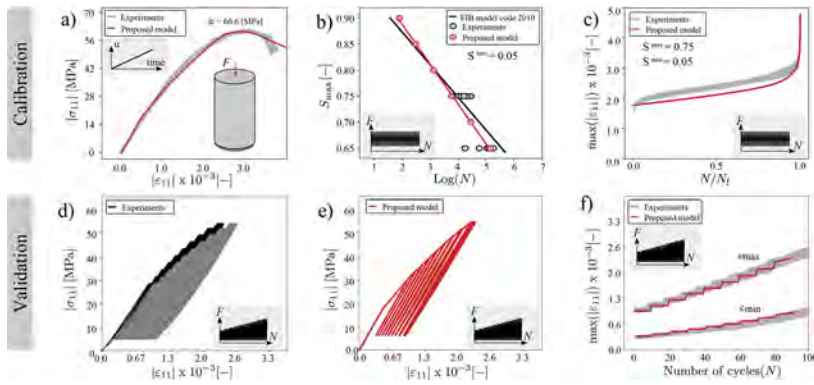

Figure 3. Cylinder test simulation under compression with the developed microplane model MS1 with calibration-validation procedure based on performed tests: a) stress-strain response under monotonic loading; b) Wöhler curve representing fatigue life; c) fatigue creep curve at the upper load level; d, e) stress-strain response under pre-peak cyclic loading; f) corresponding fatigue creep curves.

Through Shear Test (PTST) setup (Becks and Classen 2021) induce shear-dominated strain within the volume of the specimen (Figure 4a) with controllable level of compressive stresses (Becks, Aguilar, Chudoba and Classen 2022).

To provide an example of using the developed MS1 model within a finite element discretization to simulate the response of the PTST, an elemental study is shown in Figure 4. As shown in Figure 4a, an axisymmetric idealization is used in this example, to allow efficient cycle-by-cycle simulation of the PTST fatigue behavior, which nevertheless realistically represents the governing principles of fatigue propagation. The dimensions of the model are 50 mm height and 100 mm diameter. The center of the notch is located 26 mm from the axis of symmetry, has a width of 4 mm, and a depth of 10 mm. To examine the ability of the model to reproduce the shear fatigue response in combination with lateral confinement, a study with subcritical shear upper load level of 70 kN, lower level of 20 kN, and a lateral confinement of 7.5 MPa is shown in Figure 4b. The example shows a low cycle fatigue response with fatigue failure after 39 load cycles. The obtained load-displacement curve demonstrates the ability of the model to reproduce plausible cyclic behavior with a realistic shape of hysteretic loops.

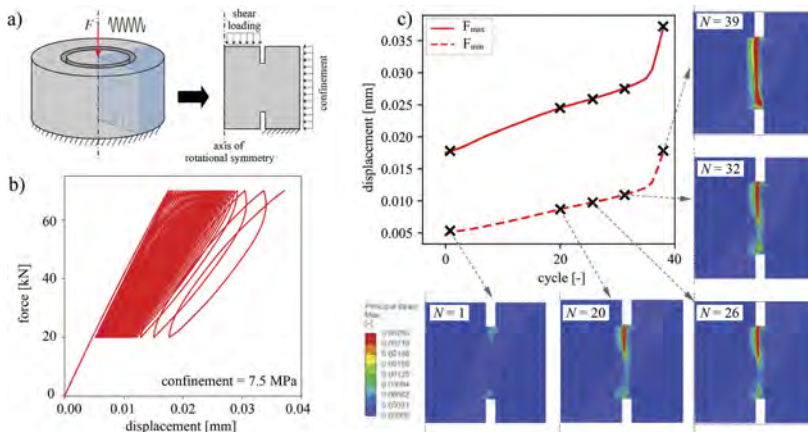

Figure 4. Elementary example of fatigue simulation of the PTST a) test setup with axisymmetric idealization used in the numerical simulation; b) force-displacement curve for cyclic shear loading with a range of 70 kN for the upper level and 20 kN for the lower level; c) corresponding fatigue creep curves at the upper and lower load level with the contour plots of the development of the principal strain during fatigue life.

Furthermore, the corresponding fatigue creep curves, i.e. the displacement increase at the upper and lower load levels during fatigue life are shown in Figure 4c. The obtained response reveals the typical shape of fatigue creep curves observed usually during fatigue experiments. The crack propagation during cyclic loading is visualized in Figure 4c, where the contours of the maximum principal strain are plotted for selected load cycles during the fatigue life.

The formulation of the model in the framework of thermodynamics allows isolating the energy release due to the individual mechanisms such as plastic deformation, plastic strain hardening effects, and damage evolution. This feature of the model can be used for objective characterization of stress redistribution effects within the material structure under fatigue loading with any complex loading scenario. Further detailed analysis of the energy dissipation during fatigue life is documented in (Aguilar, Baktheer, and Chudoba 2022).

3 EFFECT OF LOADING SEQUENCE

One of the most complex phenomena in characterizing the fatigue behavior of concrete is the effect of loading sequence on the fatigue life due to the inevitably large scatter and high cost of fatigue testing. This effect is of great relevance for any structure subjected to fatigue loading due to the nature of repeated loading in the reality. Without studying the effects of load sequencing and variable amplitudes, safety factors can be set uneconomically large or dangerously low. Due to the complexity of characterizing this effect, only little experimental research has been reported in the literature on this topic.

Recently, comprehensive studies of the concrete fatigue behavior under several uniaxial compression loading scenarios that include pre-peak and post-peak cyclic loading, low and high cycle fatigue, as well as the effect of loading sequences with variable amplitudes have been performed by the authors (Baktheer and Chudoba 2021). The results presented in Figure 5a-c show the effect of load sequence on the compressive fatigue behavior of concrete with considerable scatter of the obtained fatigue life for both High-Low (H-L) and Low-High (L-H) loading scenarios. These studies confirmed earlier observations (Holmen 1979) that the Palmgren-Miner (P-M) rule is not able to capture the load sequence effect correctly, revealing the existing deficit in the current design codes (EN-1992-2 2005). The obtained results allowed an energetic interpretation of the fatigue loading sequence effect. Assuming that energy is dissipated uniformly within the volume of the cylindrical test specimen during subcritical compressive cyclic loading the superposition of energy dissipation profiles along the lifetime measured for constant amplitudes becomes possible and can explain the experimentally observed misfit with respect to the P-M rule. The situation is sketched using energy dissipation profiles due to damage for two levels of loading in Figures 5d, e.

The recently developed PTST that allows for a simultaneous control of shear and compressive stresses can be used to systematically isolate the influence of the degree of confinement on the fatigue life of concrete under subcritical fatigue shear loading. Comprehensive experimental studies on the monotonic and fatigue behavior of concrete using the PTST test setup with radial notches (Figure 6a) have been recently performed by the authors (Becks, Aguilar, Chudoba and Classen 2022). The influence of different degrees of confinement on monotonic and fatigue behavior is depicted in Figure 6a, b. As can be seen from the experimental results, the number of cycles to failure remains nearly uniform for the studied confinement load levels (Figure 6c). Interestingly enough, the scatter of the results tends to decrease with an increasing level of confinement. This configuration offers a promising opportunity to characterize the effects of loading sequence, which are typically difficult to observe in classical experimental setups, such as cylinder tests and three-point bending tests, due to the large scatter of results as documented by (Tepfers, Friden, and Georgsson 1977; Baktheer, Becks 2021), hence only few studies focusing on the load sequence are available in the literature.

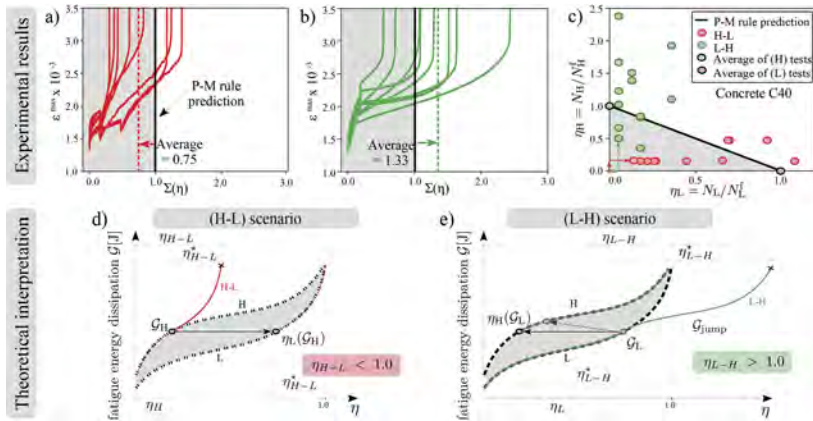

Figure 5. Experimentally observed effect of the loading sequence on concrete fatigue behavior under uniaxial compression: a, b) fatigue creep curves for (H–L) and (L–H) loading scenario, respectively; c) comparison with the predicted fatigue life using the P–M rule; d, e) theoretical interpretation based on superposition of energy dissipation profiles for (H–L) and (L–H) scenarios, respectively.

Figure 6. A) PTST setup with controllable lateral confinement; b) monotonic behavior at several levels of lateral confinement; c) fatigue life at several levels of lateral confinement.

4 CONCLUSIONS

The developed fatigue model MS1 shows promising results both at the level of a single material point and in the finite element simulation of the fatigue behavior of concrete. The model will be validated at the material level using PTST and at the structural level using prestressed bending tests that allow studying the propagation of compressive fatigue that is expected in reality. The development of a monitoring system to determine the loading effects and the transformation of the measured data into real stresses in the critical cross sections will be used to refine the space of loading parameters relevant in wind power plants. Based on this data, the validated model can be used for further investigations of the fatigue behavior of concrete under a wide range of complex loading scenarios, which in the long run can lead to the derivation of improved engineering rules for predicting the fatigue life of wind power plants that consider the effect of loading sequence.

ABSTRACT: Sustainability should become a basic concept for efficient/high quality design and operation of any structure through entire life cycle. Concrete is gradually becoming a building material with a high potential for such new technical solutions that meet new requirements, leading to the necessary reduction of environmental impacts and consequent improvement of social and economic conditions. The specific type of structures are bridges, where traditionally dominant requirements are efficiency of structural performance connected with cost efficiency, and due to a visual exposure to their architectural form and aesthetics. However, environmental quality is not usually considered. The need for an environmental assessment of different alternatives is becoming increasingly important due to the need to reduce environmental impacts, especially the carbon footprint. Environmental assessment could be done using existing standard methodologies of LCA in line with the concept of implementation of sustainability principles of concrete structures in the new fib ModelCode 2020. The paper presents a LCA case study focusing on concrete footbridge over the Labe river in Čelákovice, Czech Republic. One alternative is traditional design, and the second two represent advanced design using precast elements from UHPC. The detailed LCA analysis performed compares all three alternatives from an environmental impact point of view.

1 INTRODUCTION

The new fib ModelCode 2020 (MC2020) not only addresses traditional safety and serviceability requirements, but sustainability is seen as an overriding fundamental requirement responding to broader issues such as social responsibility, environmental quality, and economic efficiency. An intention and principal goal of MC2020 is to raise awareness of all participants and stakeholders in the process of design, construction, and operation of concrete structures regarding a wide range of sustainability criteria – social aspects, environmental aspects, and economic aspects. This should be considered within the entire life cycle of a structure (Hájek et al., 2011). An environmental assessment must be performed on complex systems (e.g., considering the whole life cycle of the entire structure) where LCA could show how particular materials could contribute in a positive or negative way to the environmental sustainability of the entire system (Asadollahfardi et al., 2021, Berndt, 2015, Blankendaal et al., 2014, Hájek, 2017, Hájek, 2013) or even considering the possible use in the following life cycle as a recycled product (Marinkovic et al., 2010, Pavlu et al., 2019).

The specific type of structures are bridges, where traditionally dominant requirements are the efficiency of structural performance connected with cost efficiency and due to a visual exposure

of their architectural form and aesthetics. However, environmental quality is not usually considered. The need for environmental assessment of different alternatives is becoming more and more important due to the need for the reduction of environmental impacts, especially of carbon footprint (Lupisek et al., 2021). The environmental assessment could be performed using existing LCA standard methodologies, which is standardised by ISO 14040 (ISO, 2006a) and ISO 14044 (ISO, 2006b). Life Cycle Assessment (LCA) is a technique to evaluate the benefits or impacts of a product or process on the environment (Laiblova et al., 2019, Pesta et al., 2020, Zenisek et al., 2020). Specific requirements for conducting an LCA study on construction products are described in EN 15 804 +A2 (CEN, 2020). According to these standards, an LCA study of construction products consists of the following phases: Goal and scope, Life Cycle Inventory (LCI), Life Cycle Impact Assessment (LCIA), and Interpretation.

The goal and scope of the study mainly consist of describing the aim of the study and the system boundary considered (Guinee, 2001). The second phase of LCA is the LCI, which involves summarising all elementary flows between the environment and the product system. That covers the consumption of raw materials, the generation of waste & emissions, and energy flow as well. LCIA is used to find the magnitude of environmental impact under different impact categories (Pesta et al., 2020). In the last part of the LCA study, the results obtained are interpreted.

The presented LCA study focused on the comparison of three variants of the bridge, which use different types of concrete and steel structures. Concrete is a composite silicate material with great potential for new technical solutions that meet new requirements. There is a challenge and expectation that the use of new types of composite silicate materials in advanced technologies could lead to the necessary reduction of environmental impacts. The goal of the presented case study is to show and discuss in detail how new advanced technology approaches could mitigate potential environmental impacts and therefore contribute to the Sustainable Development Goals (SDGs) set by the UN in 2015 as an action plan up to 2030.

2 METHODOLOGY

2.1 Footbridge

The footbridge is located in Čelákovice in the Czech Republic. It enables the crossing of the Labe river for pedestrians, cyclists, and emergency vehicles. In the tender documents, a cable-stayed footbridge with a composite superstructure consisting of two longitudinal steel side beams, steel cross beams, and a concrete slab was designed (variants V1, V2 in Figure 1). The composite slab was designed from precast concrete elements of C110/130 with steel fibre reinforcement, the elements were supported on the bottom flange of the side beams and cross beams. The contractor proposed an alternative solution of a segmental bridge deck made entirely of concrete C130/150 (for LCA analysis C110/130 only was considered) with steel fibre reinforcement (Figure 2) and the arrangement of spans 43+156+43 m.

Steel pylons with a total height of 37 m are fixed on the foundation blocks on in-situ cast piles. Stays are arranged in two planes, the lower adjustable anchorages are located on the side of the deck. The deck is supported by fully locked cable stays with galvanisation corrosion protection. The abutments on both banks of the river are massive reinforced concrete blocks in piles that form a counterweight to the uplift reactions of the superstructure. The walkable surface of the deck is covered with a sprayed waterproofing of 5mm thickness. The steel railings are 1.3 m high.

Figure 1. Variants V1 and V2 of the footbridge deck (Kalny, 2018).

Figure 2. Cross-section (Variant V3 UHPC segments) (Kalny, 2018).

2.2 Description of variants

During the conceptual study phase, 3 conceptual variants of cross section were thoroughly analysed and later evaluated from the point of view of environmental aspects. The cross-sections of variants of the footbridge deck are in Figure 1, those were not built. The cross-section of the footbridge deck that was built is in Figure 2. In variants V1 and V2 the footbridge deck is designed from longitudinal steel side beams, steel cross beams and precast concrete panels (their material consumption is described in Table 1). Variant V1 used precast panels from concrete C45/55, the variant V2 used panels from UHPC.

Table 1. Balance of input data of assessment variants.

Construction phase				
Balance of input data of assessed variants	unit	V1 Steel+ C45/55	V2 Steel+UHPC	V2 Segment UHPC deck
Cement CEM I 42,5 R	t	87.5	75.5	117.8

2.3 Environmental assessment

In accordance with the ISO 14040 (ISO, 2006a) and ISO 14044 (ISO, 2006b), the LCA study of the Čelákovice footbridge consists of four steps: Goal and scope definition, LCI, LCIA, and interpretation of results. A study of the LCA of each footbridge variant, which consists of different proportions and different types of steel and concrete components, was carried out to evaluate environmental impacts. The goal of the present study is to compare the environmental consequences of each proportion and sort of steel and concrete structure. The scope of the study is to design a footbridge variant with UHPC segment usage and to compare the influence of using different proportions and types of structures on the overall environmental impact. The considered system boundary in the scope called cradle to grave includes extraction, processing, and transportation of raw materials to the plant, manufacturing of construction elements, and construction, usage and demolition of the footbridge. The functional unit considered was the Čelákovice footbridge. The inventarization data was conducted in SimaPro software (Herrmann and Moltesen, 2015), which was also used for the creation of product system models. Specific data were used to model the proportion of materials in each variant (see Table 1) and environmental data related to processes were modelled using generic modules described in Table 2, which were obtained from the Ecoinvent 3.9 database (Frischknecht et al., 2005).

Table 2. Product system processes and the corresponding Ecoinvent module (Frischknecht et al., 2005).

Product processes	Ecoinvent modules
Cement CEM I 42,5 R	Portland (Europe without Switzerland) market for Cut-off, S
Sand I Gravel	Sand (RoW) market for sand Cut-off, S
Crushed gravel	Gravel, crushed (RoW) market for gravel, crushed Cut-off, S
Microsilica	Activated silica (GLO) market for Cut-off, S
Slag	Supplementary cementitious materials (RER) basic oxygen furnace secondary metallurgy slag, for recovery to generic market for supplementary cementitious materials Cut-off, S
Steel fibres	Reinforcing steel (GLO) market for Cut-off, S
Superplasticizer	Plasticiser, for concrete, based on sulfonated melamine formaldehyde (GLO) market for Cut-off, S It is used for mixing the materials for the preparation of mortar
Water	Water, unspecified natural origin, CZ
Reinforcing bars	Reinforcing steel (GLO) market for Cut-off, S
Construction steel	Steel, unalloyed (GLO) market for Cut-off, S
Prestressing steel	Hot rolling, steel (GLO) market for Cut-off, S
Freight traffic (long-distance and (local)	Transport, freight, lorry 16-32 metric ton, euro6 (RER) market for transport, freight, lorry 16-32 metric ton, EURO6 Cut-off, S
Demolition of RC structures	Waste concrete (Europe without Switzerland) market for waste concrete Cut-off, S/Scrap steel (Europe without Switzerland) market for scrap steel Cut-off, S

In the LCIA phase, the impact on the environment due to the consumed energy, fuel and emissions was characterised using the EF 3.0 method (Sala et al., 2022) provided in SimaPro software. The assumptions and limitations considered in the study are as follows.

- Steel element production was defined to be 14 km from the construction site.
- Production of monolithic concrete and prefabricated elements was defined as 8 km from the site. The recycling centre for concrete waste was assumed to be 30 km from the construction site.
- In the utilization phase, it was assumed to repair the surface of ordinary concrete (10% of the surface) two times.
- The concrete in waste was assumed to be recycled, and so no process was considered for waste disposal. The life cycle of the footbridge was assumed to be 100 years.
- Normalization and weighting of the obtained results were performed according to EF 3.0 method available in SimaPro software.

3 RESULTS AND DISCUSSION

The results of the environmental assessment of the design of the Čelákovice footbridge are presented in Table 3. Characterization was performed according to the EF 3.0 method.

Table 3. Results of indicators according to the EF 3.0 characterization method.

*LULUC – Land Use and Land Use Change

To analyse and compare results in different impact categories, the normalized and weighted results of the three design variants of the bridge in Čelákovice were considered. Results show that the difference among impact categories for all three bridge variants is not significant. However, it can be concluded that the second bridge variant performs the best in most of the impact categories. The sum of normalized and weighted results for each variant is shown in Figure 3.

The following graphs show the results for each of the footbridge options. In Figure 4., results for the first variant are shown. In the first footbridge variant, the production process of construction steel has the largest share in all impact categories. The second largest share in most of the impact categories is represented by the production process of reinforcing steel.

Figure 3. Normalized and weighted results (according to the EF 3.0 method).

Figure 4. Relative contribution of processes in each category, V1 (according to the EF 3.0 method).

In Figure 5, the results for the second variant are shown. In this footbridge variant, the production process of construction steel has again the largest share in all impact categories. The second largest share in most of the impact categories is represented by the steel production process, but with a smaller share in the total result of each impact category. In contrast, the share of the cement production process is higher than in the previous variant.

In the third variant of the bridge, the impact of the production processes of structural steel and reinforcing steel remains significant. However, the plasticiser share is also important in this variant. In Figure 6, the relative contributions of processes for the third variant are shown.

Figure 5. Relative contribution of processes in each category, V2 (according to the EF 3.0 method).

Figure 6. Relative contribution of processes in each category, V3 (according to the EF 3.0 method).

4 CONCLUSIONS

The perspective of sustainability should be implemented in the high-quality design and operation of any structure. Therefore, the new fib ModelCode 2020 covers even environmental assessment aiming to reduce the potential impacts of a designed concrete structure. To propose the possible use of environmental assessment in the design phase, the LCA case study was performed comparing three variants of the footbridge. Based on the LCA case study, the following conclusion can be drawn:

- The second variant has the lowest environmental impact, while the third variant has the highest overall impact.
- The result of the freshwater ETP represent main contribution to the overall impact.
- The LCA study provides detailed insight into potential environmental impacts of processes in life cycle of a concrete structure and can be used to optimized a proposed design.

Unfortunately, the final decision of the developer is usually not based only on the environmental performance of the considered structures. Therefore, the sustainability assessment in ModelCode 2020 should cover also environmental perspectives and provide robust support to assess different variant of concrete structures.

Fundamental experiments for monitoring water leakage of underground structures using plastic optical fibers

Haihua Zhang, Zhibin Liu, Xianfeng Ma & Jiangu Qian

Department of Geotechnical Engineering, College of Civil Engineering, Tongji University, Shanghai, China

Shinichi Akutagawa

Department of Civil Engineering, School of Engineering, Kobe University, Kobe, Japan

ABSTRACT: In coastal metropolises, strict regulations regarding the exploitation and utilization of groundwater have resulted in a continuous rise in groundwater levels over the past few decades. As a result, underground concrete structures are now at a higher risk of water leakage than ever before. To detect water leakage in underground structures as early as possible, this paper introduces a plastic optical fiber (POF) sensor. This sensor has a prism tip formed by two bonded parallel POFs, which enables it to detect water in real time. When the sensor comes into contact with water, the returning visible light changes due to the reflection and refraction at the prism interface. Fundamental experiments were conducted to verify the feasibility of the POF sensor. The results showed that the POF sensor is effective in detecting water in real time by measuring light intensity. Furthermore, the change of light intensity over time allowed for the observation of the water penetration process in hardened mortar specimens, enabling the estimation of the permeability of the mortar at a definite quantity. Finally, future work is discussed briefly.

1 INTRODUCTION

Groundwater is a crucial resource for human living, industrial production and agricultural irrigation. However, excessive exploitation of groundwater has led to a significant drop in groundwater levels in urban areas, causing environmental problems, such as ground subsidence and fissure. To mitigate these issues, many cities have implemented strict groundwater regulations and active water recharge methods during underground structure construction. These measures have had a positive effect, as seen in Tokyo, Osaka, and Shanghai, where groundwater levels stopped dropping after the implementation of groundwater regulations (see Figure 1). However, these measures have also led to new problems in geotechnical engineering, such as sand liquefaction, ground heaving, and building floating. Furthermore, as the groundwater level rises, water leakage in underground concrete structures becomes more difficult to manage, impacting the maintenance and durability of such structures.

Water typically leaks from tinny cracks in concrete or between the joints of new and old concrete. Leaking water can seep into poorly waterproofed underground concrete, causing cracks to form. Over time, this can lead to the corrosion of steel bars in concrete, weakening overall underground structure. To detection of water leakage early, several nondestructive inspection (NDI) technologies have been developed. However, the application of these technologies is often limited to important underground structures, as specialized equipment is required. By the time when water is found on the surface of structure, it may already be too late. Therefore, it is essential to detect underground water leakage using simple methods as early as possible, given the continuous rise of groundwater.

Figure 1. Groundwater level change over time in typical coastal big cities.

This paper proposes a new method for investigating water leakage in underground concrete structures using POF sensors. A fundamental experiment was conducted to verify the feasibility of this method, and the results demonstrate that it is possible to detect water leakage in concrete structures at an early stage. Future work is discussed finally.

2 METHODOLOGY

The proposed POF sensor is capable of detecting water through the reflection of visible light from a prism structure, utilizing a 1 mm diameter POF as the media of light transmission. A right triangle prism is formed directly at one end where two parallel bare optical fibers are bonded together, as shown in Figure 2. In air, when the light from the first fiber hits the sloped interface, internal reflection occurs rather than dispersion. Some of the light is reflected into the second fiber, passing through the boundary of the two fibers. The light is then reflected again at the sloped surface of the second fiber, which can be seen directly at the end of the second fiber. When the POF sensor is placed in water, the light is dispersed instead of reflected at the two sloped surfaces. Consequently, the light from the end of the second fiber becomes weak.

To measure the emitted light intensity, a light state sensing system (LS^3) was produced, which includes a light source, a data logger and a computer (see Figure 3). The light intensity is presented in a 12-bit RGB system, with a maximum value of 7093. The measured data can be recorded and analyzed using a notebook computer.

Figure 2. Structure of sensor and light refraction/reflection.

The POF sensor was tested to find the difference between the water and air (see Figure 4 (a)). Two POF sensors were set up in the water completely at different heights. Then, the water in the beaker was heated at the bottom so that the water level declined gradually due to evaporation. As shown in Figure 4(b), both sensors experienced a sudden change of light intensity when the sensing planes of these sensors were exposed to the air from the water. Hence, it is seen that the POF sensor could distinguish the air and water clearly by the change of returning light intensity.

Figure 3. Light state sensing system (LS³).

Figure 4. Water lowering test with POF sensors.

3 EXPERIMENTAL SETUP AND TESTING PROCEDURE

To evaluate the performance of POF sensors when detecting water leakage of hardened mortar specimens, the fundamental experiment was conducted. Four similar specimens were prepared and tested by immersing them half in water. The mixture proportions of fresh mortar are presented in Table 1. As shown in Figure 5, two POF sensors are set up in each specimen, with their tips located 5mm from the bottom of the specimen.

The experiment was carried out on Mar. 24th, 2020, 3 months after the placement of mortar. It is thought that most of the mortar hardening had been completed. The data record started before the four specimens were immersed half in the water. In about two days, the water was added so that the specimens were almost submerged completely in the water. Then on Mar. 27th, the specimens were taken out of the water and dried naturally in the room, as shown in Figure 6. The experiment lasted for about 10 days and ended on April 4th, 2020.

Table 1. Mortar mix proportions.

W/C(%)	Volume (8L)			
	Water(kg)	Cement(kg)	Sand(kg)	Air Entrainment (kg)
50.0	1.99	4.13	10.69	36.34

4 MONITORING RESULTS AND ANALYSIS

The experiment started at 11:30 on Mar. 24th. The monitoring data is shown in Figures 7–9. There are two groups among them. One is the group of ch1-6, the other is the group of ch7 and ch8. From the experiment in Section 2, we know that the POF sensor could detect the water as soon as the water arrived at the tip of the sensor. Firstly, it is found in Figure 7 that the measured light intensities began to change at intervals between 11:40 and 12:30. The light intensity of ch7 was the first to change and decreased sharply, which indicates there existed

Figure 5. POF sensors setup in the mortar specimen.

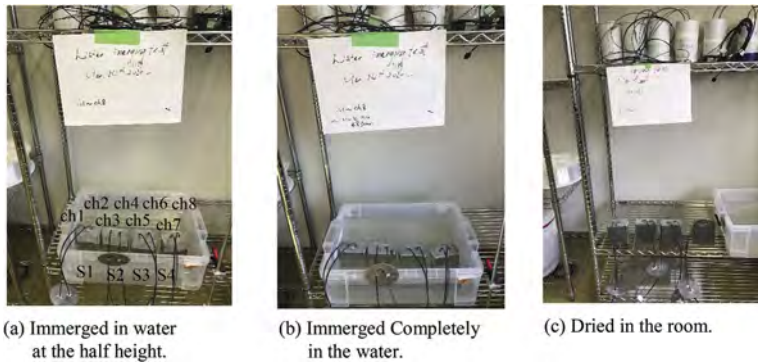

Figure 6. Water leakage test of mortar specimen.

some cracks or holes in the bottom of specimen S4 so that the water penetrated these spaces quickly (see Figure 7(b)). Secondly, the light intensity of ch2 decreased at a considerable gradient from 11:53. Thirdly, the light intensities of the other channels decreased gradually when they took action on the arrival of water. It should be noted that the initial light intensities of the 8 channels were measured under the condition of their corresponding incident light.

As shown in Figure 8, the light intensities of all the channels were tending to be stable at 9:36 on Mar. 26th. In order to make sure whether the water had penetrated the specimen to where the POF sensors were located, the water was added to immerse the specimens completely at 14:39 on Mar. 26th. There seemed to be no obvious effect on the light intensity change. Moreover, the light intensities of the 8 channels became stable on Mar. 27th. Therefore, the water immersing test ended in the afternoon. In this experiment, the coefficient of mortar permeability shall be calculated simply as follows:

$$k = \frac{L}{T} \quad (1)$$

where k is the coefficient of cement mortar permeability (cm/sec); L is the water penetration distance ($L=0.5\text{cm}$); and T is the time in seconds over which the L is measured.

Table 2 shows the permeability coefficient k measured by POF sensors. It can be seen that the coefficient of mortar permeability is in the order of 10^{-4} . The permeability coefficient k of Specimen S4 is about 2-3 times larger than that of the other 3 specimens.

Table 2. Coefficient k of mortar permeability.

Specimens	S1			S2			S3			S4		
Channels	ch1	ch2	ch3	ch4	ch5	ch6	ch7	ch8	ch1	ch2	ch3	ch4
k ($\times 10^{-4}$ cm/s)	2.17	3.57	1.40	2.58	2.02	1.69	5.10	8.06				

(a) ch1-ch6

(b) ch7-ch8

Figure 7. Light intensity change over time (from 11:30 to 14:24 on Mar. 24, 2020).

(a) ch1-ch6

(b) ch7-ch8

Figure 8. Light intensity change over time (from 11:30 on Mar. 24 to 9:36 on Mar. 27, 2020).

As long as the light intensities kept stable in the mortar permeability test, the 4 specimens were taken out of the water and dried naturally in the room. Figure 9 shows the light intensity change from Mar. 24, 2020 at 11:30 to April 3, 2020 at 0:00. As shown in Figure 9, there was some disturbance in the light intensities when the specimens were taken out of the water at 10:10 on Mar. 27th. But it is thought the trends of the light intensities would not be affected.

It is found that the light intensity (ch1-6) increased gradually with a gentle but steady gradient (see Figure 9(a)). On the other hand, the light intensities of ch7 and 8 increased dramatically till Mar. 30th and then developed slowly during the drying test (see Figure 9(b)).

Based on the previous study (Zhang et al. 2022), the light intensity would have a steep variation when the POF sensor meets the water, if there is a void around the tip of sensor (see Figure 10). Therefore, it is strongly believed that there were some non-negligible voids around the tips of the two POF sensors in Specimen S4.

It can be seen that the reduction process of water could also be monitored in detail according to the change in light intensity during the drying test. The void around the tip of POF sensor in the mortar would affect the development of light intensity.

The light intensities of ch1-8 measured at the end of the drying test were larger than their initial values in the permeability test. The existence of water at the interface between the POF sensor and the mortar might have some effect on light refraction and reflection. Further study should be taken to investigate the reason.

Figure 9. Light intensity change over time (from 11:30 on Mar. 24 to 0:00 on April 3, 2020).

Figure 10. Void around the tip of POF sensor (X-ray Photo).

5 DISCUSSIONS

The placement and installation of POF sensors are critical to ensure accurate and effective detection of water leakage. Ideally, sensors should be installed in areas with a high probability of water leakage during the concrete placement phase of new constructions. For existing underground structures, the sensors can be installed by drilling a hole in the concrete and ensuring that the waterproofing work is adequately performed. The sensor should make contact with the concrete, as even small voids can negatively impact the accuracy of the measurement. While water leakage can still be detected in the presence of a void, critical information such as the rate of water penetration may not be accurately captured.

Future work should focus on studying the influence of water on the interface between the POF sensor and concrete or mortar to better understand the observed changes in light intensity. Additionally, developing a compact monitoring device to visualize the detection of water leakage by on-site light emitting would be a useful and effective way to detect water leakage of underground structures during their life cycles. Overall, the proposed POF sensor offers a promising solution for detecting and monitoring water leakage in underground structures, which can lead to improved durability and reduced maintenance costs.

6 CONCLUSIONS

In conclusion, the proposed POF sensor has shown great potential for detecting water leakage in underground structures at an early stage. The experiments conducted in this study have demonstrated that the POF sensor can accurately distinguish between water and air, detect the arrival of water in hardened mortar specimens, and monitor the development of water penetration over time. The information obtained from the POF sensor can provide valuable insight into the permeability of the mortar and the effectiveness of protective layers, allowing for early detection and remediation of water leakage issues.

Effects of structural rehabilitation on modal parameters of the Marlo Bridge

B. Siedziako, T.S. Nord & A. Fenerci

Department of Ocean Operations and Civil Engineering, Norwegian University of Science and Technology, Ålesund, Norway

ABSTRACT: This paper examines the effects of structural rehabilitation on the modal parameters of the Marlo Bridge, which suffered damage to one of its pillars. Natural frequencies, mode shapes and damping ratios have been identified using time series of accelerations recorded at the site prior to and after the repair. In addition, complementary studies using the corresponding finite element model have been performed. It is shown that modal analysis can be a useful tool that gains insight into changes in structural behavior due to damage. The finite element model was able to accurately capture the dynamic behavior of the Marlo Bridge in its repaired state; however, the mode shapes obtained and the natural frequencies in the damaged state did not correspond well with those identified using measurement data and were found challenging to be reproduced.

1 INTRODUCTION

The Norwegian Consulting Engineers' Association estimated in 2021 that rail and road maintenance costs exceed 2 billion NOK (RIF - Rådgivende Ingeniørers Forening, 2021). A significant portion of these infrastructure maintenance costs relates to transport infrastructure that is owned by the county municipalities, and they are gradually increasing as a result of the deteriorating infrastructure combined with a risk of more common extreme loading events. Currently the state evaluation of bridges in Norway is based on visual inspections or non-destructive field and laboratory testing (Statens Vegvesen, 2019). Inspection results are then stored in BRUTUS – a database for Norwegian bridges and ferry docks that is used to prioritize maintenance works.

However, inspections are prone to errors, delays or postponements and often lack consistency as well as simple objectivity, when assessing the scale of damage. Therefore, the structural health monitoring (SHM) framework has become a very active field of research in recent years, as it has the potential to eliminate the above-mentioned issues and aid decision-makers in distributing resources more efficiently. Still, as real damage is rare, in order to examine the consequences due to its presence and validate different SHM frameworks, re-searchers have relied on numerical simulations (Ghiasi et al., 2022; Johnson et al., 2004) or laboratory tests on representative models (Malekzadeh et al., 2015; Teng et al., 2022). As pointed out in several studies, however, the research concerning SHM should be focused on tests of real structures to further develop the possibilities of employing SHM on bridges (An et al., 2019; Moughty & Casas, 2017). A great example in line with that recommendation is the Hell Bridge test arena (Svendsen, 2021), where one of the 35m spans of a railway bridge has been moved to new foundations on land to serve researchers validating different SHM strategies, and where different types of damage have been introduced onto the real structure (Svendsen et al., 2020). Another possibility for investigating changes in structural behavior in real case scenarios can be accessed during rehabilitation and upgrading projects (Costa et al., 2013) or bridge failures by conducting measurements prior to and after the repair.

Following this philosophy, we present in this paper the results from a modal analysis performed on a real structure that suffered serious damage. In this study we aim to investigate the effect of rehabilitation on the modal parameters of the Marlo Bridge in Norway, which underwent repairs during the winter of 2021/2022. The repair works included the replacement of a bridge pillar, sealing cracks with sprayed concrete, and painting the main steel beams.

2 CASE STUDY – MARLO BRIDGE

2.1 Bridge description

The Marlo Bridge shown in Figure 1 is used as a case study in this paper. The bridge is located on the FV2646 road in Skjåk in Norway. It was opened to traffic in 1959 and it is expected to be in service for 37 more years. However, in recent years, maintaining this piece of infrastructure has been troublesome for the county. The bridge had to be closed in 2018 due to damage to one of the pillars and in 2019 it was a subject of maintenance works aiming to improve the foundation under the middle pillar. Recently, the bridge was severely damaged by ice actions in 2021 and was rehabilitated in early 2022.

Figure 1. Picture of the Marlo Bridge – photography taken from Brutus (Statens Vegvesen, 2022). Red circle indicates the pillar that was damaged.

2.2 Damage description

Figure 2 shows the scope of the damage to the Marlo Bridge as of November 2021 before repairs. Although not certain, the most likely explanation for this damage is ice thermal expansion between the pillar and end support. It can be seen that pillar displacements caused by ice forces (Figure 2d) introduced stresses that led to bursting of the concrete at the support (Figure 2a). As a result of that, the bridge superstructure lost its two original support points, sank several centimeters, and rested instead on one of the concrete crossbeams that were originally not designed to serve that purpose. Figures 2c) and e) show clearly that there is large gap between the original bearings and the concrete pillar. The deflections caused by changes in boundary conditions at the Marlo Bridge were clearly visible when at the site (Figure 2b).

Although the damage on the Marlo Bridge can be considered to be very serious, forcing bridge closure, and are easily detectable by anyone present on the bridge without the need for any sensors, it was uncertain whether the state of the damage could be equally easy to identify utilizing data from measurements conducted at the site. This is because, as long as the concrete crossbeam supported the bridge deck in a similar manner to the original bearings and no significant cracks that could lead to the reduction of the stiffness of the bridge deck were present, the bridge remained almost unchanged from a structural perspective.

Figure 2. Overview of damage on Marlo Bridge – pictures taken in November 2021. Figures a), c) and e) show bursts in concrete at the support, d) – tilt of the damaged pilar, b) – forced deflection.

3 EXPERIMENTAL VIBRATION ANALYSIS

3.1 Instrumentation

The acquisition system used in this study was designed to provide flexibility when it comes to sensor placement and the possibility of fast deployment. It consists of 20 wireless G-Link-200 3-axis accelerometers with waterproof enclosure from Parker LORD MicroStrain and WSDA-2000 gateways that can communicate with a laptop via Ethernet or USB cable. The accelerometers' range and sampling frequency were set to $\pm 2g$ and 128 Hz respectively, resulting in noise density equal to $25 \mu g/\sqrt{Hz}$ as defined by the supplier (Parker Hannifin MicroStrain Sensing, 2020). The sensors were attached to the superstructure magnetically using small steel plates that were first glued to the bridge deck. These steel plates were left at the site after the tests were conducted to ensure that accelerometers will be mounted in the same positions in the second round of measurements. The location of the installed sensors and naming convention is shown in Figure 3.

Figure 3. Sensor placement at the Marlo Bridge. The sensors were placed at exactly the same spots after bridge rehabilitation.

3.2 Vibration excitation

On-site measurements were taken both before (November 2021) and after (May 2022) the repair process in order to investigate the effects of the structural rehabilitation on the modal

parameters. Several excitation methods were used to produce time series (Figure 4). In the repaired state natural traffic was used, while in the damaged state, vibrations were forced by running along the bridge and jumping or hitting with a hammer as the bridge was closed to traffic. Although the hammering was able to induce larger accelerations, it produced data that performed poorly in the modal analysis. Therefore, the data gathered from running along was used in this study. In addition, some level of vibrations induced by the river hitting the pillars is also present in the signal.

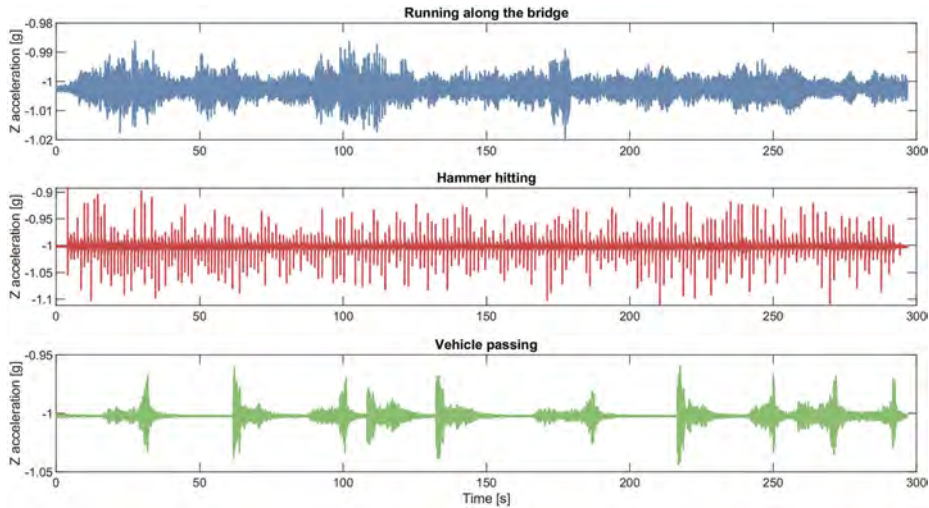

Figure 4. Time-series of vertical accelerations for sensor 142 recorded using different excitation methods.

3.3 Results from modal analysis

Modal analysis was performed with the use of the covariance-driven stochastic subspace identification algorithm (Döhler & Mevel, 2013; Reynders et al., 2008). The number of block-rows was set to 100 and the number of blocks for the covariance of the subspace matrix was set to 20. The data was high-pass filtered with a cut-off frequency of 0.5 Hz prior to the identification process. Figures 5 and 6 present the modes that were manually selected from the stabilization diagrams from the repaired and damaged states respectively.

Figure 5. First 8 vibration modes of Marlo Bridge – repaired state.

It can be seen that there are significant differences between the modes identified in the damaged and repaired states. In the repaired state, torsional and bending modes are clearly

distinguishable, while in the damaged state, they tend to blend together. Another distinction is the presence of a first mode in the damaged state at 2.57 Hz, which is significantly lower frequency than for the first mode in the repaired state, at 4.35 Hz. The modes in the repaired state tend to be symmetric or antisymmetric, which is expected from a symmetrical structure such as Marlo Bridge. This remark can be taken as a sign of a successful repair as it indicates that the damaged span and pillar have been restored to their original state. On the contrary, the vibration modes identified in the damaged state do not manifest the same property. It should also be mentioned that in the repaired state there were fewer closely-spaced in frequency, leaving a less chaotic stabilization diagram.

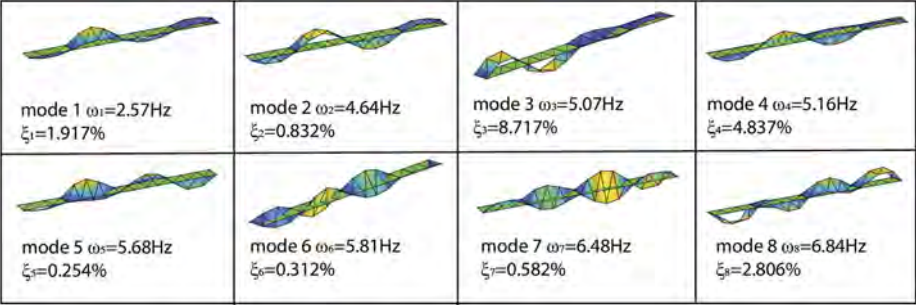

Figure 6. First 8 vibration modes of Marlo Bridge – damaged state.

4 FINITE ELEMENT MODEL

4.1 Model preparation

Complementary to the experimental studies, numerical simulations by means of finite element method were performed in order to investigate whether the results from field measurements can be reproduced. A finite element model of the Marlo Bridge is displayed in Figure 7. The model was created based on the existing drawings (see Figure 8 for cross-sectional dimensions) and it consists of DIMEL80 main longitudinal beams, concrete 300x760 mm cross-beams and a concrete bridge deck with a thickness of a maximum 20 cm. The beams were modelled using quad-trilateral finite membrane-strain shell elements with reduced integration (S4R), while the bridge deck was modelled using 8-node linear brick 3D elements with reduced integration (C3D8R) in Abaqus.

Figure 7. A finite element model of Marlo Bridge in Abaqus.

The upper flanges of the steel beams are connected to the bottom surface of the bridge deck using tie constraints such that there is no relative motion between them. The bridge is

supported in the vertical, longitudinal, and transverse directions at the locations of the pillars and abutments. The mesh was generated using a 80 mm seed size for the solid elements assigned to the bridge deck and 200 mm seed size for the shell elements assigned to steel beams.

Figure 8. Cross-sectional dimensions used to model the Marlo Bridge in Abaqus.

The Young's modulus of $E=210$ GPa, Poisson ratio $\nu=0.3$ and density $\gamma=7850$ kg/m³ were assigned to the steel beams, while for the concrete elements those properties were set to $E=21$ GPa, $\nu=0.2$ and $\gamma=2500$ kg/m³. As the type of concrete used on the Marlo Bridge is unknown, the value of the Young's modulus in the model was selected based on results from parametric studies, where the objective was to minimize the weighted error between the natural frequencies obtained from both system identification and Abaqus. MAC values were not considered due to the limited number of sensors. Weights were assigned linearly between 1.0 and 0.0 for, respectively, the first and eighth modes.

4.2 Results

Figure 9 shows the mode shapes obtained from Abaqus model of the Marlo Bridge in the re-paired state. The values of the natural frequencies and mode shapes correspond very well to those obtained using measurement data and presented in Figure 5. The order of modes 6 and 7 has been flipped and the 8th mode was not properly reproduced when using the finite element model, but, overall, it can be argued that the numerical model presented in this study is a good representation of the Marlo Bridge. It is believed that by applying more advanced finite element updating techniques such as the sensitivity method (Mottershead et al., 2011) and taking into account the stiffness provided by the pillars, would enhance the similarity between the results from the numerical simulations and system identification.

Figure 9. Mode shapes from Abaqus – repaired state.

When it comes to the damaged state, it should be emphasized that damage modelling is not a trivial task and there are many factors that influence a bridge's dynamic behavior that can-not be verified in this case, such as the precise support conditions or the presence of the axial forces due to forced displacements on the pillar. Therefore, in this study, only a simplified approach to simulate the damage state on the Marlo Bridge was attempted. It was assumed that the damage consisted of forced displacements: 120 mm in the vertical direction and 50 mm in the transverse direction, moving the support conditions from the bearings to the bottom of the concrete crossbeam, and a 50% reduction in the Young's modulus of the bridge deck due to cracking (Norsk Standard, 2005) on the two spans in contact with the damaged pillar. To simulate that, a new step was created in Abaqus where displacements were forced, and then modal analysis was performed on the deformed model with the new support conditions. The results from this analysis are displayed in Figure 10.

Figure 10. Mode shapes from Abaqus – damaged state.

This time, there were few similarities between the results obtained based on the measurement data (Figure 6) and the finite element model (Figure 10). The torsional and vertical modes were well separated in Figure 10, which was not the case for the modes based on measurements. The finite element model did not capture the low frequency mode of 2.57 Hz that appeared only in the damaged state, and further attempts to model this mode lies beyond the scope of this paper.

5 CONCLUSIONS

In this study, we examined the effects of structural rehabilitation on the modal parameters of the Marlo Bridge, which had suffered damage to one of its pillars. The natural frequencies, mode shapes and damping ratio were identified using acceleration measurements taken at the site prior to and after the repair. In addition, complementary numerical studies were performed in order to investigate whether the results could be reproduced in Abaqus software using the corresponding finite element bridge model.

Based on the presented results, it can be concluded that modal analysis can be a useful tool that gains insight into changes in structural behavior due to damage. It has been shown that the differences in the dynamic behavior of the Marlo Bridge due to the presence of damage can be distinguished using information about the mode shapes and natural frequencies in the repaired and damaged states. In the repaired state, many of the mode shapes obtained are symmetric or antisymmetric, which implies that the repair was successful, as only one of the bridge pillars suffered from the damage.

Studies using a finite element model of the Marlo Bridge have shown that, with a simple tuning of the concrete stiffness, it was possible to obtain the mode shapes and values of the natural frequencies that correspond closely to those identified using measurements. Knowing that concrete stiffness can be related to its strength, the measurements taken at the site can be further used as a non-destructive testing method for strength assessment of the concrete used at the Marlo Bridge.

Finally, an unsophisticated attempt to model the scope of the damage to the Marlo Bridge in the finite element software was deemed unsuccessful. The damage was simulated by forcing displacements on the pillar, changing the support conditions and reducing the concrete stiffness due to cracking. Nevertheless, the mode shapes and natural frequencies obtained from Abaqus did not correspond well to those identified using measurements. This study shows that proper modelling of a damaged structure is a complex process and often the full scope of the damage is difficult to evaluate. To obtain more accurate results, further work is needed.

ACKNOWLEDGEMENTS

The study was conducted with support from the Research Council of Norway through the Norwegian Regional Research fund in Møre og Romsdal county (SHMBru project 331578). This research was conducted with financial support from the Møre og Romsdal fylke. The authors gratefully acknowledge this support from Møre og Romsdal County during planning and execution of instrumentation and measurements.

Simulation of chloride ingress into aging surface-coated concrete

C. Yoshii & F. Biondini

Politecnico di Milano, Milan, Italy

M. Iwanami & K. Nakayama

Tokyo Institute of Technology, Tokyo, Japan

ABSTRACT: This paper presents a calibration of prediction model for chloride ingress into surface-treated reinforced concrete (RC) structures. Since the research on long-term durability of the coating materials is still limited, the coating degradation model about chloride resistivity is investigated and established from experimental results with accelerated deterioration tests and chloride migration tests (CMT). On the other hand, the results of AgNO₃ spray tests for surface-coated concrete specimens exposed to CMT show that chloride ions would penetrate mainly from the defective areas such as cracks and delamination in surfaces. Therefore, two different deterioration models are proposed for the coating system: averaged time-variant diffusivity and increase of local defects in coated surface. The deterioration models are implemented into diffusion analysis based on cellular automata and applied to a coated RC cross-section to investigate the residual lifetime associated with corrosion initiation of steel reinforcement.

1 INTRODUCTION

Surface coating is one of the main means to prevent chloride ingress into reinforced concrete (RC) structures in coastal environment and subsequent corrosion of steel rebars. Many researchers have reported effectiveness of coating materials against chloride penetration by investigating chloride diffusion coefficients (Buenfeld & Zhang 1998, Almusallam et al. 2003, Pan et al. 2017). Investigation on the durability has contributed to improvement on life-cycle management for surface-treated RC structures. Effects of thermal and moisture variations on coating permeability has been evaluated by Almusallam et al. (2002). In addition, the time-variant diffusivity of coated concrete specimens has been investigated with immersion tests by Moradillo et al. (2012). However, the knowledge of time-variant property of coating diffusivity is still limited to accurately predict the lifetime of surface-treated RC structures exposed to salinity of marine environment.

This paper investigates the property of chloride resistivity change of surface coating materials with chloride migration tests (CMT). An AgNO₃ spray test is also conducted to confirm the chloride path in the surface-coated concrete during CMT. The results inform two different assumptions on deterioration process of coatings on structural surface: disperse micro-damage and local defects occurrence such as cracks and delamination. In the case study of simulation of chloride ingress into a RC cross-section, the effects of these assumptions are investigated using different coating deterioration models.

2 CHLORIDE DIFFUSIVITY

2.1 Accelerated deterioration test

The experimental study with the accelerated deterioration test and CMT was conducted to investigate the long-term chloride resistivity of surface-coated concrete (Yoshii & Iwanami 2022).

The plain concrete and surface-treated concrete specimens of $\phi 100 \times 50$ mm were prepared with the same size formworks (Figure 1a). The substrate concrete had a 0.50 water/cement ratio, and 0.45 sand/aggregate ratio with the maximum aggregate size of 20 mm. Following to the casting, the concrete surface facing the casted panel were painted with four layers of

epoxy-made coating: primer, putty, middle and top coating (Figure 1b). The total thickness of the coating system was assumed as 1.0 mm.

Figure 1. (a) Casted and (b) surface-treated concrete specimens.

The test protocol shown in Figure 2a was applied for the accelerated deterioration with cyclic condition used to damage the specimens with reference to the study on coating durability by Almusallam et al (2002) and the standard of JIS-A6909-2021 (2021). The cycle of 70 ° with RH 80% and -10 ° with RH 20% was repeated each day.

CMT is one of the most useful means to estimate the chloride diffusivity of concrete specimens. This method is useful to measure high chloride resistivity of surface-treated concrete by accelerating the chloride ion migration with induced electric potential difference. Figure 2b represents a used diffusion cell following the standard of JSCE-G571-2003 (2003). During CMT, the coated surface was exposed to NaCl solution, and 60 V was induced to promote chloride ion penetration while 15 V was applied for the substrate specimen.

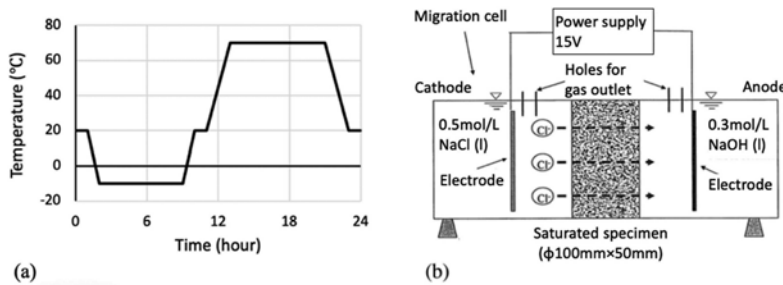

Figure 2. Experimental setup: (a) condition of the cyclic test and (b) chloride diffusion cell (adapted from JSCE-G571-2003).

Measuring chloride flux J_{cl} in the anode cell during the test, the effective diffusion coefficient D^e , the index of chloride resistivity, can be calculated as follows (JSCE-G571-2003):

$$D^e = \alpha J_{cl} \frac{L}{\Delta V} = \alpha \frac{L}{\Delta V} \cdot \frac{V^H \Delta c_{cl}^H}{A \Delta t} \left(\alpha = \frac{RT}{|Z_{cl}|FC_{cl}} \right) \quad (1)$$

where ΔV = electric potential difference between specimen surfaces; L , A = thickness and cross-section area of specimen; V^H = volume of anode solution; $\Delta c_{cl}^H / \Delta t$ = slope of chloride ion concentration change in the anode cell during the steady state; R = gas constant; T = absolute temperature (= 293.2 K); Z_{cl} = a charge of chloride ion (= 1 C), F = Faraday constant; and C_{cl} = measured chloride concentration in the cathode side.

From CMT for the specimens exposed to the accelerated deterioration test for the different duration, the change of the effective diffusion coefficient was obtained as shown in Figure 3, where D_{su}^e and D_c^e refer to the substrate and coated concrete specimens, respectively. The cyclic number t_n is equivalent to the total days under the deteriorative condition.

While the chloride diffusivity of the substrate concrete increased gradually by 220 cycles and then decreased to the initial value, that of the surface-coated concrete increased continuously. In addition, it can be seen the deterioration rate increased gradually.

Figure 3. Change of chloride diffusivity: (a) substrate concrete, D_{su}^e and (b) surface-coated specimens, D_c^e .

The ratio of chloride resistivity between substrate and surface-treated specimens, D_{su}^e/D_c^e , will be used to develop the simulation of chloride ingress into the aging surface-coated concrete structure. To obtain the diffusivity change corresponding to the real time scale based on the experimental results, it is assumed that each cycle of the deterioration test deserves one week exposure under natural environment and the coating lifetime is 20 years (i.e., $D_{su}^e = D_c^e$ at $t = 20$ years). Figure 4 represents the experimental data of the ratio, D_{su}^e/D_c^e , complemented with the assumed lifetime of $D_{su}^e/D_c^e(t = 20 \text{ years}) = 1$. As a result of a nonlinear regression, the following exponential approximation has been obtained for the time-variant diffusivity ratio with correlation $R^2 = 0.882$:

$$\frac{D_{su}^e}{D_c^e} = 400 \times \exp(-0.299t) \quad (2)$$

Figure 4. Estimate of the change of diffusivity ratio, D_{su}^e/D_c^e .

2.2 AgNO₃ spray test

The AgNO₃ spray test was carried out to confirm the chloride ion path during CMT, which can be distinguished from the difference in colors derived from AgCl (white) and Ag₂O (brown) products (Otsuki et al. 1993). First, the coated specimens exposed to CMT were cut using a dry cutter along the direction of chloride ion penetration. After wetting the cut surface with water to promote the chemical reaction, AgNO₃ solution with 0.1 mol/L was sprayed. The chloride ion path was observed in pictures of reacted surface taken about one hour after the spray.

The test was conducted for three types of the surface-treated specimens to clarify the property of the chloride ion path during CMT. The specimens had different features of surficial defects as follows: (i) pinhole, (ii) small cracks, and (iii) no visible defects. Figures 5, 6 and 7 show the reacted surface of the specimens exposed to the deterioration test and CMT after the AgNO₃ spray.

Figure 5. Specimen with a pinhole: (a) before cutting and (b) after AgNO₃ spray.

Figure 6. Specimen with small cracks: (a) before cutting and (b) after AgNO₃ spray.

Figure 7. Specimen with no visible defects: (a) before cutting and (b) after AgNO₃ spray.

In the case of a pinhole (Figure 5) the white product of AgCl was found at the part around the pinhole depicted with red arrows while the brown product of Ag₂O was found under the undamaged part of coating. Similarly, the distribution of AgCl and Ag₂O was also confirmed in the specimen with small cracks near the border between cracked and undamaged part (Figure 6). This result indicates that the chloride ion penetrated mainly from the defective part during CMT where the chloride diffusivity must be much higher compared to the undamaged parts. However, as for the specimen with no visible defects, the chloride ion seemed to pass through the coated surface entirely because the white product of AgCl can be confirmed under the coating (Figure 7). This might be because there was no local severe damage in this coated surface.

In summary, chloride ions should move into the concrete from the defective area during CMT in the specimen with a pinhole or small cracks. On the other hand, the ions penetrated equally from the whole surface of the specimen with no visible damage.

3 COATING DIFFUSIVITY

Based on the results of AgNO₃ spray test, two types of coating degradation process have been considered: gradual loss of impermeability of coating layers due to micro-damage; occurrence of visible defects such as cracks, pinholes, and delamination (with the order of 1.0-10 mm). Different models should be considered for deterioration processes. The mean time-variant chloride diffusivity of the coating system $D(t)$ would be effective to represent the disperse micro-damage on coating capacity while the increase of local defects in coated surface, $A_{dam}(t)$ would be suitable when assuming the occurrence of the visible defects. In the following, each time-variant function is introduced based on the results of CMT.

3.1 Averaged time-variant diffusivity

The assumption of the continuity condition of chloride flux during CMT is used to obtain the mean chloride resistivity of the surface coating system (Buenfeld & Zhang 1998):

$$J_{cl} = D_c^e \frac{\Delta V_o}{\alpha L_c} = D_{st}^e \frac{\Delta V_o - \Delta V_i}{\alpha L_{st}} = D_{su}^e \frac{\Delta V_i}{\alpha L_{su}} \quad (3)$$

where D_c^e , D_{st}^e and D_{su}^e = diffusion coefficient of the coated specimen, surface treatment, and substrate concrete respectively; L_c , L_{st} and L_{su} = thickness of each; and ΔV_o and ΔV_i = electric potential difference induced by the power supply and difference between two sides of the substrate, respectively.

Based on Figure 3b, which includes the diffusivity of both the substrate and coating parts, it is necessary to calculate the actual diffusivity of coating part. Considering the equilibrium of the specimen's thickness, Equation (3) can yield:

$$\begin{cases} L_c = L_{st} + L_{su} \\ \frac{L_c}{D_c^e} = \frac{L_{st}}{D_{st}^e} + \frac{L_{su}}{D_{su}^e} \end{cases} \quad (4)$$

Considering that $L_{st} \ll L_{su}$ in CMT, the following equation is obtained:

$$\frac{D_{st}^e}{D_{su}^e} = \frac{L_{st}}{L_c} \left(\frac{D_{su}^e}{D_c^e} - 1 \right)^{-1} \quad (5)$$

where the ratio of the chloride diffusivity between the substrate and surface-coated concrete, D_{su}^e/D_c^e , is approximated as Equation (2) based on the experimental results and the designed lifetime of the coating for 20 years, and $L_{st} = 50$ mm and $L_c = 1.0$ mm are substituted based on the experimental condition.

3.2 Change of defective areas

The time-variant defective area $A_{dam}(t)$ is an alternative approach to represent the deterioration of coating materials. This considers the increase of the delaminated area in coated surface. Assuming the diffusivity of surface treatment remaining extremely low, and the chloride ions pass through the specimen only from the defective areas during CMT, the relationship between the concrete diffusivity D_{su}^e and chloride flux J_{cl} is established as follows:

$$D_{su}^e = \alpha J_{cl} \frac{L}{\Delta V} = \alpha \frac{L}{\Delta V} \cdot \frac{V^{II}}{A_{dam}} \frac{\Delta c_{cl}^{II}}{\Delta t} \left(\alpha = \frac{RT}{|Z_{cl}|FC_{cl}} \right) \quad (6)$$

Comparing with Equation (1), the ratio between the time-variant defective area A_{dam} and the cross-sectional area of specimens A can be represented as that of the effective diffusion coefficient between the surface-treated specimen and substrate. Thus, the time-variant function of the defective ratio A_{dam}/A results in the inverse of the time-variant diffusivity ratio:

$$\frac{A_{dam}}{A} = \frac{D_c^e}{D_{su}^e} \quad (7)$$

When applying this deterioration model into the diffusion analysis, there is spatial uncertainty in occurrence of defects in surfaces. Monte Carlo simulation is hence applied for the analysis with the assumption of the local defects occurrence to obtain the statistical results.

4 CHLORIDE INGRESS INTO SURFACE-COATED RC CROSS-SECTION

As a case study, the RC pier cross-section of a cable-stayed bridge investigated in Biondini et al. (2006) is considered. The chloride ingress into the surface-coated RC cross-section is investigated using cellular automata (Biondini et al. 2004). This application shows the effect of the coating deterioration in the prediction of corrosion initiation time of steel rebars.

4.1 Cellular automata

The cellular automata method based on Fick's Second Law is adopted for diffusion analysis. The governing equation can be represented as follows by considering the inflow and outflow of chloride ions among divided cells (Biondini et al. 2004):

$$C_i^{n+1} = \phi_0 C_i^n + \sum_j^d \left(\phi_j^- C_{i-1,j}^n + \phi_j^+ C_{i+1,j}^n \right) \quad (d = 1, 2, 3) \quad (8)$$

where C_i^n = concentration in the cell i at time t_n ; ϕ_0 , ϕ_j^- and ϕ_j^+ = evolutionary coefficients related to the chloride diffusivity; and d = dimensions. i.e. 1D, 2D, or 3D.

The homogeneous condition is applied for simplification and the relationship among evolutionary coefficients yields as follows based on the mass conservation law:

$$\phi_j^- = \phi_j^+ = \frac{\Delta t}{\Delta x^2} D, \quad \phi_0 = 1 - 2d \frac{\Delta t}{\Delta x^2} D \quad (9)$$

where D = diffusivity; Δx and Δt = size of each cell and time increment, respectively.

As for the boundary conditions of the interface between the coating and concrete, the following relationship proposed by Crank (1974) is applied as an expanded form for 2D diffusion:

$$C_s^{n+1} = C_s^n + \frac{2\Delta t}{c_s + \Delta x} \left\{ \frac{D_{su}}{\Delta x} (C_{s+1}^n - C_s^n) - \frac{D_{st}}{c_s} (C_s^n - C_{s-1}^n) \right\} \quad (10)$$

where C_s^n , C_{s-1}^n , and C_{s+1}^n = concentration at time t_n in the cells at the interface s , in coating $s - 1$, and in concrete $s + 1$; c_s = total thickness of the coating system.

4.2 Structural model

The RC cross-section model shown in Figure 8 is used for the simulation of chloride ingress (Biondini et al. 2006). The simulation assumes the chloride penetration with constant concentration C_0 from external surface. Table 1 provides the information on the parameters related to the diffusion and structural properties.

Figure 8. RC cross-section: model and grid of the cellular automaton (adapted from Biondini et al. 2006).

Table 1. Parameters for diffusion analysis in coated RC pier.

Size of cell	Δx [m]	0.025	Section width	d_y [m]	1.15
Time increment	Δt [year]	0.010	Section height	d_z [m]	2.50
Concrete diffusivity	D_{su} [m ² /s]	1.0×10^{-11}	Cover thickness	c [m]	0.075
Chloride content on surface	C_0 [kg/m ³]	13.0	Coating thickness	c_s [m]	0.0010
			Bar spacing	s [m]	0.10

Two surface-treated RC pier models adopting different assumption of the coating diffusivity change are considered: (A) the averaged time-variant diffusivity; (B) the increase of local defects in coated surface represented by Equations (5) and (7), respectively. The goal is to investigate the effect of each deterioration process on the lifetime of surface-treated RC members and structures.

4.3 Comparison between uncoated and coated RC cross-section

Figure 9 shows the chloride concentration $C(t)$ over a 50-year lifetime at the depth of the outer layer of 66 reinforcing steel bars ($c = 7.5$ cm) for the uncoated RC cross-section as well

as for the two cases with coatings. Chloride threshold regarding corrosion initiation of the rebars is defined as $C_{cr} = 2.0 \text{ kg/m}^3$.

The coated cases reach the threshold value much later than the uncoated one due to high chloride resistivity of coating. On the other hand, the critical time T_{cr} when $C(t)$ reaches C_{cr} , is different between the two coated cases. Chloride concentration increases rapidly around defective areas in case (B), which leads to earlier corrosion initiation compared to case (A) where chloride ions diffuse homogeneously along the coated surface (Figure 10). Thus, the simulation assuming coating capacity change based on increase of local defects leads to safer evaluation of the structural lifetime compared to that using the averaged diffusivity.

Figure 9. Chloride concentration at the depth of the outer layer of 66 reinforcing steel bars ($c = 7.5 \text{ cm}$).

Figure 10. Concentration maps ($t = 18 \text{ years}$): (a) averaged diffusivity and (b) defective area change.

4.4 Effect of mesh size

It is worth noting that in case (B), the mesh size of cellular automata may influence the size and distribution of the defects in surfaces under the structural aging process. Figure 11 compares case (A) and case (B) with mesh size of 25, 12.5, and 5 mm in terms of average chloride concentration (Figure 11a) and dispersion around mean of the corrosion initiation time (Figure 11b) for the outer layer of 66 steel bars as obtained from Monte Carlo simulation with 1000 repetitions.

The results show that the chloride content increases as the size of each cell becomes smaller. However, the corresponding decrease of the corrosion initiation time is less remarkable. This is because smaller defects spread widely from early aging stage in the case with small meshes based on Equation (7). These results show that the determination of the defects size in coated structures is important to predict the actual corrosion initiation time.

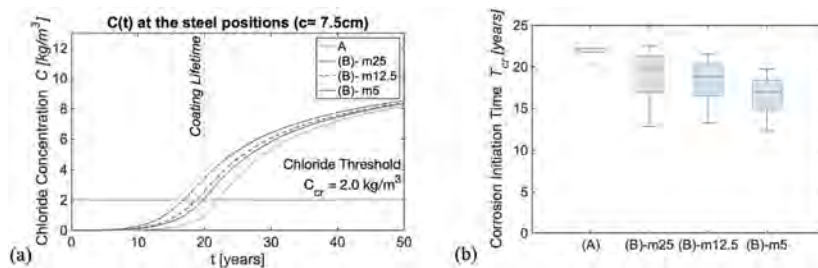

Figure 11. Effect of mesh size: (a) chloride concentration and (b) corrosion initiation time.

5 CONCLUSIONS

This study has presented an approach to predict the time-variant coating diffusivity into the chloride diffusion analysis for surface-treated RC structures based on the results of CMT and the AgNO₃ spray test. The exponential decay of the coating capacity has been estimated from the experiments with the cyclic deterioration test and CMT. Then, two deterioration models of the coating diffusivity have been established: averaged time-variant diffusivity and occurrence of local defects in coated surface. Simulation of chloride ingress into a coated RC cross-section has shown that the model assuming the local defects occurrence predicts earlier corrosion initiation compared to the averaged coating capacity loss. To improve the lifetime prediction of the coated structures, it is expected to investigate the dominance of each deterioration process in real phenomenon and determine defect sizes in coated surface of existing structures.

Y.-A. Janssens & E. Voet

Com&Sens, Eke, Belgium

ABSTRACT: Three pedestrian and bicycle bridges made from a fully recyclable bio-composite material are developed in the context of the Interreg NWE Smart Circular Bridge (SCB) project. These bridges incorporate Structural Health Monitoring (SHM) technology to assess their structural integrity and provide data for future designs. The SHM setup includes strain, vibration and environmental sensors. This paper focuses on the 90 strain and temperature sensors in the first circular bridge. The data shows a strong temperature dependency of the strain, which is addressed using a temperature compensation strategy. Traditional polynomial temperature compensation is compared to a strategy using the Savitsky-Golay filter, the latter removes almost all temperature variability in the data. The strain sensors are also used to capture the bridge dynamics, accurately tracking the first vertical mode, using DBSCAN for automated tracking. The large number of sensors allows for the tracking of the mode shape for potential damage detection.

1 INTRODUCTION

Climate protection and circular economy are increasingly important in the construction industry, leading to the development of three pedestrian and bicycle bridges in Germany and the Netherlands as Smart Circular Bridges (SCB) using an innovative, fully recyclable bio-composite material. The SCB project is part of the shift towards natural and sustainable materials in the updated EU's action plans towards a sustainable bio-economy for Europe (European Commission and Directorate-General for Research and Innovation, 2018). These bridges also incorporate Structural Health Monitoring (SHM) technology to assess their structural integrity and provide data for future designs with the novel material. The SHM system includes Fibre Bragg Gratings (FBG) strain sensors, accelerometers and environmental sensors. This generates early warnings before critical levels of material degradation occur. Additionally, the SCBs enable the acquisition of new insights into the use of bio-composites in the construction industry, promoting the use of more sustainable resources.

Previous research details the vibration monitoring of the Almere SCB through both design validation and automated Operational Modal Analysis using the 3 installed accelerometers (Weil et al., 2022). This paper focuses on the use of embedded FBG strain gauges installed by our partners at Com&Sens in the first circular bridge in Almere, the Netherlands. Early results show strong temperature variability in the collected strain data. This is accounted for by installing additional temperature sensors inside the structure of the bridge. However, given effects such as solar radiation, shadow (e.g. from the handrail) and the material properties (high thermal insulation and unknown thermal property), the temperature compensation is challenging. To resolve this, a novel temperature compensation strategy using a Savitsky-Golay (SavGol) filter (Savitzky and Golay, 1964) is developed, to remove the polynomial temperature trend in every strain sensor.

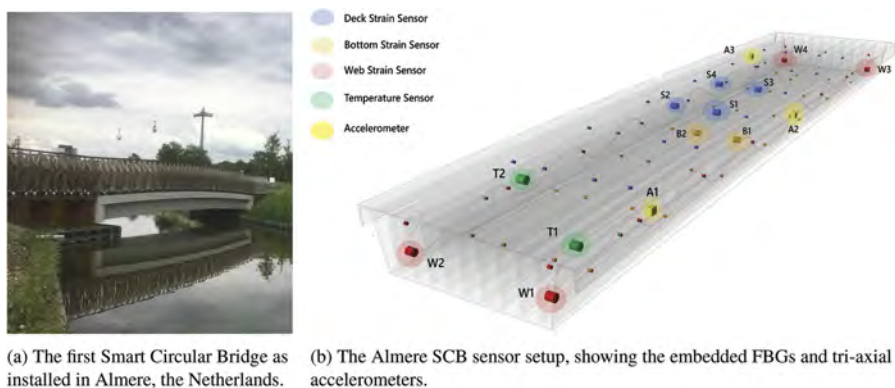

Figure 1. The Almere SCB.

Alongside the static properties, the dynamic response of the bridge available in the strain sensors is explored. It is shown that the first vertical mode can be tracked through an Operational Modal Analysis (OMA) (Devriendt et al., 2014) when the bridge sees some activity. The Linear Square Complex Frequency Estimator (LSCF) algorithm is used to detect the different modes (Magalhães and Cunha, 2011). The tracking of detected modes is done using the Density-based clustering of applications with noise (DBSCAN) algorithm (Ester et al., 1996). Because of the dense network of fibre optical sensors a lot of spatial information is contained, and in this paper, we explore the feasibility to detect and track the strain mode shapes.

2 THE ALMERE SMART CIRCULAR BRIDGE

The Smart Circular Bridge innovates both through the use of novel sustainable materials and through the use of an embedded monitoring system, making the bridge circular, safe and smart. This section will go over the first bridge installed in Almere as shown in Figure 1a and detail the installed monitoring technology shown in Figure 1b.

2.1 *Bio-composite material*

The Smart Circular Bridge in Almere is the first bridge in the world to be built from 100% natural flax fibres reinforced with 25% bio-resin (Huijgen, 2022). The material selection and bridge design were based on bending and tensile tests conducted by the project partners at the TU Eindhoven and KU Leuven to determine the material's strength and stiffness under different conditions. Following this, the 15-meter-long bridge was built at FibreCore using a vacuum-infusion method combined with internal foam shapes and external moulds. During construction, strain sensors were embedded inside the bridge and accelerometers were installed on the surface. After construction, the bridge was installed at the Floriade expo in Almere and the SHM system was connected. Data has been gathered since the 4th of April 2022 and is available on a public dashboard at <https://dashboard.smartcircularbridge.eu>.

2.2 *Embedded FBGs*

The Smart Circular Bridge has a monitoring system that includes strain, dynamic, and environmental sensors. The strain sensors are Fiber Bragg Grating (FBG) sensors, which were integrated into the bridge's structure during construction. There are 82 FBG strain sensors and 8 FBG temperature sensors on the bridge.

The dynamic sensors are tri-axial, high-resolution industrial micro-electromechanical systems (MEMS) accelerometers, which are glued to the side of the bridge at three locations. The accelerometers are used to capture vibrations and continuously track modal parameters

through automated Operational Modal Analysis (OMA) (Devriendt et al., 2014). A weather station is used to monitor the wind, air temperature, and relative humidity to normalize changes and assess the effect of the changing environment on the material.

Figure 2. One-day strain measurements and results of the SavGol filter for the 25th of November, during which a static load test using a 4-ton load is performed. The temperature variability of the strain data highlights the importance of a good temperature compensation strategy.

A previous research details how the accelerometers are used for controlled and field tests to extract modal parameters (Weil et al., 2022). On the other hand, the strain sensors are primarily used for material monitoring during construction, creep measurement, event analysis and novelty detection.

3 TEMPERATURE EFFECTS

FBG sensors are often used for strain monitoring in SHM systems due to their small physical size, lightweight and ability to be multiplexed. Additionally, FBGs can easily be embedded in a composite structure. This allows the placement of many sensor points, capturing highly spatial information about the structure. However, one issue arising when using FBG sensors is their temperature sensitivity. This can be especially problematic in a bio-composite bridge, as the material is thermally isolated, leading to slow heating and cooling of the bridge. This combined with the shadow cast by the handrails creates very local and complicated heating effects on the structure. On top of this, the thermal expansion coefficient of this material is much more complex than traditional materials such as steel and concrete, leading to complicated temperature effects (Heinen, 2022).

Furthermore, the temperature variability can hide significant events occurring on the bridge as 10°C of temperature variation can lead to an increase of more than 10µε, greatly exceeding the effects of any structural load. To demonstrate, Figure 2 shows the measured strain in 1 top and 1 bottom sensor for an entire day, during which a static load test was conducted on the bridge. The test consisted of placing and then removing 4 cubic metres of water one by one on the bridge from 8.40 am until 10.00 am. This 4-ton load results in approximately 80µε, which doesn't exceed the daily temperature variability for a day in November by far and is even dwarfed by the strain variability of more than 300µε in the top sensor due to temperature observed on a warm summer day as illustrated by the top sensor measurement in Figure 4. If we want to correctly detect the effect of a single person on the bridge, it is clear that temperature compensation is required.

3.1 Traditional regression based temperature compensation

FBG strain sensor manufacturers outline different strategies to deal with high-temperature variability in the strain data (HBK, 2021). The common practice is to install a separate temperature compensation sensor next to each FBG sensor and remove temperature effects based on the thermal expansion coefficient of the material α combined with the thermal expansion coefficient of the fibre. However, this increases the cost and complexity of the monitoring system, basically requiring an equal amount of temperature sensors as strain sensors. To balance costs in this project, for example, only 8 temperature FBG sensors are placed for 82 strain sensors. This means the relationship between the temperature and strain sensor needs to be learned. Additionally,

contrarily to steel, the bio-composite has a temperature-dependent thermal expansion coefficient $\alpha(T)$, making the relationship between temperature and strain more complex.

Figure 3. Polynomial temperature compensation for a single sensor located close to a temperature sensor in the Almere SCB. The temperature variability is reduced from $900\mu\epsilon$ to $200\mu\epsilon$.

One potential solution to this issue is to use machine learning algorithms to compensate for the temperature effects on the FBG sensors. A temperature compensation scheme using a multiple linear regression algorithm for a bio-composite bridge is given in (Heinen, 2022). The results show a prediction error below 5% but in absolute values, this is approximately $50\mu\epsilon$ or equivalent to a static load of 2 tons on the middle strain sensors.

Polynomial regression for the strain sensors closest to a given temperature sensor is tried on the SCB, and the long-term results are shown in Figure 3. This reduces the spread of the thermal effects from $900\mu\epsilon$ to $200\mu\epsilon$. A reduction of the temperature effects is observed, but even the remaining variability can hide significant events occurring on the bridge. Additionally, this could only work for the 8 sensors close to a temperature sensor. It is clear that an alternative solution is necessary to remove the temperature effects from the strain data and isolate the strain caused by the different events occurring on the bridge.

3.2 Savitsky-Golay filter for temperature compensation

In this research an alternative approach for temperature compensation is explored, using a Savitsky-Golay (SavGol) filter to follow the polynomial trend of all the temperature effects (Savitzky and Golay, 1964).

The SavGol filter is a digital filter that is commonly used for data smoothing and denoising. The SavGol filter works by fitting a set of polynomial coefficients to a window of data points by the method of linear least squares. The polynomial degree p and the size of the window n can be adjusted to control the amount of smoothing and the degree of differentiation. The window is then moved in the same way as for a moving average. The equation for the SavGol filter can be written as shown in Equation 1.

$$y(i) = \sum_{k=0}^n A_k(p) * x(i + k - m) \quad (1)$$

Here, $y(i)$ is the filtered value at point i , $x(i)$ is the original data at point i and m is the centre of the window. $A_k(p)$ are the coefficients of the polynomial derived by fitting a polynomial of degree p through a linear least squares method to the data for every window n . By adjusting the values p , n and m , the SavGol filter can be tailored to the specific needs of the data being processed.

In the context of this research, the SavGol filter is not used as a denoising filter, but rather to remove the polynomial temperature trend that is present in the strain measurements. This temperature trend is caused by changes in ambient temperature and can mask the strain changes caused by events of interest, such as a pedestrian crossing the bridge. Because the temperature effects show slow and smooth strain variations when compared to the events, the SavGol filter with an appropriate window size is able to remove the temperature trend and reveal the strain on the bridge caused solely by the events. This allows for more accurate

analysis of the event strain data and a better understanding of the behavior of the bridge under different loading conditions.

The results of applying the filter with a second order polynomial and window length of 1800 samples or 36 seconds are shown in Figure 4. In this Figure, the strain measurements and SavGol smoothed data of one top and one bottom sensor for an entire day are shown. The SavGol filter can adequately track the complex temperature trend generated in the strain sensors, enabling the removal of the trend. By removing the filtered data from the original data, the strain resulting from the events remains as shown by the pink and brown lines in Figure 4 and again in Figure 5. The temperature compensated data has a 0 strain rest state and a deviation from 0 when an event occurs. The top sensor is loaded in compression and has negative strain, whilst the bottom sensor is loaded in tension and has a positive strain. After temperature compensation, it is thus possible to use threshold-based event detection (Sadeghi et al., 2023) and labelling based on measured strain values. Additionally, it is easy to extract statistics for the different events like maximum, amount of peaks, etc. Enabling an event classification and event anomaly detection in a future study.

Figure 4. Strain data for a top (blue) and bottom (orange) sensor in the middle of the bridge on a - summer day. The SavGol filter is applied on both sensors (green and red) and the filtered signal is subtracted from the original data, isolating the strain generated by the events (purple and brown).

Figure 5. SavGol-based temperature compensated strain data for a top (purple) and bottom (brown) sensor on a warm summer day.

4 EMBEDDED FBG OPERATIONAL MODAL ANALYSIS

The modal analysis of the structure is conducted in previous research using the three accelerometers (Weil et al., 2022). Here, the modal frequencies and damping ratios are identified first through a controlled test at the construction site consisting of an Experimental Modal Analysis (EMA), and later during a field test comprising an Operational Modal Analysis (OMA). The first vertical mode, which has the highest energy for this type of structure, is identified at around 6.9Hz and shows a strong temperature dependency.

However, as only 3 accelerometers are permanently installed, the spatial resolution of the mode shape is limited. Higher resolution mode shapes were extracted from an EMA using a roving hammer experiment. But when trying to infer damage from changes in the mode

shapes (Anastasopoulos et al., 2021, 2022), then this would require reproducing a roving hammer experiment or installing more accelerometers. In contrast, the FBG sensors, which offer a high spatial resolution, open an opportunity to obtain continuous monitoring of detailed mode shapes.

Figure 6. PSD for 1 hour strain measurements with high activity on the bridge at Noon. Stepping frequency at 1.7Hz and first vertical frequency at 6.3Hz clearly stand out.

Figure 7. PSD for 1 hour strain measurements with no activity on the bridge at night. No frequencies stand out when the bridge isn't excited.

4.1 DBSCAN automated OMA tracking

If the strain sensors can capture the structure's dynamics, it is possible to track the mode shape thanks to the many strain measuring locations. With a sampling frequency of 50Hz for the FBG strain sensors, it is expected that the first vertical frequency at 6.9 Hz can be detected. This is confirmed in the Power Spectral Density (PSD) computed for the data gathered by the Bottom-Center-North (BCN) sensor line during 1 hour with a lot of activity on the bridge. In the PSD shown in Figure 6, two frequencies clearly stand out; the stepping frequency at around 1.7 Hz and the first vertical modal frequency at around 6.3 Hz. This is significantly lower than the 6.9Hz capture during the previous OMA. This is due to the temperature dependency of the first vertical mode, which tends to be lower during warmer days. Unfortunately, no dynamics are captured by the strain measurements when there is no activity on the bridge, as shown in the PSD at Figure 7 for a 1 hour measurement during the night.

The PSDs illustrate that the strain sensors can capture dynamic properties of the bridge when the bridge experiences a lot of activity, and that it should be possible to track the first vertical mode for these time periods. The modes are calculated for one month on the BCN strain line. Because there are 6 sensor locations on this strain line, it is possible to capture the vertical mode shape. The modes are calculated using the Linear Square Complex Frequency Estimator (LSCF) algorithm on 10 minutes of data with a model order of 32 and window length of 30 (Devriendt et al., 2014; Magalhães and Cunha, 2011). During this month, the bridge had a lot of activity during the day time but very little to none at night. This is clearly shown by the gaps in the extracted modes displayed in Figure 8. This figure shows that

multiple modes are detected in the 2-7 Hz range. An automated tracking method using Density-based clustering of applications with noise (DBSCAN) (Ester et al., 1996) is used to track the different modes and separate the first vertical mode. The DBSCAN is implemented because it can accurately separate cluster modes using the modal frequency, damping ratio, size in the LSCF algorithm and the time difference. Additionally, it labels many points as noise with a *label* = -1. Currently, the DBSCAN hyper-parameters ϵ and *minPts* are optimized manually. An automated tuning for this tracking algorithm is part of future research.

Figure 8. Modal frequencies calculated using the LSCF algorithm for the entire month of August 2022. The tracking and labelling of the calculated modes is then done using the DBSCAN algorithm. The different tracked modes are represented by different colours.

4.2 First vertical mode shape

The mode shape for the mode tracked above 6Hz (*label* = 1 or yellow in Figure 8) is plotted for all modal parameter estimations in Figure 9. This extracted shape confirms that the mode at 6.3 Hz is the first vertical mode. These preliminary results show the feasibility to obtain a mode shape estimate from FBGs inside the bridge. However, simultaneously shows a significant amount of scatter that still needs to be resolved in order to apply the damage detection methods (Anastasopoulos et al., 2021).

Figure 9. Early results for the mode shape of the tracked first vertical mode in the 6-6.5Hz range. This mode shape confirms that the mode is indeed the first vertical mode.

5 CONCLUSIONS

One of the key achievements of the research presented is the use of the SavGol filter for temperature compensation. This is effective in removing practically all temperature effects on the strain measurements and isolating the event strains. This is not possible using a more traditional approach involving polynomial regression and a nearby temperature sensor. A second achievement of the research is the ability to accurately track the first vertical mode using strain measurements only. This is made possible by the observation of dynamic behavior in the strain sensors through a PSD. However, the dynamic response only appears when the bridge sees high activity. The LSCF algorithm is used to calculate the modal frequency, damping ratio and mode shape for an entire month. The calculated modes are later tracked using

the DBSCAN algorithm that isolates the first vertical mode in the 6-6.5Hz range. Finally, the use of many sensor locations allows for the determination of the mode shape, which is plotted and confirms that this is indeed the first vertical mode. This provides a more complete understanding of the structural behavior of the bio-composite bridge. These achievements demonstrate the potential of the embedded FBG strain gauges and the temperature compensation techniques developed in this study for use in the structural health monitoring of bio-composite materials and structures. The methods developed in this research will be applied to the two other Smart Circular Bridges currently under construction and other types of structures. This exercise will be done to validate the findings of this study and to explore the potential of these techniques for use in other applications.

ACKNOWLEDGEMENTS

This research is being conducted within the Bio-Economy Strategy of the European Union and is supported by the Interreg North-West Europe Programme under the “Smart Circular Bridge for a circular built environment” project title.

Dissipative steel and steel-concrete composite beam-to-column joints

G. Skarmoutsos & U. Kuhlmann

Institute of Structural Design, University of Stuttgart, Stuttgart, Germany

ABSTRACT: The present paper deals with the behaviour of bolted steel and steel-concrete beam-to-column joints with endplate connections under seismic loading.

While partial-strength all-steel joints have been part of recent scientific works, the behaviour of the common composite joints for seismic loading remains unclear. Currently, in the engineering practice construction criteria according to (CEN EN 1998-1, 2004) are applied taking care that the contribution of the concrete slab is neglected, thus the joint is designed as an all-steel one.

In a recently completed experimental campaign 3 all-steel and 9 steel-concrete composite joints with 5 parameters varied were tested under seismic loading. Joints of common configuration were chosen and slightly modified by applying on them the basic seismic design principles.

Based on the experimental results composite joints can be an important and universal source of energy dissipation. They can find application in different structural systems and areas of various seismicity levels.

1 INTRODUCTION

Often in low to medium seismicity areas partial-strength beam-to-column joints according to (CEN EN 1993-1-8, 2005) and (CEN EN 1994-1-1, 2009) are used. In the current (CEN EN 1998-1, 2004) the possibility to use partial-strength joints is given provided that experimental results are available. The absence of experimental data and of a specific design process, though, do not allow for the broad use of partial-strength composite joints.

The present paper presents the objectives, methodologies and concepts followed for investigating the double-sided all-steel and steel-concrete composite joints experimentally as part of (Hoffmeister, et al., in prep.). It also provides a first insight in the results of the recently completed experimental campaign.

2 DESIGN OF SPECIMENS

2.1 *Literature on partial-strength all-steel and steel-concrete composite joints - selected parameters with an influence on the joint mechanical behaviour*

(Kuhlmann, et al., 2009), (Kuhlmann, et al., 2017) & (Rölle, 2013) investigated bolted partial-strength beam-to-column endplate connections in view of optimising their robust response to extreme events, such as the loss of a column. Among other parameters, the thickness of the endplate t_{ep} and the distance e_4 of T-stub bolt series, see Figure 2, have been experimentally and numerically investigated and their influence on the joint mechanical properties proven. An overview of the design methodologies for ductile joint response when designing for robustness is given in (Demonceau, et al., 2021). The 2 parameters, t_{ep} and e_4 , were selected also for the work presented herein and in this case the values were chosen for optimal seismic behaviour.

In (Landolfo, et al., 2017) partial-strength all-steel joints were investigated and a design process developed, which among others covers aspects such as the detailing of welds as well as the size of bolts. Those recommendations and also the concept concerning the hierarchy of strength of the different connection parts for partial-strength joints have been followed herein.

Regarding the influence of the slab on the steel part of the connection, (CEN EN 1998-1, 2004) foresees that composite joints can be designed as all-steel ones provided that in a radius equal to $2 \cdot b_{eff}$ around the column, the concrete is fully disconnected from the steel beams. Similarly, (ANSI/AISC 358-16, 2016) foresees for composite joints that no shear connectors within 1,5 times the beam depth from the face of the connected column flange are placed. The aforementioned clauses take care to mechanically disconnect the concrete slab from the steel profile in the area of the joint. Nevertheless, the continuity of the slab in combination with its high stiffness should not be neglected, since it can lead to a restriction of the (i) connection rotation and (ii) flexural deformation of the beam. Therefore, the position of the 1st shear stud was chosen as parameter.

In addition, the reinforcement ratio of the slab ρ was selected as parameter.

Generally, for seismic design symmetrical configurations are preferred. Due to the presence of the concrete slab composite joints of typical configuration are by nature unsymmetrical, so at least the steel part of the connection is usually designed as a symmetrical one. On the other hand, in very low seismicity areas where no seismic design is performed, often joint configurations with 3 bolt rows are used. It has been goal of the experimental campaign to also investigate joints as applied in the practice. Therefore, aside from the 8 composite specimens with 4 bolt rows, also 1 composite specimen with 3 bolt rows was tested. Necessary modifications, compared to the ones for non-seismic design, were realised, such as the stiffening of the column and strengthening of the welds.

2.2 Design process for the specimens

Two structural typologies were investigated (i) all-steel joints of industrial buildings, HEB 300 columns and HEA 240 beams, and (ii) composite joints of office buildings, HEA 300 columns and IPE 300 composite beams. For the optimisation of the energy dissipation the appropriate combination of moment capacity M , rotational stiffness S and rotation capacity θ is required. With the help of the component model and of a FEM model two limit cases were considered for the dimensioning of the specimens:

- 1st limit case: $M_{max}, S_{max}, \theta_{min} \rightarrow$ probably min ductility and max energy dissipation
- 2nd limit case: $M_{min}, S_{min}, \theta_{max} \rightarrow$ probably max ductility and min energy dissipation

2.3 Selected parameter values

In a FEM parametric study, not presented herein, it has been observed that for the given beam and column sections, $t_{ep} = 15$ mm serves as a lower boundary for partial-strength joints designed to be dissipative, whereas for $t_{ep} = 25$ mm yielding takes place mainly at the beams and not the endplates. The latter case is not fully in line with the concept of partial-strength joints but can be favourable for the joint seismic behaviour. The selected parameter values have been $t_{ep} = [15, 20]$ mm. For $t_{ep} = 20$ mm, aside from plastification of the endplate, also significant yielding of the beam was observed, which resulted for high deformations in a plastic hinge in the beam. The thickness of the endplate is considered as the parameter governing the response of the steel connection.

Two values for e_4 have been selected as (i) the minimum possible distance, $e_4 = 100$ mm, and (ii) the maximum one for sufficient energy dissipation, $e_4 = [130, 150]$ mm, for industrial and office buildings configurations, respectively.

For the parameter $l_{shear\ stud}$ the first value selected is $l_{shear\ stud} = 1,5 \cdot h_{beam} = 450$ mm, according to the (ANSI/AISC 358-16, 2016), and the second value is the minimum distance, $l_{shear\ stud} = 190$ mm from the face of the column or $l_{shear\ stud} = 120$ mm from the end of the concrete slab for $\varnothing 22/100$ mm shear studs. Additionally, a gap of 70 mm was foreseen between the concrete slab and the face of the column.

Regarding reinforcement ratio of concrete slab ρ two representative values were chosen. The conventions for the naming of the specimens are given in Table 1.

Table 1. Conventions – name of specimens.

Column profile	Steel or Composite	Beam profile	Steel or Composite	t_{ep}	e_4	$l_{shear\ stud}$	ρ
HEA 300-HA30	S/C	IPE 300-I30	S/C	(mm)	(mm)	(mm)	(%)

3 TEST SETUP AND TEST INSTRUMENTATION

3.1 Test instrumentation

In total 64 measuring channels per test were available, of which 16 for transducers and inclinometers and 48 for strain gauges.

The arrangement of all measurement equipment, strain gauges, inclinometers and cable transducers, as well as the boundary conditions are given in Figure 1. A photo of the test setup and of a typical composite joint specimen configuration is given in Figure 3.

Figure 1. Measurement equipment, boundary conditions and type of beam-to-endplate welds.

3.2 Loading protocol

The ANSI/AISC 341-16 loading protocol for the prequalification of beam-to-column connections was used with slight modifications. More specifically, for all tests of (Hoffmeister, et al., in prep.) 2 additional load steps at 25 mrad and 35 mrad with 2 cycles each were added.

4 EXPERIMENTAL RESULTS

4.1 Influence of the varied parameters on the mechanical properties of the joints

4.1.1 All-steel joints

It is worth mentioning that for the investigated partial-strength joints the increase of moment capacity M and rotational stiffness S through the variation of a parameter is usually accompanied by a decrease or by no reduction of the rotation capacity S . For the specimen

Figure 2. Typical steel connection configuration.

Figure 3. Typical configuration of steel-concrete composite specimen, here K-HA30V-I30V-15-100-450-p1.

K-HB30S-HA24S-20-100, the minimum value of $e_4 = 100 \text{ mm}$ leads to an increase of M and S but also of the rotation capacity θ compared to the specimen K-HB30S-HA24S-20-130. Here θ increases due to the activation of a more favourable failure mode for specimen K-HB30S-HA24S-20-100, formation of a plastic hinge in the beam after plastification of the endplate 4a.

Table 2. Influence of the varied parameters on M , S and θ .

	$e_4 \downarrow$	$e_4 \uparrow$	$t_{ep} \downarrow$	$t_{ep} \uparrow$
S	\uparrow	\downarrow	\downarrow	\uparrow
M	\uparrow	\downarrow	\downarrow	\uparrow
θ (mrad)	\uparrow	\downarrow	n.a.	n.a.

4.1.2 Composite joints

The influence of the varied parameters e_4 , t_{ep} , $l_{sh. stud}$, ρ and number of bolt rows for the endplate connection on the joint moment capacity M , rotational stiffness S and rotation capacity θ is given in Table 3.

Table 3. Influence of the varied parameters on M , S and θ .

	$e_4 \downarrow$	$e_4 \uparrow$	$t_{ep} \downarrow$	$t_{ep} \uparrow$	$l_{sh. stud} \downarrow$	$l_{sh. stud} \uparrow$	$\rho \downarrow$	$\rho \uparrow$	3 bolt rows	4 bolt rows
S	\uparrow	\downarrow	\downarrow	\uparrow	\uparrow	\downarrow	(-)	(-)	\downarrow	\uparrow
M	\uparrow	\downarrow	\downarrow	\uparrow	\uparrow	\downarrow	(-)	(-)	\downarrow	\uparrow
θ (mrad)	\downarrow	\uparrow	\uparrow	\downarrow	(-)	(-)	(-)	(-)	\uparrow	\downarrow

As expected lower values of e_4 lead to an increase of M and S and to a decrease of θ . The latter, however, is 45 mrad and in such way sufficient for seismic loading conditions, so that lower values of e_4 can be characterised as favourable for the joint seismic behaviour. In a similar way, thicker endplates result in higher moment capacity M and rotational stiffness S accompanied with lower values of rotation capacity θ , compared to thinner endplates.

No difference on the rotation capacity θ is observed, when construction measures for the disengagement of the concrete slab adopted. There is observed though, an increase of the stiffness S and moment capacity M if no construction measures taken, see Table 3. The higher stiffness, thanks to the enhanced composite action, is also observed through a more intensive cracking pattern on the concrete slab, see Figure 7b. Consequently, the seismic response of partial-strength composite joints significantly differs from the one of all-steel joints, whether the slab is locally disconnected from the beam, in a length of $1,5 \cdot h_{beam}$, or not. The high stiffness of the

composite beam restricts the deformation of the endplate, see Figure 8, and also leads to a reduced flexural deflection of the beam. It is noteworthy that only one steel profile size, IPE 300, has been tested. Stronger steel profiles might lead to a different joint behaviour.

The composite joint with unsymmetrical steel connection, 3 bolt rows, has, as expected, significantly lower moment capacity and stiffness for positive moments, 50% lower M . But for negative moments an increase of M and S is observed. The latter proves aside from the system response of two-sided joints that the concrete slab had not been fully activated. The failure took place for all specimens at the welds, in the heat affected area of the beam flange in tension.

4.2 Failure mode & experimentally derived M - θ curves

4.2.1 All-steel joints

All-steel joints presented a very ductile response up to (70-110) mrad. Such high rotations are not necessarily of benefit for seismic design and can be attributed mainly to the small beam profile size which led to a significant in plane flexural deformation of the beam. The latter resulted in a delayed activation of the connection, see Figure 5.

Figure 4. (a) Joint deformation at a rotation of 100 mrad for K-HB30S-HA24S-20-100 and (b) bolt failure after significant endplate plastic deformation at a rotation of 100 mrad for K-HB30S-HA24S-20-130.

Figure 5. M - θ curve ($M_{\text{connection}}$) for all-steel joint (a) K-HB30S-HA24S-20-100 vs. (b) K-HB30S-HA24S-20-130. Lower values of e_4 enhance the dissipative behaviour of the joint. See Figure 4 for failure mode.

The use of higher steel profile sections may activate earlier the connections. The important observation on the 2 experiments presented is that through the variation of the two most important geometrical parameters, t_{ep} and e_4 , different failure modes were activated, see Figure 4. The all-steel joints will be further optimised through FEM analyses regarding size of steel profiles.

4.2.2 Composite joints

For all composite joints a crack formed at the beam flange in the area of welds connecting the steel profile to the endplate and quickly developed till failure. Starting from a rotation of 40

mm small cracks of around 0,1 mm appeared, see Figure 6a. At the following load step, here 45 mrad, the crack further develops and forms a clear crack of more than 2 cm, see Figure 6b. At that point a clear reduction of the moment capacity of the concerned connection can be observed, while the complete failure of the specimen comes the latest in the next load step, with the rotation capacity of the composite joints tested lying between 45 mrad and 60 mrad. Additionally, concrete crushing in the area of the connection, see Figure 7a, was observed for some specimens, while the crack pattern of the slab is given in Figure 7b.

Should the damaged specimens be further tested at higher load levels, the crack formed in the beam flanges further develops and extends also to the beam web until the crack grows throughout the entire height of the steel beam. At that point the load carrying capacity of the concrete slab is preserved with no serious damages.

Figure 6. (a) Crack initiation at a rotation of 40 mrad – weld at lower beam flange to endplate (b) crack propagation at a rotation of 45 mrad.

It should be noted that total joint rotations of more than 45 mrad are not necessary, with (CEN EN 1998-1, 2004) foreseeing for partial-strength joints a minimum plastic rotation capacity

Figure 7. (a) Concrete crushing in the area of connection at a rotation of 45 mrad (b) crack pattern of the concrete slab at a rotation of 45 mrad.

Figure 8. HA30C-I30C-20-100-170-p2: no significant deformation of the endplate at a rotation of 45 mrad, yet good dissipative behaviour thanks to the contribution of endplate, beam and concrete slab.

of 15 mrad and 25 mrad for areas of low and medium seismicity, respectively. Thus, the joints conform to the minimum rotation capacity requirements of (CEN EN 1998-1, 2004).

In Figure 9a the M- θ curve of the composite joint till failure, 45 mrad, while in Figure 9b the part of the M- θ curve of the equivalent all-steel joint up to 45 mrad (test stopped at 110 mrad) is shown, so that direct comparison is easier. It can be observed that the area of hysteretic loops for the composite joint till 45 mrad is larger than the one of all-steel joint. In such way the composite joints demonstrate an enhanced dissipative behaviour compared to the all-steel ones.

Figure 9. M- θ curve (a) composite vs. (b) all-steel joint (M- θ curve plotted up to only 45 mrad for easier comparison with the composite joint).

5 CONCLUSIONS

Based on the experimental results following conclusions can be drawn:

- Partial-strength all-steel and steel-concrete composite joints can be designed as dissipative ones. Necessary modifications compared to the non-seismic design are the strengthening of the columns and of the welds. Also, the parameters influencing the joint mechanical characteristics should be selected in view of optimal seismic behaviour and not of simply largest ductility. In fact, low values of t_{ep} and very high values of e_4 would eliminate the dissipative behaviour. The activation of the beam additionally to the endplate is of advantage.
- The seismic behaviour of composite joints significantly differs from the one of all-steel joints, also if care is taken to mechanically disconnect the slab from the steel beam in a length equal to $1,5 \cdot h_{beam}$, see (ANSI/AISC 358-16, 2016). Despite the fact that the deformations in the endplates are small due to the high stiffness of the concrete slab, the seismic behaviour of composite joints is overall better than all-steel ones. The optimisation of the concrete slab strength with reference to the one of steel beam and steel connection can further enhance the seismic behaviour, here e.g. a higher steel profile size.
- Composite joints with a symmetrical steel connection part, 4 bolt rows, present a better dissipative behaviour than asymmetrical ones, 3 bolt rows. The potential of asymmetrical connections depends also on the extent up to which the joints will enter the area of positive moments for the seismic load combination in a real structure. Therefore, also pushover static analyses for some representative structural typologies will be performed.
- It has been observed on the experiments that connections with thinner endplates failed due to bolt failure at an earlier load stage compared to connections with thicker endplates. The connections were identical except of the endplate thickness, the bolts being M30 in all cases. More specifically, the specimen HB30S-HA24S-15-100 failed due to bolt failure at 70 mrad, while the specimens HB30S-HA24S-20-100 & HB30S-HA24S-20-130 failed the earliest at 100 mrad. For T-stub connections having a failure mode 2 the deformation of the bolt induced by the endplate can lead to premature failure of the bolts. Therefore, in (Skarmoutsos, in prep.) a deformation approach for the design of (i) ductile and (ii) ductile-dissipative beam-to-column connections with a failure mode 2 will be followed.

- A joint of low stiffness may develop plastic deformations only at very large rotation angles, which would have probably already caused global stability problems. Partial-strength joints present a dissipative behaviour for a limited value range of their geometrical parameters. The number of tests needed on partial-strength joints before these can be implemented in structures can be significantly reduced through the use of refined FEM models. A methodology for the design of partial-strength joints as dissipative ones will be developed (Skarmoutsos, in prep.), using validated FEM models and the experimental results. To achieve a dissipative behaviour the appropriate combination of joint (i) stiffness, (ii) strength and (iii) energy dissipation capacity is needed.

ACKNOWLEDGEMENTS

The experimental campaign presented herein is part of the research project (Hoffmeister, et al., in prep.) and financed through the Research Association for Steel Application (FOSTA), the German Federation of Industrial Research Associations (AiF) and the German Federal Ministry of Economic Affairs and Climate Action. The joint project is carried out at the Institute of Structural Design of the University of Stuttgart and at the Centre for Wind and Earthquake Engineering of RWTH-Aachen University. The presented tests were performed at the Materials Testing Institute of University of Stuttgart.

Seismic and energetic renovation of existing masonry buildings by innovative FRLM composite materials

D. Pugliese, V. Alecci, S. Galassi, A.M. Marra & M. De Stefano
University of Florence, Florence, Italy

ABSTRACT: The energy and seismic requalification of the existing building heritage is a crucial topic, usually investigated by separate approaches and procedures. In this context, the designed technologies must reflect on solutions that can be applied in redevelopment interventions from the perspective of Life Cycle Thinking. Moreover, the choice of a specific solution in the construction sector must face the rise of mechanical and energy performance levels according to the market requests, as well as the demands of a regulatory landscape increasingly focused on the principles of sustainability and LCA-based environmental impact of the entire building process.

In this framework, this research aims to design, test and implement innovative strengthening systems made of bio-composite mortar mixtures in which a high-strength fiber is embedded, covering an integrated assessment of new composite materials to reduce the seismic vulnerability of historic masonry buildings while complying with energy saving, sustainable development, and reduction of greenhouse gases emissions.

After an initial literature review outlining the progress in innovative techniques for the integrated structural and energy retrofit of existing masonry buildings, the study focuses on the applications of fibre-reinforced lime matrices (FRLM) as thermal plasters, analyzing their mechanical properties and thermo-hygrometric behaviour.

Next, a selection of thermal plasters to be used as a matrix of the innovative composite material was carried out; then, the mechanical properties were investigated through compressive and bending tests. The mortar with better mechanical properties was used to assemble composite specimens to be tested under a direct tensile test. Dynamic thermohygrometric simulations by WUFI® Pro and EnergyPlus and numerical FEM simulations using the Abaqus software were performed to check structural and thermal contributions when applied on typically arranged masonry panels of existing buildings.

The objective is to demonstrate how it is possible to provide solutions that can encourage ecological and environmental sensitivities of processes and products and define approaches for future projects to achieve sustainable targets positively.

1 INTRODUCTION

Most European masonry buildings are made in the absence of anti-seismic standards and thermal insulation requirements and do not pay attention to either structural safety or energy performance. The conservation and valorization of this heritage require a multidisciplinary approach, capable of reducing structural vulnerability by upgrading the energy performance while respecting environmental sustainability principles, from a Life Cycle Thinking perspective.

In the current literature, several methods exist to improve the thermal performance of masonry buildings (Litti et al., 2015) and for the seismic vulnerability assessment (Karantoni et al., 2012) but operate in a disjoint way.

In addition, only a few research projects are available on an integrated approach to evaluate new methods of structural and energetic requalification of existing masonry buildings (Giresini, Casapulla, et al., 2021; Giresini, Stochino, et al., 2021): a comparison between thermal performance and seismic capacity of different interventions on masonry structures, in terms of economic (e/m^2) and ecological ($kgCO_2/m^2$) costs is proposed in (Mistretta et al., 2019).

The reinforcement of masonry structures is one of the most important applications for FRLM (Fiber Reinforced Lime Matrix) composite materials. The reinforcement, defined by a fibrous base, guarantees an improvement of the mechanical characteristics, while the matrix allows the application of the reinforcement to the structural system, sometimes improving the thermo-hygrometric performance also. The challenge in introducing technological solutions as innovative composite materials compatible with the organism to preserve (Battisti et al., 2018), able to increase mechanical resistance, improving the inertia and thermal transmittance, without burdening the structures, is the aim to create sustainable strategies to improve the existing masonry heritage building subjected to energy losses and earthquake loading.

This paper aims to develop one or more innovative FRLM composite materials made by a balanced bi-axial mesh of basalt fiber and thermal plasters based on natural hydraulic lime mortar. Thermal plasters are mortars for masonry that show excellent insulating characteristics (UNI EN 998-1, 2016) and can be produced using lightweight aggregates of natural origin or recycled or recyclable materials, as a starting point to reduce the environmental impact of the construction sector. The concept of environmental impact is to be understood by observing the “From Cradle to Cradle” approach, following the Life Cycle Assessment (LCA) method, to study the influence that the production process has on factors related to climate change (Napolano et al., 2015).

Starting from these premises, first, a comparative analysis of eleven thermal plasters was made to identify the one with the best performance from a mechanical, thermo-hygrometric, and environmental perspective.

The thermohygrometric properties of the thermal plasters were evaluated through dynamic simulations with the WUFI® Pro software, while the mechanical properties were investigated through three-point bending and compression tests. The thermal plaster with the best properties was assembled with basalt fibers and tested at the laboratory under direct tension tests.

Finally, Finite element analyses with Abaqus software were performed to estimate the composite’s mechanical contributions and failure mechanism.

2 ANALYSIS OF THE INORGANIC MATRICES FOR THE FRLM COMPOSITES

After a detailed study of the state of the art through an original analysis of the products present in the literature and the international market, the first part of the research work involved the identification of lime-based thermal plasters with mechanical and energetic characteristics for the rehabilitation of existing masonry buildings.

The requirements imposed on the properties of the thermal plasters were identified concerning the following parameters: 1) compressive strength σ [N/mm^2]; 2) thermal conductivity λ [W/mK]; 3) density [kg/m^3]; 4) natural aggregates; 5) recycled or recyclable aggregates.

Table 1. lists the composition of 11 selected thermal plasters declared by manufacturers on data sheets. The symbols next to the codes (Int.01- Int.11) indicate the type of compound, in particular:

- ✓ indicates that the thermal plaster is characterized by a $\sigma \simeq 1,50 N/mm^2$ and $\lambda \simeq 0,10 W/mK$;
- 🌿 indicates that the thermal plaster is made of natural materials;
- ♻️ indicates that the thermal plaster is made of recycled or recyclable materials.

3 HYGROTHERMAL PERFORMANCES OF THE SELECTED MATRICES

With the purpose to investigate the one-dimensional transient hygrothermal behaviour of multilayer building components, thermodynamic simulations were performed using the

Table 1. Composition of Int.01- Int. 11 matrices.

Thermal Plaster	Compressive strength σ [N/mm ²]	Thermal Conductivity λ [W/mK]	Density [kg/m ³]	Binder
Int.01 ✓ 	> 3.0	0.077	380	Natural Hydraulic Lime (NHL) 3.5

WUFI ® Pro 6.5.2 software (Wärme- Und Feuchttransport Instationär Heat and Moisture Transiency) according to UNI EN standard (UNIEN15026, 2008).

The climatic reference conditions of Florence were considered with a simulation time of ten years.

Three specific technical solutions for masonry buildings were considered for the simulation, selected from the list provided by UNI/ TR standard (UNI/TR11552, 2014) in particular:

- Mas.1: one-and-a-half brick masonry, with a thickness of 380 mm;
- Mas.2: stone masonry, with a thickness of 500 mm;
- Mas.3: sack masonry with weakly bonded filling, with a thickness of 480 mm.

In the field of seismic and energy requalification of the historical heritage, the 11 selected thermal plasters were applied on both sides of the wall considering 60 mm thick on the exterior and 40 mm thick on the interior. to investigate the hydrothermal behaviour of the different scenarios varying the thermal plasters adopted to replace the traditional plaster.

For all the investigated solutions, the simulations show that the water content inside the wall [kg/m³] increases over the ten years: initially, the structure is not yet in dynamic equilibrium with the environment; once this equilibrium has been reached, the variations of the water content inside the wall depends on seasonal variations.

As regards the water content inside the internal plaster layer [kg/m³], the products with the lowest annual average value are Int.01 and Int.06. Furthermore, the results obtained from the simulations carried out with Int.06 showed no water accumulation within any of the three analyzed construction types.

Figure 1. reports each configuration's thermal transmittance values [W/m²K] of the three building envelope solutions Mas.1, Mas.2, and Mas.3 for the climate of Florence.

4 EXPERIMENTAL INVESTIGATION OF THE MECHANICAL PROPERTIES

The experimental campaign was carried out at the Laboratory of Materials and Structures of the University of Florence, which involved:

- bending tests for three points and uniaxial compression tests of the 11 selected thermal plasters;
- direct tensile test on basalt textile;
- direct tensile test on the FRLM composite constituted by the structural reinforcing textile embedded in the better thermal plaster from the structural and thermodynamic point of view.

Figure 1. Comparison between the thermal transmittance values of the different configurations.

4.1 Mechanical properties of the thermal plasters

Three mortar specimens 40·40·160 mm³ in size for each type of thermal plaster (Int.01-Int.11) were obtained using special standardized metal moulds and tested, after curing for 28 days in a controlled temperature room, under three-point bending tests, according to UNI standards (UNIEN1015, 2019). Then, axial compression tests on the two stumps obtained after the failure of each specimen due to the bending test were performed.

Figure 2a. a) Compressive stress-strain curves of Int.01-Int.11.

Figure 2b. b) Flexural stress-strain curves of Int.01-Int.11.

The tests were carried out under displacement control, using an universal hydraulic machine with a 600 kN hydraulic actuator. Results of the three-point bending test and compression test were summarized in Table 2 in terms of compressive strength (f_c), compressive elastic modulus (E_c), and flexural strength (f_b). Elastic modulus was calculated and evaluated between 30% and 60% of the maximum load (Alecci et al., 2019; Simões et al., 2015; Valluzzi et al., 2005) in the first linear branch of the stress-strain curves.

Compressive and flexural stress-strain curves of the texted thermal plaster specimens are plotted in Figures 2a) and 2b).

The results obtained from the experimental campaign concerning the four resistance categories of plaster mortar reported in the technical standards for the design, execution, and testing of masonry buildings (UNIEN998-1, 2016) identified the thermal plasters tested as belonging to category CS I ($0.4 \div 2.5 \text{ N/mm}^2$), with an average compressive strength of 1.13 N/mm^2 . For the flexural and compressive strengths, respectively, the values are in the ranges of 0.02 N/mm^2 and 0.30 N/mm^2 for flexural and 0.11 N/mm^2 and 2.49 N/mm^2 for compressive strength. Accordingly, the flexural and uniaxial compression tests show that the thermal mortar with the best compressive strength is INT.06, with a value of compressive strength equivalent to 2.46 N/mm^2 . It can be noted that thermal plasters INT.06, INT.01, and INT.10 showed the highest value of compressive strength, flexural strength, and Young's modulus, respectively.

Table 2. Mechanical properties of Int.01- Int.11 matrices (laboratory results).

Thermal Plaster	Compressive strength f_c [N/mm^2]	Compressive Young's modulus [N/mm^2]	Flexural strength [N/mm^2]
Int.01	2.41	138.7	0.30
Int.02	0.38	75.9	0.07
Int.03	0.46	10.7	0.06
Int.04	0.73	132.0	0.06
Int.05	0.89	63.7	0.10
Int.06	2.49	292.5	0.27
Int.07	0.11	3.2	0.10
Int.08	1.23	222.2	0.02
Int.09	1.15	211.3	0.03
Int.10	1.86	385.1	0.07
Int.11	0.76	77.30	0.12

4.2 Mechanical properties of the basalt textile

The textile used for the reinforcement of the new FRLM composite is a balanced bi-axial mesh made of special basalt fiber and stainless-steel micro threads.

Direct uniaxial tensile tests investigated the mechanical properties of the basalt textile, performed under controlled displacement by an universal testing machine equipped with a 600 kN load cell (Barducci et al., 2020). The load was applied with a rate of 0.25 mm/min . The tests were carried out according to the ASTM Standard (ASTMD3039/D3039M17, 2017).

Specifically, four basalt textile specimens consisting of one (1BT), two (2BT), three (3BT), and four (4BT) longitudinal multifilaments were prepared and tested.

The tensile strength f_{tf} was obtained as shown in Equation 1:

$$f_{tf} = F_{\max} / A_f \quad (1)$$

where F_{\max} is the maximum load value, $A_f = n \cdot b_f \cdot t_f$ represents the equivalent cross-sectional area of the fiber, n is the number of longitudinal fiber bundles of the specimen, b_f is the pitch between the bundles of fibers, and t_f is the equivalent thickness.

Young tensile modulus E_{tf} was evaluated in the first linear branch of the stress-strain curve.

Table 3. Mechanical properties of basalt textile.

Specimen	Tensile strength f_{tf} [N/mm^2]	Tensile Young's modulus E_{tf} [N/mm^2]	Ultimate strain ϵ_{tf}
BT	865	60487	0.017

4.3 Mechanical properties of the composite material

Basalt textile was embedded in the matrix Int.06, and six coupons labelled INT06_1-6, 500·65·10 mm³ in size, after curing for 28 days at room temperature, were tested under direct tension. Two steel plates bolted with a pressure controlled by a torque wrench were used (Figure 3). The tests were performed in displacement control, with a 0.2 mm/min rate, using an universal machine with a 600 kN load cell.

The local displacements were captured using a proper extensometer 50 mm axial gauge length positioned in the middle of each specimen (Figure 4.).

Figure 5 shows the direct tensile stress and strain response curves obtain in a direct tensile test. As visible, the tested coupons showed similar mechanical behaviour for INT06_1 and INT06_4, and for INT06_3 and INT06_5 where after reaching maximum stress, the curves show a constant descending trend. When the peak load was reached, the failure of a multifilament of the basalt textile occurred.

Figure 3. FRLM direct tensile test set-up (dimension in mm).

Figure 4. Tensile test on INT06_1.

The increase of the existing cracks characterized the post-peak softening branch, and the formation of new cracks and specimens highlighted large displacements without a high increase in applied load.

Figure 5. Stress-strain curves of the six samples INT06_1 to INT06_6.

In terms of maximum load F_{max} , tensile strength f_r , Young's modulus E , and maximum deformation ϵ_r , the results are reported in Table 4.

5 FINITE ELEMENT MODELLING

Numerical analyses were carried out using Abaqus CAE software to simulate the behaviour of a non-reinforced (NRM) and a reinforced (RM) masonry wall subjected to a diagonal

Table 4. Mechanical properties of the composite material.

Coupon	F_{\max} [N]	f_r [N/mm ²]	E [N/mm ²]	ϵ_t
INT06_1	681	327	36310	0.01
INT06_2	881	424	66577	0.01
INT06_3	704	338	34718	0.02
INT06_4	735	353	44960	0.01
INT06_5	764	367	48250	0.02
INT06_6	1059	509	52920	0.02
Average value	804	386	47289	0.015

compression test, conducted according to ASTM standards (ASTME519-07, 2010). Three parts characterize the NRM model, i.e., a brick masonry panel 1200·1200·120 mm³ in size and two steel plates fixed at the two corners of the diagonal coinciding with the load direction (Figure 6a). The steel plate on the top distributes the load on a larger surface, avoiding the concentration of compression stresses; horizontal and vertical translational constraints are located at the base of the bottom plate. Regarding the RM, model, the FRLM composite was applied at each side (with a thickness of 15 mm) of the masonry panel by considering an isotropic linear elastic behaviour (Figure 6b).

Figure 6. a) Mesh configuration of the NRM model b) Mesh configuration of the RM model.

Figure 7. Comparison of the experimental and numerical results.

The steel plates were modelled with a linear elastic isotropic material, characterized by Young's modulus equal to 210000 N/mm² and a Poisson ratio of 0.30.

A first analysis was carried out for the NRM model, characterized by a linear elastic behaviour with Young's modulus and Poisson ratio defined to match the results of the experimental shear tests conducted previously by the Authors (Alecci, Fagone, Rotunno, & De Stefano, 2013).

Figure 7 compares the numerical and the experimental results in load-displacement evaluated at the top of the tested brick masonry panel.

Once the linear elastic analysis had been carried out, the masonry panel was studied with a nonlinear behaviour (NL_NRM), using the “concrete damage plasticity” (CDP) model implemented in Abaqus CAE, adequately calibrated according to experimental tests conducted by the authors (Alecci, De Stefano, Luciano, Marra, & Stipo, 2020). Regarding the analyses on the nonlinear FEM, they are not reported since they are still in progress.

6 CONCLUSIONS

Through a theoretical-experimental analysis, based on data in the literature and materials on the market, it was found that the identification of thermal plasters compatible with the masonry substrate to be reinforced, and characterized by good mechanical as well as thermal properties, is a crucial step for the design of innovative composite materials to be used for the energy and structural upgrading of the historic building, in compliance with the instances of compatibility, sustainability, and reversibility (Romano et al., 2021).

The results reported in this paper show that Int.01, Int.06, and Int.10 mortars have good mechanical behaviour in terms of compressive strength, flexural strength, and Young's modulus values.

Regarding the energetic performance, it was observed that the walls with the lowest thermal transmittance were those retrofitted with Int.06, applied on both sides to both sides of the wall.

Finally, the INT.06 product represents the ideal matrix from both points of view and can be considered a good solution to regenerate the thermohygrometric performances of the historical envelopes, without changing their mechanical and aesthetic features.

The next step of the research will involve the seismic retrofit of masonry panels strengthened with such a composite by a nonlinear FEM analysis while enlarging the list of thermal plaster mixtures evaluated as potential matrices of the FRLM composites.

Development of a method for resource-efficient structural maintenance of reinforced concrete buildings based on digital BIM models

J.-I. Jäkel, L. Kloesgen, T. Koenig & K. Klemm-Albert

Institute for Construction Management, Digital Engineering and Robotics in Construction (ICoM), RWTH Aachen University, Aachen, Germany

H. Morgenstern & M. Raupach

Institute for Building Materials Research (ibac), RWTH Aachen University, Aachen, Germany

ABSTRACT: In the Federal Republic of Germany, around 70% of all construction work in the area of building construction is carried out on existing buildings. This large amount emphasises the need to consider the lifecycle-oriented maintenance management of buildings. Using digital methods and technologies, the existing, mostly manual processes can be optimized and automated. In addition, there is a need to integrate sustainability aspects into the decision-making process for maintenance tasks. In this technical article, a holistic method for resource-efficient building maintenance is developed by using the Building-Information-Modeling (BIM) method in combination with the integration of sustainability aspects. Thereby, methods of laser scanning are combined with the BIM method, digital maintenance and AR technology, resulting in a partially automated and interoperable workflow. In the first step, the status quo of digital maintenance at reinforced concrete structures is analyzed in a literature review. The following step is to define the process-related and data-technical fundamentals. Based on this, data acquisition is carried out using laser scanning methods and modern diagnostic procedures as well as partially automated data processing to create a refined BIM model. A digital model with integrated diagnostic data is developed from the recorded data and a comparison of different maintenance scenarios is carried out using intelligent algorithms in the context of costs, time and CO₂ emissions. For further transparent use of the digital as-built model in operational maintenance management, the model is embedded in an augmented reality environment and a common data environment. The process steps are validated using a real demonstrator at the end. The result of the article shows a partially automated process chain and decision support for resource-efficient maintenance management of reinforced concrete structures.

1 INTRODUCTION

To fight climate change, Germany decided along with the European council to pass laws aiming to reduce greenhouse gas emissions and energy expenditure, while increasing energy efficiency (*Bundes-Klimaschutzgesetz (KSG)*, Bundesministerium für Justiz, 2021). To become a climate neutral society, a reduction of 53 million tons CO₂-equivalent is required within the building sector, as it is one of Germany's main emission sources (Deutsche Energie-Agentur, 2021b). In practice, this means an emission-reduction of 65% in the year 2030 as compared to 1990 (*Bundes-Klimaschutzgesetz (KSG)*, Bundesministerium für Justiz, 2021; United Nations, 1997). Consequently, new building projects prioritize energy efficiency and the integration of renewable energies and sustainable material which necessitate digitalization and automatization of all construction processes (Hofstadler and Motzko, 2021). Thereby, energy efficiency and sustainability can be maximized, while minimizing costs and worktime (Hofstadler and Motzko, 2021; Schäfer et al., 2022). While optimizing new buildings is an active area of research, digitalization of construction processes in existing buildings has been largely avoided; probably as preexisting data of these buildings is lacking (Mellado et al., 2020). However, advancements in this area are crucial for two main reasons. Firstly, 99% of German buildings were built before 2010, contributing to 35% of

Germany's energy use (Bundesministerium für Wirtschaft und Energie, 2014; Deutsche Energie-Agentur, 2021a). Hence, around 70% of all construction work in the area of building construction is carried out on already existing buildings (Bundesinstitut für Bau-, Stadt- und Raumforschung, 2021). In addition, many processes from construction sites are still carried out manually by engineers and construction workers and there is a low degree of automation and digitization (McKinsey Global Institute, 2017). Secondly, refurbishments are costly and often carry higher risks than a new building project (Mellado et al., 2020). Digitalization can be used to incentivize refurbishments, as it enables automatization of more construction processes, thus reducing costs and risks (Mellado et al., 2020). Both facts evidently reinforce the need to consider a lifecycle-oriented maintenance management of buildings, while optimizing and automating manual processes using digital methods and technology. To address this problem and encourage further research, this article presents a holistic method for resource-efficient building maintenance that uses the digital method Building Information Modeling (BIM) while integrating sustainability aspects.

2 METHODOLOGY

The scientific article is structured in three sections - (i) literature review, (ii) concept elaboration, and (iii) proof-of-concept validation. In the first section, the status quo is reviewed and related research work is presented. The literature is searched using scientific databases (Scopus, Web of Science, Google Scholar). In the second part, the concept of the method for resource-efficient maintenance is elaborated. In this context, the procedure of the method is presented in a process model, the individual process steps are explained in more detail and the technologies used are specifically described. The data acquisition uses laser scanning technologies for the building geometry and methods of and low and non-destructive testing for the diagnostic data. The further processing of the data into an object-oriented and semantically enriched digital BIM model focuses on the openBIM approach using open data exchange formats. In the further progress of the method, the BIM model serves as the central database for the following sustainability analysis and the linking with immersive technologies. The validation of the method concept is subsequently conducted in the third part using a proof-of-concept on a real demonstrator. This demonstrates the basic feasibility of the concept. At the end of the article, the elaborated results are discussed, limitations are pointed out and an outlook on future research activities is given.

3 RELATED WORKS

In line with governmental goals to tackle climate change, approaches have been developed to address the reduction of greenhouse gas emissions and resource demand. Recently, Life-Cycle-Assessment (LCA), an inter-period approach, has received increasing attention. It uses a digitalized methodology to record and use all building data throughout planning, construction and use. One of the most common methods is BIM, a software that includes, among others, all workflows, cost- and time data, in one open-source, 3D-Model for all stakeholders (Görsch et al., 2021). (Naneva et al., 2020) shows that on the one hand, BIM has potential to reduce the effort of LCA. On the other hand, a glimpse into today's economy demonstrates that companies are not using BIM appropriately or the integration is implemented too late in the decision-making process (Morgens-tern and Raupach, 2022b; Naneva et al., 2020). Therefore, the authors are developing an integrated BIM-LCA approach using an already existing cost estimation technique that aims to implement LCA continuously through the life cycle of the building. They demonstrate that combining LCA with BIM simplifies the use and implementation of this methodology, an incentive for interested companies. Moreover, it supports the decision-making process in all life-cycle phases (Naneva et al., 2020). Furthermore, (Wastiels and Decuypere, 2019) present different strategies in relation to the BIM-LCA integration. In their first approach, a BIM-based bill of quantities, which includes all building material data, is imported to the LCA software, in which the bill of quantity is linked to predefined profiles and then analyzed in the software itself. In contrast, the authors introduce another possibility where the LCA profiles are inserted into a BIM environment as a first step. This yields the advantage that BIM objectives can be linked with LCA data, and the planning

process can be supported by a real-time data transfer. There are other sustainable methods that link material passports to the BIM model as a basic requirement for a circular economy with differences mainly in the data transfer. These material passports are material information regarding for example the greenhouse-gas emissions and circular potential and are provided by in huge data bases (Bartels et al., 2022). One approach is to export all material data from the BIM-model into a software tool that supports the user with information regarding the recyclability, costs or possible reuse of the materials (Theißen et al., 2022). In other approaches users are directly provided with a data set of material passports that can be implemented in BIM. Consequently, used materials can be linked to the data banks in the planning process before allowing data transfer between BIM and the software. As a result, the software generates a review regarding the circular potential of the project (Atik et al., 2020; Atta et al., 2021; Honic et al., 2019). Considering all the above, it is prominent that digital and sustainable construction processes receive increasing attention with many projects working on the topic of circular economy. Nevertheless, most of them focus on the implementation of new construction sites while disregarding possible applications in existing building and redevelopment projects. Therefore, the project ReBaDI introduces an implementation of BIM in a refurbishment process including automated supportive renovation suggestions based on further attributes of the materials, as their CO₂-equivalent and costs per unit. The method of ReBaDI is a further development in the area of resource-efficient building maintenance based on the precious research of Morgenstern and Raupach (Morgenstern and Raupach, 2022a).

4 DEVELOPMENT OF THE CONCEPT

The method is designed for resource-efficient and sustainable maintenance of building structures using digital methods and techniques. In this case, the focus is on building structures of reinforced concrete. Laser scanning, BIM, intelligent algorithms and AR technologies are linked along the entire process chain. For a better understanding of the method, the individual process steps were transferred into a BPMN process model (Figure 1). The method is divided into four process phases - surveying/laser scanning, building diagnostics, BIM analysis and AR data visualization. The first process phase is the laser scanning of the building structure and the semiautomated transformation of the scan data into a digital BIM-model. At the beginning the responsible engineer needs to select the preferred laser scan methods. After scanning and quality check of the acquired data, the digital model of the building structure is semi-automatically generated. In the second phase of the process, the building diagnosis is carried out to record further data sets on the structural condition and the state of the structure. Depending on the intended objective, different non-destructive or low-destructive testing methods need to be selected. After the selection of the methods, relevant parameters (e.g. concrete cover, chloride ingress, etc.) are determined. After completion and control of the data, it is stored on an additional diagnostic database, linked to the Common Data Environment (CDE). In the third process phase (BIM-analysis), the BIM model is semantically enriched with the relevant diagnostic data in the first sub-step and the recorded data is evaluated automatically. From the analyzed diagnostic data, the necessary maintenance measures for the improvement of the building structure can be derived. Furthermore, the diagnostic data can be visualized directly in the digital model. In the further progress of the phase, the digital model will act as the main database for the sustainability assessment of the resulted maintenance operations. For this purpose, the BIM model is enriched with additional sustainability parameters (e.g. CO₂-factor and transport emission for the material, etc.) and linked to a database with further sustainability parameters of individual materials. For the sustainability assessment, an algorithm based on formalized expert knowledge is used in this context, acting as a decision support system. Based on the data from the BIM model and the sustainability parameters from the database, the algorithm compares different materials and methods for the maintenance of the building structure.

The result of the consideration shows different proposals with ecological and economic priorities. This serves as a decision support for the maintenance planning. In this way, the most optimal solution for the condition optimization of the building structure can be selected. To ensure that at the end of the process chain all relevant data for the further life cycle are always

stored and managed transparently and consistently, the digital model and all diagnostic and sustainability data are transferred to a CDE. In this way, all project participants can view and use the data. The data is provided by means of open data exchange formats. For example, the digital model in IFC format, adhering to the openBIM approach. For optimized display and availability on the construction site of the digital building model including diagnostic data, the data can also be transferred to an augmented reality system after analysis (process phase 5). For this purpose, they are transferred and processed via an interface in a software/engine for augmented realities. As a result, the data can be used directly on the construction site via a terminal device (e.g. cell phone, tablet, AR glasses) and the BIM model and diagnostic data can be displayed. The use of AR and the possibility of using the data on demand in a visualized form improves the awareness of the existing condition of the building structure and at the same time offers the possibility to make internal components visible. In addition, existing problems can be detected directly on site and predictive action can be taken.

5 PROOF-OF-CONCEPT

After the method concept has been presented in detail in the previous chapter, its validation is conducted in the form of a proof-of-concept on a physical demonstrator in the next section. The demonstrator is a room of an office building of reinforced concrete structure. The validation considers the individual process phases of the method and is divided into three sub-steps - data acquisition, data processing and data provision.

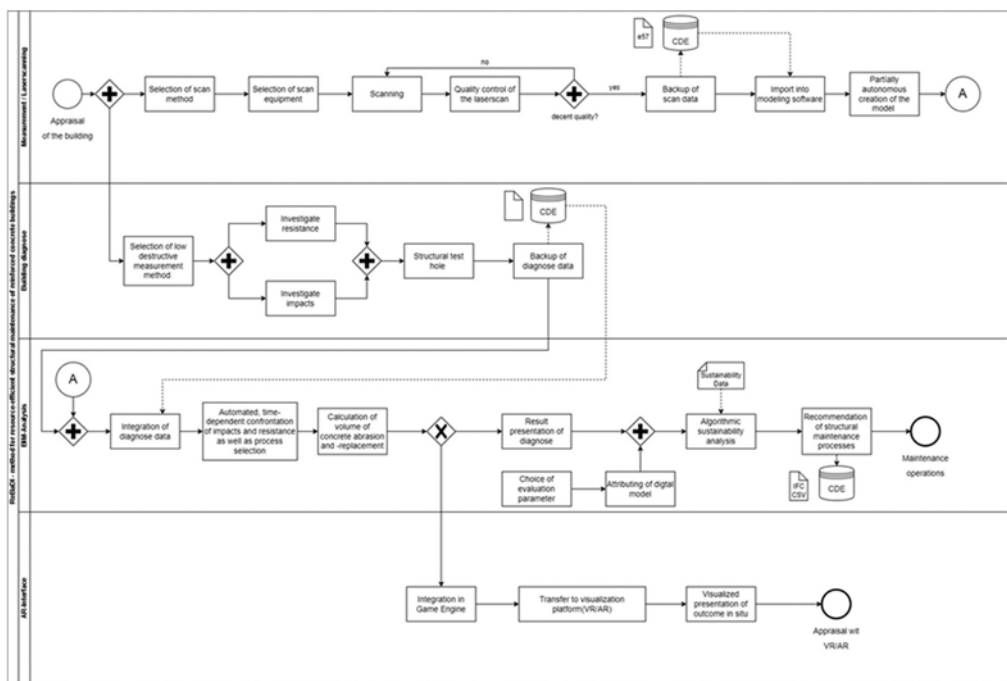

Figure 1. ReBaDI process model.

The first step of validation is the data acquisition. On the one hand, the structure of the building is recorded by laser scanning, and on the other hand, the diagnostic data is recorded using a rebar detector. Geometric data of the existing structure was collected using a terrestrial laser scanner (Trimble X7). 3D-scans of the corridor and the adjacent rooms are also required in order to determine the wall's thickness. During the scanning process, each scan is automatically registered in Trimble's authoring software (s. Figure 2).

Figure 2. Laser Scan of the demonstrator.

The fully registered point cloud is stored as an open data exchange format e57 in a CDE and can be utilized for post-modeling to an “as-is model”. The gathering of data from building components is the next stage in building diagnostics. For this, non-destructive and low-destructive measuring techniques are required. The positions of the rebars in the wall were determined through an areal scan with a grid size of 25 cm, leading to 30 (8 horizontal + 22 vertical) line scans. As a result, several measuring points were available for each rebar, so that not only the concrete cover could be determined for several points of a rebar, but also the orientation of the reinforcement could be derived. The measurement was calibrated and validated through a probe opening, gathering information about the exact concrete cover at that spot as well as the diameter of the rebars for both layers (front and rear). After the scan and diagnostic data have been successfully recorded using the real demonstrator, they were processed further in the following sub-process (data processing). The scan data were transferred into an authoring software system (Autodesk Revit) and the as-is BIM-model was created. The procedure was partially automated using the Faro Add-in “As-built” for the used authoring system Autodesk Revit. The result is a model as a reinforced concrete room which can be enriched with further semantic information. For the handling of the data series from the rebar detector and its further processing, an additional algorithm was developed. With the use of the algorithm, all lines of the rebar detection were automatically viewed and compared. In the process, measurement errors such as slippage of the displacement transducers or inaccuracies of starting points were identified and corrected. As a result, line scans orthogonal to the bars containing the points where a rebar was crossed over are transformed into lines describing the actual position and orientation of the rebars. From this transformed data, reinforcement elements were then automatically generated as digital representations, so that the actual position of the reinforcement was implemented in the model, see Figure 3.

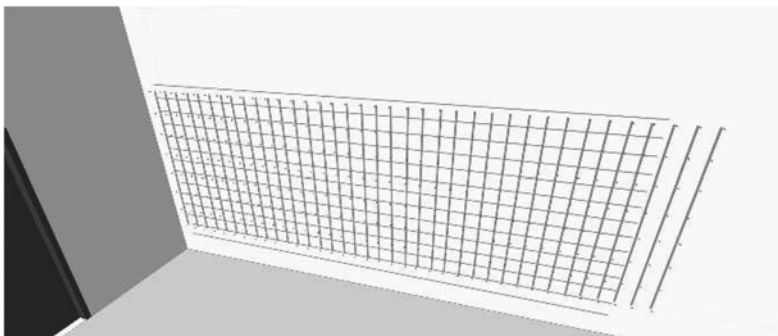

Figure 3. Digital representation of the reinforcement in the BIM-model.

For an integrated and partially automated sustainability assessment to compare maintenance operations, an additional algorithm was developed. Therefore, the open-source visual programming tool Dynamo has been used to enable an interface between the BIM model and an external database. As a minimal example, this study used an Excel spreadsheet to store all relevant material parameters rather than an entire database system. In order to be able to store the ecological and economic parameters and the results of the sustainability study directly in the model, additional common parameters were integrated. The algorithm was developed for an automated sustainability evaluation of accruing maintenance operations. In the context of the article, two scenarios are considered for the analysis as validation. One scenario considers the comparison of maintenance measures in terms of environmental sustainability with regard to CO₂-emissions. The other scenario focuses on economic sustainability by comparing the costs incurred. As parameters for each maintenance scenario, the CO₂ emissions (in kg), the material name and the associated refurbishment costs (in €) are created. The building component and accompanying face that are intended to be renovated must be chosen to employ the Dynamo script. The algorithm then calculates all scenarios and automatically extracts the data from the database. The script then analyzes the data and returns two scenarios: one with the lowest costs and another with the lowest CO₂-emissions. It then enriches these economic and ecological factors in the BIM model so that decision-makers can take them into account.

The last step of the validation is the provision of the processed data. Two different types of data provision are considered in this context. The first form is data integration and representation using AR technology, and the second is the use of a CDE as a unified single-source-of-truth. After the BIM model has been created and semantized, the method can be used to provide the data via augmented reality in addition to the sustainability analysis. As part of the validation, the BIM model of the room structure, including diagnostic data, was loaded into the Visual Live game engine (s. Figure 4).

Figure 4. Representation of the BIM-model in an augmented reality.

Through this interface, the BIM model can be used and displayed directly on site via app. For an optimal representation of the data, a uniform coordinate system between the real asset and digital model was defined after the data transfer. This results in an exact overlap of the digital image in the physical space and the data can be displayed directly without any deviations. Figure 4 shows an excerpt of the interface. Here, the exact reinforcement location and the remaining concrete cover (colored dots in the image) are displayed as digital objects on the real wall in augmented reality. With this step, hidden components, e.g. in these prototypes the

reinforcement position and properties of the wall that are not visible to the eye, can be visualized and made available to the engineer on site. This enables important properties of the building structure to be made comprehensible and efficient for maintenance management. For the permanent, consistent and transparent storage and management of data throughout the operational phase, the BIM model is transferred in IFC format and all relevant data in a CDE. This serves as a single source of truth in the operational phase of the building structure. By using the CDE, the data can be viewed and used by all relevant project participants.

6 DISCUSSION

The basic feasibility of the developed procedure is demonstrated by validation on a real demonstrator. In the context of the validation, each phase depicted in the process model is conducted and implemented in practice. By combining digital technologies, such as laser scanning, digital building models, algorithms and augmented reality, maintenance management can be further digitized and existing processes automated. As a result, the building structure and its condition can be accurately captured and represented in a digital and semantically refined BIM model and serve as a consistent database for further actions and analysis. In addition, by linking the digital model with further sustainability data, necessary maintenance measures can be evaluated so that the most sustainable variant in terms of the life cycle is always selected. Furthermore, the digital image can make all hidden conditions in the structure visible and available directly on the construction site via an AR interface.

Although this work enabled an efficient and automated workflow to identify economic and sustainable solutions, there are limitations to this method. First of all, it should be noted that the project focuses only on four different materials and strategies, preventing a more sophisticated evaluation of several materials. Furthermore, the evaluation process is based on material attributes, but to reduce the complexity of the project and enable an easy comparison between the different strategies, the focus is set on the costs and CO₂-emissions of the materials. Lastly, only one wall of one project room was considered, reducing the complexity of the algorithm.

Considering these aspects, further research is needed in order to enable evaluations of multiple building components of multiple rooms and creating a general method for a sustainable redevelopment process. The aforementioned restrictions highlight how the workflow can be enhanced or totally automated. An Excel table with four different materials was used as the bare minimum sample in this study. A bigger data collection can be considered by integrating a material data base or material passport data into the Dynamo script. Additionally, more scenarios with higher complexity can be examined in complement to the original two. Another issue that has to be addressed is that the Dynamo script is now used twice - once for scenario analysis and once for building diagnostics - and is only partially automated. By allowing only one tool to evaluate all incoming parameters, these several scripts can be consolidated into one to increase the workflow's level of automation. The level of automation in this situation can also be increased that the algorithm fully identifies the components which require correction and initiates the relevant analysis. This would enable more efficient evaluation and analysis of bigger construction structures or even transfer the application to other areas such as bridges.

7 CONCLUSION

This article presents a partially automated procedure for a resource-efficient and digital maintenance management of reinforced concrete structures. A process chain was developed to describe the procedure and the individual phases were presented specifically. For validation, the method was applied to a real demonstrator and the results discussed in the article. By using the method, existing structures and conditions of the building can be recorded and represented in a digital BIM model. Furthermore, necessary maintenance measures can be identified and analyzed under consideration of sustainability aspects. In addition, the approach enables the provision and use of the data in a CDE as well as via augmented reality directly in the real environment of the building.

ACKNOWLEDGEMENT

This research (Project ReBaDI, 10.08.18.3-22.31) is supported by the Federal Institute Research on Building, Urban Affairs and Spatial Development in the Federal Office for Building and Regional Planning in the funding program ZukunftBau.

Cost-optimization based generalized target reliabilities for reinforced concrete slab exposed to fire

F. Put, R.K. Chaudhary, A. Lucherini, B. Merci & R. Van Coile
Ghent University, Ghent, Belgium

ABSTRACT: Risk-based design of structures can be based on lifetime cost-optimization, which involves balancing the future costs with the benefits of safety investments. However, such calculations are impractical for most individual projects due to complexity and computational challenges. In normal design conditions, the explicit cost-benefit assessment has been replaced by precalculated maximum levels of failure probability (i.e., target reliability levels). For fire design, these targets have not been defined. In this study, target reliabilities for fire design are specified by generalizing optimum reliabilities obtained through lifetime cost-optimization. First, the influence of the appropriate parameters on the optimum reliability level is investigated. This is followed by the evaluation of target reliabilities considering the variability in parameters influencing lifetime cost for common types of structures.

1 INTRODUCTION

Structural fire design is traditionally presumed to be adequate when prescriptive design requirements are satisfied. These requirements reflect experience of the profession obtained over time, following disasters that indicated the need for new prescriptive guidance (Spinardi et al., 2017). As a result, prescriptive guidance focuses on common and pre-existing buildings, while new and modern structures are not covered. Moreover, technological advancement and the development of innovative structural materials and design solutions render prescriptive design guidance inapplicable (Spinardi et al., 2017). For such structures, a performance-based design (PBD), which ensures that structures meet predefined objectives, is more suitable (Van Coile et al., 2019b).

Designing a structure according to a PBD approach involves dealing with the uncertainties of the structural system (Van Coile et al., 2019a). In this respect, a probabilistic or risk-based structural design can be used where uncertainties are explicitly quantified. Generally, such probabilistic structural design should meet the ‘As Low As Reasonably Practicable’ (ALARP) criterion (Van Coile et al., 2019b), which requires a lifetime cost-minimization and involves balancing the future costs of a safety investment with its benefits (BSI, 2019). Nevertheless, such evaluations are often complicated and computationally challenging, making them impractical for application to most individual projects. This issue is not inherent to the fire design conditions, but also occurs in normal design conditions, for which design guidance proposes target reliabilities, e.g., (JSCC, 2001). These target reliabilities are predefined maximum (target) levels of failure probability and act as a substitute for the explicit cost-benefit (risk) assessment in normal design conditions.

For fire design, no generally accepted target reliabilities have been defined. The Natural Fire Safety Concept proposes to divide the normal design maximum failure probability by the fire frequency (Cajot et al., 2002). As pointed out in earlier work (Van Coile et al., 2017), these targets for normal design conditions cannot be readily transposed for structural design under fire, although the cost-optimization approach used to derive them stays relevant (Fischer, 2014). Previous work on the development of optimum reliability levels for structural fire design using such cost-optimization approach focused on the influence of the fire exposure (fire load density and opening factor) on the optimum reliability levels using a protected steel column as reference case (Chaudhary et al., 2022).

This study further elaborates on the methodology used in the latter work (Chaudhary et al., 2022), investigating the influence of the economic parameters on the optimum reliability levels through application of the lifetime cost-optimization approach. In addition, optimum reliability levels are determined for common types of structures. These optimum reliability levels can be considered as suggested values for specifying a target reliability index. The example of the reinforced concrete slab subjected to bending and exposed to natural fire from the bottom is revisited (Van Coile et al., 2014) and the axis distance is varied to obtain the optimum reliability level.

2 COST-OPTIMIZATION METHODOLOGY

The cost-optimization approach used in this study has been previously derived and a more detailed description can be found in previous work (Chaudhary et al., 2022).

The process of lifetime cost-optimization is generally achieved by maximization of the lifetime utility, which can be defined as the difference between the benefit of the structure's existence and the lifetime cost. As the expected benefit can be assumed independent of the safety investments, the maximization of lifetime utility reduces to a minimization of lifetime cost (Rackwitz, 2000).

The lifetime cost (K) can be split into three contributions, as indicated in Equation 1:

$$K = C + A + D \quad (1)$$

where C is the total cost of the structure, A refers to the obsolescence cost and D represents the cost of structural failure. The total cost of the structure, C , can be further divided into the cost of the structure, C_0 , and the added cost of the safety measure, C_1 , while for an infinite time horizon, the present net value obsolescence cost, A , can be rewritten in terms of the total cost of the structure according to Equation 2:

$$A = C \frac{\omega}{\gamma} = (C_0 + C_1) \frac{\omega}{\gamma} \quad (2)$$

where ω is the obsolescence rate and γ the continuous discount rate.

The cost of structural failure comprises direct and indirect costs related to structural failure such as reconstruction, business interruption, costs of injuries and fatalities, environmental costs etc. Although these costs generally depend on case-specific parameters, the cost of structural failure is often simplified to a factor of the initial construction cost, ξC_0 (Steenbergen et al., 2015). The structural failure cost for adverse events such as fire is assessed as the present net value of the (annual) expected structural failure cost over the entire lifetime of the structure (Steenbergen et al., 2015; Van Coile et al., 2019a). Equation 3 evaluates this present net value of the future annual expected failure costs over the lifetime of the structure (infinite time horizon):

$$D = \frac{\lambda P_f(p)}{\gamma} \xi C_0 \quad (3)$$

where λ is the annual probability of fire event occurrence and $P_f(p)$ is the structural failure probability considering a fire event, with p the design parameter being optimized. Substituting Equations 2 and 3 in Equation 1 and considering that the total cost of the structure can be rewritten as a sum of the cost of the structure and the added cost of the safety measure, the lifetime cost-minimization becomes:

$$\min_p \left[C_0(1 + \varepsilon(p)) \left(1 + \frac{\omega}{\gamma} \right) + \frac{\lambda P_f(p)}{\gamma} \xi C_0 \right] \quad (4)$$

where $\varepsilon(p) = C_1/C_0$ is the investment cost factor for the design.

As C_0 is constant and therefore does not take part in the minimization process, the final expression for the lifetime cost-minimization results in Equation 5.

$$\min_p \left[\varepsilon(p) \left(1 + \frac{\omega}{\gamma} \right) + \frac{\lambda P_f(p)}{\gamma} \xi \right] \quad (5)$$

It should be noted that Equation 5 is strictly speaking valid only when the investment in structural fire safety does not affect other performance metrics for the structure, such as its failure probability with respect to other accidental events. These effects are not considered here, and the fire design optimization is done in isolation. In the following, a constant value for the design value of the resistance in normal design conditions is maintained.

3 CASE STUDY: REINFORCED CONCRETE SLAB

As case study to investigate the influence of the economic parameters on the optimum reliability level and to derive optimum reliability levels for common types of structures, the reinforced concrete slab presented in (Van Coile et al., 2014) is adopted. The additional fire protection is the result of an increase in axis distance of the rebars (i.e., distance between the axis of a rebar and the fire exposed concrete surface), whilst maintaining the same ambient bending capacity (i.e., increasing the reinforcement area to compensate for the loss of lever arm). The sections below will discuss the slab details as well as the investment and failure costs.

3.1 Case study details

The considered slab is a simply supported one-way solid concrete slab with a fixed width and height of respectively 1 m and 0.2 m. Before cost-optimization, the slab is reinforced with Ø10 mm rebars with a 10 cm spacing. The initial axis distance is 20 mm and the resulting design value of the bending capacity in normal design conditions is 58.55 kNm. The slab is purely loaded in bending. The characteristic value of the bending moments induced by both the permanent load and imposed loads on the slab are calculated as 22.12 kNm (load ratio $\chi = 0.5$), considering full utilization in normal design conditions and combination factor ψ_0 equal to 0.7 (e.g., residential and office areas). The probabilistic models for the basic variables can be found in Table 1.

Table 1. Stochastic parameters for material properties (Qureshi et al., 2020), fire loading (CEN, 2002), mechanical loading and model uncertainties (Jovanović et al., 2021) for the analyzed concrete slab.

Stochastic variables	Distribution	Mean	COV*
Slab height, d	Normal	0.2 m	0.025
20°C concrete compressive strength, $f_{c,20}$	Lognormal	42.9 MPa	0.15
Yield strength reduction factor, $k_{fy(\theta)}$ with $f_{y,20}=581.4$ MPa	Logistic	Temperature-dependent	Temperature-dependent
Fire load density, q_f	Gumbel	Nominal value (500 – 1500 MJ/m ²)	0.3
Opening factor, O	Deterministic	0.04	
Permanent load, M_G	Normal	22.12 kNm	0.1
Imposed load, M_Q	Gamma	0.2×22.12 kNm	0.95
Resistance estimation, K_R	Lognormal	1.1	0.11
Load estimation, K_E	Lognormal	1	0.1

* Coefficient Of Variation

3.2 Cost components

The investment cost of additional fire protection, C_1 , results from the increase in reinforcement area to maintain the same ambient design bending capacity when the axis distance of the rebars is increased. The cost of steel is obtained from (Gordian, 2022) and amounts to \$2.89/kg and includes material, labor and overhead. Similarly, the initial cost of the compartment, C_0 is determined to be \$1500/m² (Table 2). Figure 1a visualizes how the investment cost increases with increasing axis distances and how this investment cost relates to the investment cost factor, $\varepsilon(p)$.

The estimated failure cost over the lifetime of the structure requires computation of the failure probability of the structural system. Failure of a system is associated with the limit state equation (denoted Z), $Z = R - E$, taking negative values, indicating that the load effect, E , exceeds the resistance effect, R . Hence, for a slab subjected to bending solely, the failure probability can be written as the probability that the induced bending moment exceeds the resisting moment of the slab, as in Equation 6:

$$P_f = P[K_R M_R - K_E M_E < 0] \quad (6)$$

where M_R is the bending resistance of the slab, M_E is the induced bending moment, K_R is the model uncertainty for the resistance effect and K_E is the model uncertainty for the load effect.

The slab is exposed from the bottom to Eurocode parametric fire curves (CEN, 2002). The fire load density is varied between 500 and 1500 MJ/m² (roughly the range from office to library), while the opening factor is kept constant at 0.04 m^{1/2} to represent a critical case with prolonged and moderate fire exposure instead of short and intense exposure. The probabilistic analysis for failure during these different fire exposures is discussed in detail elsewhere (Chaudhary et al., 2021). Figure 1b presents how the cost of the slab and failure probability for different fire load densities vary with the reinforcement axis distance to the exposed surface.

Table 2. Default values for economic parameters.

Variable	Default value	Reference
Cost of the structure C_0	1,500 USD/m ² *	(Gordian, 2022)
Steel cost	2.89 USD/kg	(Gordian, 2022)
Obsolescence rate ω	0.022 [1/year]	(Bokhari and Geltner, 2018)
Discount rate γ	0.03 [1/year]	(Fischer, 2014)
Probability of fire occurrence λ	0.151×10^{-2} (office)	(Manes and Rush, 2019)
Relative cost of structural failure ξ	4	Representative value

* Realistic estimation based on single-family dwelling and commercial office data in Table 3.

Figure 1. Influence of the reinforcement axis distance on (a) the investment cost C_1 per m² and investment cost factor $\varepsilon(p)$ and (b) the compartment cost C_0 per m² and the failure probability for different fire load densities. The cost of steel is set to \$2.89/kg and the reference cost of the compartment is \$1500/m².

The quantification of the relative cost of structural failure, ξ , in Table 2 is challenging because it depends on the extent of damage, which varies widely. The damage resulting from the failure of a slab exposed to fire, for example, can be limited to the compartment itself and its contents, but could also induce progressive collapse of an entire building. In the first scenario, the relative cost of structural failure would be several times (e.g., 2 or 3, considering the entire compartment would be lost, i.e., $\xi=1$, together with its contents (FEMA, 2015) the structural cost of the compartment, C_0 , while in the second scenario, the damage can be orders of magnitude larger than C_0 .

In order to find a representative relative cost of structural failure, the probability of different scenarios should be considered. In most cases, the damage due to failure of a slab will be limited to the compartment for which the slab fails. The probability of progressive collapse after failure of a slab is significantly lower. Consequently, a representative value for ζ is assumed to be primarily dominated by damage limited to the compartment for which the slab fails, with a slight adjustment to a higher value to account for low-probability scenarios with large consequences. Therefore, the reference value for the relative cost of structural failure is set to 4, which is in line with the values obtained for reference cases in Table 3. For comparison purposes, a value of 6.9 is listed for office buildings in earthquake scenarios (Kanda and Shah, 1997).

3.3 Optimum reliability and sensitivity analysis

The lifetime cost-minimization expression in Equation 5 is a function of multiple economic parameters (i.e., $\varepsilon(p)$, ω , γ , λ and ζ). In the sections below, these parameters are split into two groups, i.e., factors influencing the investment cost and factors influencing the failure cost. The discount rate, γ , influences both investment and failure costs and will be discussed separately.

The result of the lifetime cost-minimization is an optimum value for the axis distance of the rebars from the exposed surface of the slab. From this optimum axis distance, an optimum value for the failure probability can be determined. This optimum failure probability can be converted into an optimum reliability level as follows:

$$\beta = -\Phi^{-1}(P_f) \tag{7}$$

where β is the reliability level and Φ is the standard normal cumulative density function.

The investment cost is affected by the investment cost factor, $\varepsilon(p)$, and the obsolescence rate, ω . The obsolescence rate is constant and can readily be varied. A sensitivity study of the investment cost will be achieved by altering the cost of steel with a multiplicative factor (the ‘steel cost increase factor’). Note that this cost of steel will typically have only a very limited effect on the initial cost of the compartment, C_0 (see Figure 1b). Therefore, C_0 will be treated as constant. The resulting influence of variations in steel cost and obsolescence rate can be found in Figures 2a and 2b respectively.

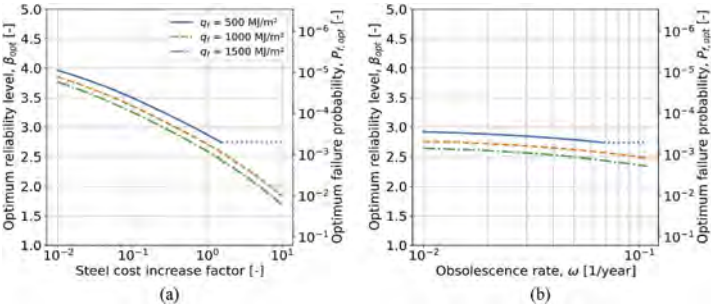

Figure 2. Influence of (a) increase in steel cost and (b) obsolescence rate on the optimum reliability level. Horizontal dotted lines mark cases with optimum axis distance outside the treated range 12 mm to 80 mm.

Both an increase in obsolescence rate and steel cost will lead to an increase in lifetime cost (Equation 5). As a result, the optimum axis distance for the rebars will be lower, which will result in a higher optimum failure probability and thus lower optimum reliability level. This behavior is also exhibited in Figures 2a and 2b. Furthermore, it can be observed that the influence of the obsolescence rate is limited compared to the influence of the steel cost.

The present net value of the structural failure cost over the lifetime of the structure depends inter alia on the consequences of failure, indicated by the relative cost of structural failure, ζ , and the annual probability of fire occurrence, λ . An increase of one of these parameters (or both) will cause an increase in lifetime cost. Further, Equation 5 indicates that ζ and λ are simply multiplying factors for the cost of structural failure. Therefore, variations in one parameter can be directly translated into an equivalent change in the other parameter, resulting in the same expected annual failure cost and thus leading to the same optimum reliability level.

Figure 3a visualizes the influence of the multiplication of the relative cost of structural failure, ζ , and the probability of fire occurrence, λ , on the optimum reliability levels. When the consequences of failure or probability of fire occurrence are low, a small value for the optimum reliability level is obtained. In these cases, it is not economic to strongly invest in additional safety as the expected cost of structural failure is low. Therefore, the optimum axis distance will be low, resulting in a higher failure probability and a lower optimum reliability level.

The discount rate, γ , influences both the investment cost and failure cost. Figure 3b demonstrates how the optimum value for the reliability level varies with the discount rate. In general, the influence of the discount rate on the optimum reliability level is limited compared to the steel cost and the factors influencing the failure cost.

Figure 3. Effect of (a) relative cost of structural failure ζ and probability of fire occurrence λ and (b) discount rate on the optimum reliability level. For (a), the dotted horizontal lines indicate cases for which the optimum axis distance is outside the optimization range.

4 OPTIMUM RELIABILITY LEVELS FOR COMMON TYPES OF STRUCTURES

A majority of the parameters used in the cost-minimization in Equation 5 are case-dependent. The relative cost of structural failure, for example, will be higher if the contents of the building are more valuable. Also, the probability of fire occurrence will differ. To guide the specification of target reliability levels, the optimum reliability level for 3 common types of structures will be determined: a single-family dwelling; a governmental office; and a commercial office. The natural fire exposure is represented by the Eurocode parametric fire curve with fire load densities according to Annex E of EN 1991-1-2:2002 and the opening factor equal to $0.04 \text{ m}^{1/2}$. The values of the fire load density are specified in Table 3.

Table 3. Realistic estimations of economic parameters for common types of structures.

Type of structure	Average structure cost (Gordian, 2022)	Fire probability λ (Manes and Rush, 2019)	Fire load density q_f (CEN, 2002)	Relative cost of structural failure ζ *
Single-family dwelling	1,305.5 USD/m ²	0.00151	780 MJ/m ²	2.6
Governmental office	3,903 USD/m ²	0.002	420 MJ/m ²	3.25
Commercial office	1,674.43 USD/m ²	0.00423	420 MJ/m ²	3.25

* Sum of content loss factor (FEMA, 2015) and indirect loss factor (Ramachandran and Hall Jr, 2002).

The relative cost of structural failure is highly dependent on the extent of failure. As a simply supported slab and compartment fire are considered, the cost of the structure and investment cost are for a single compartment only, while the extent of failure can reach beyond the compartment

boundaries. In the most severe cases, the failure of the slab can result in progressive collapse of the entire structure. The values of ζ provided in Table 3 are reference values, but can differ significantly from case to case. They consist of a content loss factor, including the loss of property and content, and an indirect loss factor, considering, e.g., cost of injuries and deaths, business interruption etc. An overview of how the optimum reliability level changes as a function of ζ for the types of structure in Table 3, can be found in Figure 4. Based on the reference values for ζ in Table 3, optimum reliabilities are derived. For a single-family dwelling, governmental office and commercial office, the optimum reliability indices are 2.59, 3.19 and 3.16 respectively.

In order to verify whether the calculated optimum reliabilities can be considered generally applicable for these types of buildings and can thus be recommended as target reliabilities, a sensitivity analysis is performed for the relative cost of structural failure, ζ . The influence of variations in fire probability, cost of the structure and relative cost of structural failure are the same (meaning that a doubling of the fire probability has the same effect as a doubling of the relative failure cost). Therefore, of these parameters only the relative cost of structural failure, ζ , is considered below. The obsolescence rate and discount rate are not considered as the previous results have already indicated the insensitivity of the optimum reliability level for variations in these parameters.

The results, provided in Table 4, indicate that the obtained target reliability levels are relatively insensitive to changes in the relative cost of structural failure. These results suggest that a target reliability index of approximately 3.2 could be recommended for non-residential buildings (governmental office, commercial office), while for residential buildings a lower target reliability index of 2.6 could be recommended on cost-optimization grounds.

Figure 4. Target reliabilities for different buildings types as function of the expected relative cost of structural failure ($\omega = 0.022$; $\gamma = 0.03$). Lines for governmental and commercial offices approximately coincide.

Table 4. Sensitivity analysis for calculated target reliabilities based on a 10% increase of ζ .

Type of structure	Percentage change optimum reliability level
Single-family dwelling	1.20%
Governmental office	0.82%
Commercial office	0.81%

5 CONCLUSIONS

The influence of economic parameters on the optimum reliability level in fire has been determined using an explicit cost-benefit analysis. This analysis was based on the reference case of a reinforced concrete slab exposed to natural fire. It was found that the cost of additional fire protection, the probability of fire occurrence and the relative cost of structural failure have a significant influence on the optimum reliability level, whereas the influence of the obsolescence rate and discount rate are limited.

Based on reference values for the economic parameters, the optimum reliability level has been determined for common types of structures. First, the optimum reliability index was presented as a function of the relative cost of structural failure, because the extent of damage due to structural failure significantly influences this optimum reliability index. Based on reference values for these

relative costs of structural failure, the target reliability indices have been determined to be 2.59, 3.19 and 3.16 for a single-family dwelling, governmental office and commercial office respectively. The results of the sensitivity analysis indicate that these values are insensitive to changes in input parameters. Except for situations where the expected consequences are significantly higher than normally expected from structural failure due to fire exposure, these values can be considered as a basis for defining target reliabilities for structural fire engineering. Thus, a target reliability index of 3.2 is put forward for the structural fire design of non-residential buildings (office), while a target reliability index of 2.6 is put forward for residential buildings. These target reliabilities were derived from a case study of a simply supported reinforced concrete slab. Further case studies are recommended before adoption in guidance documents.

Sensitivity of the seismic response to the modelling variables defining constitutive models of reinforced concrete frames

G. Karaki

Department of Engineering Design and Mathematics, University of the West England Bristol, UK

ABSTRACT: Probabilistic performance-based methods are well integrated into earthquake engineering applications. Therefore, the seismic response uncertainty and its sources must be adequately characterized for a more reliable seismic assessment. The paper examines the sensitivity of the RC frames response to the variables defining the constitutive models and their uncertainties. Floor displacements, floor accelerations, and section curvature were used in the sensitivity analysis, and the effect of the input variables defining the nonlinear material behavior on seismic response was investigated. The approach's algorithm was applied to a reinforced concrete moment-resisting frame. It was found that the variables defining the constitutive models; compressive strength of concrete, yield strength of steel, ratio of confined concrete strength to unconfined strength, variable that influences the shape of transition steel material curve, and modulus of elasticity of steel had a significant influence when considering inelastic behavior. This pattern was more evident for the curvature.

1 INTRODUCTION

The probabilistic performance methods have been intensively integrated into earthquake engineering applications. Many publications document probabilistic performance methodologies and their implementation for a broad representation of structural types and configurations, e.g. fib 2012, Ghosh et al. 2017, Karaki 2018, and Li et al. 2019, among others. Furthermore, the influence of the uncertainty of the input variables on the seismic response has also been investigated, and adequate characterization of output uncertainty to assess the reliability of the seismic response and design has been performed (e.g. Saha et al. 2016). Therefore, it is of essential importance to identify the main variables that contribute the most to the uncertainty of the seismic response. Sensitivity analysis is used to quantify the effects of inputs uncertainty on the output of interest. Many studies addressed the application of sensitivity analysis in earthquake engineering. However, the focus is given to the ones that included the uncertainty of material properties in their examination. Lee and Mosalam (2005) performed a sensitivity analysis and studied the uncertainty of global structural response, i.e., peak roof acceleration and displacement and maximum inter-story drift ratio, and local structural responses, i.e., curvature demand at critical sections. The material properties considered in this study were compressive strength of concrete, yield strength of steel, and moduli of elasticity E_c and E_s of concrete and steel, respectively. Kim and Han (2013) investigated design variables' influence on the seismic response of staggered wall structures. They used tornado diagrams and first-order second-moment method to determine the sensitivity and reliability measures. The yield strength of steel and ultimate strength of concrete were the considered variables defining the material behavior. Furthermore, the fragility curves to assess the seismic risk and loss estimation have been used as an objective function for the uncertainty and sensitivity analysis. For example, Padgett and DesRoches (2007) examined the sensitivity of seismic response and fragility to input variables uncertainty. They reported that preliminary screening of modeling variables might achieve savings in the simulation and computational effort in

fragility estimation. Other studies considered loss and risk functions as their objective function for the uncertainty and sensitivity analysis, e.g., Gokkaya et al. (2016) quantified the modeling uncertainty of ductile and non-ductile reinforced concrete buildings using Monte Carlo simulations. The influence of the uncertainty of the variables was evaluated for fragility functions, mean annual rates for drift limits and collapse, and the values of drift demands. The inclusion of the modeling uncertainty (input variables uncertainty) increased the mean annual frequency of collapse and drift ratios, affecting the buildings' seismic performance assessment. Celarec and Dolšek (2013) studied the impact of modeling uncertainties on seismic performance assessment of reinforced concrete frame buildings. The authors concluded that explicit consideration of epistemic uncertainties in the assessment of structural performance could lead to more accurate results and a more reliable assessment of seismic risk.

Only a few uncertainty and sensitivity studies have considered the nonlinear material properties in their analysis. For example, Celarec et al. (2012) studied the sensitivity of the seismic response to uncertain variables of masonry-infilled reinforced concrete frames; among the considered variables were the concrete and steel strengths, the infill material properties, and the plastic hinge properties. Heo & Kunnath (2009) examined the sensitivity of the seismic response to constitutive models used in the nonlinear analysis of reinforced concrete frame systems. Barbato et al. (2014) investigated the uncertainty of the seismic response due to the variability of input variables defining the material nonlinearity of steel and concrete.

In this study, a methodology to perform a sensitivity analysis to measure the effect of input variables defining nonlinear material behaviour on the maximum temporal responses was developed. In this examination, we aim to investigate the effect of the variables defining constitutive models on the uncertainty of seismic responses. The methodology allows essential screening of the input variables in a time-efficient manner. The output of the screening process may justify more experimental work or simplifications in the models used in the assessment or design frameworks.

2 METHODS

2.1 Sensitivity analysis

There are many methods to conduct sensitivity analysis; one way to categorize them is local and global methods. Local sensitivity analysis also known as one-at-time (OTA) is performed by keeping all input variables fixed and varying one input variable and examining the effect of this variation on the output. Global sensitivity analysis (GSA) examines the variation of all input variables on the output (all-at-a-time). GSA uses a probabilistic framework, therefore, it is often a computationally expensive method. A group of GSA methods, the so-called Morris screening method, can be described as an enhanced OTA method. The screening method mainly ranks input variables by their importance in descending order using only a relatively small number of model evaluations. Morris screening was used in this study.

2.2 Morris screening method

Screening methods, also known as elementary effects methods, belong to the One-at-Time (OAT) design class. These methods are attractive as they are computationally inexpensive and ideal for models with many input variables. Morris method overcomes the shortcomings of a typical local sensitivity method, running multiple OTA for the variable to explore all possible variations covering its feasible range. The average response of these multiple OTA is a measure of the sensitivity index (Saltelli et al. 2008). Therefore, screening methods can be considered as examples of global sensitivity analysis. In this study, we adapted the elementary effects method to perform the sensitivity analysis. The main algorithm of the method was retrieved from Morris (1991).

The input variable $X = (X_1, X_2, \dots, X_k)$ is any selected value in p-level Ω with a transformed point $X + e_i \Delta$, in which p is number of selected levels, Ω is the possible space of the input

variables, and Δ is the relative distance in the coordinate X_i . The elementary effect of the i^{th} input variable is defined as

$$EE_i = \frac{Y(X_1, X_2, \dots, X_i + \Delta, \dots, X_k) - Y(X_1, X_2, \dots, X_k)}{\Delta} \quad (1)$$

The distribution of elementary effects associated with the i^{th} input variables is obtained by randomly sampling \mathbf{X} from Ω and is denoted F_i , i.e., $EE_i \rightarrow F_i$.

Morris (1991) proposed two sensitivity measures; the mean value (μ) of F_i , which captures the overall influence of the i^{th} variable and the standard deviation (σ) of F_i , which estimates the nonlinear effects between the variables (Saltelli et al., 2008).

However, in the case of more complex models, Campolongo et al. (2007) proposed using the corrected average μ^* , which considers the absolute EE_i in the calculations of μ^* . Such a modification prevents the canceling of variable influence if opposite signs exist in EE_i values.

$$EE_i^* = \left| \frac{Y(X_1, X_2, \dots, X_i + \Delta, \dots, X_k) - Y(X_1, X_2, \dots, X_k)}{\Delta} \right| \quad (2)$$

To estimate these sensitivity measures μ^* and σ , the elementary effects method consists of sampling a number r of elementary effects. Therefore, the implementation algorithm for the sampling procedure of elementary effects method consists of creating r trajectories of $(k+1)$ points from the input space.

The randomized sampling matrix \mathbf{B}^* is built as follows:

$$\mathbf{B}^* = \left(\mathbf{J}_{\{k+1,1\}} \mathbf{P}^* + \left(\frac{\Delta}{2} \right) [(2\mathbf{B} - \mathbf{J}_{\{k+1,1\}}) \mathbf{D}^* + \mathbf{J}_{\{k+1,k\}}] \right) \mathbf{M}^* \quad (3)$$

in which \mathbf{B} is a $(k+1) \cdot k$ matrix with elements that are 0s and 1s such that for every column two rows of \mathbf{B} differ in only one element (a convenient choice is a strictly lower triangular matrix of 1s), $\mathbf{J}_{\{k+1,1\}}$ is a $(k+1) \cdot k$ matrix of 1s, \mathbf{D}^* is a k diagonal matrix with elements either +1 or -1 with equal probability and \mathbf{M}^* is a $(k \cdot k)$ random permutation matrix in which each column contains one element equal to 1 and all others equal to 0 and no two columns have 1s in the same position (Saltelli et al., 2008). Simulations are required to calculate screening measures $r \cdot (k+1)$. An important point when implementing the elementary effects method is the value of Δ . It must always represent a sampling step in the range of $[0, 1]$. In the case of non-uniform distribution and different scales of input variables, Δ should represent the variation in the quantiles for the variables, and the inverse of the cumulative distribution function is used to retrieve the values of the variables from their distribution functions.

2.3 Implementation process

MATLAB code (MATLAB, 2014a) is responsible for generating random samples of input variables, creating and exporting the ground motion records following a seismic hazard level to OpenSees, processing the output of analysis from OpenSees, and determining the sensitivity measures defined in the earlier sections. The numerical model in OpenSees includes the definition of the structure's geometry, nonlinear constitutive models, the structure's elements and their connectivity, boundary constraints, and analysis variables and types. The computational cost of the proposed sensitivity algorithm is the time required to run $m \cdot (r \cdot (k+1))$, in which m is the number of examined ground motion records, r is the number of sample trajectories, and k is the number of input variables. The implementation of the methodology is computationally efficient as r and k are taken below 50; this gives the approach a competitive advantage over other methods.

3 CONSTITUTIVE MODELLING

3.1 Constitutive modeling of concrete

The stress–strain curve of concrete in compression, confined or unconfined, starts with an ascending curve up to the maximum compressive strength followed by a descending line up to the residual strength, as displayed in Figure 1. The equation defining the ascending curve of the stress–strain curve was proposed by Sargin (Sargin, 1971):

$$\frac{f'_c}{f'_{co}} = \frac{A\varepsilon_c/\varepsilon_{co} + (D - 1)(\varepsilon_c/\varepsilon_{co})^2}{1.0 + (A - 2)(\varepsilon_c/\varepsilon_{co}) + D(\varepsilon_c/\varepsilon_{co})^2} \quad (4)$$

in which f'_c and ε_c are the strength and corresponding strain of the concrete, respectively, and f'_{co} and ε_{co} are the corresponding unconfined maximum strength and corresponding strain, respectively. Factors A and D depend on materials used to produce the concrete. For the purpose of this study, a similar form of the stress–strain curve was used for both unconfined and confined concrete. The constitutive model is available in OpenSees.

Figure 1. The constitutive model of concrete.

Confined models for concrete: the effect of confining reinforcement is generally modelled as a strength enhancement using a magnifying factor to f_{co} . A widely used model for predicting the strength of confined concrete was proposed by (Mander et al. 1988) and is expressed by the following equation:

$$\frac{f'_{cc}}{f'_{co}} = 2.254 \sqrt{1 + 7.94 \frac{f_L}{f'_{co}}} - 2 \frac{f_L}{f'_{co}} - 1.254 \quad (5)$$

in which f_L is the effective lateral confining pressure. The model of strength enhancement has been considered to account for the confined concrete in this study.

3.2 Constitutive modelling of steel

There are a limited number of models for the constitutive laws of the reinforcing bars; the one used in this investigation is a smoothed bilinear model with isotropic hardening, referred to as Steel02 in OpenSees (Figure 2). The model exhibits linear behaviour with an initial elastic modulus E_s up to yield stress f_y , followed by a strain hardening branch with a slope of $b \cdot E_s$. The transition curve between the curves branches asymptotes is governed by the parameter R_0 , which represents the Bauschinger effect (Menegotto and Pinto 1973).

3.3 Probabilistic models for material properties

The probabilistic models used in the sensitivity analysis are presented which some are adopted from the literature and others are assumed due to the lack of statistical studies. Table 1

documents the variables that define the probabilistic model of the material input variables. A correlation was assumed between the compressive strength (f_c) and the modulus of elasticity (E_c). The assumed correlation coefficient was 0.8 (Lee and Mosalam 2005). The modal damping ratio (ζ) of the frame system is taken as a random variable with a nominal value of 5% and COV of 40% (Lee and Mosalam 2005).

Figure 2. The constitutive model of steel.

4 NUMERICAL ANALYSIS & RESULTS

The developed algorithm was applied for a reinforced concrete frame system. The frame is a three-story three-bay frame with a column height of four meters and a beam span of seven meters. The frame's geometry and its reinforcement details are presented in Figure 3. The frame was taken from a building designed following the capacity design requirements following the seismic design regulations of the 90's, which was moderately new. The construction in that period lacked strict quality assurance protocols regarding building material testing. Therefore, uncertainty in the material behaviour is expected for such buildings, especially its nonlinear behaviour, and this uncertainty needs to be assessed and quantified.

Table 1. Variables defining the probabilistic model of input variables of constitutive models.

Variable	Probabilistic Model Description	Reference
Compressive strength (f_c)	Concrete grade C25 $F_{co} = \exp(m'' + tvs''(1+1/n'')^{0.5})$	JCSS
Modulus of elasticity (E_c)	Write the equation for the distribution	JCSS
Ratio of confined to unconfined concrete (k_{cf})	Normal Distribution, mean=1.3 COV=0.19	—
Ratio of residual to ultimate maximum stress (k_{res})	Normal Distribution, mean=0.2 COV=0.2	—
Concrete Ultimate strain (ϵ_{ult})	Lognormal Distribution, mean =0.37% COV=0.21	Baji 2014
Yield strength (f_y)	Normal Distribution, mean=420MPa COV=0.05	Nowak and Szerszen 2003
Modulus of elasticity (E_s)	Normal Distribution, mean=202GPa COV=0.04	Wisniewski 2012
(R_0) variable that influences the shape of transition curve	Normal Distribution, mean=15, COV=0.20	—
Strain hardening ratio (b)	Normal Distribution, mean= 0.15 COV=20%	—

The numerical model of the frame system, a two-dimensional idealization, was developed using the modelling capabilities of the software OpenSees. The frame's beams and columns were modeled using Force-Based Beam-Column Element with fibers representing concrete cover, concrete core, and reinforcement layers. The beam-column element has two transitional and

one rotational degree-of-freedom at the end nodes, and it has five monitoring cross-sections with fiber element discretization. As described above, Concrete02 (linear tension softening) was used for concrete and Steel02 (Menegotto-Pinto model with isotropic strain hardening) was used for reinforcing bars. The mass of the building was modelled using lumped masses at the nodes; the source of the nodal masses was the total dead load. The Newmark b-method was used as the time integrator with typical coefficients $\gamma=0.50$ and $\beta=0.25$. The time integration algorithm of nonlinear time history analysis (NLTH) uses a time step of half the time discretization of the generated ground motions. Furthermore, the solution algorithm of NLTH uses a modified Newton–Raphson solution algorithm that updates the stiffness matrix at the beginning of each time step. Newton with line search algorithm and Boyden algorithms were used in failing convergence in the given order. The sensitivity analysis examined the effect of input variables on the dynamic response considering two seismic hazard levels following ASCE 7-16; BSE-1E seismic event (50% exceedance in 50 years) and BSE-2N (10% exceedance in 50 years).

Figure 3. The details of the reinforced concrete frame used in the numerical simulation.

For the sensitivity analysis, the samples of the input variables were created taking $p=6$, $\Delta = 0.167$ and $r=50$. The elementary effects EE_i of the examined variables were determined for the maximum values of temporal responses. The examined input variables were: the compressive strength of concrete (f_c), the modulus of elasticity for concrete (E_c), ratio of confined to unconfined concrete (k_{cf}), ratio of residual to ultimate maximum stress for concrete (k_{res}), ultimate strain at concrete crushing (ϵ_{ult}), yield strength of steel (f_y), modulus of elasticity for steel (E_s), (R_0) variable that influences the shape of transition curve and takes into account the Bauschinger effect during first loading, the strain hardening ratio (b), and damping ratio (ζ). The EE_i 's were calculated r times, and the corrected average value (μ^*) for EE_i was calculated to rank the variable's influence on the examined output. The symbol μ is used instead of μ^* for convenience in discussing the results.

Figure 4. Screening measures considering the global responses considering for BSE-1E events.

The same procedure was repeated $m=25$ times for different sets of random ground motion records to assess the confidence of the identified rank for the input variables. The sensitivity measures were normalized to compare the results of the different responses. Furthermore, to check the consistency of the ranking of the input variables when considering different sets of

ground motion records, the sensitivity measures (μ) were calculated $m=25$ times. The median (M) of the (m) sensitivity measure (μ) was calculated and used for the final ranking of the variable's influence on the response maximum value.

The median values (M) of μ and their upper and lower values considering global responses; roof displacement and acceleration, are shown in Figure 4 and Figure 5. For the BSE-1E event, variables are classified into three groups based on their influence on the global response, high influence; f_c , ζ , intermediate influence; E_s , k_{cf} , f_y , E_c , and low influence; R_0 , b , k_{res} , ϵ_{ult} . Furthermore, the variation of sensitivity measures indicates that the ranking of the input variables of strong influence was more sensitive to record-to-record variability. For the BSE-2N event, variables were of three groups in their influence on the response, strong influence; ζ , f_c , R_0 , f_y , E_s , intermediate influence; k_{cf} , E_c , and low influence; b , k_{res} , ϵ_{ult} .

Figure 5. Screening measures considering the global responses considering for BSE-2N.

The median (M) values of sensitivity measure (μ) and their upper and lower values for the input variables considering the local response, curvature, are shown in Figure 6. For the BSE-1E event, variables groups of influence on the response were: strong influence; f_c , ζ , and intermediate influence; E_s , k_{cf} , f_y , E_c . This finding is even clearer for the seismic event BSE-2N as the variables f_c , ζ , R_0 , f_y , k_{cf} are of high ranks of influence on the response. The impact of constitutive model and its uncertainties is higher on local responses when compared with the global ones.

Figure 6. Screening measures considering the local responses.

5 CONCLUSIONS

The elementary effects method was adapted to rank the influence of the input variables, especially the variables that define the nonlinear constitutive models of concrete and steel. The elementary effects were determined for the maximum structural responses local and global. The method's algorithm was applied to a reinforced concrete moment-resisting frame considering two seismic events; the responses examined were the structure's displacement, acceleration, and curvature of the frame's section. It was found that the variables defining the constitutive models, f_y , E_s , f_c , R_0 and k_{cf} were significantly influential when considering stronger seismic events as inelastic behavior is expected. The input variables defining the material nonlinearities that indicate hysteresis damping has an impact as the viscous damping on the maximum response.

Effect of concrete age on the reliability of existing reinforced concrete columns

L.C.R. Castro

ISQ, Belo Horizonte, Brazil

S.M.C. Diniz

Federal University of Minas Gerais, Belo Horizonte, Brazil

ABSTRACT: Condition assessment of existing reinforced concrete (RC) structures has been a major issue. Nevertheless, analysis of existing structures requires a distinct approach as compared to design of new ones, with particular emphasis on the selection of the target reliability index. When comparing reliability levels of new RC structures and existing ones, it must be considered that the analysis corresponds to two different times. In the design of new structures, there is an unaccounted extra safety margin due to concrete strength gain with age. The research presented herein evaluates the reliability of existing RC columns based on the same time reference. To this end, an equivalent 28-day concrete strength is obtained from the one associated to the existing structure. Probabilities of failure are computed by Monte Carlo simulation and the effects of different parameters are investigated. The results indicate that the effect of concrete gain with age should not be overlooked.

1 INTRODUCTION

Concrete is the most used construction material in the world; its production and utilization are responsible to 5 – 10 % of the global production of CO₂. Moreover, concrete production and utilization involve large resources consumption and waste generation. As such, life-cycle extension of existing RC structures and infrastructures is a major issue, and, consequently, adequate tools for condition assessment of existing RC structures are needed.

Different reports and initiatives (e.g. ACI 562; ASCE 2021) have corroborated the need for extension of the life cycle of structures and infrastructures. For instance, according to the 2021 ASCE Report Card for America’s Infrastructure (ASCE 2021), in 2021, 7.5 % of the US bridge inventory were rated “*structurally deficient*” (46,154 out of 617,000); 42% of all bridges are at least 50 years old. It is estimated that 178 million trips are taken across these structurally deficient bridges every day.

One of the key tasks in the decision making process over strengthening/ retrofitting or demolishing an existing structure or infrastructure is its condition assessment and checking against expected performance rules, usually established in technical codes (Badimuena & Diniz 2018).

From the perspective of the treatment of uncertainties, the problem of performance evaluation of existing RC structures and infrastructures is quite distinct from design of new ones (Melchers 2001). Design codes for new structures deal with uncertainties related to design and construction process; on the other hand, there is a change in the nature of such uncertainties, from inherent to epistemic, for a number of the variables involved in the performance of the existing RC structure.

Design of new reinforced concrete (RC) structures/ components is based on semi-probabilistic approaches. An important concept in the semi-probabilistic design format is the target reliability index, β_T , used in the calibration of a given design code (Diniz 2008). In the assessment of existing structures, there is no consensus on the target reliability index to be used. However, different

aspects - economic, social and sustainability - point to the need to accept lower reliability indexes than those taken as reference for new structures (Diamantidis *et al.* 2012).

In the development of procedures for the condition assessment of existing RC structures, it is important to define the target reliability index to be used in this context. This is a complex issue and very different understandings exist on this topic. For instance, Steenbergen *et al.* (2015) point out that the requirements for the same target reliability for existing and new structures is uneconomical. Similarly, ISO 13822 (ISO 2010) suggests that lower target reliability levels for existing structures may be used if they can be justified on the basis of socio-economic criteria. On the other hand, Wang & Ellingwood (2015), in the context of bridge engineering, state that rehabilitated bridges should have comparable reliability to new bridges.

There is still another issue related to the reliability of existing RC structures that has not received proper attention. When comparing reliability levels of new RC structures and existing ones, it must be taken into account that the analysis corresponds to two different times. Along the life cycle of the structure, concrete is affected by two different phenomena: (i) strength gain with age, and (ii) strength loss due to sustained loads (Diniz 2005; Diniz & Frangopol 2003). In the design of new structures, there is an unaccounted extra safety margin due to concrete strength gain with age. Therefore, a rational comparison between the safety levels associated to new and existing RC structures shall be based on the same time reference.

In this research, reliability levels associated with short, axially-loaded, existing RC columns are evaluated. The scope of the research presented in Badimuena & Diniz (2018) is enlarged by including the effect of concrete age on the concrete compressive strength used in the analysis. The influence of different parameters (number of cores, concrete compressive strength and attendant coefficient of variation, strength gain with age, dead-to-live-load ratio, and longitudinal reinforcement ratio) on the resulting reliability levels is discussed.

2 DETAILS OF THE SELECTED COLUMNS

The selected columns have been defined and analyzed according to the requirements of ACI 562 (2016) for minimum reinforcement and minimum cross-sectional dimensions. They correspond to square cross-sections (30 x 30 cm²) and three mean concrete compressive strengths ($f_{cm} = 15, 30,$ and 50 MPa), defining column series P1, P2, and P3, respectively.

It was assumed that the information on the concrete strength comes from extracted cores; the number of samples, n , taken as 3 and 8. The former value is the minimum number of cores recommended by ACI 562. The coefficient of variation (COV) of concrete (cores strength) is assumed as 5, 10, and 15 %. As a reference, 10 % is the value of the COV that has been used in the calibration of ACI 318, i.e. in the design of new structures.

With respect to the concrete strength gain with age, as related to the 28-day strength, three different assumptions were made: (i) no gain, meaning that this effect would be disregarded; (ii) 30% increase; and (iii) 18.5% increase (designated as I, II, and III, respectively). The values of 30% and 18.5% increase in concrete compressive strengths are suggested by Mehta and Monteiro (2006) when comparing 5-yr to 28-day strengths.

Three longitudinal steel ratios ($\rho_l = 1, 2,$ and 4 %) are considered. The characteristic steel yield strength is taken as 500 MPa for all columns. Details of the selected columns are presented in Table 1. In each column series, three dead-to-live-load ratios are assumed: 0.5, 1.0, and 2.0 resulting in 486 axially-loaded RC columns.

3 STRUCTURAL RELIABILITY BASICS

The basic problem of structural reliability may be cast as a supply versus demand problem, i.e. to ascertain that the supply (e.g. column capacity), X , is larger than the demand (e.g. load effects), Y , throughout a reference period (e.g. the newly defined service life of the existing structure), represented by ($X > Y$). Considering the uncertainties associated to these variables, this assurance is possible only in terms of the probability $P(X > Y)$, thus providing a metric of the reliability of the structural component (Ang & Tang 1984).

Table 1. Summary of the selected columns.

Series	COV (%)	n	ρ_I (%)	r	Type	
P1, P2, P3 $f_{cm} = 15, 30, 50$ MPa	5	3	1	0.5, 1, 2	I, II, III	
			2	0.5, 1, 2	I, II, III	
			4	0.5, 1, 2	I, II, III	
		8	1	0.5, 1, 2	I, II, III	
			2	0.5, 1, 2	I, II, III	
			4	0.5, 1, 2	I, II, III	
		10	3	1	0.5, 1, 2	I, II, III
				2	0.5, 1, 2	I, II, III
				4	0.5, 1, 2	I, II, III
	8		1	0.5, 1, 2	I, II, III	
			2	0.5, 1, 2	I, II, III	
			4	0.5, 1, 2	I, II, III	
	15	3	1	0.5, 1, 2	I, II, III	
			2	0.5, 1, 2	I, II, III	
			4	0.5, 1, 2	I, II, III	
8		1	0.5, 1, 2	I, II, III		
		2	0.5, 1, 2	I, II, III		
		4	0.5, 1, 2	I, II, III		

The supply-demand problem may be formulated in terms of the margin of safety, $M = X - Y$. Since X and Y are random variables, M is also a random variable with probability density function, $f_M(m)$. Failure is associated to the condition ($M < 0$); if the probability distribution of M is known, the corresponding probability of failure, P_f , may be computed by:

$$P_F = \int_{-\infty}^0 f_M(m) dm = F_M(0) \tag{1}$$

where $F_M(\cdot)$ is the cumulative distribution function of the variable M . Graphically, this probability is represented by the area below zero under the curve $f_M(m)$.

For statistically independent random variables X and Y , represented by Normal distributions, i.e., $N(\mu_X, \sigma_X)$ and $N(\mu_Y, \sigma_Y)$, respectively, the margin of safety M is also a Normal random variable, $N(\mu_M, \sigma_M)$. The notation $N(\mu, \sigma)$ represents a Normal variable with mean μ and standard deviation σ . In this case, the probability of failure is given by:

$$P_F = F_M(0) = \Phi\left(\frac{-\mu_M}{\sigma_M}\right) = 1 - \Phi\left(\frac{\mu_M}{\sigma_M}\right) = \Phi(-\beta) \tag{2}$$

where Φ is the standard Normal cumulative distribution function, and the probability of non-failure, P_S , is:

$$P_S = 1 - P_F = \Phi\left(\frac{\mu_M}{\sigma_M}\right) = \Phi(\beta) \tag{3}$$

From Eq. (3) it is seen that reliability is a function of the ratio μ_M/σ_M , which is the margin of safety expressed in units of σ_M and is known as “reliability index” and denoted by β . In this specific case (linear performance function and Normal variables), the reliability index can be computed based solely on the information on the means and the standard deviations of the basic variables pertaining to the problem (Ghosn *et al.* 2016). For nonlinear performance functions and/or non-Normal variables, other methods such as FORM or Monte Carlo simulation shall be used (Ang & Tang 1984).

4 PERFORMANCE FUNCTION

The ultimate limit state function for short, axially-loaded RC columns is given by:

$$M = [\alpha_c F_c (A_g - A_s) + F_y A_s] E_M - (G + Q) \quad (4)$$

In the above equation, M is the margin of safety, and the random variables F_c is the 28-day equivalent concrete compressive strength, A_g is the area of the gross cross-section, F_y is the steel yield strength, G and Q are the dead and live loads acting on the column, respectively, and E_M is the model error associated to the estimation of column resistance. The area of longitudinal steel, A_s , is taken as deterministic; the deterministic parameter α_c is taken as a function of the concrete grade. It should be noted that, according to the goals of the research reported herein, the random variable F_c incorporates the effects of the concrete strength gain with age and the action of sustained loads on concrete compressive strengths. This topic will be discussed in the following section.

5 STATISTICS OF THE BASIC VARIABLES

The statistics of the basic variables, to be used in the Monte Carlo simulation procedure for the safety assessment of existing RC columns, are discussed in this section. As a full-probabilistic approach, Monte Carlo simulation requires the complete description of all random variables in the attendant performance function, Eq. (4).

The procedure used in the definition of the statistics of the load effects (mean dead load, μ_G , and mean live load, μ_Q) is summarized in Badimuena and Diniz (2018). For each selected column, design loads, S_d , from which the statistics of the acting loads may be derived, are obtained by assuming $S_d = R_d$, i.e. design loads are equal to design column resistance (Diniz & Frangopol 1997).

In the calculation of the design column resistance, R_d , according to ACI 362 (2016), the value of the equivalent specified compressive strength, f'_{ceq} , is required. The equivalent specified compressive strength is given by:

$$f'_{ceq} = 0.9f_{cm} \left[1 - 1.28 \sqrt{\frac{(k_c V)^2}{n} + 0.0015} \right] \quad (5)$$

where f_{cm} is the mean resistance of cores (after adjustments for size effects and humidity), V is the coefficient of variation of the cores strength, n is the number of cores used in the estimation of f_{cm} , and k_c is a modification factor for the coefficient of variation of the cores strength that depends on the number of cores (assumed as $n = 3$ and 8 in this study).

For each column, based on the corresponding design loads, S_d , the assumed load ratio r ($r = \mu_G/\mu_Q$), and the information presented in Galambos *et al.* (1982) for the dead load, G , and the live load, Q , then the complete statistics (mean, COV, and type of distribution) of G and Q are defined. In this study, the following values are assumed for the ratio r : 0.5, 1.0, and 2.0.

Regarding the statistics of the variables related to column resistance, special attention was given to those associated to the *in situ* concrete compressive strength. A discussion on the statistics to be used in the description of the *in situ* concrete compressive strength as given by concrete cores extracted from the existing RC structure is presented in Castro & Diniz (2020).

A summary of the statistics of the basic variables related to the corresponding performance function (Eq. 4) is displayed in Table 2.

In this paper, the effect of the concrete strength gain with age in the reliability of existing RC structure is sought. As such, the same time reference is used, given by the 28-day strength. To this end, after obtaining the concrete strength information for the existing structure, as given by the extracted concrete cores, the equivalent 28-day strength is calculated by dividing the strength obtained from cores by a factor $(1 + i/100)$, where i is the strength gain in percentage. It is assumed that the full potential for the concrete strength development has been achieved.

As such, an important issue is the value of the strength gain to be considered in the analysis. In this study, three different considerations are made: (a) neglecting the effect of the strength

gain, (b) assuming a 30 % increase, and (c) assuming an 18.5 % increase. For the same concrete strength obtained from extracted cores, a higher strength gain translates into a smaller equivalent 28-day compressive strength. Additionally, an existing RC structure has also been affected by the action of sustained loads. In order to account for this effect, the strength obtained from the extracted cores is further divided by a factor, k_{sl} , given by (Diniz & Frangopol 2003):

$$k_{sl} = 1 - 0.2 \left(\frac{r}{r + I} \right) \quad (6)$$

where r is the ratio mean dead load, μ_G , to mean live load, μ_Q .

Table 2. Statistics of the basic variables.

Mean	Coefficient of Variation (%)	Type of distribution	Reference
Concrete Compressive Strength $f_{cm} = 15, 30, 50$ MPa	5, 10, 15	Lognormal	Assumed
Longitudinal Steel $f_{ym} = 572.5$ MPa	10	Lognormal	Assumed
Cross-Section Geometry B=30 cm H= 30 cm	1.93 1.93	Normal Normal	JCSS (2001)
Model Error 1.0	11	Normal	Diniz & Frangopol (1997)
Dead Load μ_G	10	Normal	Galambos <i>et al.</i> (1982)
Live Load μ_Q	25	Gumbel	Galambos <i>et al.</i> (1982)

6 RELIABILITY RESULTS

The reliability assessment was performed for the 486 existing RC columns described in Table 1. Loads acting on the column have been obtained from the assumption $S_d = R_d$, where R_d is taken as the column resistance according to ACI 562 (ACI 2016). Monte Carlo Simulation was used in the reliability analysis of each existing RC column with respect to the ultimate limit state. Probabilities of failure (and corresponding reliability indexes) were computed for each column at a given scenario (V_c , n , and concrete strength gain with age). Considering the large volume of data that resulted from these analyses, only reliability indexes are presented in Tables 3 and 4 (corresponding probabilities of failure are given by Eq. (2)).

Tables 3 and 4 display reliability indexes for the scenario $n = 3$ which represents the minimum number of cores allowed by ACI 562, and an upper bound for the probabilities of failure in each case. It is seen that V_c has a great influence on the corresponding reliability index. For instance, the results shown in the first line of Table 3, representing an existing RC column with $f_{cm} = 15$ MPa, $\rho_l = 1\%$ $r = 0.5$, $n = 3$, and neglecting the effect of the strength gain, the reliability indexes are 3.57, 3.26, and 2.98, for V_c equal to 5, 10, and 15 %, respectively. All other factors remaining the same, the values displayed in Table 3 (neglecting concrete strength gain) represent upper bounds for the reliability indexes.

For the sake of brevity the results corresponding to 18.5 % strength gain are not shown here, they are found in Castro (2019). From the results obtained, it was found that the higher the concrete gain, the smaller the equivalent reliability index. This fact is easily understood; for the same strength measured by extracted cores, the higher the strength gain the smaller the equivalent 28-day strength and, consequently, the smaller the equivalent reliability index.

In this paper, the assessment of the reliability levels of existing RC columns is based on the same time reference as used in the design of new ones. To this end, an equivalent 28-day concrete strength is obtained from the one associated to the existing structure according to the methodology described in Section 5. The number of cores, assumed here as 3 or 8 cores, has a positive impact on the safety levels as the sample size increases. For instance, for $n = 3$, $f_{cm} = 15$ MPa, $\rho_l = 1\%$, $r = 0.5$, and neglecting concrete strength gain, reliability indexes are 3.57, 3.26, and 2.98, corresponding to $V_c = 5, 10$, and 15% , respectively. For $n = 8$ and all other conditions remaining the same, reliability indexes are 3.59, 3.44, and 3.28, corresponding to $V_c = 5, 10$, and 15% , respectively. Accordingly, the discussion presented herein will be based on results related to $n = 3$.

It is noted that the higher the coefficient of variation, the higher the impact of the number of cores on the resulting reliability index. While this impact is minimum in the case of smaller values of V_c , the differences are more significant for higher values of V_c . In the previous example, an increment in the number of cores from 3 to 8 translates into an increase of about 0.02 in the reliability index for $V_c = 5\%$; conversely, this increase is about 0.30 in the case of $V_c = 15\%$.

Tables 3 and 4 display reliability indexes for the scenarios “neglecting strength gain” and “30% strength increase”, respectively. It is seen that the coefficient of variation associated to the concrete strengths has a significant impact in all the considered scenarios. For instance, for $n = 3$, $f_{cm} = 15$ MPa, $\rho_l = 1\%$, $r = 0.5$, and neglecting concrete strength gain, reliability indexes are 3.57, 3.26, and 2.98 for $V_c = 5, 10$, and 15% , respectively; for “30% strength increase” the reliability indexes are 3.32, 3.05, and 2.79 for $V_c = 5, 10$, and 15% , respectively. The condition “neglecting strength gain” represents usual assumptions in reliability analyses. The reliability indexes in Table 3 are in the range 3.51 – 3.99, 3.23 – 3.62, and 2.87 – 3.34, for $V_c = 5, 10$, and 15% , respectively.

Table 3. Reliability index, $n = 3$, neglecting the effect of the concrete strength gain.

3	4	2.0	3.37	3.12	2.90

Considering that in this study the analyzed columns follow ACI 562, in this research, β_T will be taken as 3.5 as suggested in ACI 440 (2017). From the values displayed in Table 3, it is seen that β_T is met in all columns corresponding to $V_c = 5\%$. The target is also met in columns corresponding to $V_c = 10\%$, exception made for the combination of low concrete compressive strengths ($f_{cm} = 15$ MPa) and small amount of longitudinal steel ratio ($\rho_l = 1\%$). The target is not met in columns corresponding to $V_c = 15\%$. The scenario “30 % strength increase” (Table 4) represents concretes made with usual cements, thus providing an upper bound on the probabilities of failure of existing RC columns (and lower bounds on the corresponding reliability indexes). The reliability indexes displayed in Table 4 are in the range 3.29 – 3.55, 2.97 – 3.25, and 2.64 – 3.13, for $V_c = 5, 10$, and 15 %, respectively. This corresponds to a drop of 0.22, 0.26, and 0.23 in the minimum β values from the “neglecting strength gain” condition to the “30 % strength increase” one, for $V_c = 5, 10$, and 15 %, respectively. In this scenario, β_T is not met in almost all cases, even for $V_c = 5\%$. Considering, for instance the reliability index decrease from 3.51 (“neglecting strength gain”) to 3.29 (“30 % strength increase”), this translates in terms of probabilities of failure in an increase from 2.24×10^{-4} to 5.01×10^{-4} , i.e. more than doubling the probability of failure.

7 CONCLUSIONS

The results obtained point out to the need to address the effect of the concrete strength gain with age on the safety of existing RC columns. All other parameters remaining the same, the larger the strength gain, the smaller the corresponding 28-day equivalent reliability index. By neglecting this effect, an overestimation of the reliability index is obtained. In other words,

this reduced 28-day equivalent reliability index reflects the reliability of the existing column that will not be able to offer a hidden safety margin in its extended service life. The results also indicate that the number of cores and coefficient of variation of the cores' strength have an important effect on the existing column reliability. Reliability indexes below target values ($\beta_t = 3.5$) were found for the combination of minimum number of extracted cores ($n = 3$) and higher values of V_c (15 %), even in cases when concrete strength gains are neglected. The decrease in the reliability index is roughly 0.2-0.4 when the strength gain effect is considered and $V_c = 5$ %; nevertheless, the associated probability of failure may be twice or six times higher. This may be particularly important in the case of life cycle costs where probabilities of failure should explicitly be taken into account.

ABSTRACT: Infrastructure Smart Service System (iS3) is an open source and dataflow-integrated platform that promotes the data sharing in the life-cycle civil engineer. As the application layer of iS3, this paper constructed a microservice for evaluating lifecycle resilience of water distribution network (WDN). The implementation of the microservice includes two main steps: (1) encapsulate the resilience assessment module WARA into a microservice based on Django framework; and (2) deploy the microservice on iS3 platform by calling a WebAPI. An application of the microservice was demonstrated through a WDN in a seismically active region. The results were calculated in the microservice and then returned to the iS3 platform. The iS3-based resilience assessment microservice for WDN may serve as a handy yet scientific tool to evaluate the disaster resistance capability of WDN over its life cycle, and provide a reproducible template for other smart infrastructure application in the field of life-cycle civil engineering.

1 INTRODUCTION

The traditional infrastructure governance mode (i.e., “smokestack” mode) in the field of life-cycle civil engineering often suffers from “isolated” data and low efficiency of urban management, and has been no longer suitable for the development of future cities (Lv et al., 2020). With the rapid development of information technology (e.g., the Internet of Things, big data and artificial intelligence), intelligent management of infrastructure injects new thought to the innovation of urban infrastructure development mode and brings the tangible development benefits for urban residents (Gharaibeh et al., 2017). However, a truly open source and dataflow-integrated platform have not been well developed (Gharaibeh et al., 2017) to considerably exploit the value of the shared-data. The current research particularly focuses on a certain stage of the information flow chain and develops mutually independent systems, such as smart Internet of Things system (Jin et al., 2014, Lv et al., 2020, Talari et al., 2017), and smart analysis system (Tang et al., 2017, Ullah et al., 2020). To make up this deficiency, infrastructure Smart Service System (iS3) was developed by Tongji University (Zhu et al., 2018) from the perspective of information flow to serve infrastructure objects such as tunnels (Zhen et al., 2021, Chen et al., 2020), metro stations (Chen et al., 2020), roads, bridges, pipe corridors (Yang, 2018), and foundation pits. In some sense, iS3 is essentially an “operating system” and a shared data warehouse. As an application of iS3 platform, this paper developed a microservice by building a Django-based WebAPI for evaluating lifecycle resilience of WDN, where the resilience of the entire WDN could be attained in the microservice and then

will be returned to the iS3 platform by calling the WebAPI. The innovations of this paper are twofold: (1) to improve the efficiency of engineering data analysis in the field of life-cycle civil engineering by structuring the data and storing them in the data layer of iS3; and (2) to make an attempt to the smart WDN application and provide a reproducible template for other smart infrastructure application in the field of life-cycle civil engineering based on iS3.

2 THE BASIC OF IS3

iS3 is an integrated decision-making service system for the data collection, processing, expression, analysis and integrated decision services of the life-cycle data of infrastructure. Meanwhile, equipped with a microservice architecture and rich data and graphical interface (Zhu et al., 2018), iS3 could enable a microservice to be deployed on iS3 platform in a pluggable way (Li et al., 2020). The core functions of iS3 include 2D/3D graphics, GIS maps, databases, project object management, and project life-cycle data management (Zhu et al., 2017). The system framework of iS3 can be divided into five layers: base layer, data layer, service layer, application layer and user layer, as shown in Figure 1. The base layer is the hardware equipment set of the system. The data layer is to provide the service layer with the required computing and storage resources. The service layer is a logical layer that provides data access and analysis service interface for the application layer, which unifies the way of data access and the calling way of the underlying hardware devices, and ensures the security of data. The application layer is a user-oriented client program that provides users with friendly access to the system. At present, iS3 has developed four types of applications, namely iS3 Desktop, iS3 Web, iS3 Mobile and iS3 Cloud, to meet different user requirements. The iS3 project is now hosted on github at <https://github.com/iS3-Project>.

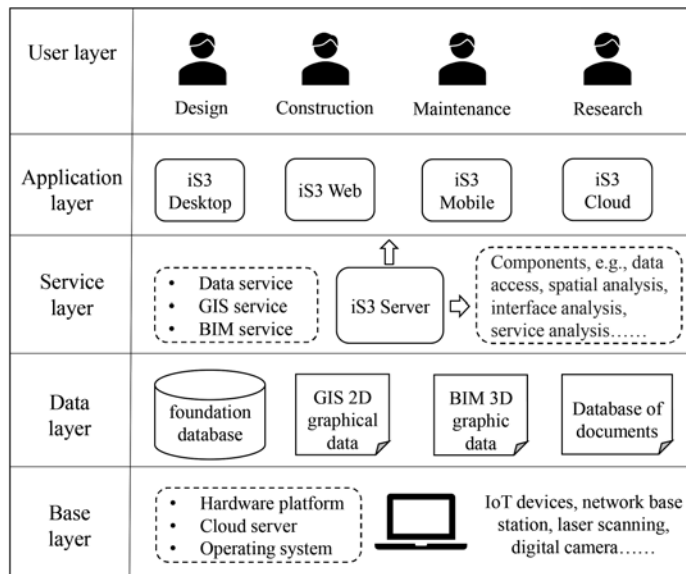

Figure 1. The architecture of iS3 platform (Zhu et al., 2018).

3 IMPLEMENTATION

3.1 Lifecycle resilience evaluation for WDN

The life-cycle resilience evaluation for WDN in this paper is based on the model WARA of Zhou et al. (2019), the workflow of which is shown in Figure 2. As shown in Figure 2, the life-

cycle resilience of a WDN is evaluated considering internal deterioration and external perturbation in a predefined exposure time period at different hazard scenario:

$$h_i = [(d_1, t_1), (d_2, t_2), (d_3, t_3) \dots \dots (d_k, t_k)] \tag{1}$$

where h_i is the i^{th} hazard scenario, and d_k is the hazard intensity measure at time $t_k = k\Delta t$.

At each time step t_k , a six-step analysis is conducted for resilience calculation, which includes (1) random hazard scenario generating, (2) component survival assessment considering the simultaneous effect of deterioration and perturbation, (3) system response analysis through hydraulic simulation to gain the system functionality, (4) recovery analysis, (5) functionality trajectory obtaining, and (6) resilience of that scenario quantifying. By dividing the life cycle of the WDN into different time t_k and repeating the above six-step analysis at each time t_k , the life-cycle resilience of WDN would be obtained. Details about the model are available in the reference (Zhou et al., 2019).

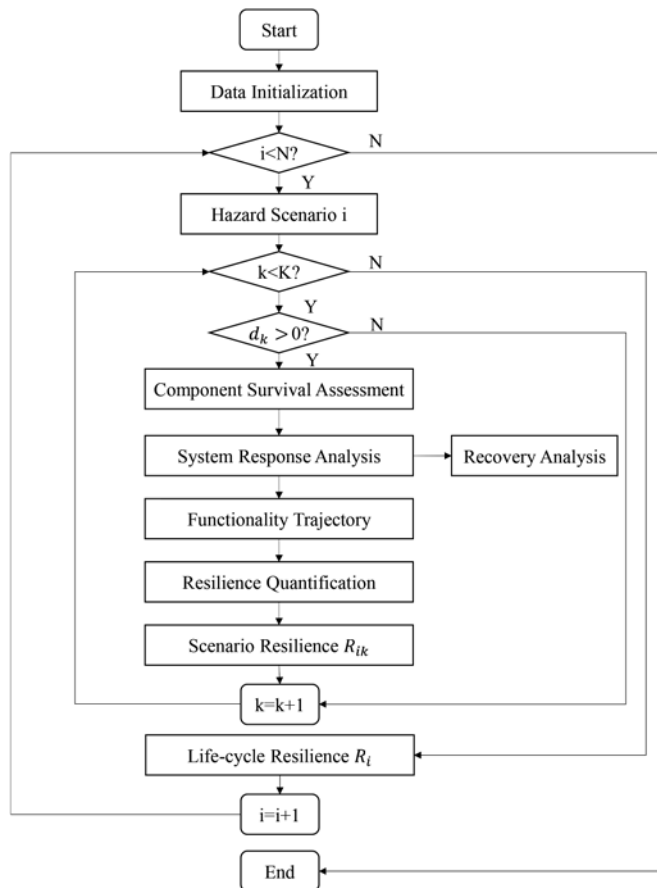

Figure 2. Workflow of WARA (Zhou et al., 2020).

3.2 Microservice development

Compared with stand-alone programs, microservices have the advantages of flexible updating and reusing. Thus, this study encapsulated WARA into a microservice by building a Django-based WebAPI (Django-Software-Foundation, 2022). The workflow of encapsulating WARA is shown in Figure 3. We firstly built a python-based virtual environment to avoid the contradiction caused by different application services required by different versions of dependent libraries. Secondly, we structured the data of WDN based on the data standard of iS3 and

uploaded the structured data into the data layer of iS3 platform through the data interface of iS3. The structured data are shown in Table 1.

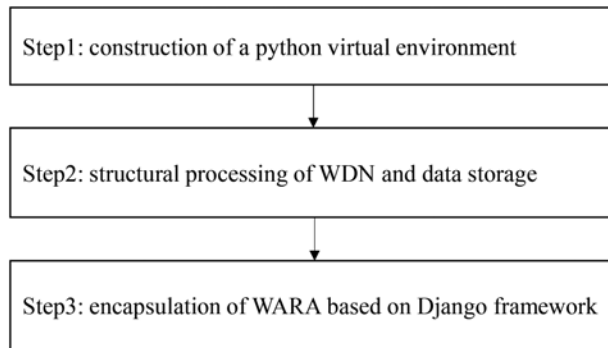

Figure 3. The workflow of encapsulating WARA.

Table 1. Pipe network components and properties.

Element	Attribute
demand nodes	ID, coordinates, altitude, initial water demand
pipe	ID, start node, end node, length, diameter, roughness, age, material, status
tank	ID, altitude, initial water level, the highest water level, the lowest water level, diameter, coordinates
reservoir	ID, initial water head, coordinates
pump	ID, start node, end node, type, pump speed setting
valve	ID, start node, end node, diameter, type

Finally, we encapsulated the WARA module based on the MTV response pattern of Django framework (see Figure 4). The purpose of template is to essentially control the display of content and accept user input, where the HTML code is usually placed to render the data. We mainly encapsulated python code of WARA in view and model modules. The project framework is shown in Figure 5. As shown in Figure 5, the setup file is the internal parameter file of the whole website, which sets all the basic parameters of the website running, including the database instance name, WebAPI name, template name and other basic content. The URL file identifies the locations where all websites invoke resources. To maintain independence and portability, the WARA module is placed in WebAPI, which is a sub-application that runs on the web site. The HTML template is used to send front-end files to the browser so that the client can receive content from the server graphically. Model file is the classes that interact with the database. View control file contains a series of functions, which calls the corresponding view function and sends it to the front end to change the content of the front end after receiving the response from the client. The URL file contains the location of all resources in the WebAPI, which can be directly invoked in the URL file at the website level. The script file is a script file that calls all the libraries in the python internal environment for specific project instance operations, and can be used to try to call functions inside the file. The Manage.py file is a website-level control file that enables operations such as starting servers and setting ports.

3.3 *Microservice deployment on iS3*

iS3 is a platform with a microservice architecture (Li et al., 2020), which provides various interfaces (e.g., data and visualization interface) for microservice to invoke and present the

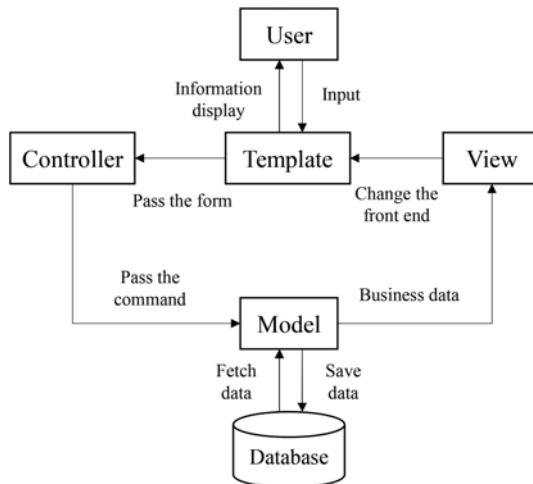

Figure 4. MTV response pattern diagram.

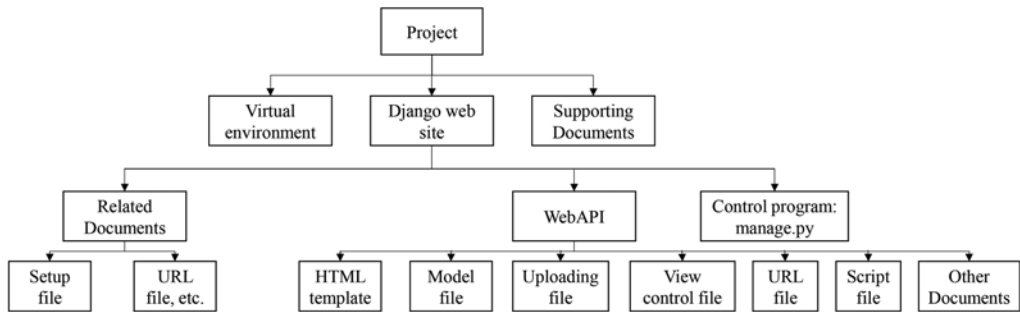

Figure 5. Project frame drawing.

calculation results at visualization center by calling the WebAPI of the microservice. Figure 6 shows the deployment of the microservice on iS3 platform.

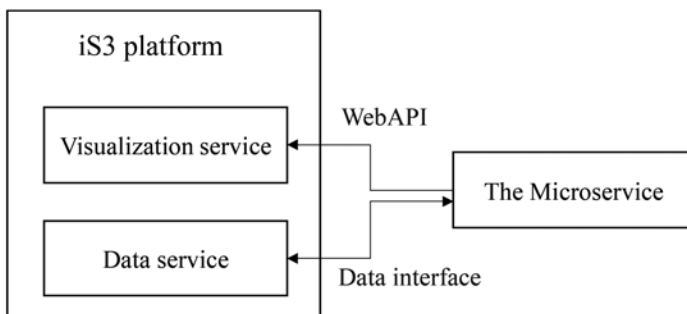

Figure 6. Deployment of the microservice module on iS3 platform.

4 APPLICATION

4.1 Description of the WDN application

A hypothetical Water District exposed to an earthquake disaster was studied to examine the capability of the microservice. The water network is composed of 2 reservoirs, 3 tanks, 2

pumps, 92 demanding nodes, and 117 pipes, and the basic hydraulic data is accessible from the Water Distribution System Operational Toolkit Website (<http://www.uky.edu/WDST/index.html>). Due to the information about the pipes that constitute the WDN and the earthquake disaster is unavailable, some assumptions were made, details of which can be referred in literature (Zhou et al., 2019). Besides, it was assumed that the entire WDN was in good condition before the earthquake, and only the aging impact on the system performance was considered before the simulation of earthquake perturbation.

4.2 Result and future work

A total of two earthquake levels ($PGV = 6.6$ and $PGV = 7.0$) were considered. A total of 1000 Monte Carlo simulations were conducted to simulate various possible earthquake damage states. The visualization of the basic data and damage scenario were presented on iS3 platform

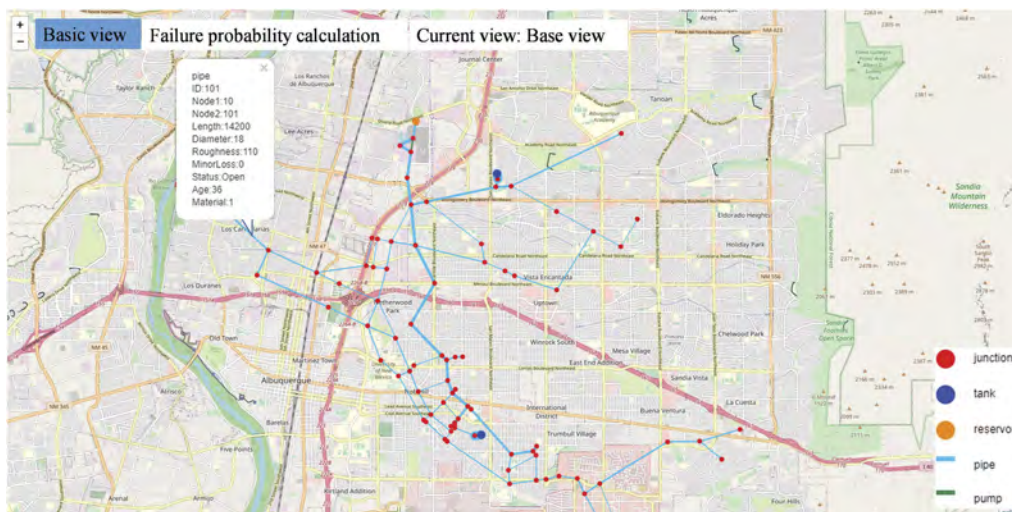

Figure 7. Visualization of the basic information of WDN on iS3 platform.

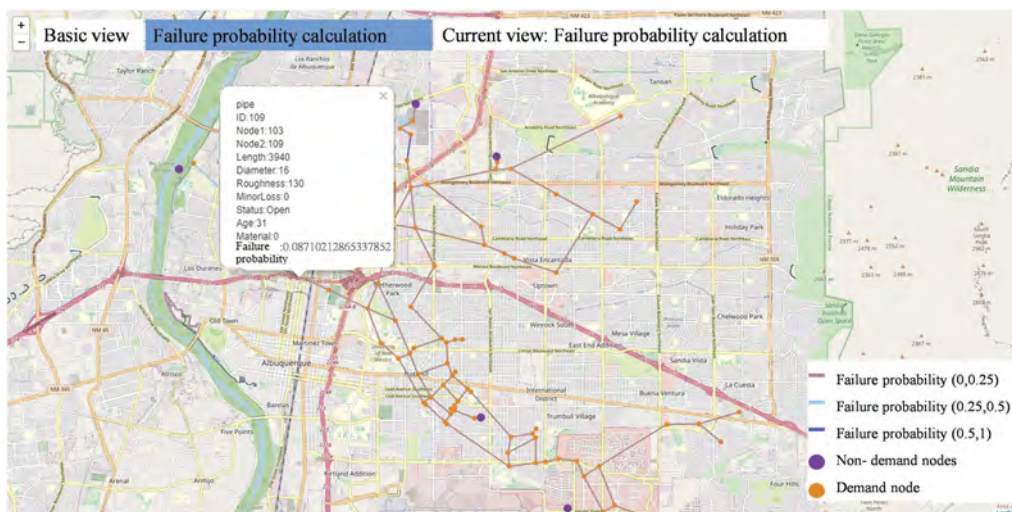

Figure 8. Visualization of pipeline failure probability on iS3 platform.

(see Figure 7-8). Figure 7 shows the interactive interface for users to obtain the basic information of the WDN application when they click the pipe or the node, and Figure 8 presents the interactive results of failure probability of pipelines returned from the microservice.

The statistical results of the lifecycle resilience of the WDN at the given magnitude of earthquake were obtained in the form of pictures (see Figure 9), which were calculated in the microservice and returned to the back end of iS3 platform by calling the WebAPI. It can be seen from the analysis results in Figure 9 that with the increase of pipe age, the resilience of the WDN presents an obvious downward trend. Meanwhile, the higher the earthquake magnitude, the lower the resilience of the WDN will be.

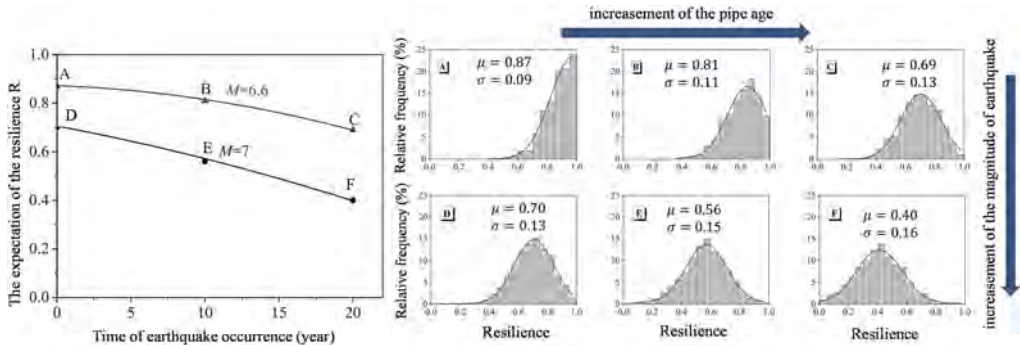

Figure 9. (a)The expectation of the resilience R at given magnitude of earthquake M_0 and year t_0 . (b) The frequency distribution of the resilience R at given M_0 and t_0 of points in (a).

It is noteworthy that the date and key parameters of the simulation are pre-defined. In the future, we plan to expand the function that users can interactively input the basic parameters and obtain the predicted analysis results presenting on iS3 platform, as shown in Figure 10.

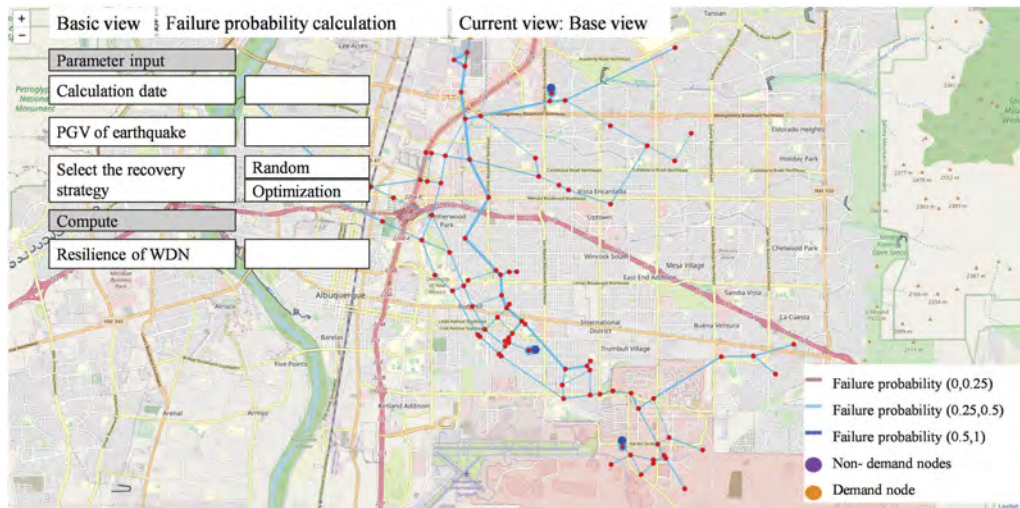

Figure 10. The future work we plan to realize.

5 CONCLUSIONS

This paper developed a microservice for evaluating lifecycle resilience of WDN considering both the internal degradation and external perturbation over its lifecycle under the framework

of Django based on the iS3 platform. Especially, this paper structured the data of WDN and stored them in the data layer of iS3 platform, which greatly improves the efficiency of life-cycle engineering data analysis. Meanwhile, the advantage of the flexible updating and easy sharing of microservice greatly benefits the iteration and development of smart WDN application. The iS3-based resilience assessment microservice for WDN provides a handy yet scientific tool to evaluate the disaster resistance capability of WDN over its life cycle. As the application layer of iS3 platform, this paper could also be a template for developing other smart infrastructure applications. In the future, we would consider further improving the accuracy of resilience evaluation module and expanding the interactive display function on the iS3 platform.

Project management and life-cycle cost evaluation using infrastructure-building information modeling techniques: A railway infrastructure design case study

M. Pasetto & G. Giacomello

Department of Civil, Environmental and Architectural Engineering, University of Padua, Padua, Italy

ABSTRACT: Building Information Modeling has reached a certain level of maturity in the field of vertical constructions, but it is still in an initial phase in the field of horizontal ones as transport infrastructures. This is due to the lack of a proper format for data interchange, capable of representing all the peculiarities of such constructions, like the wide extension of the model over a surface and its very heterogeneous components. In recent years, this gap has been partially bridged with the development of the Industry Foundation Classes (IFC) format for different categories of transport infrastructures, as also for the railway infrastructure sector. The goal of this work is to assess the maturity of the available tools and the difficulties concerning the project management of transport infrastructures using Building Information Modeling software in the design phase with special attention to interoperability of the data. The authors focused their attention on the identification of a new railway layout in Italy (Padua - Chioggia connection), through the implementation of an information flow between different software tools to test the information exchange and the export of data in the IFC 4x3 standard format. Starting from the definition of the territorial constraints, the geometric parameters, the unit costs and the railway service of the project, a set of design alternatives was generated. Through the railway line life-cycle cost and a decision-making analysis, the optimal solution was identified among the various track layouts. The several issues related to different software packages demonstrate that the information exchange for horizontal constructions is still far from reaching a good degree of maturity, especially regarding the lack of a univocal transfer of information. To spread the Building Information Modeling methodology as a standard for infrastructure design, it is required to overcome these technical obstacles to get a collaborative work process.

1 INTRODUCTION

Transport infrastructures are important elements for all human activities because they contribute to the social and economic development of the inhabited areas. A transport infrastructure during its life cycle follows a path that starts from its conception, passes through the design, its construction and continues during operation and maintenance up to the end of its useful life. Within this process, the actors involved in the different phases are many: from the designer to the construction company, from the work owner to the maintenance company. Often this process and this multitude of actors involved do not allow an adequate information exchange.

The Building Information Modeling (BIM) method allows the works life cycle process to be more efficient and sustainable, not so much for the digital representation potential, but above all for the possibility of transmitting information from one phase to the next without any loss or distortion. The BIM is a consolidated technique used to design, build, manage and monitor different vertical or punctual works, such as buildings and bridges (Deng et al. 2022, Alwisly et al. 2019). Recently, this method was successfully applied to various engineering works, such as old buildings monitoring, archaeological findings study (Skrzypczak et al. 2022, Biancardo et al. 2020) and horizontal structures, such as roads, railways and airport, i.e. transport infrastructures (Bosurgi et al. 2022, Vignali et al. 2022, Matejova & Sestáková 2021, D'Amico et al. 2020). BIM also helps the

check of a work during its life through the information storage and distribution using a sensors network (Lenart et al. 2021). BIM allows for economic and time savings (better investment planning, cost reduction, design errors identification, etc.), leading to the correct definition of the costs and the schedule of the works in the design phase (Biancardo et al. 2023; Cantisani et al. 2022, Santos et al. 2019). The information exchange allows for other possible evaluations in the work design phase that can maximize the design efforts, such as energy performance, operational management (maintenance of the work throughout the life cycle) and risks/accidents prevention (Yakhou et al. 2023, Deng et al. 2022, Rezaei et al. 2019).

The digitization of processes and the exchange of information allow to optimize and streamline all the steps necessary for the construction phase of a work and therefore it is possible to industrialize and make the construction sector more productive thanks to new technologies and the integration of data (physical, commercial, environmental, etc.). This allows to align all the subjects who participate in the life cycle of the construction and optimize each phase.

Unfortunately, the level of maturity of the BIM methodology for transport infrastructures is still in an initial phase: the software for transport infrastructures have not yet implemented methods for importing and exporting the model according to all the standards and, above all, the standard is still being implemented. The buildingSMART international (bSi) organization and researchers are carrying out a complex harmonization and standardization of the different parts/components of a transport infrastructure (Häußler et al., 2021). The Industry Foundation Classes (IFC) format for the information exchange of the BIM model was standardized according to the ISO 16739 standard for vertical constructions. During the last years, the IFC standard was expand and made it usable also to develop BIM models of horizontal structures. Recently the lack of entities that would represent the components of the infrastructure in the IFC language for the linear/horizontal structures was overpassed: the layout entities and the specific geometrical railway aspects (e.g., cant and transition curves) are introduced realizing the file interoperability.

Although the use of BIM in transport infrastructure projects is still limited, in Italy the implementation of BIM for public works contracts and design competitions has been provided for by some laws, introducing the use of methods and tools electronic gradually. Some specifications provide for a particular section regarding the presentation of projects developed through BIM and the Italian railway organization published a masterplan for the BIM implementation (Italferr SpA 2019). It is therefore important to improve the IFC standard and the related data model to have the most appropriate tool possible. Some shortcomings have recently been corrected in the extension project IfcRail of bSi, validating the new standard for railways. In Italy, recently, the guidelines have been also released for the application of the IFC language for bridges and viaducts, while for roads have recently been published. However, a study in 2021 demonstrated the limited use of the BIM in railways and the insufficient knowledge of the technical standards and the BIM tools for infrastructures (Minnucci & Alfieri 2021).

With this work the authors evaluate how the issues currently influence the use of BIM in the field of transport infrastructures. Among these, the main one is constituted by the technical limitations concerning the flow of information, mainly due to the lack of interoperability between the different software tools and the modeling of the infrastructure components. These technical limitations can be solved by developing software with better functionality. It is important to highlight that the elements constituting the railway infrastructure have significant differences in scale between them, varying from centimeters to kilometers, and therefore their modeling could represent a problem. By defining specific BIM uses, it is possible to define the granularity of the information necessary for a specific purpose (preliminary design, maintenance plan, etc.).

The authors focused the work on a technical-economic feasibility of the new railway line between Padua and Chioggia in Veneto Region, to identify the best railway layout and giving valuable help to decision makers. This railway line is important both for passenger and freight traffic because would connect local touristic beach resorts and seaport of Chioggia with the city and dry port of Padua (Pasetto & Giacomello, 2023). The authors evaluated five possible railway layouts using the results from a software (named Software 1), assessing the costs of the projects to manage the railway line for the useful life. Using Multi-Criteria Analysis (MCA) and Analytic Hierarchy Process (AHP), the authors defined the best railway layout, designing all parts of this layout through a second software (named Software 2) and evaluating the BIM techniques issues.

2 METHODS AND TOOLS

2.1 *Methods: Life-cycle cost and multicriteria analyses*

The design of transport infrastructures in Italy is regulated by state laws since generally are public works. The main design steps are technical-economic feasibility design, final and executive ones. In this study, BIM methodologies were applied to the project management of a new railway line, from the identification of the railway line layout to the assessment of the life-cycle cost (LCC) of the designed line. The authors carry out the project of a railway line at a preliminary level (technical-economic feasibility), through the definition of several layouts, the subsequent evaluation of the best option and the preliminary design of this layout.

LCC analysis is most effective when it is conducted in the initial phases (i.e., planning and design phases) of a construction project. Cost planning in the design phase and monitoring in the construction phase are very important management activities that can determine the success of a construction project. The LCC evaluation (Santos et al. 2019, Lee et al. 2020, Shin & Cho 2015) involves all the phases in the life of the transport infrastructure. The total cost is defined as the LCC of the transport infrastructure, and it is divided into the planning and design cost (expenses for planning, field survey, design activities, etc.), construction cost (contracts, site management, inspection, support, etc.), management cost (personnel, control and signaling systems, surveillance, etc.) and maintenance cost (check and control operations, personnel, vehicles, etc.).

Although the increased focus on the economic performances of construction projects, there have few studies in the literature focused on the application of the BIM approach with the evaluation of the LCC for transport infrastructure. Moreover, the LCC analysis required a large volume of data and information. For these reasons, in this work the analysis was limited to a small number of design alternatives and a roughly evaluation of the costs was performed. In this study the LCC is conducted excluding the costs not directly affected by the selection of de-sign alternatives (i.e., construction, service and maintenance costs of the stations and the stops; purchase, service and maintenance costs of the trains, etc.). The LCC is calculated per alternative by adding up the costs according to the type of alternative. In addition, the LCC analysis depends on the software used to calculate it. Although, each software used the same data and information given by the authors at the initial design step, the information exchange between software depends on the file format.

The MCA is used to evaluate the best solution from a range of possibilities, also in the case of a railway line (Yücel & Taşabat 2019, Camargo Pérez et al. 2015). In complex decision-making problems, where the wide choice between alternative solutions is not related to a single goal, this type of analysis allows to compare and order the possible solutions based on data relating to the objectives set. It is therefore a method to support the decision maker to carry out a given project.

The process is carried out with the AHP method by structuring criteria and elements in a hierarchical form and comparing the elements to each other in pairs. With this comparison, the preference (i.e., the judgment) of an alternative over the other is expressed for each criterion, up to an overall weight for each alternative that represents the synthesis of the analysis. The alternative with the greatest weight (referring to the established criteria) is the best. The goodness of the analysis is verified by means of the sensitivity analysis to check the results stability (Saaty 1987).

2.2 *Tools: Software and information exchange*

There are several software which already integrate the BIM methodology, design railway lay-outs and export or import IFC files. Since this type of language is constantly evolving, software often must update itself. bSi established the ways to evaluate the interoperability of software assessing of the Model View Definition (MVD). This is the definition of a subset of the IFC schema that must be implemented in software to meet the data exchange requirements of a defined process or activity, described in the Information Delivery Manual (IDM). In this work, two different software were used to evaluate the status of the current information exchange by inserting the model produced by one software into another one.

The Software 1 allows engineers in the construction of the alignment from the starting point to the ending one and transport infrastructure alternatives analysis to create the most efficient layout. This software includes tools for the infrastructures planning. In this paper, the optimal railway

layout of the case study was evaluated with the Software 1 (see Section 3). Starting from the definition of the constraints of the study area (inhabited areas, existing infrastructures, rivers, and Venice Lagoon), and the stations (i.e., the fixed points of the route), the Software 1 has drawn the axis of various layouts (Figure 1a). Having set the size and the cost per unit of length of the infrastructure for the different section types (embankments, trenches, bridges, etc.), the costs of the various layouts were inserted into the LCC analysis. Identifying the best solution from the result of the MCA, the railway layout was designed with the Software 2. This is a traditional railway design software implementing BIM functions allowing to produce, edit, share and analyze railway information models. Starting from a three-dimensional Digital Terrain Model (DTM) and implementing data and the information from the Software 1, the Software 2 specifically defines the planimetric and the altimetric layouts, the cross sections and other parts of the project of the railway line (Figure 1b).

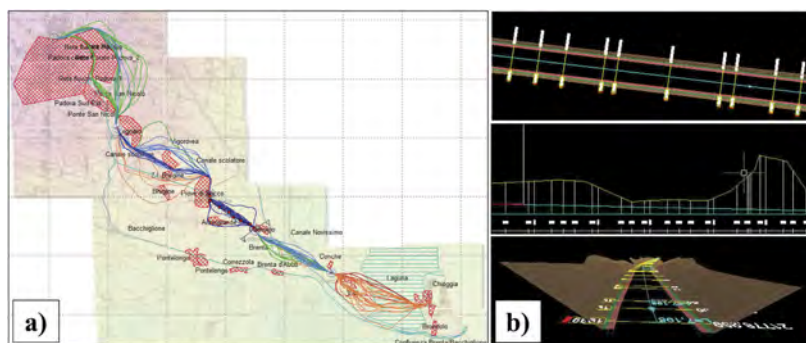

Figure 1. a) Example of the alternative railway layouts drawn with the Software 1 between Padua and Chioggia; b) Project drawings of the railway layout with the Software 2.

3 THE ITALIAN RAILWAY CASE STUDY

3.1 *Railway line design data and railway timetable evaluation*

The case study concerns the project of a new railway line between Padua and Chioggia. Padua is an important economic and historical city and a railway junction located in center of the Veneto Region. Chioggia is a city located on the sea, geographically placed in the southern part of the Venice lagoon, with many beach resorts which attract about 2 million tourists per year (both local inhabitants and foreign tourists). Chioggia is part of the Venice seaport through the North Adriatic Sea Port Authority, and it is one of the main fishing seaports of Italy. The construction of the new railway line could be a great opportunity for the territory due to the improvement both the regional public transport (passenger flow increase) and the rail intermodal freight transport (expected increase in the capacity of the port terminals of Chioggia).

Setting design criteria and territorial constraints, the authors defined several planimetric railway layouts between the stations of Padua and Chioggia using the Software 1. It was therefore decided to design a single-track railway line, managing the intersection of the trains in the stations. Some layouts designed with the Software 1 are unfeasible due to the economic boundaries. Then, the authors selected only the five layouts listed in the Table 1.

All the layouts start from the existing railway station of Padua, pass through railway station of Piove di Sacco and arrive to the existing railway station of Chioggia. The layouts n. 1, 2 and 5 pass also through the existing railway station of the dry port of Padua (“dry port PD”, i.e., a logistic terminal inland), while the layouts n. 3 and 4 pass through the eastern suburbs of Padua (“east suburbs PD”). Moreover, the layouts n. 2, 4 and 5 use the existing railway stretch between Piove di Sacco and Pontelongo stations, passing through the existing railway stop of Pontelongo. This is currently part of the Adria-Mestre railway line. Only the layout n. 5 does not cross the Venice lagoon with a bridge (Table 1).

Table 1. Summary of five railway layouts selected from the Software 1.

Layout number	dry port PD/ east suburbs PD	Use of existing railway stretch between Piove di Sacco and Pontelongo	Venice Lagoon bridge
1	dry port PD	NO	YES
2	dry port PD	YES	YES
3	east suburbs PD	NO	YES
4	east suburbs PD	YES	YES
5	dry port PD	YES	NO

The authors estimated the travel time necessary from Padua to Chioggia stations and evaluated the number of trains that can transit in one hour in both directions per layout. To design the rail service, the authors considered both tourist and local movements. Traffic data from re-cent years show systematic mobility with a flow of around 2000 people per day per direction (Padua and Chioggia). About 270,000 tourists (100,000 are from Veneto region) arrive in Chioggia every year. Since about 70% of tourist arrivals are concentrated in summer (between June and September), there could be about 1500 people per day, which, added to the previous one, would lead to an average daily flow in the summer months of about 3500 people per day. If 30% of the users may prefer to travel with the train, the daily movements would be around 1000 (people/day). By referring to the most recent trains with four-car composition with a capacity of about 500 seats, the minimum number of trains to satisfy the travel demand should be about two.

Similarly to previous study (Pasetto et al. 2017), the authors hypothesized some data to evaluate the rail service: distance travelled between every stop/station, travel time of these di-stances, stopping times at the single stops/stations (4 minutes in the stations with more than one track, to allow trains coming from opposite directions to pass, and 2 minutes in the other stops), average speed.

The travel time between Padua and Chioggia results as being 67 minutes. In 1 hour, two pairs of trains can transit in opposite directions, with a minimum time separation of about 30 minutes (Figure 2a). It was hypothesized that the transport service could be scheduled following the passengers peak-hours, placing most of the trips during the morning, the noon and the evening.

Figure 2. a) The best option for the railway layout between Padua and Chioggia (Pasetto & Giacomello, 2023); b) Example of timetable for the railway layout n. 5.

3.2 Life-cycle cost assessment

The LCC analysis was carried out according to the design alternatives. The construction costs of the different railway layouts were calculated using the Software 1. The authors used an Excel spreadsheet to integer the data obtained from the Software 1 to complete the LCC analysis with the service and maintenance costs, supposing that the railway line has a useful life of 50 years.

The data obtained from Software 1 are readily compatible with the Excel Software. The data have been extracted automatically using the BIM methodologies (IFC/XML) and have been entered manually in the Excel spreadsheet. In the Table 2 were depicted the costs of the construction phase, meanwhile in the Table 3 were displayed the costs of the operation and maintenance phases. To calculate the construction costs, it was used the length of the railway lay-out not already built, while to calculate the service and maintenance costs it was used the total length of

the railway layout. The unitary costs come from the price list of the Italian railway infrastructure manager (Rete Ferroviaria Italiana SpA 2022).

Table 2. Construction costs of the railway layout alternatives.

	Total length of railway layout *	Embankment/ Trench costs	Bridges cost	Infrastrucuture cost	Signaling system cost	Total cost
N.	[km]	[millions of Euros]				
1	45.0 (37.5)	0.89 €	143.20 €	356.25 €	9.00 €	509.34 €
2	51.0 (36.5)	1.06 €	160.40 €	346.75 €	10.20 €	518.41 €
3	52.0 (47.5)	0.75 €	158.00 €	451.25 €	10.40 €	620.40 €
4	53.0 (41.5)	0.76 €	160.40 €	394.25 €	10.60 €	566.01 €
5	53.0 (36.5)	0.75 €	16.00 €	346.75 €	10.60 €	374.10 €

* Length of the railway layout to be built is indicated between brackets.

Table 3. Service and maintenance costs of the railway layout alternatives.

	Total length of bridges*	Bridges cost	Infrastrucuture cost	Signaling system cost	Total cost
N.	[km]	[millions of Euros]			
1	3.6	0.86 €	67.50 €	0.09 €	68.45 €
2	4.2	1.02 €	76.50 €	0.10 €	77.62 €
3	4.0	0.95 €	78.00 €	0.10 €	79.05 €
4	4.2	1.02 €	79.50 €	0.11 €	80.62 €
5	0.9	0.21 €	79.50 €	0.11 €	79.82 €

* The length of railway bridges includes the existing ones.

Table 4. Criteria and weights of the MCA/AHP analysis.

Criteria	Railway layout alternatives				
	1	2	3	4	5
Layout total cost	0.16	0.20	0.17	0.22	0.25
Environmental impact	0.17	0.19	0.17	0.19	0.28
Project complexity	0.22	0.22	0.18	0.18	0.20
Transport efficiency	0.22	0.22	0.17	0.17	0.22
Total weight of the alternative	0.19	0.21	0.18	0.19	0.24

Summarizing the results, the cost in millions of Euros for each railway layout is: 1) 577.79 €, 2) 596.03 €, 3) 699.45 €, 4) 646.63 € and 5) 453.92 €. The layout n. 5 is the cheapest and the n. 3 is the most expensive. These results are used to select the best layout (see section n. 3.3).

3.3 Selection of the best layout

The authors perform the selection of the best layout using MCA and AHP methods based on technical and economic data of the five layouts described. In the Table 4 the criteria and the weights of the MCA/AHP are displayed.

The criteria used in the MCA/AHP are project complexity and transport efficiency (data from the railway timetable evaluation, see section n. 3.1), total cost of the layout (data from the LCC analysis, see section n. 3.2) and environmental impact. Using the AHP method, the authors subdivided the criteria “environmental impact” and “transport efficiency” in 6 and 3 sub-criteria, respectively. The sub-criteria for “environmental impact” are production of waste materials, materials to be taken to the construction site, work footprint on the territory, transit on the Venice Lagoon, bridges visual impact on the landscape, and layout length in areas subjected to constraints. The sub-criteria for “transport efficiency” are layout travel time, number of locations served, and passage through the dry port of Padua.

As result from the MCA/AHP methods, the best railway layout is the n. 5 (Figure 2b).

Table 5. Cut and fill volumes calculation in the two software.

	Software 1	Software 2
	[m ³]	
Cut (trenches)	448,000.00	797,704.00
Fill (embankments)	562,000.00	250,610.00

3.4 Design and exchange information issues

During the design phase with the Software 1 and during the information exchange between the two software, some problems were found. The first concerned the difficulty to import into the Software 1 the information regarding the DTM (the file format was not compatible with Software 1). Another problem arose when, having found a compatible format, the file was loaded by the Software 1, generating a file with dimensions that could not be managed by the computer. The issue was solved by making use of an image editing software. Moreover, the data for the LCC analysis were extracted from the Software 1 in a partial way due to the impossibility to transfer data from the proprietary file format to the IFC/XML file format.

Additional problems were encountered in the transition from the two software. By exporting the file from Software 1 using landXML file format, the DTM was not transferred to Software 2. To overcome this problem, another DTM (using another file format) was imported into Software 2, which led to a different representation of the ground from that used in the Software 1. This aspect led to a different calculation of the cut and fill volumes in the two software (Table 5). The lines drawn by Software 1 to define the planimetry and the longitudinal profile, once imported into the Software 2, were read as generic lines because the information was not correctly transferred from one software to the other one. For the same reason, the LCC performed on the data from the Software 2 change respect to the analysis done with the data from the Software 1.

Finally, the last issue refers to the design regulations. In Italy, the national railway infrastructure manager has specific standard for the infrastructure design. Software 1 does not contain this regulation, while software 2 contains it and can design the railway layout complying with this standard. Therefore, transferring the information from Software 1 to Software 2, the layout is not correctly designed according to the Italian rules.

These aspects jeopardize the correct information exchange flow through different software respect to that indicated by the BIM methodologies.

4 CONCLUSIONS

For a fully integration and exploitation to BIM full potential, a reorganization of the design process within the construction sector is necessary. The development of a collaborative approach between the various actors involved in the process and a push towards digitization are required to encourage the adoption of BIM by both professionals involved in the design and public bodies.

This study is an example of the issues encountered in the transport infrastructures design with BIM methodologies. The way to reach a full interoperability in the data/information transfer between different software is still long: the software and the IFC language are not still adequately developed for such works and the collaborative design between different expert in this fields is not possible yet. Currently the information exchange is difficult, and the information are not written into a file format that use the standards promoted by bSi. Furthermore, software often requests data with file extensions that are not always available.

Although the IFC language and the software change very quickly, the transport infrastructure design is far from a fast and effective exchange of information that allow to a full project management, that include the LCC analysis and the definition of the railway timetable.

As proved, currently the management of the project is fragmented, and the various actors involved are unable to exchange information in a suitable way.

A non-Gaussian algorithm to simulate the earthquake motion phase difference

Tadanobu Sato

Emeritus Professor, Kyoto University, Kyoto, Japan

Research Associate, Kobe-Gakuin University, Kobe, Japan

ABSTRACT: The purpose of this paper is to develop a method to simulate the earthquake motion phase for simulating a design response compatible earthquake acceleration time history. A method is developed to calculate the earthquake motion phase as a function of the circular frequency without the unwrap procedure. Then the earthquake motion phase is decomposed into a linear delay and fluctuation parts. The fluctuation part of phase is named the phase throughout of this paper. First, a mean phase gradient is defined by dividing the phase difference with its circular frequency interval. The probability density characteristics of the mean phase gradient is discussed, and it is found that the mean phase gradient is obeyed the Levy-flight distribution. A new stochastic process is developed and named the fractional Levy-flight process to simulate the mean phase gradient.

1 INTRODUCTION

The classic seismic intensity method has been used for long time, but it was created to consider the flexibility of structure system in the seismic design method, which is the response spectrum (Housner, 1941). Since many observed acceleration time histories have demanded high level design response spectra (Douglas, 2002), the yield strength demand spectrum (YSDS) (Iemura & Mikami, 2001) has become a common tool for designing large scale civil infrastructures. The designed structures, however, must be checked their seismic performance through the dynamic analyses. The design response spectrum compatible acceleration time history (DRSCATH) becomes very common for an input motion to the structural system to evaluate the seismic performance of designed structural systems (Tsai, 1972).

Because the time history of DRSCATH is strongly affected by the assigned Fourier phase spectrum (Shrihande & Gupta, 1996) we propose a method to extract the probability density function of the mean phase gradient from an observed acceleration time history at the design site and to simulate many sample Fourier phase spectra that can be used to simulate Fourier phase spectrum at the design site. The phase is decomposed into the linear delay and fluctuation parts. First, the phase difference of the fluctuation part is divided by the circular frequency interval, This is named the mean phase gradient, then develop a method to simulate non-Gaussian process for the mean phase gradient. It is discussed a possibility to express the mean phase gradient by a Levy-flight probability density function (Nolan, 2015). Then the mean phase gradient is expressed by a new stochastic process, namely, the fractional Levy-

Figure 1. The design response spectrum used in this analysis. (red line).

flight motion, by which a stochastically rigorous sample earthquake motion phase can be simulated. This is made possible by using the Levy-flight noise process and the kernel with the fractional characteristic (Sato, 2017).

2 USED DESIGN RESPONSE SPECTRUM AND CONVERGENCE

The used design response spectrum is shown in Figure 1 by spectrum II (red line), which is defined in the code to design railway facilities in Japan. This design response spectrum is expressed by $S_E(T)$, in which T is the natural period of the structural system. To simulate DRSCATH we must assign the fixed Fourier phase $\phi_a(\omega)$ and the initial Fourier amplitude $A_0(\omega)$, which is modified as $A_l(\omega)$ at the iterative calculation step l . The acceleration time history at the step l is expressed by $x_l(t)$, which is obtained by using the Fourier inverse transform of $A_l(\omega)e^{i\phi_a(\omega)}$, of which elastic response spectrum is expressed by $S_l(T)$. The matching rate in the iteration is evaluated by the following equations.

$$E_l(T) = \left| \frac{S_E(T) - S_l(T)}{S_E(T)} \right| \quad (1)$$

$$e_l = \sqrt{\frac{1}{T_L} \int_{T_s}^{T_e} (E_l(T))^2 dT} \quad (2)$$

The $E_l(T)$ at each natural period T is integrated as expressed by Eq.2, in which $T_L = T_e - T_s$, T_s and T_e are the natural periods of a single degree of freedom system to evaluate the matching rate of $E_l(T)$. To estimate $x_l(t)$, the modification of the initial Fourier amplitude $A_0(\omega)$ is needed. Let $l = 1, 2, \dots, \infty$ be the repetition number and the Fourier amplitude $A_l(\omega)$ at the l step, then $x_l(t)$ is obtained by the Fourier inverse transform of $A_l(\omega)e^{i\phi_a(\omega)}$. At the l step, $A_{l+1}(\omega) = (S_E(T)/S_l(T))A_l(\omega)$ is assumed to be effective under the assumption of $T = 2\pi/\omega$.

The initial Fourier amplitude is chosen to be the Fourier amplitude $A_a(\omega)$, which is calculated from the same acceleration time history to obtain the phase $\phi_a(\omega)$, because the causality condition must be satisfied at the initial stage as a minimum requirement.

Figure 2. The DRCATHs calculated by using the fixed Fourier phase $\phi_a(\omega)$ and the initial Fourier amplitude $A_a(\omega)$ that are obtained from the recorded observed at Kushiro(black line), Kobe(red line) and Kameoka(blue line) Observatories.

For six different acceleration time histories observed at Kushiro, Suttsu, Nemuro, Amagasaki, Kobe and Miyagi observatories, the relationship between e_l and the repetition number l is obtained. All e_l go down until e_l reaches to certain % around $l=27$ and then fluctuate around

e_1 = certain % as the repetition number l increases. Therefore, $l = 27$ is fixed to calculate the DRSCATH for assigned $\phi_a(\omega)$.

As examples Figure 2 shows three DRSCAHs that are obtained by using three different observed acceleration time histories recorded at Kushiro (black line), Kobe (red line) and Kameoka (blue line) observatories, from which the initial Fourier amplitudes and fixed phases are obtained. From this figure, it is concluded that the time histories of DRSCATHs are strongly affected by the assigned Fourier phase spectrum.

3 MODELING PHASE SUECTRUM

3.1 Phase computation

To avoid a trouble-some unwrap procedure of argument phase, the increment of arctangent phase is calculated (Sato, 2017) by

$$d\phi(\omega) = \frac{d\Im(\omega)\Re(\omega) - \Im(\omega)d\Re(\omega)}{\Re^2(\omega) + \Im^2(\omega)} \quad (3)$$

$$\phi(\omega) = -\omega t_0 + \psi(\omega) \quad (4)$$

in which $\Re(\omega)$ and $\Im(\omega)$ are the real and imaginably parts of the Fourier transform of observed acceleration time history. By integrating $d\phi(\omega)$ with respect to (wrt) the circular frequency ω , the phase $\phi(\omega)$ is obtained as a function of ω . $\phi(\omega)$ is decomposed into a linear delay part $-\omega t_0$ and the fluctuation part $\psi(\omega)$ as expressed by Eq.4.

Figure 3. Change of the variance of mean phase gradient $\Delta\psi/\Delta\omega$ for the circular frequency interval $\Delta\omega$. The variance of the mean phase gradient approaches to a constant value when $\Delta\omega$ approaches zero. The color differences of open circles are the difference of observed records.

Figure 4. The probability density functions (PDFs) of the mean phase gradient for Kushiro record with different circular frequency intervals $\Delta\omega$, which are defined by $(n = 0, 1, 2, 4, 6, 8, 10, 12)$. All PDFs coincide each other and its theoretical PDF is defined by Levy-flight distribution function with parameters of $\alpha = 1.5$ and $\gamma = 5.9$.

All numerical analyses are discretized. We, therefore, use a small circular frequency interval of $d_0\omega = 100\pi/2^{25}$ rad and the circular frequency is a discretized as $\omega_l = l \cdot d_0\omega$, then the small discretized phase difference is obtained by $d\psi_l = \psi(\omega_l) - \psi(\omega_l - d_0\omega)$. Moreover, the larger circular frequency interval is calculated by $\Delta\omega = k \cdot d_0\omega = 2^n d_0\omega$. The difference of fluctuation part of phase for this large circular frequency interval is calculated by Eq.5.

$$\Delta\psi_i = \sum_{l=0}^{k-1} d\psi_{k(i-1)+l} \quad (5)$$

$$X_i = \left\{ \frac{\Delta\psi_i}{\Delta\omega} \right\} \quad (6)$$

where $(i = 1, 2, \dots, M)$, M is a total number of discrete points to calculate the phase difference for a large circular frequency interval $\Delta\omega = 2^n d_0\omega$, which is defined by changing n values.

Since the value of the phase difference depends on the circular frequency interval $\Delta\omega$, a stochastic valuable is defined by Eq.6. This value is a mean gradient of fluctuation part of phase, which is called, hereafter, the mean phase gradient. Figure 3 shows the change of the variance of X_j wrt the circular frequency interval. It is concluded that the variance of X_j approaches a constant value as approaches zero without depending on the observed records. Because the mean phase gradient approximates the grope delay time, the grope delay time can be used as the stochastic value to evaluate phase. Figure 4 shows the probability density function (PDF) of $\{X_j\}$ for several $\Delta\omega = 2^n d_0\omega$ values, in which n values are controlled the values of $\Delta\omega$ Even if n values were changed as $(n = 0, 1, 2, 4, 6, 8, 10, 12)$, all cases are coincided each other. This means that the mean phase gradient has the fractal characteristic (Falconer, 2003). The brown line in Figure 4 is the symmetric Levy-flight probability density function $s(\alpha, \gamma, X_j)$ with the characteristic index $\alpha = 15$ and the scale parameter $\gamma = 5.9$. Then the PDF of $\{X_j\}$ is expressed by

$$p(X_j) = s(\alpha, \gamma, X) \quad (7)$$

The red dotted line is the normal probability density function $N(0,8)$, which means that the PDF of $\{X_j\}$ is non-Gaussian.

3.2 Definition of the Levy-flight noise process

Based on the previous study (Sato, 2017) of the stochastic process, of which PDF is defined by Eq. 7, it needs that a simple noise process obeying the Levy-flight distribution similar to the Brownian noise (Karatzas & Shreve, 1991), which has used as the fundamental stochastic process to develop the modern stochastic theory. This process is called the Levy-flight noise process, $dy(\omega)$, and defined as follows:

$$dy(\omega) = (d\omega)^{1/\alpha} \gamma_L Z(\omega) \quad (8)$$

in which α and γ_L the parameters to define the Levy-flight noise process, $Z(\omega)$ is a random number at ω generated from the standard Levy-flight distribution function $S(\alpha, 1, Z)$ based on the independent and identically distributed (iid) assumption. To make clear the stochastic characteristics of this noise process, we consider the following discretized process $\{d_0 y_i\}$ with the small circular frequency interval $d_0\omega = 100\pi/2^{25}$ rad:

$$d_0 y_i = (d_0\omega)^{1/\alpha} \gamma_L Z_i \quad Z_i \sim S(\alpha, 1, Z) \quad (9)$$

in which the lower suffix means the value at the discretized circular frequency ω_i . Moreover, we consider a new Levy-flight noise process Δy_j with a large circular frequency interval $\Delta\omega = k \cdot d_0\omega = 2^n d_0\omega$ that is realized by summing up k numbers of $d_0 y_i$ as follows:

$$\Delta y_i = \sum_{l=1}^k d_0 y_{k(i-1)+l} = (d_0\omega)^{1/\alpha} \gamma_L \sum_{l=1}^k Z_{k(i-1)+l} \quad (10)$$

Because Δy_i is a sum of random numbers generated from the standard Levy-flight distribution under the iid assumption we can use the generalized central limit theorem (Mantegna & Stanley, 2004), which gives the relationship $k(d_0\omega)\gamma_L^\alpha = \Delta\omega\gamma_L^\alpha$ to get the following relation for Δy_i :

$$\Delta y_i = (\Delta\omega)^{1/\alpha} \gamma_L Z_i \quad (11)$$

in which Z_i is an iid generated random number from $S(\alpha, 1, Z)$. Because the formulas expressed by Eqs 8 and 11 are almost the same. This means that Δy_i is independent to the value of $\Delta\omega$, therefore, the Levy-flight noise process has the fractal nature. Moreover, the process $y(\omega)$ is a continuous but un-differentiable wrt the circular frequency ω due to the facts that Δy_i approaches zero and $\Delta y_i/\Delta\omega$ diverges infinite as $\Delta\omega$ approaches zero.

Here a simple procedure is introduced to simulate a stochastic process obeying Eq.7. Without losing generality we can write $\Delta\psi = \psi - \psi_0$ and $\Delta\omega = \omega - \omega_0$ as well as $\psi_0 \equiv 0$ and $\omega_0 \equiv 0$. Then Eq. 7 is rewritten as follows:

$$\psi/\omega^{1/\alpha} \sim S(\alpha, \gamma, Y) \quad (12)$$

To simulate the stochastic process ψ obeying Eq.12, we need almost the same algorithm to simulate the fractional Brownian motion process (Karatzas & Shreve, 1991).

3.3 Fractional Levy-flight process

The essential problem to simulate phase difference is that the phase is an asymmetric function wrt the circular frequency. This condition requires the following constrain:

$$\phi(\omega) = \phi(-\omega) \quad (13)$$

This means that the fluctuation part of phase $\psi(\omega)$ defined in Eq.4 and its difference have the same characteristic. The circular frequency domain defining the phase is $[0, \infty]$ and then its value in $[-\infty, 0]$ can be defined automatically by using Eq.13. Therefore, the phase cannot be simulated by only applying the simple fractional Levy-flight process defined by the similarity of the fractional Brownian motion (Sato, 2017). We discuss this point in this session.

To develop a phase process satisfying the constrain given by Eq.13, the phase process at the circular frequency ω is assumed to be composed of two functions, one is a function $\psi_1(\omega)$ expressing the contribution from the zero circular frequency, and the other is the function $\psi_2(\omega)$ expressing the contribution from the infinite circular frequency as follows:

$$\psi(\omega) = \psi_1(\omega) + \psi_2(\omega) \quad (14)$$

Here we assume that those two functions are expressed by the following Lebesgue-Stieltjes integral using the Levy-flight noise process $dy(\tau)$ defined in Eq.8 as follows:

$$\psi_1(\omega) = \eta \int_0^\omega K_1(\omega - \tau) dy(\tau), \quad \psi_2(\omega) = \eta \int_\omega^\infty K_2(\tau - \omega) dy(\tau) \quad (15)$$

in which η is the coefficient that controls the equality of Eq.15, the integral kernels of $K_1(\omega - \tau)$ and $K_2(\tau - \omega)$ as well as β are defined by

$$K_1(\omega - \tau) = (\omega - \tau)^\beta, \quad K_2(\tau - \omega) = (\tau - \omega)^\beta \quad (16)$$

$$\beta = 1 - 1/\alpha \quad (17)$$

To make clear the stochastic characteristic of phase difference, it is discretized by using the circular frequency interval $\Delta\omega$ but to do so it is necessary to take care of the direction calculating the phase difference. If we considered a case taking the backward difference for the function $\psi_1(\omega)$ it was given by ${}_b\Delta\psi_1(\omega) = \psi_1(\omega) - \psi_1(\omega - \Delta\omega)$ but for the function $\psi_2(\omega)$ it should be ${}_b\Delta\psi_2(\omega) = \psi_2(\omega) - \psi_2(\omega + \Delta\omega)$, because the origin of both functions are at the circular frequency of ω . Then the backward difference of $\psi(\omega)$ is expressed by the sum of ${}_b\Delta\psi_1(\omega)$ and ${}_b\Delta\psi_2(\omega)$ as follows:

$${}_b\Delta\psi(\omega) = \{ \psi_1(\omega) - \psi_1(\omega - \Delta\omega) \} + \{ \psi_2(\omega) - \psi_2(\omega + \Delta\omega) \} \quad (18)$$

The terms appeared in the first parentheses $\{ \}$ of the right side of Eq.18 are expressed by

$$\psi_1(\omega) = \eta \int_0^\omega K_1(\omega - \tau) dy(\tau), \quad \psi_1(\omega - \Delta\omega) = \eta \int_0^{\omega - \Delta\omega} K_1(\omega - \Delta\omega - \tau) dy(\tau)$$

For $\psi_2(\omega)$ and $\psi_2(\omega + \Delta\omega)$, similar formulas are obtained. The discrete formula of this first parentheses of Eq.18 with the circular frequency interval $\Delta\omega$ is, therefore, given by

$${}_b\Delta\psi_i = (\Delta\omega)\eta\gamma_L \left\{ \sum_{l=0}^{i-1} {}_bP_{il}Z_l + 0 \cdot Z_i + \sum_{l=i+1}^{\infty} {}_bF_{il}Z_l \right\} \quad (19)$$

in which γ_L is an undefined parameter of the Levy-flight noise process appeared in Eqs.8 and 11. The procedure to define this value is given later. ${}_bP_{jl}$ and ${}_bF_{jl}$ are defined by

$${}_bP_{il} = (i - l)^\beta - (i - 1 - l)^\beta, \quad {}_bF_{il} = (l - i)^\beta - (l - i - 1)^\beta \quad (20)$$

On the other hand the forward difference of $d\psi_1(\omega)$ and $d\psi_2(\omega)$ are expressed by ${}_f\Delta\psi_1(\omega) = \psi_1(\omega + \Delta\omega) - \psi_1(\omega)$ and ${}_f\Delta\psi_2(\omega) = \psi_2(\omega - \Delta\omega) - \psi_2(\omega)$. Then the discretized forward difference of $\psi(\omega)$ is given by the sum of these two expressions as follows:

$${}_f\Delta\psi_i = (\Delta\omega)\eta\gamma_L \left\{ \sum_{l=0}^{i-1} {}_fP_{il}Z_l + 2 \cdot Z_i + \sum_{l=i+1}^{\infty} {}_fF_{il}Z_l \right\} \quad (21)$$

${}_fP_{jl}$ and ${}_fF_{jl}$ are defined by

$${}_fP_{il} = (i + 1 - l)^\beta - (i - l)^\beta, \quad {}_fF_{il} = (l - i + 1)^\beta - (l - i)^\beta \quad (22)$$

Taking mean of backward and forward differences, the phase difference can be defined by

$$\Delta\psi_i = \frac{1}{2} \{ {}_b\Delta\psi_i + {}_f\Delta\psi_i \} = (\Delta\omega)\gamma_L \sum_{l=0}^{\infty} W_{il}Z_l \quad (23)$$

in which W_{jl} is given by

$$W_{il} = \begin{cases} \frac{1}{2} ({}_bP_{il} + {}_fP_{il}) & l \leq i - 1 \\ 1 & i = l \\ \frac{1}{2} ({}_bF_{il} + {}_fF_{il}) & i + 1 \leq l \end{cases} \quad (24)$$

Separating the weight W_{il} into the $l \leq i - 1$ part and the $i + 1 \leq l$ part, and rewriting them as P_{il} and F_{il} , the following formulas are obtained:

$$P_{il} = \left((i + 1 - l)^\beta - (i - 1 - l)^\beta \right) / 2 \quad (25)$$

$$F_{il} = \left((l + 1 - i)^\beta - (l - 1 - i)^\beta \right) / 2 \quad (26)$$

To simplify the formula of $\Delta\psi_i$, a new weighting sequence $\{a_m\}$ is defined by using an integer number $m = |i - l|$, which is increased from 1 to infinite.

$$a_m = \frac{1}{2} \left\{ (m + 1)^\beta - (m - 1)^\beta \right\} \quad (27)$$

Figure 5. The simulated sample fluctuation part of phases. The parameters defining PDF of the fluctuation part of phase is defined in Eq.7.

Figure 6. Eight different design response spectrum compatible acceleration time histories (DRSCATHs).

Eq.23 can be rewritten by using $\{a_m\}$ as follows:

$$X = \gamma_L \left(\sum_{m=1}^L a_m Z_{i-m} + Z_i + \sum_{m=1}^L a_m Z_{i+m} \right) \quad (28)$$

in which γ_L is defined in Eq.8. Because $\{Z_i\}$ is the iid random numbers generated from $s(\alpha, \gamma = 1, Z)$, the value of γ_L is obtained by using the generalized central limit theorem (Mantegna & Stanley, 2004) as follows:

$$\gamma_L = \frac{\gamma}{A}, A = \left(2 \sum_{m=1}^L a_m^\alpha + 1 \right)^{1/\alpha} \quad (29)$$

Based on the algorithm introduced here we can simulate earthquake motion phases. If $\{X_i\}$ is simulated, $\{\Delta\psi_i\}$ is obtained by multiplying $\Delta\omega$ to $\{X_i\}$. Figure 5 shows the simulated eight fluctuation part of phases, which are obtained by using eight different initial random number to generate iid random number series $\{Z_i\}$.

Then calculating the cumulative sum of $\{\Delta\psi_i\}$, $\{\psi_i\}$ is obtained. Substituting $\{\psi_i\}$ into Eq.4, in which $t_0 = 98s$ is assigned, from which $\{\phi_i\}$ is obtained. Using eight different series of $\{\phi_i\}$, DRSCATHs can be simulated, which are shown in Figure 6. The eight-time histories with different colors are obtained, which are correspond to the colors in Figure 5.

3.4 Autocorrelation coefficient of mean phase gradient

The autocorrelation coefficient of the mean phase gradient is shown in Figure 7 by the light-blue zigzag line, which is obtained by using acceleration time history recorded at Kushiro observatory. The theoretical autocorrelation function $R(k)$ is obtained by

$$R(k) = E[X_i X_{i+k}] \quad (30)$$

from which the theoretical autocorrelation coefficient $\rho(k)$ is defined by

$$\rho(k) = R(k)/R(0), k = 0, 1, \dots, \infty \quad (31)$$

X_i is obtained (Sato, 2017) and automatically and X_{i+k} is defined by

$$X_i = c \left\{ \sum_{l=1}^L a_l Z_{i-l} + a_0 Z_i + \sum_{l=1}^L a_l Z_{i+l} \right\} \quad (32)$$

$$X_{i+k} = c \left\{ \sum_{l=1}^L a_l Z_{i+k-l} + Z_{i+k} + \sum_{l=1}^L a_l Z_{i+k+l} \right\} \quad (33)$$

The blue squares in Figure 7 are the theoretically obtained autocorrelation coefficients for $k = 0, 2^2, 2^4, 2^{10}, 2^{18}, 2^{23}, 2^{24}$ under the following assumption for any number of k .

$$E[Z_j Z_l] = \begin{cases} 0 & j \neq l \\ \sigma_c^2 & j = l = k + i \end{cases} \text{ for arbitrary } i$$

4 YIELD SEISMIC COEFFICIENT DEMAND SUECTRUM

The yield strength demand spectrum is commonly used for designing economical structures, but we propose a new concept, which is named the yield seismic coefficient k_h demand spectrum (YSCDS) defined by dividing yield strength with the structural weight.

Table 1. Summary of yield seismic coefficient of Kushiro record case at different natural period (the first line) and ductility responses for different record cases (below the second lines).

T	0.5	0.7	1.80
k_h	0.4606	0.2867	1481
Kushiro ph.	4	4	4
Kobe ph.	4.320	5.484	4.189
Kameoka ph.	4.263	4.848	2.670

4.1 Definition of YSCDS and their uncertainty

Figure 8 shows the relationship between T and k_h relation keeping a constant response ductility μ value such as $\mu = 4$, which is named the yield seismic coefficient demand spectrum (YSCDS). There is no effect of Fourier phase on the linear response of structural system because the input acceleration time history is the DRSCATH. However, the case for nonlinear response of the structural system. The yield strength P_y , in other word, the yield seismic coefficient k_h , fluctuate strongly as shown in Figure 8. For examples, corresponding to the colored lines, it is possible to read that $k_h = 0.4606, 0.4838, 0.4880$ at $T = 0.5s$, $k_h = 0.2867, 0.4718, 0.329$ at $T = 0.7s$ and $k_h = 0.1481, 0.1561, 0.1039$ at $T = 1.8s$, respectively.

Assuming that the YSCDS for Kushiro (black line) in Figure 8 is the YSCDS for design purpose. The first line in Table 1 gives k_h at $T = 0.5, 0.7$ and $1.8s$ for Kushiro DRSCATH, of course $\mu = 4$ as given in the second line in Table 1. Below the third line, we show the ductility responses of structures designed by using the seismic coefficient in the first line. These ductility responses are obtained for structures inputting the different DRSCATHs (Kobe and Kameoka), which are shown in Figure 2. To make clear uncertainty of response ductility, it is assumed that the Kushiro YSCDS is the design YSCDS, and the structures are designed at the natural period of $T = 0.5, 0.7$ and $1.8s$. The yield seismic coefficients at these natural periods are given in the first line of Table 1 as $k_h = 0.4606, 0.2867$ and 0.1481 , respectively. Simulating 1000 of DRSCATHs at Kushiro site, we calculate the probability density function of ductility responses. Figure 9 shows the PDF of ductility responses at the natural period of $T = 0.5, 0.7$ and $1.8s$.

The brown, blue and red lines corresponding to the natural period of $T = 0.5, 0.7$ and $1.8s$, respectively. The gray vertical line is for $\mu = 4$. From this figure it is concluded that the uncertainty of ductility responses is the largest at $T = 1.8s$.

Figure 7. The autocorrelation coefficient of the mean phase gradient of Kushiro record (zigzag light blue line) and theoretically derived one at the designated circular frequency (blue squares).

Figure 8. Yield seismic coefficient demand spectrum obtained by using DRSCATHs shown in Figure 2. Each color corresponds to the recorded acceleration time history, from which the fixed Fourier phase $\phi_d(\omega)$ and the initial Fourier amplitude $A_d(\omega)$ are obtained.

Figure 9. The probability density function (PDF) of ductility response at the natural period of 0.5, 0.7 and 1.8s. Simulating 1000 DRSCATHs at Kushiro site and calculate ductility responses. The distribution of these ductility responses is plotted as the PDF. The brown, blue, red lines are corresponding to each natural period.

5 CONCLUSIONS

It has been discussed that the effect of earthquake motion phase uncertainty on the nonlinear response of the structural system. The main research results are summarized as follows: The discussion was placed on the convergence of the response spectrum calculated from the design response spectrum compatible acceleration time history (DRSCATH) to the target design response spectrum. The DRSCATH was strongly affected by the assigned phase. A method to calculate the phase as a function of the circular frequency was introduced. A method to identify the stochastic characteristic, especially, the probability density function of the mean phase gradient was introduced. The method to simulate earthquake motion phase was introduced. A method to evaluate the phase uncertainty was discussed based on the nonlinear response of structural system. For that purpose, the Clough type constitutive relation of the structural system was used. The uncertainty of ductility responses of nonlinear systems was discussed mainly.

ACKNOWLEDGEMENT

This research was funded by Grant-in-Aid Scientific Research, JSPS (#21K04242) and the author would like to acknowledge Japan Meteorological Agency and National Research for Earth and Disaster Resilience to provide valuable observed earthquake motion records.

Health monitoring of long-span bridges using deep learning driven by sensor measured and numerical response data

Z. Xue, W. Sebastian & D. D'Ayala
University College London, London, UK

ABSTRACT: Both the vibration and quasi-static load responses of cable-stayed bridges affect their long-term behaviours (eg in fatigue) and so their structural integrity. The associated modal behaviours and (owing to their statically indeterminate nature) the static response are strongly influenced by the spatial stiffness profiles of the bridges. Translation into loads and response of data from a comprehensive network of multi-sensors, shows huge potential to drive a deep learning (DL) approach which can identify these spatial stiffness profiles, and so can reveal any spatial stiffness perturbations arising from any damage states. The role of sensor-verified FE analysis is discussed in providing a means to assess likely damage states for training the DL approach to enable the early defect detection. A significant impact of data quality and sample size on the DL method is discussed in the paper. This paper compares generation of data sets, establishment of learning frameworks, and performance of each DL application. A review of existing literature in the wider field of SHM is also provided, to strengthen the case for this novel approach.

1 INTRODUCTION

With the continuous construction of long-span bridges, bridge damage caused by dynamic problems becomes an increasingly important consideration. Accidents caused by dynamic load, such as seismic load, wind load and passing vehicle load are common during bridges' service period. The Viadotto Polcevera bridge in Italy collapsed during a rainstorm on 14 August 2018, lead to forty-three people deaths. The Silver bridge crossed Ohio River in U.S. collapsed under the weight of rush-hour traffic on 15 December 1967, resulting in the deaths of forty-six people. Damage detection technology is crucial to preventing these serious bridge accidents.

Over the years, with the rapidly development of computer-based technologies, structural damage detection methods have evolved from the traditional visual inspection to the modal parameter identification (Salawu et al. 1997), (Pandey et al. 1991), (Sampaio et al. 2003) to the CNN-based image recognition method (Sandeep Sony et al.). To this end, due to its low cost and high accuracy, vibration-based deep learning is increasingly popular in recent years (Avci et al. 2021).

In the structural health monitoring of large civil structures, the application of deep learning method driven by monitoring data of sensor networks in damage identification has also attracted great attention of researchers. Deep learning networks were presented that they have better performance than shallow learning (like support vector machine) while processing data mining under noise effects (Lin et al. 2018). Another review is provided of the application of deep learning in SHM, including the vibration method and visual processing method (Azimi et al. 2020). Meanwhile, new technologies are being introduced that are aimed at identifying SHM damage, such as sensors and UAVs. The damage detection methods of bridge structures based on big data and artificial intelligence methods in recent years are summarized (Sun et al. 2020).

A review of the papers that have been published most frequently during the past decade is presented in this paper. The purpose of this review is to provide an overview of bridge SHM, and DL techniques (Convolutional neural network methods are mainly focused on in this paper) in defect detection, summarize the most recent research developments, and discuss future directions. Following is a description of the paper's structure. In section 'Bridge structural

health monitoring’, This paper discusses first the types and locations of potential defects in long-span bridges, then it introduces the sensor networks in SHM systems. In section ‘Vibration-based defect detection’, it mainly focuses on structural defect detection method using DL method driven by time series vibration data. The generation of damage data sets is the core content of deep learning damage detection. In this section, the methods for generating damage data sets are divided into three categories, including vibration testing, numerical simulation, and the combination of vibration testing and numerical models. The performance of deep learning models in different applications is discussed respectively. Section ‘Summary and prospects’ discusses the limits, challenges, and future trends of structural defect detection using DL method.

2 BRIDGE STRUCTURAL HEALTH MONITORING

2.1 Defect of long-span bridge structures

Cable stayed bridges are the most widely used long-span bridges in the world. a cable-stayed bridge is mainly composed of the main girder, pylons and stay cables. Figure 1 shows the axial force paths in a cable-stayed bridge. The main girder is generally a composite steel-concrete structure, the pylons are mostly concrete structures, and the stay cables are made of high-strength materials.

Figure 1. Force paths of cable-stayed bridges.

As to the cables, continual exposure to environmental factors will cause corrosion of steel, which will result in cracks or even fractures in the cable. As a result, it can seriously degrade the stress state of the cable-stayed bridge. Furthermore, the stiffness of the cable is low, making it easy for external loads to cause vibration. Vibrations of this intensity will accelerate the abrasion of the anti-corrosion coating on the cable and aggravate the corrosion of the cable. Vibrations will also accelerate the development of original defects. Stay-cables and its anchoring details are the most common positions for defects (Pulkkinen et al. 2015).

The main girder of long-span cable-stayed bridge is usually composed of steel-concrete. Contact with soil and water will also cause corrosion of the main girder exposed to the air. Furthermore, vehicle overloads and traffic accidents may damage the structure locally, causing cracks and peeling of the main girder surface. In addition, the changes in cable force and the deflection deformation of the pylons will also cause the structural damage of the main girder.

The pylons of the cable-stayed bridge are usually composed of concrete. Common defects of the pylon include deflection deformation, fatigue crack and shear crack. Natural load like wind and unbalanced tension between cables can cause pylons to deflect. In the anchorage area of the cable, frequent changes in cable force and temperature can lead to fatigue cracking of the concrete. The shear crack usually caused by bridge state changes. The shear crack was discovered on the Viadotto Polcevera bridge collapsed in 2017 (Sandberg et al. 2010).

According to above, the stay cable is the most susceptible to damage in a long-span cable-stayed bridge, followed by the main girder and the pylons. It is corrosion and fatigue cracking that cause the majority of damage to structures. To study fatigue damage on long-span bridges, a 1:4 suspension bridge model was developed in 2019 (Zeng et al. 2019), the model includes the main cable, anchorage zone, hanger, and box girder. Fatigue experiments were applied to the model. The high-strength steel wires of the hangers were gradually evolving into a fatigued state after 2 million loading cycles, and some of them broke after 2.4 million loading cycles. The hanger wire lost transfer force ability after 2.8 million loading as a result. This shows that the early fatigue damage in the cable will gradually accumulate over time and eventually lead to structural failure.

According to an analysis of the fatigue damage in the bridge by establishing the finite element model of Tsing Ma bridge (Chan et al.2015). The FE model was updated by comparing the modal characteristics identification results based on measured data (using SHM system on

the Tsing Ma bridge) and FE model results. It is found that the stress spectra in the elements were reduced when considering fatigue damage effects.

The defects of long-span cable-stayed bridges have strong randomness, which brings challenges to the damage detection and maintenance of bridges (Sandberg et al. 2010). A sea crossing cable-stayed bridge was detected that the shortest cable near the pylon was overstress. In 2004, fatigue cracks were detected in new cables after the first round of maintenance and a small amount of cable replacement in 1999. The condition of only a small number of cables is monitored by an acoustic monitoring system, which is not capable of accurately assessing the health of the remainder. In order to ensure safety, all remaining cables were replaced as part of the project.

In conclusion, it can be observed that a method of accurately detecting damages to key parts of a cable-stayed bridge is extremely important for ensuring the safety of the bridge.

2.2 Long-span bridge sensor networks

The interest in structural health monitoring (SHM) has grown in order to objectively manage civil infrastructure systems. Use of a long-term SHM can enable determination of structural property changes over a long period of time, by either continuous monitoring or by intermittent live load tests. The health of a bridge is monitored by the use of sensors that measure external loads, dynamic responses, etc. For instance, strain gauges were used to infer the biaxial response to live loads in a bridge with reduced transverse distribution capability (Sebastian et al. 2018).

Over the past few decades, a large number of newly built long-span bridges have been equipped with rich sensor networks for real-time monitoring of environmental response and response signals on bridges. It provides a valuable and large database for the condition description of bridges.

Table 1 lists several SHM sensor networks installed on the bridges opened in recent decades. The rich sensor network provides a barge bank of sensor data that enables quantification of both the loads and the associated responses, both traffic and environmental loads can be assessed.

Table 1. SHM sensor networks of long-span bridges.

Long-span bridge	Open year	Length of main span	Number of sensors	SHM sensor networks*

3 VIBRATION-BASED DEFECT DETECTION

3.1 Deep learning-based defect detection method

Structural health monitoring (SHM) is a promising technique, it can identify the presence, severity and location of any damaged areas by analysis of recorded signals in various forms.

Convolutional neural network (CNN), as an important branch of deep learning, can be used to automatically discover various features in large raw datasets by backpropagation algorithm, it can reduce both research time and expert knowledge of physical problems.

With rapid advances in deep learning technology, the structural health monitoring community has witnessed a prominent growth in deep learning-based condition assessment techniques of structural systems. Deep learning has ushered in many breakthroughs in vision-based detection via convolutional neural networks (CNNs), but the vibration-based structural damage detection by CNN remains being refined. Thus, a fast and accurate structural damage detection system using one dimensional (1D) CNNs was presented in recent years. One major advantage is that a real-time and low-cost hardware implementation is feasible due to the simple and compact configuration of 1D CNNs. Figure 2 illustrates the flow chart of a typical CNN model training process.

Figure 2. A CNN training flow chart.

Convolutional layers extract features, pooling layer reduces the dimension of the data, and a full connection layer classifies the input signal, then compares it to a preset label to determine the loss function. Trained models with a lower loss function have a higher classification accuracy.

Next, according to different methods of generating damage data sets, the structural damage detection based on CNN method will be introduced in three categories: vibration test, numerical simulation, and using numerical simulation together with vibration test. The content includes the characteristics of each study, the unique CNN model stratification, the existing shortcomings, etc.

3.2 Vibration test

CNN training requests a damage dataset with a large capacity. Only if the damage can be easily added to the structure, a large number of damage data can be collected through vibration tests at low cost. Using loosened bolts is a repairable method to applying damage in steel structures (Osama et al. 2017). Damage at the steel frame can be simulated by loosening the bolts at joints. A modal shaker excited the structure, and acceleration signals were collected at the joints.

Figure 3 shows an effective way to increase the capacity of the dataset by slicing the signal with overlay. To that end, in their follow-up research (Onur et al. 2018), the acceleration sensors in the experiment was replaced by wireless sensors with a computationally low cost. On this basis, they represented a 1D-CNN-based damage detection method with only two experiments (Osama et al. 2018): test on undamaged structure and test on fully damaged structure. This method can enable judgement as to whether the structure is damaged under the condition of limited damage data.

Adding extra mass blocks is another way to applying repairable damage to real structures. A three-span reinforced continuous beam bridge was established using the finite element method (He et al. 2020). As part of this study, the damage was simulated by loading extra block masses (20kg and 40kg, respectively) where it is expected to occur (close to the mid span). Experiments conducted on the beam at both a laboratory scale and in a numerical model show that this method accurately predicts damage along its middle span.

A similar method to obtain the damage data of a steel girder bridge (Zhang et al. 2019). According to the results, the proposed CNN model is sensitive to tiny local mass changes at 8 different positions of the in-lab steel beam structure. It can greatly detect the tiny mass changes.

At the end of this section, Table 2 summarizes the CNN-based defect detection approaches that generate damage data sets through vibration tests, including the applied excitations, the various types of damage, the dataset capacity, and the performance of the defect detection.

Figure 3. Data augmentation method.

Table 2. Review of CNN-based defect detection methods, datasets collected by vibration tests.

Ref	Test structure	Type of damage	Data generation	Dataset capacity	Performance
(Osama et al. 2017)	A 4.2m length steel grandstand simulator	Loosen the bolts at beam-to-girder connections	Random shaker excitation	12288 acceleration samples	Damage identification and damage localization
(Onur et al. 2018)	A 4.2m length steel grandstand simulator	Loosen the bolts at beam-to-girder connections	Random shaker excitation	5280 acceleration samples	Damage identification and damage localization
(Osama et al. 2018)	A 3.6m height four-story steel benchmark frame	Loosen the bolts and remove the brave members	Random shaker excitation	8988 acceleration samples	Damage quantification
(He et al. 2020)	A 9.8m length girder bridge	Adding additional mass blocks	Random shaker excitation	800 acceleration samples	Damage localization and quantification
(Zhang et al. 2019)	A 2.09m steel beam (S1), a 6.45m girder bridge (S2) and a 27.3m long girder bridge (S3)	Adding additional mass blocks	Random shaker excitation (S1 and S2), white noise excitation (S3)	14465 acceleration samples (S1), 8595 samples (S2), 4800 acceleration samples (S3)	Damage localization and quantification

3.3 Numerical simulation

For structures in service, it is often difficult to obtain the data set under damage state, which brings difficulties to the training of deep learning model. In this case, numerical models provide damage simulation and data generation efficiently. As to a rectangular section beam with 40 beam elements, damage cases can be easily simulated by reducing the local stiffness of beam elements (Guo et al. 2020). In total of 1.5×10^6 samples were generated for training and 5×10^4 samples for validation. This method is robust to data loss and noise interference, and the damage location and damage degree can be well detected.

It should be noted that the actual structure of the application often has errors with the model used in training. Therefore, the randomness of structural parameters should be taken into account when establishing the finite element model (Yulin et al. 2021). With the enhancement of noise, the accuracy of the model considering the randomness of structural parameters in training is significantly higher than that of the model without randomness.

The damage was also simulated by reducing the stiffnesses of the beam elements in a three-span continuous concrete beam (Yang et al. 2021). As stiffness and flexibility are reciprocal, when a structure is damaged, the local stiffness will decrease and the local flexibility will increase. This article briefly introduces the application of CNN method in prestressed concrete structures.

Due to the difficulty in extracting damage-sensitive and noise-resistant features from the response of structures, structural damage detection remains a challenging problem. It has an excellent performance of the deep learning method in detecting damage under the influence of

noise in the data set (Lin et al. 2017). In this basis, to gain a physical understanding of how the network works, hidden layers were visualized in the network.

As the main weighing component of long-span bridge, the health of the cables largely determines the health state of the bridge. The Fourier amplitude spectra (FAS) of acceleration responses are used without extensive pre-processing for modal identification directly from the raw measurement data (Duan et al. 2019) (Chen et al. 2021). According to their results, the current CNN has been shown to be robust under a variety of observational noise levels and wind speeds.

At the end of this section, Table 3 summarizes the CNN-based defect detection approaches that generate damage data sets through numerical simulations.

Table 3. Review of CNN-based defect detection methods, datasets generated by numerical simulations.

Ref	Test structure	Type of damage	Data generation	Dataset capacity	Performance
(Guo et al. 2020)	A numerical model of Euler-Bernoulli beam	Reduce the stiffness of local beam elements	Gaussian white noise excitation	1.5*10 ⁶ mode shape samples	Damage localization and quantification
(Yulin et al. 2021)	A 2m length simply supported concrete FE beam model	Reduce the stiffness of local beam elements	Random hammer excitation	20000 acceleration samples	Damage localization and quantification
(Yang et al. 2021)	A 55m length continuous beam bridge	Reduce the stiffness of local beam elements	No excitation, analyzed by ANSYS	Flexibility diagonal curvature as samples	Damage localization and quantification
(Lin et al. 2017)	A 10m length simply supported beam	Reduce the stiffness of local beam elements	Random white noise excitations	6885 acceleration samples	Damage localization and quantification
(Duan et al. 2019) (Chen et al. 2021)	A 2-D FE model of a 140m length tied-arch bridge	Decrease the cross-sectional area	Wind force excitations	28950 Fourier amplitude spectra samples	Damage localization and quantification

3.4 Combination of numerical simulations and vibration tests

It is easy and efficient to acquire damage data when a numerical model is established. A major problem is the failure to match the numerical model to the original structure, which may lead to a reduction in data quality. Hence, using the data from actual structural experiments used to update a numerical model, it is available to efficiently enhance the fidelity of the numerical model, then to accurately simulate a wide range of damage data (Franchini et al. 2022).

The updated numerical model can be used to generate recurrence graph for CNN training (He et al. 2020). However, the proposed method is an image recognition method in essence. The vibration signal is converted into a recursive graph, and then the damage is detected by image recognition. This will lead to complex computation for large structures.

In order to ensure the fidelity of the dataset generated by Finite element (FE) models, it's necessary to consider various uncertainties, including modeling errors, measurement errors, and environmental noises based on FE model and real intact state (Zohreh et al. 2020).

In order to ensure the fidelity of damage dataset generated by numerical models, it is also necessary to compare the modal parameters of actual structure and numerical model under damage conditions (Hakim et al. 2015). The damage in the experiment can be achieved by introducing a slot in turn obtained by grinding from the different locations of the structure. Meanwhile the damage was simulated by reducing the local stiffness in FE model.

The measured data from the vibration experiment as well as the data generated by the finite element model can both be used as input signals when training the deep learning model, which further guarantees the fidelity of the dataset (Teng et al. 2019). In this study, the data set required for CNN training was generated through the finite element model, and then the training results were verified by the data collected from the laboratory scale structure.

Table 2 summarizes the CNN-based defect detection approaches that generate damage data sets through the combination of numerical simulations and vibration tests.

Table 4. Review of CNN-based defect detection methods, datasets based on numerical simulations & vibration tests.

Ref	Test structure	Type of damage	Data generation	Dataset capacity	Performance
(He et al. 2020)	A 9.8m length girder bridge and a 75m length FE model	Reduce the local stiffness, load additional mass blocks	Random hammer excitation (Exp), noise excitations (FE)	800 recurrence graph samples (Exp), 10000 samples (FE)	Damage localization and quantification from 10 structural states
(Zohreh et al. 2020)	A 2m height jacket structure and its FE model	Remove the diagonal braces	Shaker excitations (Exp), noise excitations (FE)	500 FRFs samples (Exp), 1500 samples (FE)	Damage localization from 5 structural states
(Hakim et al. 2015)	A 3.2m length steel I-beam structure and its solid FE model	Grinding the structure (Exp), remove solid elements (FE)	Random shaker excitations (Exp), modal analysis (FE)	104 sets of mode shape value samples (52 Exp), (52 FE)	Damage localization and quantification from 101 structural states
(Teng et al. 2019)	A 10.62m length steel frame with 381 rods and its FE model	Cut rod section (Exp), reduce the stiffness of the rods (FE)	Hammer excitations (Exp)	17 modal strain energy samples (Exp), 44 samples (FE)	Damage localization from 136 structural states

4 CONCLUSIONS

In this paper, a systematic overview of vibration-based deep learning techniques in structures is provided, several conclusions can be drawn as follows.

Deep learning methods based on CNN have great potential for detecting structural damage to bridges. An important factor in determining the detection accuracy is the quality of the data set formed by the vibration response signal. A large capacity and high-fidelity data set are prerequisites for the successful application of this method in bridge structures.

The combination of vibration test and numerical model is an advanced method. The numerical model can be updated using modal parameter identification with the measured data from real structures. It can greatly improve the fidelity of the generated dataset from numerical models. To this end, the SHM sensor network of the bridge can provide vibration response data sets under different environments and vehicle excitation, which will greatly improve the robustness of the depth learning model to environmental and other impacts when conducting damage identification.

In conclusions, it is a low-cost and efficient way to update the high-fidelity numerical model based on the measured data of its sensor network and generate a large sample size damage dataset to train the deep learning model, which should be a future trend of bridge SHM.

ABSTRACT: Ageing reinforced concrete (RC) structures were observed to be much more vulnerable to progressive collapse than newly constructed ones. Deterioration due to severe reinforcement corrosion can significantly affect progressive collapse resistances of the RC structures. Hence, this contribution aims at numerically investigating the progressive collapse behavior of the deteriorated RC frame structures subjected to uniform reinforcement corrosion. Both static and dynamic progressive collapse analyses in relation to a deteriorated RC frame subjected to a middle column removal scenario are carried out. It is observed that both static and dynamic progressive collapse resistances significantly decrease with increasing corrosion level. The reinforcement corrosion is found to be the predominant cause to the deterioration of the progressive collapse resistances, while the effect of concrete deterioration has limited influence. Reinforcement corrosion in the beams in the bays directly above the removed column controls the structural progressive collapse performance, while the reinforcement corrosion in other locations has little influence. The dynamic resistances are found to decrease larger in percentage than the static resistances with increasing corrosion level.

1 INTRODUCTION

Progressive or disproportionate collapse of reinforced concrete (RC) building structures due to accidental loads may cause considerable losses of life and property (Ding et al., 2018, Parisi et al., 2019, Feng et al., 2021, Ding et al., 2021). Considering civil engineering structures are prone to ageing and deterioration processes from aggressive chemical attacks (Feng et al., 2021, Biondini and Vergani, 2014), it is of great importance to not only reduce the risk of progressive collapse for new constructions but also assess the structural robustness or safety of existing buildings (Parisi et al., 2019). RC structures may suffer from carbonation of concrete cover and penetration of chloride ions, which will result in reinforcement corrosion and significantly reduce the performance of the structures. In this context, a life-cycle performance assessment becomes very important (Biondini and Frangopol, 2016). However, at present very limited information is available in literature with respect to its quantification in the context of structural robustness or progressive collapse (Botte et al., 2016, Feng et al., 2021, Yu et al., 2017). Botte *et al.* (2016) numerically investigated the influence of corrosion effects on the tensile membrane behavior of RC slabs subjected to middle support removal scenarios. A significant influence on the ultimate load-bearing capacity of the slabs due to the corrosion was observed, even for a small corrosion level. Yu *et al.* (2017) studied progressive collapse behavior of ageing RC frame structures subjected to middle column removal scenarios. The ageing structures with

severe corrosion were observed to be much more vulnerable to progressive collapse than newly constructed ones. The ultimate deformation capacity was reduced by over 40% after 50 years of corrosion, while the ultimate load-bearing capacity was reduced almost by 20%-30%. Feng *et al.* (2021) numerically studied the time-dependent reliability and redundancy of a RC frame subjected to column removal scenarios. All of these investigations show that corrosion can significantly affect the progressive collapse behavior of RC structures.

In light of the above background, this contribution aims at numerically investigating progressive collapse performance of deteriorated RC frame structures subjected to uniform reinforcement corrosion. Following the introduction of the implemented deterioration models in Section 2, an example RC frame is described in Section 3. Subsequently, the influence of different deterioration models (Section 4), different corrosion locations (Section 5), as well as dynamic effects (Section 6) are investigated. Eventually, conclusions are addressed in Section 7.

2 CORROSION MODELING

The process of corrosion in RC structures includes an initiation phase and a propagation phase (Botte *et al.*, 2016, Yu *et al.*, 2017). The reinforcement in RC structures will become depassivated due to the ingress of chlorides or carbonation in the initiation phase. In the propagation phase the actual cross-sectional area of the reinforcements is reduced and the volume of the bars start to expand due to the accumulation of corrosion products. Currently, only the propagation phase is considered in this contribution, as the duration of the initiation phase and the end of service life determination is not within the objectives of the investigations in this contribution. In general, damage modeling includes the following four aspects (Biondini and Vergani, 2014, Botte *et al.*, 2016, Yu *et al.*, 2017): (1) Reduction of cross-sectional area of the corroded reinforcement; (2) Reduction of mechanical properties of the reinforcement; (3) Deterioration of concrete due to cracking and spalling (expansion of corrosion products); and (4) Reduction of bond behavior between the reinforcing bars and the surrounding concrete. The reduction of bond behavior is not taken into account in the present work and can be the subject of future investigations.

2.1 Effect of corrosion on cross-sectional area of reinforcing steel

The reduction of cross-sectional area of reinforcing bars is one of the most relevant effects of corrosion (Cairns *et al.*, 2005). The corrosion mechanism can relate to uniform corrosion, pitting corrosion, or a mix of both (Biondini and Vergani, 2014). Generally, the carbonation of concrete cover may produce uniform corrosion, while pitting corrosion is mainly developed in the presence of chloride ions (Du *et al.*, 2005). In the following uniform corrosion is considered to investigate the progressive collapse behavior of deteriorated RC frames. However, the analysis could be also extended to take into account pitting corrosion by incorporation of a pitting factor (Biondini and Vergani, 2014).

Figure 1. Modeling of cross-section reduction of a corroded bar.

The average loss of cross-sectional area in case of uniform corrosion can be calculated if the corrosion penetration depth x is known, see Figure 1. The original radius of the reinforcing bar is R_i , while the effective radius after corrosion is $R_{eff} = R_i - x$. Consequently, the percentage of cross-sectional area loss α (or corrosion level) can be calculated as follows:

$$\alpha = \frac{\Delta A_s}{A_s} \times 100\% \quad (1)$$

where ΔA_s is the area reduction due to corrosion; and A_s is the original area of the bar.

An empirical model can be adopted to determine the time-dependent corrosion penetration depth x . The corrosion rate i_{corr} is calculated by (Biondini and Frangopol, 2016):

$$i_{\text{corr}}(t) = 0.85 \cdot i_{\text{corr}}(0) \cdot t^{-0.29} \quad (2)$$

$$i_{\text{corr}}(0) = \frac{2.7(1 - w/c)^{-1.64}}{d_c} \quad (3)$$

where $i_{\text{corr}}(t)$ [$\mu\text{A}/\text{cm}^2$] is the corrosion rate at time t [year] since corrosion initiation; $i_{\text{corr}}(0)$ is the corrosion rate at the start of corrosion propagation; w/c is the water cement ratio; and d_c [cm] is the concrete cover. Consequently, the corrosion penetration depth x [mm] can be calculated using Equation (4) as an integral of the corrosion rate:

$$x(t_n) = 0.0116 \int_0^{t_n} i_{\text{corr}}(t) dt \quad (4)$$

where 0.0116 is the unit conversion factor since $1 \mu\text{A}/\text{cm}^2 = 0.0116 \text{ mm/year}$.

2.2 Effect of corrosion on mechanical properties of reinforcing steel

The influence of corrosion on the strength of reinforcement steel, i.e. the yield stress and the ultimate strength, has been studied by many researchers (Almusallam, 2001, Du et al., 2005, Cairns et al., 2005, Zhu and François, 2013). However, contradictory conclusions were drawn. Several investigations (Almusallam, 2001, Botte et al., 2016) indicated that the tensile strength of steel bars was not influenced by the level of reinforcement corrosion when the actual (reduced) area of cross-section was adopted. In this regard, the reduced cross-section area (i.e. actual area of the corroded rebar) can be used to simulate the reduction of the capacity of the corroded rebar, where no reduction of the yield stress and the ultimate strength is considered in the current study.

Almost all experimental studies explicitly showed that corrosion may result in significant reduction of the ductility of reinforcement steel (Botte et al., 2016, Coronelli and Gambarova, 2004). Based on fitting of available experimental data, different mathematical models for the ductility loss have been developed. According to references (Biondini and Vergani, 2014, Feng et al., 2021), the loss of steel ductility is expressed as an exponential reduction model, which is adopted herein, as the following model:

$$\varepsilon_{su,c} = \begin{cases} \varepsilon_{su}, & 0 \leq \alpha < 0.016 \\ 0.1521\alpha^{-0.4583} \varepsilon_{su}, & 0.016 \leq \alpha \leq 1 \end{cases} \quad (5)$$

2.3 Effect of corrosion on concrete properties

With increasing reinforcement corrosion level, considerable internal pressure can be developed due to the formation of corrosion products (i.e. iron oxides) along the surface of reinforcing bars and this may lead to cracking and spalling of the concrete cover. The mechanical properties of both the cover concrete and the core concrete may be affected. Regarding the cover concrete, the effect of cracking and spalling is considered by reducing the compressive strength of the concrete (Coronelli and Gambarova, 2004). The reduced concrete strength f_c^* is expressed as follows:

$$f_c^* = \frac{f_c}{1 + \kappa(\varepsilon_{cr}/\varepsilon_{c1})} \quad (6)$$

where f_c is the concrete peak compressive strength with no reduction; κ is a coefficient related to bar roughness and diameter, where a value of 0.1 has been adopted for medium-diameter ribbed bars (Coronelli and Gambarova, 2004); ε_{c1} is the concrete peak strain; and ε_{cr} is the average tensile strain in the cracked concrete and is calculated by (Coronelli and Gambarova, 2004):

$$\varepsilon_{cr} = n_{\text{bar}}\omega_{cr}/b_0 \quad (7)$$

$$\omega_{cr} = 2\pi(\gamma_{rs} - 1) \cdot x \quad (8)$$

where b_0 is the initial section width; n_{bar} is the number of bars under compression; ω_{cr} is the total crack width for a given corrosion level; γ_{rs} is the ratio of volumetric expansion due to corrosion products (Figure 1), which is set as 2 based on the assumption that all corrosion products accumulate around the corroded bar and are incompressible; and x is the corrosion penetration depth.

In terms of the core concrete, the strength and ductility may decrease as well, since the confinement effect provided by the transverse bars decreases due to the corrosion. When updating the reduced properties of the core concrete, the reduced cross-sectional area of the corroded transverse bar is adopted. The modified Kent-Park model can be adopted to calculate the strength of the core concrete (Feng et al., 2021):

$$K = 1 + \frac{\rho_{st}f_{yt}}{f_c} \quad (9)$$

$$f_{c,cor} = Kf_c \quad (10)$$

$$\varepsilon_{c,cor} = K\varepsilon_{c1} \quad (11)$$

where K is the confinement ratio; ρ_{st} is the volume ratio of corroded transverse reinforcement; f_{yt} is the yield stress of corroded transverse reinforcement; and $\varepsilon_{c,cor}$ is the peak strain corresponding to the strength $f_{c,cor}$ of the confined core concrete.

3 DESCRIPTION AND NUMERICAL MODELING OF A RC FRAME

A 5-story 4-bay RC frame shown in Figure 2a is used to investigate progressive collapse behavior of RC frames subjected to simulated reinforcing corrosion in this work. The height of the first story is 4.5 m, while the height for the other four stories is 3.6 m for each. The dimensions of beams and columns are 250 mm × 500 mm and 500 mm × 500 mm, respectively. Details of reinforcement is also shown in Figure 2a. The columns are labelled as A, B, C, D and E from left to right (Figure 2a). The concrete cover is 30 mm in all elements. The concrete of type C20/25 (CEN, 2004) is used, i.e. the characteristic cylinder compressive strength is $f_{ck} = 20$ MPa, while the mean compressive strength of the concrete is assumed to be $f_{cm} = f_{ck} + 8 = 28$ MPa and the mean tensile strength is $f_{ctm} = 0.3(f_{ck})^{2/3} = 2.2$ MPa (CEN, 2004). The compressive peak strain for the concrete is $\varepsilon_{c1} = 0.0021$. The elastic Young's modulus for the concrete is $E_{ci} = 30.3$ GPa. The aforementioned modified Kent-Park model is used to calculate the confinement effect on core concrete. The characteristic yield stress and tensile strength of reinforcing steel are $f_{yk} = 500$ MPa and $f_{uk} = 575$ MPa (ductility class C), respectively (CEN, 2004). Mean yield stress of the steel is assumed to be $f_{ym} = f_{yk} + 2\sigma_1 = 560$ MPa, where $\sigma_1 = 30$ MPa is the standard deviation (JCSS, 2001). The mean tensile strength is assumed to be $f_{um} = f_{uk} + 2\sigma_2 = 655$ MPa, where $\sigma_2 = 40$ MPa is the standard deviation (JCSS, 2001). The ultimate strain for the reinforcing steel is $\varepsilon_u = 12\%$. The elastic Young's modulus for the reinforcing steel is 205 GPa.

A finite element (FE) model for the RC frame using the software package OpenSees (OpenSees, 2006) is created. Regarding the beam and column components, the force-based fiber beam-column elements with 5 integration points is used. The co-rotational transformation is adopted to consider geometrical nonlinearity. The ConcreteD material and the Steel02 material in OpenSees are adopted for concrete and steel fibers, respectively. More details can be found in relevant references (Feng et al., 2021, OpenSees, 2006). To validate the previously described modeling techniques, a 1/3-scale 3-story 4-bay RC frame (Figure 2b), experimentally tested by Yi *et al.* (2008), subjected to a middle column removal scenario is employed. Figure 2c shows that results between the numerical simulation and the experimental test agree well with each other, which means a good performance of the modeling techniques.

4 INFLUENCE OF MATERIAL DETERIORATION

4.1 Corrosion of reinforcement

In this work, the RC frame subjected to a ground middle column C removal scenario (Figure 3a) is investigated. The mean values with respect to the material mechanical properties in Section 3 are adopted. The FE model is subsequently adopted to perform nonlinear static pushdown analyses. As a first step in the assessment of the influence of corrosion, it is assumed that all the beams and columns are exposed on four sides and all the reinforcements in both the beams and the columns are subjected to uniform corrosion, i.e. deterioration of concrete is not considered and will be investigated in the following section. Note that all the reinforcement is assumed to be subjected to a same corrosion level at a certain moment and no pitting corrosion is considered, i.e. a general influence of the corrosion degradation is investigated rather than localized (spatial variable) degradation phenomena. In the static pushdown analyses, uniformly distributed vertical loads are imposed on the entire structural system. A displacement-controlled analysis is carried out, where the displacement at the top of the removed column C is controlled. The displacement at the control point against the imposed load is recorded, which results in the pushdown curves in Figure 3b.

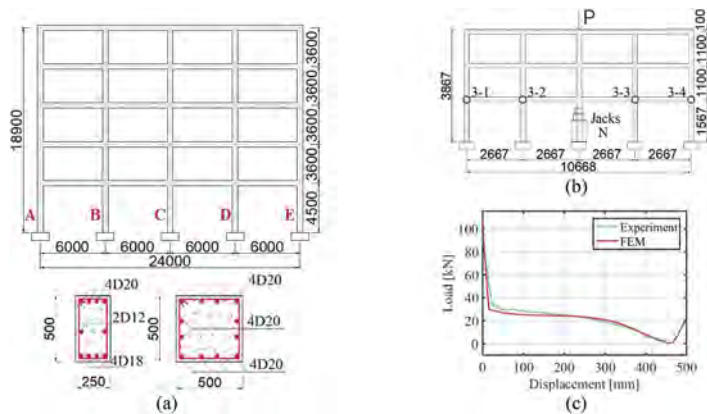

Figure 2. (a) Layout of the RC frame and column and beam cross-sections; (b) 1/3-scale RC frame used for validation; and (c) comparison between test and simulation results. (dimensions in mm).

Figure 3. (a) Removal of the ground column C; (b) load-displacement relationships considering different corrosion levels; and (c) resistance vs. corrosion level.

Figure 3b shows the load-displacement (pushdown) curves under different corrosion levels α . It can be observed that both ultimate load-bearing capacities (corresponding to a first local failure) and corresponding displacements decrease with increasing corrosion level. This is as expected because a larger reduction of the reinforcement cross-sectional area is obtained under a higher corrosion level. Moreover, the corroded rebar becomes less ductile with increasing corrosion level. It is worth emphasizing that different failure modes may be observed, considering different

corrosion levels. In general, the first failure (either concrete crushing or reinforcement rupture) in a system is important, as it can be considered as the onset of failure. The progressive collapse analysis beyond the first failure after column removal is outside of the scope of investigations herein. Different failure modes (varying among the beam ends of BC1 – BC5 in Figure 3a) are observed under different corrosion levels. First failure always occurs in the bays directly above the removed column but varies at different beam ends (i.e. beam ends in different floors). The change of the failure modes may result from the load redistribution mechanism, such as the Vier-eendeel action. Code-compliant shear capacity verifications are also included in all the progressive collapse simulations. Shear failure is never observed in these progressive collapse simulations. The ultimate load-bearing capacities obtained from the results in Figure 3b against the corrosion levels are collected and presented in Figure 3c (the curve designated as ‘Rebar’).

4.2 Deterioration of concrete

Based on the models introduced in Section 2.3, the phenomenon of cracking and spalling in the compressed cover concrete is simulated by reducing its compressive strength, while the confinement effect on the core concrete is determined by using the modified Kent-Park model with the properties of the corroded transverse bars. Likewise, the frame subjected to the loss of the column C (Figure 3a) is considered and pushdown analyses are carried out. Results of resistances against corrosion levels are presented in Figure 3c (the curve designated as ‘Rebar + Concrete’). Compared to the response without considering the deterioration of concrete (the curve ‘Rebar’), the same tendency is observed and the results are almost identical. The influence of concrete deterioration on the progressive collapse resistance is very limited, i.e. resulting in only a slight reduction of the load-bearing capacity. This indicates that the reinforcement corrosion is the predominant cause to the deterioration of structural progressive collapse resistance.

5 INFLUENCE OF CORROSION AT DIFFERENT LOCATIONS

When the RC frame is subjected to the loss of column C (Figure 3a), the bays immediately above the removed column can be regarded as the directly affected part (DAP), while the remaining part is the indirectly affected part (IAP). The DAP will be the most affected part in the context of progressive collapse since large deformations are expected to occur there. Considering that corrosion may occur at specific locations in a frame, the generalized influence of having corrosion at different locations is investigated. In order to do so, the same column C loss situation as that in Section 4 is considered and static pushdown analyses considering two additional cases are performed.

The first case is that all the beams from the first to the fifth floors (designated as ‘Beam:12345’) are subjected to reinforcement corrosion. The curve of resistance against corrosion level is presented in Figure 4a. Note that the curve designated as ‘Entire’ corresponds to the situation where the entire system, i.e. the reinforcement in all beams and columns, is subjected to corrosion as investigated in Section 4 (Figure 3c). It is found that the curve ‘Beam: 12345’ is almost identical to the curve ‘Entire’, which means the corrosion effects in the beams completely governs the reduction of structural load-bearing capacity with increasing corrosion level.

Figure 4. (a) Resistance vs. corrosion level considering corrosion at different locations; and (b) time history displacement responses when $\alpha = 20\%$.

Next, a situation is considered such that only the beams from the first to the fifth floors in the DAP are subjected to reinforcement corrosion (designated as ‘DAP: 12345’). In this case no reinforcement corrosion is considered in the beams in the IAP. Again, the curve ‘DAP: 12345’ is almost identical to the curves ‘Entire’ and ‘Beam: 12345’ (Figure 4a). This indicates that the load-bearing capacity for the RC frame subjected to the reinforcement corrosion is determined by the capacities of the beams in the DAP for the particular case under investigation.

6 INFLUENCE OF DYNAMIC EFFECTS

Incremental dynamic analyses (IDA) (Parisi and Scalvenzi, 2020, Ding et al., 2021) are performed to investigate dynamic progressive collapse behavior of the deteriorated RC frame, through progressively increasing the imposed uniform loads on all beams until collapse. The entire RC frame subjected to reinforcement corrosion (in all beams and columns) is considered. The IDA including a series of nonlinear time history analysis are carried out for the removal of column C (Figure 3a). Rayleigh damping with a damping ratio of 5% is adopted in all dynamic analyses (Parisi and Scalvenzi, 2020). To accurately determine the ultimate load-bearing capacity, a final load increment resolution of 0.1 kN/m is taken. An IDA is executed for each corrosion level. For instance, the time history displacement responses when corrosion level $\alpha = 20\%$ are shown in Figure 4b. The system oscillates around the equilibrium position and the oscillation decays due to damping effect after the sudden column removal. Further, the peak values of the time history displacement responses against the imposed loads are collected to get dynamic capacity (or IDA) curves. The IDA curves for different corrosion levels obtained from the IDA are shown in Figure 5a. It can be seen that the ultimate load-bearing capacities and the ultimate displacements decrease significantly with increasing corrosion levels from 0% to 60%. Note that the static load-displacement (or pushdown) curves are also presented in Figure 5a, as a comparison. The IDA curve is significantly lower than the pushdown curve at the same corrosion level, which means the influence of dynamic effects is significant. The maximum displacements in the IDA curves are almost identical to the displacements corresponding to the ultimate load-bearing capacities (corresponding to the first local failure) in the pushdown curves. Moreover, the failure mode of the dynamic analysis is found to be similar to that in the static analysis at the same corrosion level.

Figure 5. (a) Load - displacement relationship; (b) resistance vs. corrosion level; and (c) percentage of resistance vs. corrosion level.

Subsequently, the dynamic resistances obtained from the IDA are collected to plot the resistance - corrosion level curve, as shown in Figure 5b. As expected, the curve from the IDA is markedly lower than the curve from the static pushdown analysis. Figure 5c further shows the percentages of the dynamic and static resistances (R_d) against corrosion levels, comparing to the corresponding values at $\alpha = 0\%$ (R_0), i.e. R_d/R_0 . It can be seen that the dynamic resistances almost always decrease larger than the static resistances with increasing corrosion levels, resulting in larger dynamic amplification factors. Actually, the influence of the coupling of the corrosion effects and the dynamic effects needs to be further investigated.

7 CONCLUSIONS

In this contribution the progressive collapse behavior of a deteriorated RC frame subjected to a middle column removal scenario has been investigated, particularly with respect to the

influence of reinforcement corrosion, the influence of deterioration of concrete due to the corrosion effect, the influence of different corrosion locations, and the influence of dynamic effects.

Both static and dynamic progressive collapse resistances of the deteriorated RC frame are found to significantly decrease with increasing corrosion level. The reinforcement corrosion is found to be the major cause to the deterioration of the progressive collapse performance with increasing corrosion level, while the effect of concrete deterioration is observed to have limited influence. It is found that the reinforcement corrosion in the beams in the DAP controls the structural performance for the column loss case. The reinforcement corrosion in other locations has little influence. The progressive collapse resistances obtained by dynamic analyses are significantly lower than the static resistances. Moreover, the dynamic resistances are found to decrease slightly larger in percentage than those from static analyses with increasing corrosion level.

It must be emphasized that the obtained results are on the basis of some assumptions, e.g. uniform corrosion is assumed but pitting corrosion may be more realistic in real RC structures and the bond behavior between reinforcing bars and concrete is not taken into account. Nonetheless, the above investigations provide a first stepping stone towards further investigation of progressive collapse in case of degrading concrete structures.

Numerical simulation of non-Fick moisture diffusion of pultruded GFRP bolt connection

Y. Sun, Y. Liu & X. Wang
Tongji University, Shanghai, China

H. Xin
Xi'an Jiaotong University, Xi'an, China

ABSTRACT: With the advantage of easy construction and disassembly, the bolt connection is the most common form of pultruded GFRP profile connections. In coastal areas, long-termed exposure to the combination of high temperature and humidity leads to the degradation of mechanical property of FRP material. The moisture diffusion process plays a significant role in understanding the degradation of pultruded GFRP bolt connection in hygrothermal environments. In this paper, the non-Fick moisture diffusion process in pultruded GFRP bolt connection is numerically simulated. The moisture diffusion parameters were calibrated by gravimetric test of pultruded GFRP coupons. Parametric analysis is conducted to reveal the effect of temperature (40°C, 60°C, 80°C), solution type (fresh water and artificial sea water) and moisture absorption path in single-bolt connection. Besides, the moisture absorption of multi-bolt connection with different arrangements is compared. The results showed that the moisture absorption of specimen exposed to artificial sea water was obviously higher than specimen exposed to fresh water. For structures without damage, the moisture enters the panel mainly from surface; for structures with damage, the moisture from the open-hole plays an important role. The moisture diffusion behavior of specimens under 40°C environment was similar to specimens under 60°C environments. The moisture diffusion of specimen at 80°C was significantly more severe. By comparing multi-bolt connection with different arrangements, it was found that for structures with damage the moisture distribution was more concentrated near the open-hole in parallel bolt distribution than staggered bolt distribution.

1 INTRODUCTION

In the past few decades, fiber reinforced polymers (FRP) have attracted an increasing attention in the field of civil engineering, both in the maintenance of existing structures and the construction of new structures (Bakis et al. 2002; Keller 2001). Since joints are usually the weakest part of load-bearing structures, the short-term and long-term behavior of joints is crucial to achieve expected structure performance. With the advantage of easy construction and disassembly, the bolt connection is the most common form of pultruded GFRP profile connections (Galinska 2020). In coastal areas, long-termed exposure to the combination of high temperature and humidity leads to the degradation of mechanical property of FRP material. The open-hole and discontinuous geometry characteristics can both contribute to the acceleration of degradation of GFRP bolted joints' mechanical properties in hygrothermal environments.

The moisture diffusion process plays a significant role in understanding the degradation of pultruded GFRP bolt connection. In fact, moisture diffusion, stress redistribution and damage evolution constitute a complicated coupled multi-physics process (Ye & Zhang 2022). The effect of moisture diffusion includes: (i) polymer chain relaxation and plasticization of the resin due to bulk volume expansion, which is caused by hydrogen bonds between water molecules (Hu et al. 2020); (ii) fiber/polymer interface decohesion due to capillary transport into the defects at the interface or through microcracks in the bulk matrix (Prolongo 2012).

The previous research showed that the moisture uptakes of a pultruded GFRP plate can be divided into three stages: diffusion-dominated uptake, polymer relaxation-dominated uptake, and composite damage-dominated uptake (Xin et al. 2016). Xin developed a numerical simulation model to investigate the non-Fick moisture uptake behavior of GFRP plates, which corresponds well with the gravimetric test results (Xin et al. 2021a).

The primary objective of this paper is to clarify the moisture diffusion process in pultruded GFRP bolted connection by numerical simulation. The non-Fick moisture diffusion model was adopted in the simulation to consider the coupling effect of diffusion, stress redistribution and damage evolution. Parametric analysis is conducted to reveal the effect of temperature (40°C, 60°C, 80°C), solution type (fresh water and artificial sea water) and moisture absorption path in single-bolt connection. Besides, the moisture absorption of multi-bolt connection with different arrangements is compared.

2 MODELING OF NON-FICK MOISTURE DIFFUSION

2.1 Moisture diffusion theory

The basic solution variable is the normalized concentration, which is defined as follows (Abaqus 2019):

$$\phi = \frac{c}{s} \quad (1)$$

where c is the mass concentration of the diffusing material and s is its solubility in the base material.

Due to the requirement of mass conservation for the diffusing phase, the diffusing problem can be defined as following equation (Abaqus 2019).

$$\int_V \frac{dc}{dt} dV + \int_S \mathbf{n} \cdot \mathbf{J} dS = 0 \quad (2)$$

where V is any volume whose surface is S , \mathbf{n} is the outward normal to S , \mathbf{J} is the flux of concentration of the diffusing phase, and $\mathbf{n} \cdot \mathbf{J}$ is the concentration flux leaving S .

The diffusion is driven by the gradient of a general chemical potential, which is defined by the following relation (Abaqus 2019):

$$\mathbf{J} = -s\mathbf{D} \cdot \left[\frac{\partial \phi}{\partial x} + \kappa_s \frac{\partial}{\partial x} (\ln(\theta - \theta^z)) + \kappa_p \frac{\partial p}{\partial x} \right] \quad (3)$$

where $\mathbf{D}(c, \theta)$ is the diffusivity; $s(\theta)$ is the solubility; $\kappa_s(c, \theta)$ is the ‘‘Soret effect’’ factor, providing diffusion because of temperature gradient; θ is the temperature; θ^z is the value of absolute zero on the temperature scale being used; $\kappa_p(c, \theta)$ is the pressure stress factor, providing diffusion driven by the gradient of equivalent pressure stress.

In previous research (Xin et al. 2016), the moisture diffusion in pultruded GFRP laminate exhibit non-Fick behavior. Time varying boundary conditions are applied to describe this behavior by multi-stage points in the amplitude table. The values of the multi-stage points are determined by calibration of experimental data in the previous publication (Xin et al. 2021b).

2.2 Diffusion parameters

In the previous publication (Xin et al. 2021a), gravimetric tests for thin plates were conducted to calibrate one-dimensional moisture diffusion parameters of pultruded GFRP laminates. The moisture diffusion coefficients of pultruded GFRP laminates are summarized in Table 1. The freshwater refers to distilled water while the artificial seawater was made from artificial sea salt dissolved in distilled water. The concentration of artificial seawater is 3.5%, whose content can be found in (Xin et al. 2016). The solubility of GFRP laminates is assumed to be 1.0. Table 2-4 are the time-varying boundary conditions for specimens aged in both freshwater and artificial seawater environments at different temperatures. The parameters of boundary conditions were calibrated by gravimetric tests under different environments.

2.3 Finite element models

As is shown in Figure 1, the diffusion process in single-bolted and multi-bolted FRP joints were simulated using the Abaqus/Mass Diffusion solver. Linear heat transfer brick elements DC3D8 were used with a mesh size of 1mm. D_{11} time-varying boundary conditions were applied to the left edge of panel, which described the non-Fick moisture diffusion along the roving direction. The right edge was a cutting edge, and therefore no boundary conditions were applied. The top surface and two side surfaces were all applied D_{22} time-varying boundary conditions, which described the non-Fick moisture diffusion vertical to the roving direction. No boundary conditions were applied to the bottom surface. In order to consider the effect of absorption path, there are two kinds of models, i.e. for structures without damage and for structures with damage. For structures with damage, the hole wasn't applied to any additional boundary conditions, since in the undamaged situation, the bolt and FRP panel surface are in good contact, which prevents the moisture enters the open-hole. However, for structures with damage, the moisture enters the FRP open-hole due to the loss of bolt pre-load and the cracks near the hole. Therefore, the hole was applied D_{11} time-varying boundary condition.

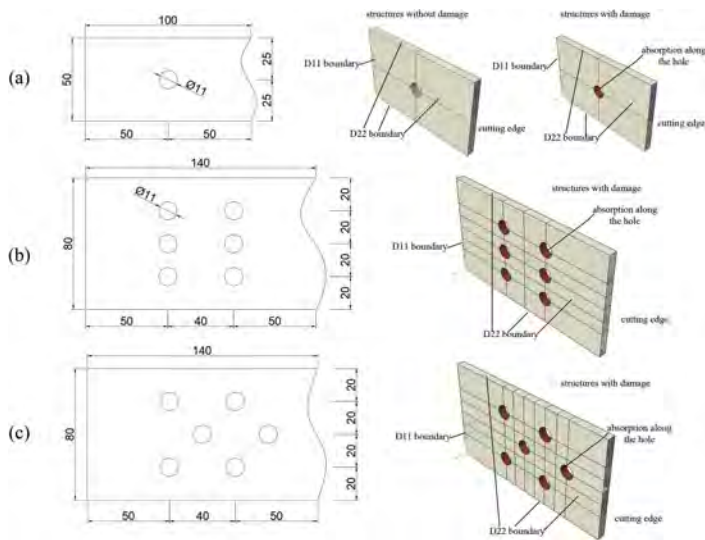

Figure 1. Geometry and schematic diagram of finite element models (units: mm).

3 MOISTURE DIFFUSION SIMULATION OF GFRP SINGLE BOLT CONNECTION

3.1 Effect of temperature

Figures 2-4 show the moisture diffusion process of undamaged single-bolt connection exposed to freshwater at the temperature of 40°C, 60°C and 80°C respectively. With the time increasing, the normalized mass concentration CONC of the whole single-bolt connection specimen gradually increased. The higher the environment temperature, the higher the mass concentration at same diffusion time. The moisture diffusion from the end of the panel was more pronounced than the moisture diffusion from the panel surface. The moisture diffusion behavior of specimens under 40°C environments was similar to specimens under 60°C environments, with the moisture diffusion from the end of the panel dominating the whole diffusion process. The moisture diffusion of specimen at 80°C was significantly more severe, in which the moisture diffusion from the surface of the panel plays an important part.

Figure 2. Mass diffusion process of undamaged single-bolt connection exposed to the freshwater at 40°C.

Figure 3. Mass diffusion process of undamaged single-bolt connection exposed to the freshwater at 60°C.

Figure 4. Mass diffusion process of undamaged single-bolt connection exposed to the freshwater at 80°C.

3.2 Effect of solution type

Figure 5 shows the moisture diffusion process of undamaged single-bolt connection exposed to artificial seawater at the temperature of 60°C. Comparing Figure 3 and Figure 5, the mass diffusion process of specimens under artificial seawater was quite same as the diffusion process under freshwater, because the diffusion rate along the roving direction has little difference between the freshwater environment and the artificial seawater environment. Figure 6 shows the mass distribution of mid cutting plane at $t=1.00E+07s$. The maximum CONC along the hole

was 4.13×10^3 ppm for the specimen exposed to freshwater environment while the maximum CONC along the hole was 2.94×10^4 ppm for the specimen exposed to artificial seawater environment. The moisture absorption of specimen exposed to artificial seawater was obviously higher than specimen exposed to freshwater. It was because that the diffusion rate vertical to the roving direction in artificial seawater environment was larger than in the freshwater environment.

Figure 5. Mass diffusion process of undamaged single-bolt connection exposed to the artificial seawater at 60°C.

Figure 6. Mass distribution of mid cutting-plane of undamaged single-bolt connection at $t=1.00E+07s$.

3.3 Moisture absorption path

Figure 7 shows the moisture diffusion process of damaged single-bolt connection exposed to freshwater at the temperature of 60°C. Figure 8 shows the moisture distribution of mid cutting-plane of undamaged and damaged single-bolt connection. The maximum CONC along the hole was 4.31×10^5 ppm for the damaged single-bolt connection exposed to the freshwater at 60°C, which is nearly 104 times of the undamaged structures. For structures without damage, the moisture enters the panel mainly from surface; for structures with damage, significant amount of moisture enters the panel from the open-hole. The moisture from the open-hole could be detrimental, since the moisture diffusion is usually coupled with stress concentration and damage evolution in the open-hole areas.

Figure 7. Mass diffusion process of damaged single-bolt connection exposed to the freshwater at 60°C.

Figure 8. Mass distribution of mid cutting-plane of single-bolt connection exposed to freshwater under 60°C environments at $t=1.00E+07s$.

4 MOISTURE DIFFUSION SIMULATION OF GFRP MULTI BOLT CONNECTION

Figure 9 shows the surface moisture distribution of parallel and staggered bolt distribution exposed to freshwater under 60°C. It was found that the moisture distribution was more concentrated near the open-hole area in parallel bolt distribution than staggered bolt distribution. Compared with parallel bolt distribution, the spacing between bolts was larger in staggered bolt distribution, with the same ratio of e/d and w/d . Therefore, the coupling effect between moisture absorption from adjacent open-holes is weaker. As a result, the moisture distribution was less concentrated near the open-hole area in staggered bolt distribution.

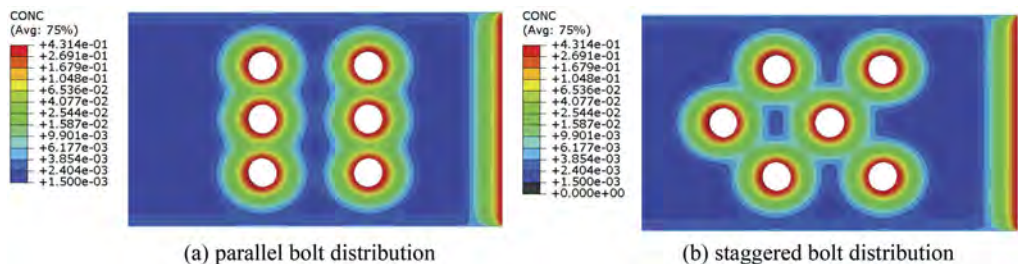

Figure 9. Surface moisture distribution of (a)parallel and (b)staggered bolt distribution exposed to freshwater under 60°C at $t=1.00E+07s$.

5 CONCLUSION

In this paper, the non-Fick diffusion process in pultruded GFRP bolt connections is numerically simulated using time-varying boundary conditions. The moisture diffusion parameters and multi-points value in the amplitude of boundary conditions were calibrated by gravimetric tests. Then, the effects of temperature, solution type and absorption path on single bolt connection and the effect of bolt distribution on multi bolt connection were investigated. The main conclusions are summarized as follows:

- (1) The moisture diffusion behavior of specimens under 40°C environments was similar to specimens under 60°C environments, with the moisture diffusion from the end of the panel dominating the whole diffusion process. The moisture diffusion of specimen at 80°C was significantly more severe, in which the moisture diffusion from the surface of the panel plays an important part.
- (2) The diffusion rate along the roving direction has little difference between the freshwater environment and the artificial seawater environment. However, the diffusion rate vertical to the roving direction in artificial seawater environment was larger than in the freshwater environment.
- (3) Under 60°C freshwater environment, the maximum CONC along the hole was 4.31×10^5 ppm for the damaged single-bolt connection, which is nearly 104 times of the undamaged structures.
- (4) For GFRP multi bolt connections, the moisture distribution was more concentrated near the open-hole in parallel bolt distribution than staggered bolt distribution.

A methodology for the service life estimation of timber structures

D. Marranzini, G. Iovane, L. Cascini, R. Landolfo, M. Nicolella & B. Faggiano

University of Naples Federico II, Naples (NA), Italy

ABSTRACT: Driven by the development of energy saving and environmental sustainability policies, the use of timber as a building material has found wide development during the last decades. An integral part of the design of timber buildings is the evaluation of durability, which strongly affects the material performances and therefore the building service life. In the design process the service life of the building components can be estimated through different methodologies. A deterministic approach is based on the *Factor Method* (ISO 15686). In this regards, the present paper briefly introduce an innovative application of the Factor Method for the prediction of the service life of timber structures. The proposal is based on the use of the *Multi-Criteria Decision-Making (MCDM) methods* as support tool for the determination of the correction factors. The method is applied and validated on a sample of four case studies.

1 INTRODUCTION

Nowadays, timber-based materials such as glued laminated timber and cross laminated timber (CLT) are competitive in the construction world. Especially in the last decade, the use of CLT in residential buildings has also spread in Italy. Thus, new records have been achieved in the field of timber constructions (Svatoš-Ražnjević et al., 2022). This trend is certainly due to a greater knowledge of the potential of timber buildings in terms of thermal, acoustic and structural performances, as well as to the sustainability of wood.

Although timber constructions are a good answer to the demand for sustainable, thermally efficient and resilient buildings, they are susceptible to environmental degradation. Prolonged exposure to the deteriorating agents can cause decay of thermo-hygrometric performance and, in the most severe cases, structural problems, up to the collapse of the structure, undermining the safety of the users. Therefore, design and maintenance require great awareness to this issue.

In such scenario, the methods for the service life design of timber structures fit in. Nowadays several methods for service life prediction of building components are spread in literature. Among them the Factor method (ISO 15686:2011) stands out as simple and effective. Nevertheless, the application to timber structures is limited to specific cases and therefore still under development.

In this paper a combined method based on Factor method (FM) and Multi-Criteria Decision-Making (MCDM) methods is proposed for the evaluation of the service life of timber structures. The method is applied and validated on a sample of four case studies that are located in Southern Italy, allowing for the evaluation of suitability of the proposed methodology.

2 SERVICE LIFE AND DURABILITY CONCEPTS

Since the end of the 1980s, the concept of durability has spread in the building sector. The Construction Products Directive (CPD) (EU, 1988) was the first regulatory reference to introduce the concept of durability and sustainability in the production of building materials. The aim was

to direct the building sector on a new path, based on the limited use of non-renewable resources, as well as the reduction of management and maintenance costs in the building life-time. Subsequently the topic was at the center of the international research. Thus a new regulation (ISO 15686:2011) was published in short time, it providing the know-how about the methodologies for service life planning. Nowadays it is still considered one of the most relevant sources of information in this field. The concept of service life (SL) was developed, it being defined as the actual period of time after manufacturing or installation during which relevant properties of a component meet or exceed minimum acceptable values (Landolfo and Vesikari, 2008).

Afterward, the concept of durability was also brought to the light in the field of structural design. It was understood that a material deterioration process could lead to such a performance decrease that a structure may not be able to respond to service or safety requirements before the design life is over. This is due to the fact that either the actions on the structures or the capacity of the structure are time-dependent variables; furthermore, in absence of an adequate and planned maintenance operation, the resistance tends to decrease over time due to the deterioration process of the material. Within Eurocode 0 (EN 1990:2006) and ISO 13823 (ISO 13823: 2008) general indications for the design of structure service life (SL) were definitely given. The EN 1990 prescribes that degradation can be estimated through calculations, experimental tests or empirical methods. These methods are aimed at estimating the period of time during which a structure or any component is able to achieve the performance requirements defined at the design stage with an adequate degree of reliability (Landolfo and Vesikari, 2008). About the calculation methods, different approaches can be used to assess the SL: prescriptive, deterministic, semi-probabilistic or probabilistic approaches (Trinius and Sjöström, 2005).

3 THE SERVICE LIFE OF TIMBER STRUCTURES

3.1 *Main durability issues*

Durability is a fundamental requirement for a construction. It is influenced by several factors, like physical properties of materials, service condition, design, as well as protection and maintenance measures put in place to prevent degradation of materials and structures.

Timber is particularly susceptible to the deterioration process. The wood decay agents are generally classified into biotic and abiotic (Piazza, 2005). The first category includes insects, fungi, bacteria and marine organisms. Concerning the condition favourable for the biotic attack, the action of most insects is generally influenced by the wood species, whereas the action of fungi and bacteria is strongly influenced by the moisture contents of wood (Viitanen et al., 2010). In this case the environmental thermo-hygrometric conditions and the presence of water determine the risk of degradation. In this regard, different scenarios of degradation are evaluated through the “classes of use” defined by the EN 335 (EN 335:2013). Insects generally produce a reduction of the cross section of a timber member. This can also occur in case of fungi and bacteria attacks, which in addition alterate the chemical composition of the material with consequent deterioration of the mechanical properties of timber (Wood handbook, 2021). Photolysis and chemical degradation processes belong to the abiotic category (Wood handbook, 2021). In the latter case the magnitude of damage caused is typically lower than the biotic one.

Generally, as function of the physical and chemical composition of wood, a different behaviour against degradation is shown by different wood species. A ranking of the most resilient timber species is given by the EN 350 (EN 350:2016) through the “durability classes”. However, in addition to the inherent durability of the timber members, degradation conditions can be mitigated through appropriate design choices, preservative treatments and proper design of construction details (Ayanleye et al., 2022), as well as by the efficient planned maintenance activities.

3.2 *The service life design methods*

Different approaches can be used to evaluate the reliability of timber structures against durability. The standards prescriptive approach consists in instructions and design rules aimed at

preserving the components against typical degradation process. About timber constructions Eurocode 5 (EC5, EN 1995-1-1:2004, section 2.1.3) establishes that durability should be a fundamental design requirement and provides a framework of rules for the design of timber structures exposed to biological degradation (section 4.1). However, these are general and qualitative indications that do not allow an analytical evaluation of the service life (SL).

To this purpose, the factor method (FM; ISO 15686:2011) provides the SL estimation according to a deterministic approach. At the state of the art, the applications of FM to timber structures are limited to the secondary components, as timber claddings (Viitanen et al., 2011; Silva and Prieto, 2021). Further to FM, other calculation methods, based on deterioration models, have been proposed. Among them empirical deterioration models were proposed by Wang et al. (2008) and Leicester et al. (2003) for predicting the depth of fungal attack as a function of the time of exposure, for both in and above-ground decays, by Viitanen et al. (2010) for the prediction of the mass loss due to the brown rot attack as a function of the climate condition. Isaksson et al. (2013) defined a deterioration model based on experimental tests, namely “dose-response function”. Besides, a risk-based method to predict the fungal timber decay has been recently proposed by Gaspari et al. (2021). It is based on a decision trees model, where a risk class can be assigned to the timber component and proper prediction function for decay depth estimation can be selected.

4 THE PROPOSED GLOBAL DURABILITY FACTOR METHOD

The Global Durability Factor Method (GDFM), herein proposed, is based on the combined application of the factor method (FM) and the Multi Criteria Decision Making (MCDM) method.

The FM (ISO 15686:2011) allows to simply estimate the service life (ESL; in years) of a building element by adjusting the value of the reference service life (RSL) through a set of modification factors, *A, B, C, D, E, F, G*, related respectively to quality and design level of components, work execution level or skill level of the installers, indoor and outdoor environments, service conditions, maintenance level (Equation 1):

$$ESL = RSL \cdot A \cdot B \cdot C \cdot D \cdot E \cdot F \cdot G \quad (1)$$

The ESL takes into account the differences from the reference conditions through the modification factors. The RSL is determined on the basis of data gained from experimental tests on components, as well as codes, expert judgments and construction site environment, while the modification factors (A-G) have to be defined by the designers, based on expertise and real service data. The proposal intervenes at this stage, by introducing the MCDM methods (MCDMm) for the determination of the correction factor of the RSL.

MCDMm are tools commonly used in the decision-making process when the decision makers have to choose among different alternatives. Indeed, MCDMm provides the optimum solutions among a set of alternatives available to the decision maker. Nowadays the MCDMm are used in a wide range of fields (Zavadskas et al., 2014). At the state of art several types of MCDMm are spread (Gebre et al., 2021), among them TOPSIS method (Hwang and Yoon, 1981) stands out for the simplicity and efficiency. The latter is already commonly used in building/civil engineering for different scopes, like for quick level vulnerability assessment of the built-up (Faggiano et al., 2011) and for comparative analysis of structural retrofitting systems (Terracciano et al., 2015; Formisano and Mazzolani, 2015). The TOPSIS method is generally based on the preliminary definition of criteria qualifying the alternatives (such as the examined buildings) according to the specific solving problem, and their weight that measures the relative impact on the decisional process (Bagga et al., 2019). Each criteria can be classified as benefit or cost criteria. The final result consists of an index for each alternative, which provides the relative closeness of the alternative to the ideal solutions (positive A^+ and negative A^-). A^+ and A^- are obtained by considering for each criterion the best and the worst performance offered by the examined alternatives. Subsequently the calculation of the Euclidean distances (S_i^+ and S_i^-) of each real alternative from the ideal positive and negative solutions is

carried out. In the end, the relative closeness (RC) index of each alternative to the ideal solutions can be evaluated through the Equation 2:

$$RC = Si^- / (Si^+ + Si^-) \quad (2)$$

Higher the relative closeness, RC index, to the ideal solution is, better is the alternative. Based on this a rank is achieved.

Definitely, in the proposal, the TOPSIS method is applied. The criteria correspond to the FM factors. They are set taking into account the aspects that influence the durability of timber constructions. Hence, for each factor a set of sub-factors is fixed (Table 1). It is relevant to highlight as the sub-factor “E5 – Use class” and “F1 – Shock class” respectively are the most and least influential sub-factors. Therefore every timber case study can be qualified through the FM factors. It is also necessary to introduce and qualify the reference case (C_r) corresponding to ESL = RSL, further to the ideal positive and negative solutions. Through the RC indexes calculated for each case, it is possible to determine a single modification factor, called “Global Durability Index” (I_{GD}), according to Equation 3, which is a function of all the subfactors:

$$I_{GD} = RC_i / RC_{Cr}; \quad I_{GD} = f(A \cdot B \cdot C \cdot D \cdot E \cdot F \cdot G) \quad (3)$$

Evidently for C_r it is $I_{GD}=1.00$.

Therefore the ESL is calculated as it follows (Equation 4):

$$ESL = RSL \cdot I_{GD} \quad (4)$$

It is apparent that higher is the I_{GD} , higher is the ESL of the structure. It means that in a set of structures, the one with the highest I_{GD} is the less vulnerable to the deterioration process. In Table 1 the numbers corresponding to the order of importance assumed for the subfactors are reported.

Table 1. List of durability factors and sub-factors (ISO 15686:2011).

Factor	Sub-Factor (criterion)	
A Quality of components	A1 Type of timber product	10
	A2 Presence of sapwood	5
	A3 State of conservation	9
	A4 Wood species	3
	A5 Quality of storage system at the building site	18
	A6 Quality of transport system (from industry to building site)	22
	A7 Presence of quality management system of industry (ISO 9001)	20
	A8 Presence of Declaration of Performance (DoP) (CPR 305/2011)	19
B Design level of a component or assembly installation	A9 Quality of wood seasoning	4
	B1 Quality of construction details (as designed)	14
C Work execution level or skill level of the installers	B2 Type of protective treatment	7
	C1 Quality of construction details (as built)	15
D Indoor environment	C2 Quality of protection system during the construction steps	21
	D1 Amount of environmental humidity	11
E Outdoor environment	D2 Water condensation risk	12
	E1 Climate zone	6
	E2 Average annual precipitation	13
	E3 Service class (NTC 18)	2
	E4 Average annual solar irradiance	16
F In-use condition	E5 Use class (EN 335)	1
	F1 Impact class	23
G Maintenance level	G1 Inspectability conditions	17
	G2 Quality of maintenance	8

5 APPLICATION OF THE GDFM TO THE CASE STUDIES

The method is applied and validated on four simple case studies located in different municipalities of the Southern Italy. They are selected for the sake of representativeness of recurrent timber types of constructions and structural types, as well as different environmental exposure and age of construction (Recorded Lifetime: RLT). The proposed method is applied to specific members of the case studies, as shown in Figure 1 (a, b, c, d). The survey has allowed to identify the characteristics and the state of conservation (Faggiano et al., 2022). Although the state of preservation of the investigated structures is not critical, they show different degradation types:

case a) It is placed outdoor, part of the member has fine cracks due to direct exposure to UV radiation and contact with rainwater;

case b) The roofing structure is placed outdoor; some parts are directly exposed to UV radiation and rainwater, showing discoloration, while columns show also fine cracks;

case c) The intermediate floor is placed inside a residential building; the beams show the evidence of insect attack (*Cerambycidae*), due to the presence of sapwood; however, the decay is confined to a thin layer of the cross-section.

case d) The structure is placed at the roof level; struts and ties show degradation by insect attack (*Cerambycidae* and *Anobium*), mainly due to the presence of sapwood in the members.

Figure 1. Case studies (specific component): roofing structure a) primary beam; b) column; residential building c) primary beam of the intermediate floor; d) struts and ties of the roof.

The global durability factor (I_{GD}) and the ESL, calculated for each case studies, are shown in Table 2. In absence of experimental tests and considering the design life prescribed by the Italian building Code (D.M. 17/01/2018) for ordinary buildings, a RSL equal to 50 years is assumed for all. The longest ESL is determined for case studies “c” and “d” (52 and 59 years respectively), probably because they are placed in indoor environment, although case studies “a” and “b” are made of “new timber”, but they are outdoor. Nevertheless, the ESL values obtained for cases c) and d) are far from the recorded lifetime (RLT), since they were built more than 150 years ago and they are still in service. At the same time for cases a) and b) a ESL equal to 50 years has been found. Hence, they should still keep in service for a lifetime respectively equal to 44 and 39 years.

Table 2. The results of GFM application to the case studies (a, b, c, d).

Case study	RSL	RC	I_{GD}	ESL	RLT
	years			years	years
a)	50	0.49	1.00	50	6
b)	50	0.49	1.00	50	11
c)	50	0.52	1.05	52	150
d)	50	0.59	1.19	59	200
C_r	50	0.49	1.00	50	-
A^+	-	1.00	1.74	-	-
A^-	-	0.00	0.76	-	-

6 CONCLUSIVE REMARKS

The design of timber structures taking into account the durability issues is a very topical subject, since deterioration is one of the most recurrent cause that leads to a reduction of serviceability or safety performances during the structures service life. In this context the methods for predicting the service life, as the factor method (FM), fit in.

A new method, namely Global Durability Factor Method (GDFM), based on the application of FM combined with TOPSIS method is proposed for estimating the service life (ESL) of timber structures, by determining the modification factors. Thus, the aspects influencing the durability of timber structures are evaluated and proposed as factor and sub-factors, they being ordered according to the impact on durability. In the end the “Global Durability Index, I_{GD} ” is calculated, as a single parameter accounting for all the durability factors. The GDFM is applied on simple case studies, proving the feasibility and the effectiveness.

Future work will aim at the validation of the methodology on a larger sample of timber structures with heterogeneous characteristics and service conditions.

Multi-scale structural integrity assessment of a series of identical components in cultural-heritage structures: The case of the Clifton suspension bridge

R. De Risi, T. Moody, E. Voyagaki, S. Gunner, M. Pregnotato, N. Grilli & C. Taylor
University of Bristol, Bristol, UK

ABSTRACT: Cultural-heritage structures may be characterised by structural elements that are geometrically identical for cosmetic or functional reasons but can be subjected to a significant variable stress distribution because they are located in different positions on the structural system. This can lead to a variety of damage and failure phenomena that will probably occur asynchronously. Damage occurrence triggers discussions among the stakeholders and decision-makers. For heritage structures, repair and restoration actions are costly and constrained by laws regulating grade-listed systems. Therefore, it becomes imperative to understand if such actions are necessary and to identify the most suitable intervention. The research question is: how can future maintenance costs be minimised while preserving the historical value of legacy structures? The answer lies in the reduction of uncertainties using a multi-scale approach that combines: (a) multi-scale knowledge of the material nature and fabrication, (b) multi-scale empirical evidence on material mechanical properties, (c) detailed geometrical description of the system, and (d) multi-scale numerical models. The challenge is finding the optimal trade-off between maintenance and historical value. Such a multi-scale framework is applied to the parapet stanchions of the Clifton Suspension Bridge in Bristol, UK. Stanchions are vertical cast-iron structural elements providing: (a) lateral support to parapets and anti-climb barriers and (b) partial support to the maintenance under-deck gantry. There are 162 identical parapet stanchions on the bridge. These structural elements may suffer heavy damage due to wear and tear. The damage consists of cracking in zones of stress concentration. This damage is unrepairable, and stanchions must be replaced when cracks appear. Their substitution is operated by the Clifton Suspension Bridge Trust (CSBT), which is particularly interested in science and technology for conservation and awareness. By applying the proposed multi-scale assessment framework, we provided essential insights into the structural integrity of such elements that are fundamental for informed decision-making.

1 INTRODUCTION

Many components of the built environment present a degree of repetitiveness in terms of structural and non-structural elements. This feature is even more distinct in cultural-heritage structures, where the repetitiveness of geometrically identical elements is due to functional or cosmetic reasons. Figure 1a shows four typical structural, non-structural and hybrid elements that can be found in cultural-heritage structures: mullioned windows, balustrades, stone columns, canopies and shelters. These elements are generally placed in a precise order according to specific patterns that may be locally interrupted only in some discontinuity areas of the system fabric. Such a spatial variability leads to a variable stress distribution induced by the spatial variability of vertical loadings (e.g. self-weight, live load), horizontal loadings (e.g. wind, earthquake, crowd push), distortion (e.g. thermal distortion), settlements, and ageing phenomena (e.g. protected vs unprotected areas against atmospheric agents). These different stress distributions and ageing phenomena may lead to the asynchronous onset of defects and damages that have multiple consequences (e.g. structural integrity) and raise several questions. First, a symmetric system with a pattern of identical structurally damaged elements will behave globally asymmetrically, changing the stress distribution in the whole structure. Second, the residual life of damaged components must be adequately assessed so that, when damage is identified after an inspection, maintenance and restoration of

damaged and undamaged elements can be planned well in advance. Finally, it is well known that repair and restoration operations for cultural heritage assets are costly and constrained by laws regulating grade-listed systems; therefore, it is essential to achieve solutions from a technical point of view that are compatible with conservation restrictions.

Figure 1. (a) Examples of identical components in cultural-heritage structures. (b) Side view of the Clifton Suspension Bridge. (c) Zoom in on the parapet stanchion.

In other words, the issue, and therefore the challenge, is the trade-off among inspection, damage-tolerance assessment, maintenance costs and the preservation of the historical value of legacy structures. To address such a challenge, uncertainties must be reduced and knowledge improved within a multidisciplinary framework comprising surveying engineering, material science, mechanical testing, non-destructive testing, and analytical and numerical structural modelling. Such a holistic approach requires a multi-scale methodology encompassing both temporal and spatial scales. Multi-scale approaches in the field of cultural heritage are not new (Salonia et al., 2009; Parent et al., 2017; Noardo, 2018; Sileo et al., 2022). The temporal scale is essential because collecting information along the asset lifespan of maintenance, restorations, and replacements allows the development of probabilistic models that can be used to forecast successive damages and consequent interventions. The spatial scale is also critical in the context of conservation and safeguarding because it is oriented to the detailed knowledge of the geometrical features of the asset of interest, including detailed description and representation of damages and imperfections.

In this study, three levels of multi-scale assessment are employed to identify the structural integrity of a component: (i) material, (ii) geometry, and (iii) structural modelling. Regarding the material level, the multi-scale approach spans from studying the material nature and fabrication to identifying the mechanical properties. The geometric multi-scale approach spans from the simple description of the system to advanced laser scanning. Finally, structural modelling can shift from simplistic elastic beams to a complete non-linear continuous finite element model. The more uncertainties decrease, the more sophisticated the assessment can be, i.e. it is possible to evolve from a simple analysis scale, requiring scarce to little data, up to a superior analysis scale, where more advanced information can be retrieved. Such a methodology has been preliminarily applied to the parapet stanchions of the Clifton Suspension Bridge (Figure 1b,c) in Bristol (UK).

1.1 *The parapet stanchions of the Clifton Suspension Bridge (CSB)*

The CSB spans the Avon Gorge in Bristol, UK. The bridge was initially designed by Isambard Kingdom Brunel; it was completed after his death by William Barlow and John Hawkshaw in 1864. A detailed description of the bridge can be found in Macdonald (2008), Pregnolato et al. (2022) and Voyagaki et al. (2022). The bridge is about 215 m long between the centerlines of the piers; however, the suspended part is about 194 m long. It is supported by a wrought iron catenary system connected to saddles on rollers in the towers and then anchored into the rock on each side via inclined shafts. Rods hold up the roadway, which is made of wooden planks. Figure 2a shows a partial cross-section of the bridge. The roadway is about 6.10 m wide between the two longitudinal girders, which are supported by rods at about 2.44 m interspaced along the bridge.

Footways on both sides of the deck, outside the girders, are present. The total deck width between the parapets is about 9.46 m. Figure 2b shows side and top views of the parapet stanchion.

Figure 2. (a) Partial cross-section of the bridge. (b) Side and top views of the parapet stanchion.

The parapet stanchions are $\frac{3}{4}$ " (about 20 mm) thick cast iron cantilever beams with a variable I-shape cross-section. They are about 1450 mm tall and are installed symmetrically on both footways with the same spacing as the suspension rods (i.e. about 2.44 m) for a total of 162 (2×81) elements. Four bolts connect the stanchions to the cross girders (the red component in Figure 2a). Close to the bottom flange, there is a triangular hole (presumably initially realised to reduce the weight of the component) that presents some re-entrant corners with a radius that is not sufficient to reduce the stress concentration. The parapet girder (the white rhombic lattice shown in Figure 1b, and indicated with a green line in Figure 2a) is connected to the stanchions with two bolts, one at the top and one at the bottom. On top of the parapet girder, a timber rail (the brown element shown in Figure 2a) is installed to allow the maintenance gantry to run under the bridge deck. Finally, anti-climb barriers are clamped to the stanchions with four bolts.

1.2 Loadings and observed damage

Parapet stanchions are subjected to several loading conditions. First, the wind pressure acting on the parapet girder and the anti-climb barrier is directly transferred to the stanchions as a horizontal action. Second, the crowd pushing on the barriers is also transformed into a horizontal action on the stanchions. Third, the gantry produces both vertical (self-weight) and horizontal actions on the stanchions. The gantry is subjected to wind and, when in use, can induce crabbing forces on the rail. Wind and crabbing forces act transversally and longitudinally to the bridge axis, respectively. Other stresses generated in the stanchions are due to the global behaviour of the deck; the stanchions create a C-section with the cross girder. In addition, the stanchion is subjected to thermal expansion-contraction cycles and vehicular- and pedestrian-induced vibrations. Figure 3 illustrates the damage typically observed in the stanchions utilising magnetic particle inspection.

Figure 3. Observed damage in the (a) corner and on the (b, c) bottom flange.

More specifically, Figure 3a shows typical corner cracks evolving in the web of the stanchion. In some cases, the cracks are just partial-thickness (blue line), i.e. they do not extend the full thickness of the flange; in many other cases, the crack extends the entire width of the corner and is characterised as full-thickness (red lines). Figures 3b and c show typical cracks

developed in the base flange of the stanchion. Such cracks can be either full-thickness (red lines) or partial-thickness (blue lines). Also, these can be a single crack (Figure 3b) or double cracks isolating an entire piece of the base flange (Figure 3c). In both cases, cracks are in the region of the holes where the bolts tighten the stanchion to the cross girder.

Since 1993, 21 stanchions have been replaced; a storm damaged a few in 1990, while others were substituted due to crabbing of the gantry. Two more stanchions are planned to be replaced in the near future. There are no historical records of stanchions damaged before 1990. Other defects that can be identified mainly include: (i) casting defects creating blow holes on the surface and (ii) corrosion. The latter can occur only at the bottom of the base flange of the stanchion as it is the only element that is unprotected, i.e. not painted. However, it has been demonstrated by COWI, engineering consultants managing the maintenance of the bridge, that corrosion is not a primary driver of the observed damage, as the stress induced by the oxide expansion does not exceed the material's capacity. All these observations led the Clifton Suspension Bridge Trust (CSBT) to start studying this issue with two questions in mind: (i) what is the main driver of the problem, and (ii) what is the residual life of the parapet stanchion after the onset of the damage? In the following, the envisaged structural integrity assessment provides an initial answer to the first question. Future steps necessary to answer the second question are also identified in the Conclusions. The answers provided in this paper are derived from studying two damaged stanchions that the CSBT provided to the University of Bristol. One of the two stanchions was in the form of chopped pieces used to test welding strategies (Figure 4a).

2 MATERIAL

Multiple techniques and technologies can be exploited to understand a construction material and its properties, from the microstructure level to the adoption of destructive and non-destructive tests (Figures 4b,c). The first step of the multi-scale approach was the microscopy study of a few samples extracted from the S2-p4 piece (Figure 4a), polished with colloidal silica. The microscopy was carried out at multiple magnifications (10 \times , 20 \times , and 50 \times). Figures 5a and b show the results for a magnification of 10 \times before and after etching with Nital 2%. The combination of pearlites and flakes of graphite provides an early indication that this is grey cast iron due to the high percentage of graphite and the nature of flakes distribution. According to the ASTM A247-19 (2019), given the long shape of the flakes in a matrix of ferrite and pearlite, the graphite can be classified as ranging from A to C, most probably type B. Figure 5c shows that the pearlite constitutes the majority of the microstructure which suggests a moderate cooling rate. A higher cooling rate would have produced a higher fraction of cementite with smaller graphite flakes. Using a Matlab-based image-processing tool to highlight the dark colour of graphite, an average content of about 7.5% was identified. This is consistent with the typical range of 6%-10% for grey cast iron.

Figure 4. (a) Available stanchions. (b) Non-destructive and (c) destructive tests setup.

A considerable amount of porosity was also observed in the microscopy images. The microstructure shows that the web has a higher porosity content than the flanges. Specifically, using the same Matlab-based tool used for the quantification of the graphite content, a maximum porosity of about 3% and 0.5% is assessed for the web and the flanges, respectively. Also, porosity can be seen without microscopy in elements extracted from the web and the joint between the web and the flange. The porosity was also investigated by looking at the density

Figure 5. Microscopy at (a) 10× before etching, (b) 10× after etching, (c) 50× after etching.

of the material. To measure the density, the immersion in fluid method (commonly used for geotechnical applications) was employed (BS EN ISO 17892-2, 2014). The experimental data provide an overall density of 7 t/m^3 ; the density of the web is, on average, 1.2% lower than the overall density and 1.4% lower than the flanges density.

Such porosities made it very difficult to cut the material into standardised dog-bone (DB) specimens using Electrical Discharge Machining according to the ASTM E8/E8M – 13a (2013); therefore, a slitting saw was used to cut a total of 40 pieces: 27 DBs from the S2-p1 piece and 13 DBs from the S2-p3 piece (Figure 4a). An additional 8 non-standard chunky prismatic elements have also been obtained from the S2-p4; these non-standard elements have been used to preliminary investigate the tensile strength of the material and to test the non-destructive assessment.

The non-destructive testing consisted of using the Equotip Piccolo 2 device (Figure 4b), a portable metal hardness tester (Proceq, 2016). This is a spring-loaded device that launches an impact body consisting of a metal indenter at a sample. This impact body rebounds, and the velocities before and after the impact are measured through a voltage reading. The ratio of these velocities multiplied by 1000 is known as the Leeb hardness (Leeb 1978). The Equotip device can convert the Leeb hardness to the Brinell (1990), Vickers (Smith and Sandland, 1922), and Rockwell (1914) harnesses using empirical relationships (e.g., ISO 18265, 2013) after defining the material in hand. These hardness tests have been carried out for all specimens subsequently tested to destruction, both standard and non-standard. This verification intends to check if any correlation exists between the destructive and non-destructive tests, i.e. between the yield/tensile strength and the hardness index, similar to Tabor (1951). Tensile tests with a 0.001 mm/min loading rate have been performed to measure the tensile strength of the material (Figure 6).

Figure 6. (a) All tensile-test results. (b) Flange tensile-test results. (c) Web tensile-test results.

Figure 6a shows the experimental results for all 40 available standardised DBs specimens. The material exhibits a brittle behaviour; therefore, only the tensile rupture strength can be retrieved (Figure 6a). Also, looking at the non-parametric distributions of both strain and stress reported on the horizontal and vertical axes (with thick black lines), it is possible to observe that the variability is high. Figures 6b and c show the tensile strength of the flange and the web, respectively. The strength values of elements extracted from the flanges are larger than those from the web. Also, it seems that the variability of S2-p1 (blue curves) and S2-p3 (red curves) are comparable. This result may indicate that the geometry does not influence the strength.

Studying only the first 5% of available force and strain data, it is possible to obtain an estimate of the elastic modulus. The value obtained by averaging all the tests is 60 GPa. However, experimental data for the flanges show a 7% higher elastic modulus with respect to the web.

Finally, by comparing the tensile strength and the hardness indexes, interesting observations were made. First, the Leeb hardness index should be preferred to the other. Second, for the non-standardised prismatic elements coming from the S2-p4, it was possible to identify a ratio between hardness index and tensile strength ranging between 2 and 3, which is not far from some literature observations (e.g., Baron and Palatkina, 2016; Kim et al., 2008). On the contrary, very small values are obtained when such correlations are repeated for the standardised specimens. For the latter case, also hardness scale saturation was observed. This result is probably associated with the adopted non-destructive testing protocol and the fact that standardised specimens are tiny and sometimes full of imperfections. Finally, on the basis of the collected information and following the ASTM A48/A48M – 03 (2016), it is possible to conclude that the material at hand can be classified as a class 20 grey cast iron, at best. This new knowledge is very important as, so far, literature values have been used for these elements (DMRB BD21, 2021).

3 GEOMETRY

Survey methodologies play a primary role in the understanding of cultural heritage. Structural and non-structural components in cultural heritage structures can have very sophisticated geometries that may be very difficult to represent with conventional 2D drawings. A simple 2D representation of the parapet stanchion is herein provided in Figure 2b. However, better documentation and representation are recognised as essential to guarantee asset preservation and promotion and educate the broader public towards these ambitions (Noardo, 2018). The demand for 3D models of cultural heritage assets is continuously increasing in the field of conservation. To this aim, laser scanning was carried out using an Artec Eva device, which is ideal for medium-sized objects. The point cloud obtained from the survey has been adequately post-processed in Rhino (McNeel et al., 2020) to obtain a mesh of the system. Figure 7a shows the setup employed to suspend the stanchion for easier survey operations. Figure 7b shows the post-processing of the acquired data with a focus on critical parts such as the top part and the top and bottom views of the bottom flange. These data allow remote measurements of the beam as well as structural modelling.

Figure 7. (a) Setup for the laser scanning. (b) Laser-scanning results.

4 STRUCTURAL MODELLING

Multi-scale finite element (FE) modelling in the field of cultural heritage may have multiple interpretations. Some research studies proposed a virtual lab where destructive tests are modelled with FE, materials properties are modified in order to match the experimental results, and eventually, such properties are applied to the larger asset of interest at a larger scale (e.g., Parent et al., 2017). This is also known as the shift from micro-modelling to macro-modelling (Giordano et al., 2021). Another potential interpretation consists of modelling the system of interest with an increasing level of sophistication, initially using beams (Figure 8a), then bi-dimensional elements such as plates and shells (Figure 8b), and eventually 3D continuum elements, such as bricks and tetrahedra (Figure 8c). This research adopted the second interpretation of the multi-scale modelling approach. As FE modelling tool, the OpenSees software was used (McKenna et al., 2011) employing the advanced Graphical User Interface STKO (Petracca et al., 2017).

The first modelling level employs beam elements. This approach may not always be possible; when it is possible, simplifications should be applied. For the case of the stanchion, both prismatic and non-prismatic beams have been used. The most irregular parts connecting the different sections that could have been modelled as beams were modelled as rigid links (Figure 8a). This modelling approach does not allow appropriate studying of the stress concentration in the corners that are the main driver for the damage onset. Therefore, to study such an aspect, either code-based providing stress concentration factors as a function of the geometrical features of the system are used (e.g., Annex H, BS 5400-10, 1999), or a sub-structuring approach can be employed. A substructuring approach consists of more precisely modelling the connection zones with shells or bricks, using the reactions coming from the beam schematisation as loading conditions.

The second modelling level employs shell elements (Figure 8b). This approach requires a manual interpretation of the geometry using CAD tools. Layered shell elements were used in this case. A simple support has been used for the bottom flange. No specific care was paid to the bolted connection, as this was a preliminary analysis. A maximum load of 5 kN was applied to the top of the beam, which corresponds to the wind loading on the under-deck gantry combined with crowd pushing (this is an unusual situation here investigated just for the sake of representation). Elastic modelling was considered. Figure 8b presents the FE analysis results in terms of vertical stress. It is possible to observe a tensile stress concentration in the web corner where the damage is usually experienced.

The last modelling level consists of using solid tetrahedral FE elements. The model and corresponding results are provided in Figure 8c. As for the previous modelling approach, in this case, it is possible to observe a stress concentration in the web corner. As previously, simple support has been used for the bottom flange. No specific care was paid to the bolted connection, as this was a preliminary analysis. As before, for this case, a loading of 5 kN was used, and elastic modelling was used. Computational time increases exponentially with respect to the previous case.

Figure 8. (a) Beam-based, (b) shell-based, and (c) tetrahedra-based FEM modelling.

5 CONCLUSIONS

A multi-scale approach oriented on assessing the structural integrity of the parapet stanchions of the Clifton Suspension Bridge was presented. Three aspects have been investigated: materials, geometry, and structural modelling. New insights were identified into the material properties, and the material porosity is identified as the potential cause of the observed damage. Structural models have been developed after the acquisition of geometry. Next steps to study the residual life of the system after damage include: (1) fatigue tests, (2) additional non-destructive tests, (3) shaking table tests on both damaged and undamaged elements to study the frequency response, and lastly (4) the S1 parapet stanchion will be tested with a cyclic protocol to experimentally investigate how many cycles a damaged stanchion can resist before being ultimately damaged to destruction.

ABSTRACT: Damages due to complex loading or under natural disasters may cause progressive collapse (PC) in structures have not received much attention despite the importance of the potentially catastrophic impact of these types of deteriorations. When a structure is exposed to external excitations, an energy flow in the structural components is accumulated and stored depending on the effective stiffness of these components. Any modification in the material properties, connections between components, or structural continuity would modify the effective stiffness, thus leads to the energy distribution variation in structural components. Once a member fails the load supported by the lost member is redistributed to the adjacent structural members. If these members are incapable of withstanding the additional loading, they continue to fail and that gives rise to damage and may result in a PC. The objective of this study is to use continuous wavelet transform (CWT) to study the consequences of the PC distribution trend and the energy redistribution after one of the structural members is lost due to external loading event. An efficient strategy based on various scenarios is developed and used via a robust finite element computational tool to model and simulate the damage in order to capture the structural vibration responses. Nonlinear static and dynamic analyses are used using Abaqus and CWT are used for investigation purposes. The results show proper and effective analysis of the structures having high potential to PC.

1 INTRODUCTION

All buildings types may be exposed to extreme events due to natural hazards. Such events can lead to local damage to the structure, which can cause collapse. This is where the term progressive collapse (PC) comes in and describes the initial local failure spread (ASCE 2016). According to (ASCE/SEI 7-05 2005), the PC is defined as the propagation of initial localized failure from element to element, leading to the entire collapse or a disproportionately large part of a structure. The PC is triggered by abnormal loading that causes localized failure of one or more columns if the building lacks sufficient ductility, continuity, and redundancy. The column loss can be caused by natural disasters such as earthquakes, or accidental actions such as explosions (Mahmoud *et al.* 2018). After failure of the columns, an alternative load path transfers the load to other structural members. Suppose adjacent elements are not designed to withstand the redistributed loads. In that case, failure will occur with a large redistribution of the load until equilibrium is reached, leading to structure failure. The localized collapse can result in casualties and damage disproportionate to the initial failure. The interest in PC is traced back to the partial collapse of the Ronan Point apartment in London in 1968 due to an

accidental gas explosion. This event prompted extensive research on PC and led to developing guidelines for the PC prevention (Tavakoli and Amir 2017).

In recent years, various work have been carried out in this regard. Marjanishvili et al. (Marjanishvili and Agnew 2006) analyzed a 9-story steel moment-resisting frame (SMRF) considering the edge column loss through linear and nonlinear static and dynamic analyses and recommended nonlinear dynamic analysis. Hyun et al. (Kim *et al.* 2009) analyzed 2D- 2-storey and 3-storey SMRF regarding intermediate column loss. The results showed that the dynamic amplification factor could be larger than two as stated by (GSA 2003). Fu (Fu 2009) studied a multi-story steel building's response considering various column removal scenarios using 3-D models. It was concluded that multiple column removal yields different plasticity formations. Tavakoli et al (Tavakoli *et al.* 2012) investigated the SMRFs capability with various damaged columns scenarios under seismic loading based on Iranian seismic codes to resist the PC. It was stated that the buildings in question were able to withstand PC under various scenarios, involving the ground floor columns loss. Tavakoli and Hasani (Tavakoli and Amir 2017) studied the seismic capacity for the PC of SMRF to special moments. The results showed that the probability of PC relies on the floors number and the earthquake characteristics, and the removed column. Shi et al (Shi *et al.* 2017) investigated the effect of composite slabs on the PC resistance of SMRF. It was concluded that the presence of slabs increases the ductility of the structure and its PC resistance. Chuquitaype et al. (Chuquitaype *et al.* 2016) investigated the gravity frames effects in mitigating collapse in SMRF buildings exposed to extreme loads such as earthquake and explosion scenarios.

Despite various studies carried out in recent years, there is still no practical guidance to prevent a structure's collapse due to the localized damage of structural member. Most of the studies reported in the literature are static on sub-assemblages and dealt with resisting mechanisms quantification using the 2D frame. To the best of the authors' knowledge no study has been reported in the investigating the consequences of the PC distribution trend and the energy redistribution to evaluate seismic collapse potentials of a steel frame. This study aims to create a 3-D model and remove a column under earthquake to evaluate the resistance performance based on the energy redistribution. This work novelty is the development of an algorithm based on CWT to evaluate the internal energies redistribution.

2 WAVELET TRANSFORM

Wavelet analysis is a multi-resolution analysis in the time and frequency domain. Due to its potential characteristics can provide valuable information about the damage and analyze the signal's energy distribution at different bands. The idea is to correlate the signal $x(t)$ with a set of known functions and then quantify the similarity between them (Silik *et al.* 2021b).

$$w = \int_{-\infty}^{\infty} x(t) \cdot \psi_n^*(t) dt \quad (1)$$

The scaled and translated version are associated with the adopted mother wavelet $\psi(t)$.

$$\psi_{s,\tau}(t) = \frac{1}{\sqrt{s}} \psi\left(\frac{t-b}{s}\right) \quad (2)$$

2.1 Energy distribution-related features

The total energy is computed by squaring the magnitude of the data and integrating it. In the wavelet domain, the energy distribution is generated by the transform's squaring modulus.

$$SG(a, b) = |W(a, b)|^2 \quad (3)$$

The mean wavelet spectrum is estimated by the integration over the time variable as

$$S_{wt}(a) = \frac{2}{C_g} \left[\frac{1}{T} \int_0^T SG(a, b) db \right] \quad (4)$$

Energy accumulations in the frequency domain are defined by at each frequency band as

$$E(f_i) = \int_{f_1}^{f_i} S_{WT}(f_0/f)df \text{ for } i = 1, 2, \dots, n \quad (5)$$

Similarly, a time analog to the MWS may be defined by

$$s_{WT}(b) = - \int_{f_1}^{f_n} SG(f_0/f, b)df \quad (6)$$

Energy accumulations in the time domain are then appropriately determined by

$$E(b_j) = \int_{b_1}^{b_j} S_{WT}(t)db \text{ for } j = 1, 2, \dots, m \quad (7)$$

A decrease in potential energy ratio is defined as (Noori *et al.* 2018):

$$E = \frac{E_0 - E_f}{E_0} \quad (8)$$

where E_0 and E_f are the potential energies of models at the initial and final states, respectively.

2.2 The cross wavelet transforms

The theoretical distribution of the signal cross-wavelet power with background power spectra P_k^X and P_k^Y is given in Torrence and Compo (1998)

$$D\left(\frac{|W_b^X(S)W_n^{Y*}(S)|}{\sigma_X\sigma_Y} < p\right) = \frac{Z_v(p)}{v} \sqrt{P_k^X P_k^Y}, \quad (9)$$

where $Z_v(p)$ is the confidence level associated with the probability p defined by the square root of the product of two χ^2 distribution (Silik *et al.* 2021a).

For wavelet selection, the Morlet wavelet is a complex function that can be considered as a modulated Gaussian function (Silik *et al.* 2020). It has equal variance in time and frequency and is suited to detect time and frequency localized information (Silik *et al.* 2021a). It is similar to the impulse component, which is indicative of damage in many dynamic signals (Silik *et al.* 2021c). Thus, it was chosen for this research and expressed as

$$\psi(t) = \frac{1}{\sqrt{\pi F_b}} e^{i2\pi F_c t} e^{-\frac{t^2}{F_b}} \quad (10)$$

F_b is a bandwidth factor that controls the wavelet shape, and F_c is a central frequency that define the oscillations number. Mostly, $F_c = 6$ for engineering applications, and trainable parameter F_b is taken as [0.5, 1, 1.5, 2]. It is seen that 1.5 is better for tradeoff between them as shown in Figure 1.

3 FINITE ELEMENT MODEL

3-D finite element model of steel frame is developed using Abaqus version 6.13. The models are initially built using beam elements in Abaqus. The C3D8 element for column and beam and C3D20R for the slab is used to build up the models. Both elements are integrated numerically

Figure 1. Acceleration of the FE models: (left) undamaged state; (right) damaged state.

over the section, where the material behavior is evaluated independently at each point. The loads considered are dead loads, live loads, and the El-Centro earthquake (EQ). Dead and live loads were 1 and 2.0kN/m², respectively, while the infill effects are not considered. According to GSA, dead loads plus 25% live loads are applied downward to the structure for dynamic analysis purposes. The structure characteristics have been considered so that the study can be generalized for a wide range of two-story short buildings. All members are tied to each other using the tie constraint, equivalent to providing a rigid connection (GSA 2003). In this study, a corner column in the ground floor has been removed under an EQ to investigate the PC potential of the structure. The EQ record was normalized to PGA to exert the severe effects of EQ loads on the structure. The EQ record was applied to the model in the horizontal direction Z. Figure 2 shows the two-bay steel frame model; the beams and columns are connected through their centroid using default rigid connections. All the models have two bays in each direction and two stories. Bay width is 4 m in the long and 2 m in short direction, and each floor height 2m. A reinforced concrete slab with a 130 mm thickness and concrete characteristic strength is 25 MPa. The longitudinal and transverse rebar in the slabs were arranged with 150-mm spacing. The external perimeter frames are designed to withstand the lateral and gravity loads, while the inner frames to withstand only gravity loads. The Isotropic material properties were assigned throughout the structure. Poisson's ratio, young's modulus, ultimate tensile, and minimum steel yield stress are 0.3, 2.06×10^5 N/mm², 460 N/mm², and 355 N/mm², respectively. The steel density is 7850 kg/m³. All column supports were defined as fully fixed in all translational and rotational axes.

Figure 2. Finite element model of the two-bay steel frame structure.

4 STRUCTURE PERFORMANCE UNDER THE COLLAPSE

In this study, the Abaqus was used for creating a model and performing the analysis. Both material and geometric nonlinear behaviors were considered. For investigating seismic collapse potentials of the SMRF, the corner column of analytical models was exposed to seismic excitations of the El-Centro earthquake, which caused a sudden loss of the column. The maximum acceleration of the excitation was scaled to 0.4g for dynamic analysis (GB50011,2010). After the column is removed, the structure goes through various stages and tries to resist the collapse using various mechanisms in order to compensate for the missing vertical components of the building by finding another load path or by redistributing the load to adjacent undamaged structural members, which can prevent further damage from scattering. The damaged propagation is tracked to understand these mechanisms and follow the collapse distribution trend in the model. Figure 3 shows the behavior of the building subjected to El-Centro wave. The relative distortion is shown in term of acceleration and displacement distribution on the model to show the collapse distribution patterns

due to the removal of the corner column and its effects. Before the column removal, there seemed to be no significant damage, while after the column removal damages appear. It is showed that the collapse mainly starts from the top of column removed in the first ceiling and then propagates to the beams connected to the removed column and the corresponding beams of the first and the upper floor. Finally, it is distributed to other structural elements. It is clear that after the damage, the load was redistributed. The adjacent columns carried more loads than before the column was removed. An alternate load path occurred in the steel frame after the sudden removal of a column, and the column removal did not lead to the PC because of the concrete slab's influence. After the column removal, the loads and internal forces are redistributed in the remaining columns and beams. The redistribution occurred in the remaining structure as a result of the concrete slab's action. Based on the analytical results, as shown in the Figure 3, the floor slab action has adequate load paths and redundancy to resist the local collapse spread owing to sudden column removal. This reflects the ability of energy dissipation of the remaining structure after a corner column is removed. Also, it is clear that there is a less spatial effect, and so the model members may dissipate the energy. The distribution of the structure's collapse occurs around the removed column's location, vertically along with the structure height, mainly from the bottom to the top, then horizontally in the floors. It can be concluded that the columns neighboring the failed column are the key ones that affect the redistribution of internal force and should be strengthened. Also, the beams directly connected to the removed column are the most likely elements to cause collapse because the moment in the beams increases when the columns are suddenly removed, and the contact action also provides an additional tensile force in the beams.

Figure 3. Acceleration and displacement distribution on the finite element model.

5 NUMERICAL ANALYSIS RESULTS AND DISCUSSION

For evaluating the collapse distribution trend, collapse distribution scenarios were investigated based on the nonlinear time history analyses under earthquake records, in such a way that the collapse sequence followed from the element to the other, one after another, until the structural system became unstable. The critical elements and the collapse propagations were predictable in the two-story frame due to the corner column removal in the ground floor. The internal energy redistributions were compared as shown in the Figure 4 to evaluate collapse potentials. The T-F energy distribution from points near the removed column was analyzed using wavelet cross-spectrum, T-F -amplitude representations, and wavelet power spectrum. Figure 4 compares internal force redistribution in terms of the entire energy. The energy change can lead to ambiguous results even if the total energy is different. Generally, at the moment of component failure, internal forces are redistributed in the structure, and damage does not occur yet. Thus, the structure's dynamic effects after loss of vertical components are of greater concern.

Figure 4. The total energy of the model in both states.

Figure 5 a, b shows the node above the removed column's acceleration representation in the time and in T-F domain before and after damage. In the time-domain after removing the column, the signal shows apparent semi-periodicity after 0.5 seconds reflecting the column's oscillation cyclic nature. The signal periodicity may be due to the combined effect of the beam and the slab motion. Figure 5c, d shows wavelet scalograms for both states, which reveal the signal energy distribution and shows how the signal energy density is distributed with respect to time and frequency. The x-axis represents position along the time, y-axis represents the frequency, and the color scale at each x-y point reflects the increasing power from blue to violet. Finally, it is clear that the removed column forces the signal energy to migrate towards lower frequencies. There are a lot of T-F dynamics contained within 12-13Hz thus, there seem to appear some features are present that are sort of leaking out. For understanding the instantaneous effect on the structural behavior, Tensor Flow implementation of the CWT is conducted and represented as in Figure 6. It can be seen that the coefficients in Figure 6 right under small scale (<45) are huge only at time number 100 and then continue in the time axis, which is precisely the moment that the corner column of the first story is removed. It should also be noted that lack of a continuous line in Figure 5 left corresponds to the fact that frequencies are not constant in time. Figure 7 shows regions in time-frequency space to localize time-frequency energy density where the signals show high power across time for all frequencies. The cross wavelet's high values indicate a vigorous structure response to an input with corresponding scale at a given time instant. This reflects the spread the of local collapse due to sudden column removal. The analyzed signals are aligned, reflecting the T-F energy distribution and localizing the similarities in energy redistribution. Figure 8 shows T-F -amplitude representations. It is shown that there are multiple time-varying frequencies and how rapidly the coefficient magnitude grows. This reflects the signal's spectral content evolution in time due to variations in the signal components' amplitudes and frequencies.

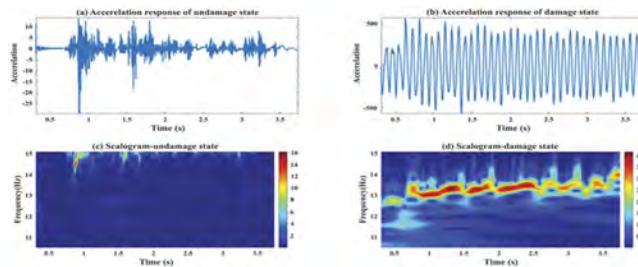

Figure 5. Time history and T-F representations.

Figure 6. The time-frequency energy distribution (left) undamaged state; (right) damaged state.

Figure 7. A local time-frequency energy density (left) undamaged state; (right) damaged state.

Figure 8. T-F amplitude representations (left) undamaged state; (right) damaged state.

Figure 9 shows wavelet power spectrum (WPS) over time and over scale, which is normalized to equal the analyzed signal variance. The WPS describes how the power of a time signal is distributed with frequency or scale. The power over scale before damage ranges between 0-5, whereas, after the damage, it ranges between 0.1-0.6. Also, power overtime before the damage is between 0-800, whereas after damage range between 0-300. Figure 9c shows how the power is redistributed within the model and reflects the energy distribution over time and the remaining structure's energy dissipation. Since the internal energy acquisition is synchronized, the cross- WPS's content and energy distribution show the global change in the frame energy. At lower scales, information about abrupt changes can be obtained, while at higher scales, information about slowly changing damages can be extracted. To validate the technique effectiveness, short Fourier transform and CWT are used to track the peak of internal energy distribution (IED) and their results is compared. Figure 10 shows the tracking of IED in model of removal column. Its clear that the proposed technique-based CWT show better results than a method based on short Fourier transform.

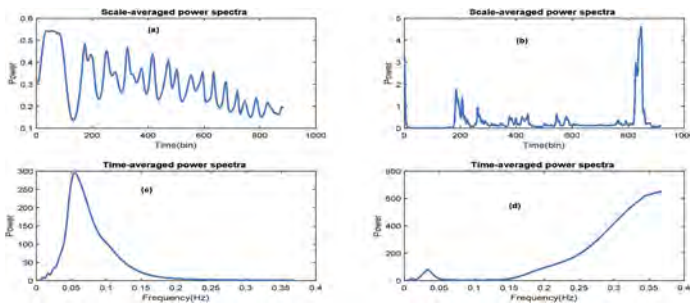

Figure 9. Various wavelet power spectrums (a) after removal column (b) before removal column (c) after removal column (d) before removal column.

Figure 10. Tracking of the peaks of internal energy distributions (left) based on CWT (right) based on Short Fourier transform.

6 CONCLUSIONS

In this study, a 3-D 2-story steel frame model is developed and investigated using the nonlinear dynamic procedure in Abaqus software to simulate lower steel frame buildings' behavior under a sudden column loss. A two-story conventional frame building was used because, as it is known, many old and traditional buildings around the world are low-rise buildings, and the PC mechanism of such buildings is not considered. The beam and shell elements are used to simulate the

steel frame and concrete slab, respectively, from the Abaqus library. The analysis is conducted under corner column removal scenarios. Observations regarding the PC's behavior were drawn while focusing on energy action values. Continuous Wavelet are adopted to evaluate the distributed damage effect. Based on the analytical results, the following conclusions are drawn. The columns neighboring to the removed column are the key ones that affect the internal force redistribution. The beams connected to the removed column are the most probable elements to be affected, so the moment in the beams increases under sudden column removal. Implementation of CWT makes it possible to get a precise energy redistribution that allows the user to detect the PC's effect on the structure components. Based on the analytical results, it is concluded that cross wavelet analysis is a powerful technique for testing energy linkages between two-time series, and CWT affords multiscale analysis of absorption features due to PC and the spectral continuum that offers an opportunity to capture the relevant information that is manifested at different scales and show how the energy is redistributed and finally show the high potential to PC.

Application of infrared thermography in civil engineering: Limits and drawbacks

D. Meloni, G. Sechi & G. Concu

Department of Civil and Environmental Engineering and Architecture, University of Cagliari, Italy

ABSTRACT: Infrared thermography (IRT) is an effective diagnostic methodology for existing buildings monitoring, whose efficiency is however affected by the operator's technical knowledge. This paper presents experimental research aimed at evaluating the accuracy of IRT temperature measurements with respect to the incorrect setting of five input parameters required to be set by the operator: emissivity, reflected apparent temperature, ambient temperature, relative humidity, and distance. The goal was to highlight how their accurate evaluation and setting affects the thermographic survey and the post-processing stage. To this end, IRT experimental investigations were carried out on materials characterized by different emissivity and surface roughness, such as concrete, granite and steel. The experimentation outcome has pointed out the factors that most affect the temperature measurement error and allowed to quantify the error on the temperature measurements deriving from the incorrect setting of these parameters during the acquisition phase of the thermogram.

1 INTRODUCTION

Thermal controls represent the set of methods in which appropriate devices for the detection of heat are used to measure the temperature variation in physical components, structures, systems, or processes. Among the thermal control methods, Infrared Thermography (IRT) is a non-destructive investigation technique without physical contact with the inspected element based on the measurement of the electromagnetic energy radiated by the object in the infrared range of the electromagnetic spectrum. Infrared rays are related to heat as they originate from the emission of energy resulting from collisions between the molecules of the body because of their thermal agitation. All bodies having a temperature above absolute zero emit infrared radiations with increasing intensity as the body temperature increases due to the greater thermal energy radiated. Therefore, IRT remotely measures the thermal energy possessed by an object starting from the detection of the intensity of the infrared radiation emitted, allowing to trace back to the object surface temperature. Thanks to the amount of data that can be collected, the ease of inspection and the immediacy of the information, IRT used in the context of existing buildings diagnostics makes it possible to identify:

- thermal bridges,
- defects in thermal insulation,
- non-homogeneity of the walls,
- possible detachment of plasters or coatings,
- presence of humidity, condensation, water infiltrations,
- concealed systems,
- non-visible structural elements.

In addition, it is a supporting tool for:

- energy certification of buildings,
- investigations on historic buildings,
- diagnostics and restoration of decorated surfaces.

The main tool of IRT investigations is the infrared camera or thermal camera, which detects the intensity of the infrared radiation emitted by the body and generates thermal maps or thermograms in chromatic scale representative of the distribution of temperatures in the scenario framed by the thermal camera, in which the hot spots, the cold ones and the heat gradients existing between the various parts of the examined surface are highlighted and quantified. In this way, a representation of the thermal gradients between different areas of the body and a model of the thermal distribution is obtained. However, thermal cameras observe the energy radiated by objects and not their temperature, therefore the temperatures are calculated indirectly by means of algorithms needing the setting of appropriate parameters - emissivity, reflected apparent temperature, ambient temperature, relative humidity, and distance - that the operator provides to the instrument in the phases preceding the measurement.

This paper reports an experimental work aimed at evaluating the accuracy of the temperature measurements, carried out by IRT, with respect to an incorrect setting of these parameters, to highlight how fundamental their accurate evaluation and setting is before running the thermographic survey and afterwards in the post-processing stage. To this end, IRT was carried out on specimens made of different materials, namely concrete, granite and steel, characterized by different physical characteristics.

2 INFRARED THERMOGRAPHY

The thermal camera not only detects the radiation emitted by the object, but also that which originates in the surrounding objects and reflected by the object itself. Both radiations vary according to atmospheric absorption, and the measurement can be strongly influenced by the ambient temperature. For a precise detection of the surface temperature of the object it is therefore necessary to consider these phenomena through appropriate algorithm and parameters that allow to account for the characteristics of the inspected elements and the operative environmental conditions, to correct the disturbance factors of the measurement. These parameters are the following.

- Emissivity ϵ of the object. Emissivity refers to the amount of thermal energy radiated by the object and expresses the ratio between the radiation emitted by the body at a given temperature and that emitted by the black body at the same temperature ($\epsilon=1$); its values are therefore included in the range 0-1. A body with an emissivity close to 0 reflects all the incident energy, while if the emissivity is close to 1 the object has a behavior like the black body, tending to absorb all the incident energy without any reflection. The values included in the range 0-1 are typical of the so-called grey bodies, where part of the incident radiation is absorbed, and part reflected. The emissivity coefficient depends on the material, the surface conditions (roughness), the temperature and the wavelength.
- Reflected apparent temperature T_{rif} . The reflected environmental temperature permits to balance the radiation reflected by the object and that emitted from the atmosphere between the thermal camera sensor and the object itself. It is of fundamental importance to accurately set this value when the emissivity is low, the distance from the element under investigation is very high and its temperature is like that of the environment.
- Distance d between the object and the thermal camera. Setting this distance is important to balance the radiation absorption between the object and the thermal camera due to the transmittance, which decreases as the distance increases. When operating IRT, it is necessary to consider the presence of a medium between the source and the detector, represented in general by the atmosphere, whose gases have thermal properties as well, which need to be considered to avoid excessive attenuation of the radiation emitted by the object.
- Atmospheric temperature T_{atm} . It affects the thermal properties of the environment and the object.
- Relative humidity RH%. Relative humidity affects the transmittance to a certain extent. However, for short distances between object and detector and for standard humidity a default value of 50% can be used without excessive error.

The radiation recorded by the thermal camera is converted into an electronic signal which is then processed by specific software to produce digital images and map the distribution of

surface temperatures through analytical calculations. The thermal camera's own processing algorithm operates based on a mathematical model according to a relationship of the type:

$$T = f(\varepsilon, T_{\text{rif}}, d, T_{\text{atm}}, \text{RH}\%) \quad (1)$$

IRT efficiency is therefore conditioned by the operator's technical knowledge and his ability to recognize and interpret the phenomena taking place around the object at the time of acquisition of the thermograms, as thermal cameras typically require the operator to set the five input parameters previously mentioned. Since the relationship (1) is highly non-linear, to evaluate the specific influence of the input parameters, in this paper the error was studied as a function of each individual parameter. It's worth underlying that the thermograms can be revised afterwards by previously mentioned post-processing codes, but information about real-time environmental conditions is needed and are to be recorded in situ. Another parameter which influences thermograms is surface roughness. In fact, the surface characteristics of the object are decisive for measuring the temperature by means of IRT. Depending on the surface condition, the degree of roughness and the type of coating, the emissivity changes. Smooth, shiny, mirror and/or polished surfaces usually have lower emissivity than matt, textured, rough, broken and/or scratched surfaces. The influence of surface roughness has been also investigated in this paper.

3 MATERIALS AND METHODS

3.1 Materials

IRT has been applied on specimens made of different building materials having different emissivity and with different surface roughness, as specified in Table 1. Specimens are also shown in Figure 1.

Table 1. Specimens' properties.

Material	Size (mm)	Roughness	Emissivity
Concrete	150x150	low	0.95
Concrete	150x150	high	0.95
Granite	120x200	low	0.80
Granite	120x110	high	0.77
Steel	50x80	low	0.35
Galvanized steel	50x80	high	0.27

3.2 Methods

IRT has been carried out using a high-resolution thermal camera SC660 R&D by FLIR Systems (Figure 2a).

Atmospheric temperature T_{atm} and Relative humidity $\text{RH}\%$ have been measured using a thermo-hygrometer MENGSHEN M350 (Figure 2b).

Emissivity ε and Reflected apparent temperature T_{rif} have been determined according to the procedures specified in standard ISO 18434-1:2008 Part 1, Annex A.2 and A.1 respectively.

To avoid interferences, during IRT running the specimens were housed in a structure specially made for shielding the rays reflected from other bodies (Figure 2c).

The Distance d between the specimen and the thermal camera has been set at 1m.

The active IRT has been carried out heating the specimens with two 400 W halogen lamps.

Having completed the preliminary operations and having introduced the input parameters into the thermal camera, the indirect measurement of the temperature has been carried out, acquiring the thermograms relating to the specimen at regular object temperature intervals, and subsequently proceeding to their post processing by means of the supplied software of the thermal camera.

To evaluate the influence on the temperature returned by the thermograms of the error committed in setting the input parameters of the thermal camera, sensitivity analyses have been conducted, consisting in analysing the deviation of the temperature returned by the

thermogram with respect to the exact temperature measured with a contact thermometer, by varying a single input parameter at a time. The variation of each input parameter has been established within a range that simulated real operating conditions.

4 RESULTS AND DISCUSSION

4.1 Sensitivity analysis. Emissivity

Figure 3 shows the percentage deviation δT_{IRT} of the temperature returned by the thermogram with respect to the temperature T_{exact} measured with the contact thermometer as a function of the percentage emissivity deviation $\delta \epsilon$ with respect to the correct value ϵ_{exact} for the concrete specimen with low surface roughness. The latter has been determined according to the procedure recalled in ISO 18434-1 Part 1, Annex A.2, at different temperatures. The terms involved in the subsequent diagrams are defined in Equations 1 and 2 as follows:

$$\delta T_{IRT} = \frac{T_{IRT} - T_{exact}}{T_{exact}} \cdot 100 \quad (2)$$

$$\delta \in = \frac{\varepsilon - \varepsilon_{\text{exact}}}{\varepsilon_{\text{exact}}} \cdot 100 \quad (3)$$

Figure 3. Influence on the temperature T_{IRT} returned by the thermograms of the error $\delta\varepsilon$ committed in setting the emissivity for the concrete specimen with low surface roughness.

With the same parameters meaning defined above, Figure 4 shows the deviation δT_{IRT} of the temperature returned by the thermogram with respect to the temperature T_{exact} as a function of the emissivity variation $\delta\varepsilon$ for the granite specimen with low surface roughness.

Figure 4. Influence on the temperature T_{IRT} returned by the thermograms of the error $\delta\varepsilon$ committed in setting the emissivity for the granite specimen with low surface roughness.

Figure 5 shows the deviation δT_{IRT} of the temperature returned by the thermogram with respect to the temperature T_{exact} as a function of the emissivity variation $\delta\varepsilon$ for the steel specimen with low surface roughness.

A summary of the errors according to the type of material and surface roughness is shown in Table 2.

4.2 Sensitivity analysis. Reflected temperature

Figure 6 shows the deviation δT_{IRT} of the temperature returned by the thermogram with respect to the temperature T_{exact} measured with a thermometer as a function of the reflected apparent temperature deviation δT_{rif} with respect to the exact value $T_{\text{rif,exact}}$, for the

Figure 5. Influence on the temperature T_{IRT} returned by the thermograms of the error $\delta\epsilon$ committed in setting the emissivity for the steel specimen with low surface roughness.

4.3 Sensitivity analysis. Atmospheric temperature, relative humidity, and distance

Table 4 summarizes the deviation δT_{IRT} of the temperature returned by the thermogram with respect to the temperature T_{exact} measured with a thermometer as a function of the Atmospheric temperature T_{atm} , the Relative humidity RH%, and the Distance d.

Table 4. Deviation δT_{IRT} with respect to T_{exact} as a function of material and surface roughness determined for T_{atm} , RH%, and d variation.

	Concrete		Granite		Steel	
	LR*	HR**	LR*	HR**	LR*	HR**
T_{atm}	0.2%+0.4%	0.3%+0.4%	0.4%+0.4%	0.4%+0.4%	0.9%+0.5%	1%+0.9%
RH%	0.2%+0.3%	0.3%+0.2%	0.3%+0.2%	0.2%+0.3%	0.4%+0.2%	0.3%+0.3%
d	+3%	+3%	+3%	+3%	+3%	+3%

*Low Roughness, **High Roughness.

4.4 Discussion

The results of the tests carried out on materials with different emissivity and surface roughness show that the input parameters that most influence the error of temperature measurement via IRT are the emissivity ϵ of the object and the reflected apparent temperature T_{rif} , while the other parameters, i.e., atmospheric temperature, relative humidity, and distance, have a less significant, even negligible, influence.

The results also highlight that the roughness of the surfaces can significantly affect the correct value of the temperature measurement, especially in the case of concrete and steel, since they affect remarkably the emissivity.

For all materials examined, the incidence of emissivity deviation increases with increasing temperature difference between the object and the environment, while the incidence of reflected temperature increases with decreasing temperature difference.

The influence of the latter error component increases significantly the more the material has a reduced emissivity, and therefore a high reflectivity, such as steel.

The results point out that the incorrect setting of emissivity has a strong impact on the accuracy of the temperature measurement. Since the thermal camera allows the user to set a single emissivity value for each object falling into its focus range at the time of acquisition of the thermogram, it is essential to identify the different emissivity of each framed object. In this regard, it is useful to examine Tables 5, 6 and 7, which report the entity of the possible errors in the case of material with high emissivity such as concrete (Table 5), medium-high emissivity such as granite (Table 6), low emissivity such as steel (Table 7).

Table 5. Error of T_{IRT} measurement as a function of incorrect setting of ϵ for concrete. $T_{atm} = 20^\circ\text{C}$.

$\epsilon = 0.95$ (correct value)		$T_{exact} = 30^\circ\text{C}$	$T_{exact} = 50^\circ\text{C}$
$\epsilon = 0.65$	$\delta\epsilon = 30\%$	$\delta T_{IRT} = 11\%$	$\delta T_{IRT} = 22\%$
$\epsilon = 0.50$	$\delta\epsilon = 48\%$	$\delta T_{IRT} = 21\%$	$\delta T_{IRT} = 40\%$
$\epsilon = 0.30$	$\delta\epsilon = 68\%$	$\delta T_{IRT} = 48\%$	$\delta T_{IRT} = 89\%$

Table 6. Error of T_{IRT} measurement as a function of incorrect setting of ϵ for granite. $T_{atm} = 20^{\circ}C$.

$\epsilon = 0.80$ (correct value)		$T_{exact} = 30^{\circ}C$	$T_{exact} = 50^{\circ}C$
$\epsilon = 0.55$	$\delta\epsilon = 30\%$	$\delta T_{IRT} = 11\%$	$\delta T_{IRT} = 21\%$
$\epsilon = 0.40$	$\delta\epsilon = 50\%$	$\delta T_{IRT} = 24\%$	$\delta T_{IRT} = 45\%$
$\epsilon = 0.30$	$\delta\epsilon = 62\%$	$\delta T_{IRT} = 39\%$	$\delta T_{IRT} = 71\%$

Table 7. Error of T_{IRT} measurement as a function of incorrect setting of ϵ for steel. $T_{atm} = 20^{\circ}C$.

$\epsilon = 0.27$ (correct value)		$T_{exact} = 30^{\circ}C$	$T_{exact} = 50^{\circ}C$
$\epsilon = 0.35$	$\delta\epsilon = 30\%$	$\delta T_{IRT} = 7\%$	$\delta T_{IRT} = 12\%$
$\epsilon = 0.40$	$\delta\epsilon = 48\%$	$\delta T_{IRT} = 10\%$	$\delta T_{IRT} = 18\%$
$\epsilon = 0.95$	$\delta\epsilon = 250\%$	$\delta T_{IRT} = 23\%$	$\delta T_{IRT} = 40\%$

It is interesting to note that if for concrete (Table 5) or granite (Table 6) the emissivity of steel is accidentally set ($\epsilon=0.30$) a temperature measurement error of up to 70% can be made. Similarly, if for steel (Table 7) the emissivity of concrete ($\epsilon=0.95$) is accidentally set, a temperature measurement error of up to 40% can be made. With this respect, it is worth noticing that, even though in post-processing codes it is usually possible to set different values of emissivity or reflected apparent temperature on different areas of thermograms, while carrying out an in-situ survey, the contemporary presence of different materials on the frame can be a critical issue, since the distribution of temperatures and consequent observations can be seriously affected. Therefore, when thermography is employed for in situ investigations aimed at real-time searching for structural anomalies or criticalities, attention need to be paid to a proper setting of the parameters.

5 CONCLUSIONS

This paper analyzed the influence on the temperature measurement via IRT of the incorrect setting of the input parameters that the operator must set in the thermal camera before the test, i.e. the emissivity of the object, the reflected apparent temperature, the atmospheric temperature, the relative humidity and the distance between the camera and the object.

The tests were carried out on samples of building materials with different emissivity and different surface roughness.

The results showed that the most influential parameters on the error are the emissivity and the reflected temperature, and that this influence generally increases as the surface roughness increases.

The operator must therefore be able to set these parameters correctly to avoid significant measurement errors which would distort the results of the IRT test and affect the temperature gradients in the thermograms to an extent that the structural anomalies or damage searched for in civil engineering surveys could be undetectable.

Soundness evaluation of small-scale bridge decks with portable FWD tests

Taichi Sasaki & Atsuya Tsuboi

Yuma Sugimoto, Haruto Kakeda & Hiroshi Onishi

Faculty of Science and Engineering, Iwate University, Morioka, Japan

ABSTRACT: The number of aging bridges that have been constructed more than 50 years is increasing in Japan. It is necessary to establish an efficient and quantitative bridge inspection method. From this background, we proposed an efficient deck health evaluation method using an impact vibration test with a portable FWD (Falling Weight Deflectometer). The objective of this study is to improve the accuracy of damage detection of slabs by FWD testing with field test and FE analysis. In the field FWD test, we got response acceleration data from several points on deck before and after the slab replacement. By comparing them, we found that the correlation coefficient of response acceleration between the measurement points was related to the soundness of the slab. We also estimated the damage area of the deck by correlating the difference in response acceleration between the measurement points. From the 3D FE (Finite Element) analysis modeling the target bridge, the effect of partial deterioration of the deck slab on the vibration response from field test was simulated.

1 INTRODUCTION

Development inspection methods for bridges is important issue in Japan. Visual inspection is one of the most common inspection methods used for periodic inspections (National Roads and Engineering Division. 2019), but it lacks quantitiveness. Vehicle loading tests (Chiba. 2016) (Kasai. 2015) are often used to confirm the effectiveness of bridge reinforcement and the load-bearing capacity of newly constructed bridges. This inspection method uses many sensors, making quantitative testing possible, but consideration of sensor locations is difficult.

In this study, a quantitative and simple method for evaluating the health of bridge decks was investigated using impact vibration tests with a portable Falling Weight Deflectometer (FWD). Previous studies focused on the natural frequencies of the entire bridge for evaluating the bridge soundness (Haneya. January 2008) (Sasaki. June 2021). On the other hand, the authors aimed to estimate the local damage location in the deck slab which was difficult to do only by identifying the natural frequencies by using response acceleration obtained from the portable FWD test. First, the correlation of the difference in response acceleration between multiple measurement points was investigated, and the results were compared before and after the slab replacement work. Second, a 3D FE model of the target bridge was created, and a dynamic analysis was conducted to reproduce the portable FWD test. From the analysis results, the effect of partial damage to the deck slab on the vibration response was investigated.

2 STUDY OVERVIEW

2.1 Target bridge

The bridge has been in service for more than 40 years since 1974, and various damages were found during a periodic inspection in 2015. The upper structure of this bridge is a steel composite simple H-girder bridge consisting of three main girders and RC (Reinforced Concrete) slabs (slab thickness: 160 mm) with a bridge length of 16.0 m, a width of 8.2 m, and a girder

Table.1. Akayama bridge specification (Unit: mm).

Superstructure	Steel composite, Simple H-beam bridge
Substructure	Reversed T-type abutment
Foundation work	Spread foundation
Deck type	RC deck
Bridge bearing	Steel line bearing
Bridge length	16,000
Span length	15,550
Width	600+7,000+600=8,200
Skew	83°
Design load	TL-14

Figure 1. The exterior appearance of Akayama Bridge.

Figure 2. Portable FWD & accelerometer.

height of 700 mm. The bridge has a slant angle of 83°. Corrosion was found in the girder members, and cracks and damage suspected to be ASR (Alkali Silica Reaction) due to drying shrinkage were found in the deck slabs. Therefore, reinforcement work including slab replacement was performed in 2019. Table 1 and Figure 1 show the specifications and the exterior appearance of the target bridge, respectively.

2.2 Portable FWD test

In this study, shock and vibration tests were conducted using the portable FWD system “FWD-Light” manufactured by Tokyo Measuring Instrument Lab. The tester consists of a weight, a drop mechanism, and a loading board, and is equipped with displacement values transducer and a load cell. The free-fall of the weight applies a constant impact force to the slab, and the load value and displacement can be measured. Since the purpose of this test was to obtain response acceleration, an accelerometer was used near the FWD as an external sensor to measure the vertical response acceleration caused by the impact vibration. The weight of the portable FWD was 25 kg, the drop height was 1 m, and the sampling interval for the acceleration measurement was 0.1 ms. Figure 2 shows the appearance of the portable FWD, and accelerometer used in the test.

3 CONSIDERATION BY RESPONSE ACCELERATION DIFFERENCE

3.1 Outline of examination

In this study, 9 accelerometers were placed on the slab to measure the response acceleration generated by the impact vibration of a portable FWD. The names of the loading points and measurement points are CH1 to CH9 as shown in Figure 3.

Figure 4 shows a schematic chart of the method used to investigate the difference in response acceleration. The impact generated by the portable FWD vibrates each part of the slab and arrives at each measurement point, and the response acceleration is measured by

each accelerometer. In Figure 4, two sections OA and OB, consisting of two accelerometers A and B equidistant from the loading point of the portable FWD and accelerometer O are the sections under consideration. If the stiffness of the slab is the same in the two sections, the same acceleration values are measured at the measurement points A and B. In contrast, if the stiffness is different, the measured values are considered to be different. The same trend can be obtained for the difference between the measured values at accelerometer O and accelerometers A and B, “O-A” and “O-B”. By comparing the difference in response acceleration at the two measurement points, it is possible to estimate slab soundness.

Figure 3. Arrangement of loading points and accelerometers.

Figure 4. Schematic chart of Acceleration gap.

Figure 5. The time variation curve of the acceleration gap (loading at 1/4,3/4 points of span).

In impact vibration tests using portable FWD, the weight falls and bounces multiple times. In this study, to remove the influence of the impact from the second and subsequent bounces, the acceleration data was extracted for 0.5 seconds after the maximum value of acceleration due to the first impact. The effect of noise is reduced by averaging the acceleration at each time (every 0.1 ms). Next, standardization processing described in Equation (1) is performed to suppress variations in the magnitude of the amplitude of the vibration at each measurement point.

$$z_i = (x_i - \bar{x})/s \tag{1}$$

z_i : Standardized data, x_i : Original data(Average acceleration), \bar{x} : Average of original data, s : Standard deviation of original data

The data after the standardization process was used to calculate the time variation of the response acceleration difference between the loading point and the other measurement points.

3.2 Calculation of correlation coefficient of response acceleration difference

As an example, Figure 5 shows the time variation of the acceleration gap between the measurement points in longitudinal direction when striking the 1/4 and 3/4 points of the main girders G1 and G3. In the following text and figures, “CH4-CH1” and “CH4-1” are used to denote “(loading point)- (measurement point where acceleration difference is taken)”. Before the slab replacement, the acceleration difference waveforms are generally more erratic than after the slab replacement, and the agreement between each section is lower. The different vibration response of each section is assumed to be due to the non-uniform stiffness of the slab before the repair

work. On the other hand, after the slab replacement, the acceleration gap waveforms in each section are good agreement because the slab stiffness became uniform after the repair work.

Table 2. Measured correlation coefficient (Section of longitudinal direction).

Section combination	Deck replacement	
	Before	After
(CH1-4) ×(CH7-4)	0.44	0.84
(CH1-4) ×(CH3-6)	0.65	0.68
(CH1-4) ×(CH9-6)	0.19	0.86
(CH7-4) ×(CH3-6)	0.68	0.75
(CH7-4) ×(CH9-6)	0.27	0.77
(CH3-6) ×(CH9-6)	0.17	0.77

Table 3. Measured correlation coefficient (Section of transverse direction).

Section combination	Deck replacement	
	Before	After
(CH1-2) ×(CH7-8)	0.54	0.78
(CH1-2) ×(CH3-2)	0.69	0.76
(CH1-2) ×(CH9-8)	0.06	0.80
(CH7-8) ×(CH3-2)	0.79	0.75
(CH7-8) ×(CH9-8)	0.40	0.87
(CH3-2) ×(CH9-8)	0.32	0.79

Table 4. Measured correlation coefficient (Section of diagonal direction).

Section combination	Deck replacement	
	Before	After
(CH1-5) ×(CH7-5)	0.40	0.84
(CH1-5) ×(CH3-5)	0.52	0.74
(CH1-5) ×(CH9-5)	0.38	0.85
(CH7-5) ×(CH3-5)	0.81	0.77
(CH7-5) ×(CH9-5)	0.29	0.92
(CH3-5) ×(CH9-5)	0.28	0.81

Regardless of whether before or after the slab replacement, the waveforms of the acceleration gap between the section on the outer girder and the section on the middle girder show different shapes. This reason is that the section on the outer girder is strongly affected by torsional vibration when struck on the outer girder, while the section on the middle girder shows bending vibration behavior when struck on the middle girder.

To quantitatively evaluate the degree of agreement between the acceleration differences of the two intervals, the correlation coefficient is first used in this study. The correlation coefficient is calculated by Equation (2).

$$r = s_{xy}/s_x s_y \quad (2)$$

s_{xy} : Covariance of acceleration x & y , s_x : Standard deviation of acceleration x , s_y : Standard deviation of acceleration y

In general, when the absolute value of the correlation coefficient is 0~0.2, there is almost no correlation, 0.2~0.4 indicates a weak correlation, 0.4~0.7 indicates a moderate correlation, and 0.7~1.0 indicates a strong correlation. In this study, the correlation coefficients of the acceleration gap before and after the slab replacement were calculated for three different sections in longitudinal direction, transverse direction, and diagonal direction when loading the 1/4 and 3/4 points of the G1 and G3 main girder supports, respectively.

3.3 Correlation coefficient results and discussion

Tables 2-4 show the correlation coefficients for the combined acceleration differences for the sections along longitudinal direction (CH1-CH4, CH7-CH4, CH3-CH6, CH9-CH6), transverse direction (CH1-CH2, CH7-CH8, CH3-CH2, CH9-CH8), and diagonal direction (CH1-CH5, CH7-CH5, CH3-CH5, CH9-CH5) when loading the 1/4 and 3/4 points of the span on main

girders G1 and G3. The correlation coefficients increased for all combinations after the slab replacement, and all correlations are stronger than 0.7. On the other hand, the correlation coefficients before the slab replacement are lower than those after the slab replacement for all combinations of sections. As shown in red in the table, the correlation coefficients for all combinations including CH9-CH6, CH9-CH8, and CH9-CH5 are particularly low compared to the other combinations.

As mentioned above, the correlation coefficients for the acceleration differences between adjacent measurement points in longitudinal direction, transverse direction, and diagonal direction were determined. For all combinations of sections, the correlation coefficients tended to be higher after the slab replacement than before the replacement. This may be because the stiffness of the slab became uniform throughout the slab after the slab replacement. In the three-directional combinations, the correlation coefficients between CH9-CH6, CH9-CH8, and CH9-CH5, which include the section where CH9 was hit before the slab replacement, tend to be particularly low. This suggests that changes in the relative vibration characteristics of the slab occurred in the vicinity of these sections and CH9 before the slab replacement.

2nd torsional	22.6	22.54

4 DYNAMIC FE ANALYSIS

4.1 Analysis model overview

In this study, a FE model of the target bridge superstructure was created using the 3D FE analysis software ANSYS. The slab, main girder, and transverse girder were created using shell elements. Rigid beam elements are used to connect the upper flanges of the main girders and end transverse girders to the vertical direction of the deck slab. Figure 6 shows a three-dimensional model of the bridge. The model is set up so that the Young's modulus and other properties of the members can be changed for each color range. The Young's modulus of the RC slab was obtained by substituting the design basis strength of the replaced slab, 40 N/mm², into Equation (3).

$$E_c = \left(3.1 + \frac{f'_c - 40}{50} \right) \times 10^4 \quad (3)$$

E_c : Young's modulus (N/mm²), f'_c : Design basis strength of concrete (N/mm²)

Here, $40 \leq f'_c < 70$. Table 5 shows the material properties of the model.

To simulate the boundary conditions of target bridge, a translational spring element that restrains horizontal movement was introduced to the movable bearing. In the following analysis, a spring element with a spring constant of 1.1×10^4 N/mm is applied to the movable bearing. In a previous study, the authors obtained the natural frequencies of the first order and second order bending and torsional vibration modes of the subject bridge before and after the replacement of the deck slab from measured accelerations. Table 6 shows the measured natural frequencies of each vibration mode and the natural frequencies of the first order and second order bending and torsional vibration modes of the FE model.

Figure 8. The time variation curve of the acceleration gap obtained from FE analysis (Sections of longitudinal direction).

4.2 Time history response analysis

The impact loads applied to the FE model were the measured loads recorded by the load cell built into the portable FWD in the field test. Figure 7 shows the impact load curves used in the time history response analysis. As in the portable FWD test on the actual bridge, impact loads were applied to the 1/4, 1/2, and 3/4 points of the G1~G3 girders, and a time history response analysis was conducted. The difference in response acceleration in the vertical direction is output at nine measurement points from CH1 to CH9. The response acceleration data is output for 0.5 seconds (5000 data) at a sampling interval of 0.1 ms.

In a study based on the acceleration gap obtained by field measurements, a change in vibration response relative to other parts of the slab was estimated in the vicinity of the area including the sections CH9-CH6, CH9-CH8, and CH9-CH5 before the slab replacement. Therefore, in this analysis, a sound model and a partially deteriorated model were created and analyzed in order to confirm the change in vibration response. The sound model has a uniformly stiffened slab using the material properties shown in Table 5. The partial degradation model has reduced Young's modulus in Area 7, which includes the sections CH9-CH6, CH9-CH8, and CH9-CH5, as shown in Figure 6. The Young's modulus of the slab is reduced from 10% to 50%.

In previous studies (Chiba, December 2021), the authors used 0.5 seconds of data (5,000 data) immediately after the impact to calculate the correlation coefficient. In this study, the authors calculated the correlation coefficient using 0.05 seconds of data (500 data) and compared it with the result calculated using 0.5 seconds of data.

4.3 Analysis results and discussion

Figure 8 shows the time variation of the acceleration difference between the healthy model and the partially deteriorated model (Young's modulus 50%) in longitudinal section when impact loads were applied to CH1, 3, 7, and 9. The waveform of the acceleration gap in the partially deteriorated model (Figure 8(a)) is generally scattered. On the other hand, the waveform of the sound model (Figure 8(b)) shows less variation. These trends are also observed for the transverse sections and the diagonal direction. Figure 8 shows that the sections on the G2 girder (CH2-CH5 and CH8-CH5) behave differently from the sections on the G1 and G3 girders. This is thought to be due to the difference in response behavior caused by torsional vibrations that are strongly excited when a point on the outer girder is struck. This feature tended to be same in field test.

Table 7 shows the correlation coefficients between the sound model and the partially deteriorated model for each combination of three directional sections. This is the result of the

correlation coefficient calculation when the Young's modulus of Area7 is 100%, 90%, 80%, and 50%. In both cases where the data range was 0.5 and 0.05 seconds, the correlation coefficient tended to decrease as the Young's modulus of Area 7 decreased. When the Young's modulus of Area 7 was high, the correlation coefficients tended to be larger than those of other combinations of sections with point symmetry at the center of the slab (CH5) (e.g., (CH1-4)×(CH9-6) and (CH1-2)×(CH9-8)). This is considered to be due to the similar vibration characteristics of the diagonal sections of the bridge, since the bridge is a diagonal bridge and its shape is point symmetrical around the center of the deck (CH5). These two characteristics are common to the three directional sections: longitudinal, transverse, and diagonal direction.

Table 7. Correlation coefficients for each interval calculated from FE analysis results.

	Sampling time							
	0.5 sec.				0.05 sec.			
	Decreasing rate young's modulus

(CH7-5) ×(CH9-5)	0.65	0.73	0.74	0.51	0.78	0.80	0.80	0.59
(CH3-5) ×(CH9-5)	0.62	0.59	0.55	0.34	0.75	0.75	0.73	0.53

In the results for the longitudinal section in Table 7, the decrease in the correlation coefficient is uniform for all combinations, making it difficult to determine which part of the slab is damaged compared to the measured results. In the results for the transverse section in Table 7, when the Young's modulus of Area 7 was reduced to 50%, the correlation coefficient was smaller for the combination including CH9-8 than for the others. In the results for the diagonal section in Table 7, the correlation coefficients were smaller for the combination including CH9-5 on Area 7 when the data range was 0.5 seconds, but the correlation coefficients were also weaker for the section not included in Area 7. However, it was difficult to determine the damaged area because a weak correlation was obtained even in the section not included in Area 7.

One difference between the 0.5 second and 0.05 second data ranges is that the correlation coefficient is not very high when the data range is 0.5 seconds, even if the Young's modulus of Area 7 is high, while the correlation coefficient is generally high for all combinations when the data range is 0.05 seconds. The acceleration difference data for the 0.5-second period includes data affected by damped vibration after the loading, which may have led to the overall decrease in the correlation coefficient due to waveform distortion. On the other hand, the

0.05 second acceleration difference data does not include the effect of damped vibration, so the correlation coefficient is expected to be higher overall.

In the model used in this analysis, the Young's modulus of Area 7, which includes the intervals CH9-CH6, CH9-CH8, and CH9-CH5, was reduced. However, the section CH9-CH6 and CH9-CH8 are located on the boundary of Area 7. Therefore, the decrease in Young's modulus had less effect on the acceleration difference between these sections than expected, which may have made it difficult to determine the damage site. Further study is needed to determine the extent to which Young's modulus should be reduced.

5 CONCLUSION

This study proposed a method for detecting damage locations on slabs using correlation coefficients from response acceleration data obtained from portable FWD tests. The summary of this study are as follows.

- (1) Portable FWD tests were conducted on the target bridge before and after reinforcement work, including slab replacement, and applied a load and measured response accelerations at 1/4, 1/2, and 3/4 points along the three main girder spans. Using the acceleration data, the degree of agreement of the response acceleration differences between the measurement points was compared for each section in longitudinal direction, transverse direction, and diagonal direction using correlation coefficients to detect relative damage areas in the slab. The correlation coefficients tended to be lower for combinations that included certain sections before slab replacement, suggesting that changes in relative vibration characteristics may have occurred in the vicinity of these sections.
- (2) A 3D FE model was created by introducing spring elements into the movable bearings of the target bridge, and a time history response analysis was conducted to reproduce the time history response analysis. The analyses were conducted using a sound model with a uniform Young's modulus for the entire slab and a partially deteriorated model with a reduced Young's modulus for a portion of the slab, and the response acceleration in the vertical direction was obtained. Correlation coefficients were calculated for the difference in acceleration between each measurement point using the obtained response acceleration. The correlation coefficients for each section were found to decrease in accordance with the partial decrease in Young's modulus of the slab.
- (3) In the 3D FE analysis, the range of data used to calculate the correlation coefficient was also examined. 0.5 and 0.05 seconds of data were used to calculate the correlation coefficient. This is thought to be because of the damping vibration of the impact load on the waveform of the response acceleration.

In the future, we would like to conduct a more detailed study on how to estimate the damage areas of slabs from 3D FE analysis, and to investigate an evaluation method using an index different from the correlation coefficient.

ABSTRACT: Rut depth is one of the main indices in road maintenance. The current practice to evaluate rut depth is by manual inspection or by an irradiator and a special camera installed on an inspection vehicle. A new method to estimate rut depth by image processing that only needs an in-vehicle camera is presented. Images extracted from video captured by a camera are transformed into top-view images, and then two consecutive images are compared through feature matching techniques to evaluate the image distortion due to rutting. Rut depth information can thus be obtained from 2D camera images. This method is applied to road surfaces and estimation results are compared with true values. The results show that rut depth can be evaluated with good accuracy in this inexpensive and efficient way.

1 INTRODUCTION

Road infrastructure maintenance relates to the safety and comfort level of roads. In Japan, roads are mainly performed from IRI (International Roughness Index), crack ratio, and rut depth. Evaluation of the rut depth, which is the focus of this paper, is by manual inspection or by an irradiator and a special camera installed on an inspection vehicle now as shown in Figure 1. The efficiency of manual measurement is low while the irradiator is expensive, which limits frequent measurements. Thus, an inexpensive and efficient way to measure rut depth is expected. With the evolution of smartphones and the development of algorithms, IRI and crack ratio now can be evaluated using GNSS, IMU (Inertial Measurement Unit), and camera in a smartphone. This inspires us to consider estimating rut depth only using a smartphone in an image-processing way. In this paper, a method of distortion analysis of images taken by an in-vehicle camera via top-view transformation is proposed to estimate rut depth.

Figure 1. Current methods for rut depth measurement.

2 RELATED WORK

2.1 Structure from Motion (SfM)

(Tomasi et al., 1993) published a paper titled “Shape and Motion from Image Streams: a Factorization Method,” which established the foundation for the Structure from Motion (SfM) technique. SfM is a photogrammetric range imaging method that estimates three-dimensional structures from two-dimensional image sequences, potentially combined with local motion signals.

(Imai et al., 2021) attempted to use the SfM software Agisoft Metashape to measure the depth of blocks with asphalt pavement. They found that rut depth could be estimated using 4K 60fps video shot by a camera on a bicycle, with an error of about 40%. Besides, because only images taken from one direction were used and images were acquired through the windshield, point cloud data reconstructed by both 4K and 8K images taken inside the vehicle were curved. Unfortunately, the experiment did not involve actual road surfaces with rutting, but rather asphalt paving slabs with recessed areas. Therefore, the results of the road cross section obtained through SfM were not compared to the true value.

The process of rut depth estimation by SfM can be summarized in Figure 2. Points are matched between every two images, requiring $n(n-1)/2$ matching operations for n input photos. This process can be time-consuming, as it must be completed before the 3D model can be reconstructed.

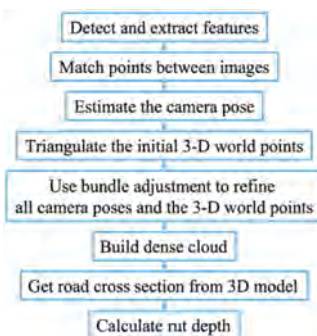

Figure 2. Rut depth estimation by SfM.

2.2 Top-view transformation

(Geda et al., 2022) proposed a vision-based top-view transformation algorithm for road crack ratio evaluation. This method involves capturing video with an in-vehicle smartphone camera, with parameters calibrated using parallel lane lines and circular manholes. The top-view image can be obtained by transforming the camera-view image with the following equations:

$$x' = \frac{f'}{H_{VC}} \cdot \frac{H_C x}{f \sin \theta - y \cos \theta} \quad (1)$$

$$y' = \frac{f'}{H_{VC}} \cdot \left\{ \frac{H_C (f \cos \theta + y \sin \theta)}{\sin \theta - y \cos \theta} - D_{VC} \right\} \quad (2)$$

where x and y are the pixels coordinated from the camera view. x' and y' are the corresponding top-view coordinates after transformation. f and f' are the focal lengths (in pixels) of the in-vehicle camera and virtual camera, respectively.

By assuming the presence of a virtual camera above the road surface, top-view transformation allows for easier analysis of road features.

3 METHODS

To address the challenges of reconstructing road cross sections using images taken from inside a vehicle and the high computation cost of SfM, we propose a method for measuring rut depth that involves two steps using top-view transformation and the basic perspective principle: 1) Obtain the shape of rutting by extracting rut information from the video. The unit of rut depth at this stage is in pixels. 2) Convert the pixel information in step 1 into millimeters to measure rut depth by determining the scale.

3.1 Basic idea

Figure 3(a) and (b) show two images taken by an in-vehicle camera as the vehicle passes a road surface with severe rutting and a shadow cast by a pillar. Figure 3(c) and (d) show the results of applying the top-view transformation to these images. The shadow, which should be straight, is distorted due to the rutting. By applying image binarization, the shape of the shadow can be extracted from the two images, as shown in Figure 3(e). The level of distortion of the shadow in the two images is different because the virtual camera of the top-view transformation is located at different positions relative to the shadow as the vehicle approaches it. This difference in distortion can be used to extract rutting information.

This concept can be extended to a road surface without shadows, i.e., a general road surface. As shown in Figure 4, the road surface can be thought of as a combination of a flat surface and a rutted surface. Since the distance between the flat surface and the virtual camera is smaller than the distance between the rutted surface and the virtual camera, there should be a difference in the y direction for the same area when the viewing angle changes. This means that rutting information can be extracted by matching the same part in images taken from different angles.

Figure 3. Road surfaces and top-view transformed images.

Figure 4. Flat surface and rut surface.

3.2 Matching

However, traditional matching methods may not be suitable in this case. According to Sun et al. (2021), most existing matching methods follow a sequential process of feature detection, feature description, and feature matching. The first step, feature detection, involves identifying salient points, such as corners and edges, as interest points in each image. This may be unsuccessful in extracting enough repeatable interest points between images due to various factors such as poor texture and motion blur. Road surfaces, which are often made of asphalt and concrete, tend to have poor textures. In addition, the two images used for matching are obtained from top-view transformed images, with the upper image (the farther part in the original images) being more blurred than the lower image. This further complicates the matching condition. E.g., as shown in Figure 5, Using the SIFT (Lowe, 2004) matching algorithm, there are no matches found for the right images in this case.

Figure 5. Bad matching condition for detector-based methods.

To address the limitations of traditional matching methods, detector-free local feature matching methods have been explored in the field of computer vision. One such method is LoFTR (Sun et al., 2021), which establishes pixel-wise dense matches at a coarse level and then refines the good matches at a fine level using convolutional neural networks (CNNs). This allows LoFTR to find correspondences on texture-less surfaces, Figure 6 shows the result of applying LoFTR to the road surface in Figure 5.

Figure 6. Matching result by LoFTR.

3.3 Rut shape calculation

The shape of the rut is calculated from the matching result, so the number of matches affects the accuracy. To increase the number of matches, we use six 640x480 pixel images with 320x480 pixel overlap for each road cross section being measured, as shown in Figure 7(a). The images are this size because LoFTR was trained with this size. Figure 7(b) shows the integrated matching result for images taken at a 2-meter interval.

To extract the shape of the rut from the matching result, the following data processing steps are followed: 1) Calculate the difference between the y-coordinates of every pair of matches. 2) Average the differences corresponding to the same x-coordinate, assuming that the rut depth for every road cross-section within the 480-pixel length range is the same. This process can be expressed in Equation (3), where x and y are the coordinates of the data point to be used to generate the rut shape, (x_i, y_i) and (x'_i, y'_i) are the coordinates of matches of the 1st and 2nd image respectively, and n_x is the number of x . 3) Interpolate the data to make the road cross

Figure 7. Images with overlap and integrated matching result.

section successive. 4) Calculate the moving average of the data to smooth the road cross-section. 5) Calculate the distance from each data point to the line connecting the leftmost and rightmost data points, to correct for the incline introduced by the top-view transformation, as shown in Equation (4), where p_i is the coordinate of data point i , p_l and p_r are the coordinates of the leftmost and rightmost data point, respectively.

$$y = \frac{1}{n} \sum_{x_i=x} (y'_i - y_i) \quad (3)$$

$$d_i = \frac{\left| \frac{p_r - p_l}{p_i - p_l} \right|}{\|p_r - p_l\|} \quad (4)$$

3.4 Calibration

To convert the rut shape information (expressed in pixels) into rut depth (expressed in millimeters), calibration is required. This can be done using a plate ($910 \times 450 \times 18$ millimeters in this experiment). As shown in Figure 8, the thickness of the plate occupies a different number of pixels in two images taken at a 2-meter interval. This information is used to convert the pixel-by-pixel information into millimeters.

Figure 8. Calibration by the thickness of a plate.

4 EXPERIMENTS

4.1 In-vehicle smartphone setup

The smartphone used in this study is an iPhone 13 Pro, mounted on the vehicle's windshield with the camera facing the road, as shown in Figure 9. The measurement video was recorded at 4K (3840×2160) resolution and 30 frames per second. At the same time, the global navigation satellite system (GNSS) was also recording the vehicle's position once per second. The

vehicle used was a Honda N-BOX, chosen because its short nose allows for a wider view of the closer part of the road from the camera.

Figure 9. In-vehicle smartphone setup.

4.2 Measurement

A 100-meter road in Koshigaya city, Saitama Prefecture, Japan, was measured both manually as the true value and by a smartphone for estimation. The interval between each road cross section was 10 meters, as shown in Figure 10.

Figure 10. Overview of the measurement target (Nichireki, 2022).

4.3 Results

Figure 11 shows the results of the true value (blue), proposed method (red), and SfM (yellow). Based on the definition shown in Figure 12 (OWP: Outer Wheel Path, IWP: Inner Wheel Path), D_1 and D_2 are calculated as shown in Figure 13. The road cross section calculated by SfM differs significantly from the true value, while the proposed method provides a good fit. The errors in D_1 and D_2 , show that most results of the proposed method are within the criterion of 3mm, while most results of SfM are outside this range.

5 CONCLUSION

This paper presents a novel image-processing-based method for estimating rut depth. The proposed method involves performing top-view transformation and using a detector-free matching method to analyze image distortion caused by rutting. Our experiments demonstrate that the proposed method outperforms SfM in estimating rut depth. We believe that the proposed method offers a promising approach for evaluating rut depth and could potentially be extended to other challenging scenarios, such as evaluating potholes.

M-integral applied to fatigue life prediction in notched elastic-plastic material

Z.J. Zhang & Q. Li

State Key Laboratory for Strength and Vibration of Mechanical Structures, School of Aerospace, Xi'an Jiaotong University, Xi'an, China

ABSTRACT: In this paper, an innovative fatigue model is investigated based on the concept of *M*-integral in notched elastic-plastic material. The new form of fatigue damage evolution rate (dA_D/dN) and fatigue driving force (ΔM) are introduced. The fatigue experimental evaluations of No. 45 steel with a circular notch have been carried out. The change of the total potential energy (*CTPE*) is introduced to measure the value of *M*-integral. The results demonstrate that dA_D/dN shows an apparent power law relation with ΔM in notched elastic-plastic material. The slope *n* and intercept λ of $\lg(dA_D/dN)$ - $\lg(\Delta M)$ curve has linear correlation with the initial notch radius *R*, but not with applied stress σ . Moreover, the model can clearly describe the two-stage process from the initiation of microcracks to the growth of macrocracks in notched body. It is concluded that the proposed fatigue model can accurately predict the fatigue lifetime of the notched elastic-plastic material.

1 INTRODUCTION

A lot of fatigue failure problems in engineering structures are due to the existence of notches (Wen et al., 2018). During past years, numerous efforts have been made to predict the fatigue limit of a given material or structure in presence of notch. Among those, the methodologies can be classified under two main headings: (i) critical distance or stress based approach and (ii) fracture mechanics based approach. In general, both critical distance and stress based approach can be included in the classical fatigue techniques, which correlate stress or strain at the notch area with the number of cycles to failure, for example, the S-N curve introduced by Wöhler (1871). As for the method based on fracture mechanics, the Paris's law (Paris and Erdogan, 1963; Lesiuk et al., 2018) is the mostly adopted one. However, there is a large scale yielding plastic zone occurred along the notch, thus the total fatigue lifetime consists of crack initiation life accompanying with the formation of plastic zone and crack propagation life. On one hand, it is difficult to evaluate the fatigue lifetime in ductile metals accurately since the lifetime of crack initiation and propagation are mixed together by the critical distance or stress based approach. On the other hand, the Paris's law is hardly used to character the notch at the initial stage of fatigue cycle in the absence of macrocracks (Rice, 1968; Sangid, 2013). Therefore, there is a lack of reliable fatigue model which can predict the lifetime of elastic-plastic material with considering both notch and material elastic-plastic behavior, and is suitable for total stage from crack initiation to propagation. For this reason, it is important to study the damage calibration criterion and establish an appropriate fatigue model to predict the lifetime of notched elastic-plastic material.

In recent years, the theory of configurational forces attracted the attention of many scholars for the investigations of material fracture and failure. Basically, the concept of configurational forces is defined as the driving forces associated with the dissipative mechanisms related to the configuration (e.g., size, shape and location) changes of material points (Maugin, 2011). Eshelby (1951) proposed the concept of energy-momentum tensor in continuum mechanics of solids. After decades of development, several invariant integrals have been proposed to describe the failure behavior of materials. Among them, it is known that the *M*-integral has the apparent physical interpretations which can be explained as the energy release rates due to the self-similar expansion of defects (Chen, 2001a, b; Ma et al., 2001). The *M*-integral is carried out along an arbitrarily chosen closed path enclosing all defects due to its path independence property

(Knowles and Sternberg, 1972), which implies it can be used to describe the failure behavior of materials with complex defects. As a result, it is expected that the concept of M -integral has the potential applicability to predict the failure of notched elastic-plastic materials.

Typically, Hu and Chen (2009) studied the relationship between effective elastic modulus and the M -integral when the coalescence of cracks and other defects occurs. Li et al. (2013) proved that the M -integral is inherently related to the change of total potential energy ($CTPE$) due to the formation of the defects with the addition of the nonlinear elastic strain energy within the area enclosed by the integral contours. A unified failure criterion based on M -integral was proposed (Yu and Li, 2013), in which the Π -parameter was derived to characterize the damage level of materials by the appropriate formulation via the M -integral, the remote load, and the inner variable of the damaged area. Lv et al. (2019) put forward a method of equivalent damage area calibration by M -integral, which can quantify the damage level caused by different types of defects.

In this paper, the M -integral method is introduced to study the fatigue lifetime of notched elastic-plastic material since it has a unique advantage in dealing the complicated failure problems in material space. The new definitions of fatigue damage evolution rate dA_D/dN and fatigue driving force ΔM are presented on the basis of M -integral, where A_D denotes the equivalent damage area of notch, plastic zone and cracks, N is the number of cycles, and ΔM corresponds to the M -integral range per load cycle. Then a unified notch fatigue model is proposed to predict the lifetime of elastic-plastic material. The equivalent damage area characterized by the M -integral in elastic-plastic material is calculated numerically. An experimental method for measuring the M -integral and the notch fatigue damage evolution rate of elastic-plastic materials is proposed. Finally, the apparent power law relation is found between the ΔM and dA_D/dN . The slope n and intercept λ of $\lg(dA_D/dN)-\lg(\Delta M)$ curve has linear correlation with the initial notch radius R , but not with applied stress σ . It is demonstrated that the proposed fatigue model based on M -integral is able to predict the lifetime of the notched elastic-plastic material under cyclic loading.

2 DAMAGE CALIBRATION BASED ON THE M -INTEGRAL

The original formulation of the M -integral is given as follows (Knowles and Sternberg, 1972):

$$M = \oint_C (wx_i n_i - T_k u_{k,i} x_i) ds \quad (i, k = 1, 2) \quad (1)$$

where w denotes the total strain energy density, T_k denotes the traction acting on the outside of a enclosed contour C surrounding whole defects, σ_{ij} and u_k are the components of stress tensor and displacement vector, respectively, and s is the arc length of the contour C .

Generally, the fatigue failure process of notched elastic-plastic material under cyclic loading can be divided into two stages: (i) the stage of the formation and growth of plastic zone accompanying the initiation of microcracks (Stage I) and (ii) the stage of macrocracks propagation and finally sudden fracture (Stage II) (Zerbst et al., 2018), as shown in Figure 1.

Figure 1. Fatigue process of notched elastic-plastic material.

However, it is difficult to use a unified method to evaluate the overall complex damage level of notched materials. The previous researches demonstrated that M -integral can characterize the influences of loading conditions, material properties and defect morphology on damage

level when the integration path was enclosed curve and all defects were surrounded in calculation of M -integral (Knowles and Sternberg, 1972). In this case, a unified standard defined by the equivalent damage area A_D is proposed with the aid of M -integral. The damage area can be contributed from the inherent defects inside body and plastic zone induced by the remote loading. Herein, it is assumed that the damage area induced by underlying multiple defects in elastic-plastic material is equivalent to the area of an individual circular notch in elastic material when the values of M -integral are equal for both cases. The equivalent damage area A_D in notched elastic-plastic material is depicted in Figure 2. The same M -integral value represents the same damage level, so the damage level caused by complex defects can be quantified by the equivalent elastic circular notch area with the equivalent M -integral under the same load.

Figure 2. Schematic diagram of the equivalent damage area A_D in notched elastic-plastic material.

In order to facilitate a better understanding of the proposed damage calibration method, numerical implementation (FEM) is performed to calculate A_D in notched elastic-plastic material. The calculation of M -integral only requires the evaluation of contour integrals along a path enclosing all defects. It has been demonstrated that the M -integral is path-independent enclosing the notches in elastic material (Radi, 2011). In present study, the plate with dimensions of 30mm×30mm is simulated, the radius R of the central notch is 2.0mm. The selected material is No. 45 steel, whose elastic modulus and Poisson’s ratio are 195.6GPa and 0.3, respectively. The yield strength is 344.4MPa and a multi-linear elastci-plastic stress-strain curve is input by APDL program in the form of data points for numerical computation. The integration paths are circles surrounding the central notch with radius of 14.0mm.

The evolution of plastic zone (gray segment) in elastic-plastic material with a central notch ($R=0.5$ mm) for increased remote load is presented in Figure 3. As shown in Figure 4, the

Figure 3. Plastic zone distribution characterized by von-Mises stress in elastic-plastic material for increased remote load when $R=0.5$ mm (gray segment): (a) $\sigma=100$ MPa; (b) $\sigma=150$ MPa; (c) $\sigma=200$ MPa; (d) $\sigma=250$ MPa; (e) $\sigma=300$ MPa; (f) the contour of von-Mises stress (unit: MPa).

Figure 4. Numerical results of the M -integral and A_D for elastic-plastic specimens with different magnitude of initial notch: (a) the M -integral versus remote load σ ; (b) the A_D versus remote load σ .

M -integral and A_D of the elastic-plastic material both increase with the increase of remote load. This phenomenon is introduced by the enlarged plastic deformation due to the increased load in elastic-plastic materials as presented in Figure 3. In comparison with the pure linear elastic problems, the equivalent damage area A_D shows a typical loading dependence for non-linear elastic-plastic material. The new parameter A_D can effectively characterize the damage level of elastic-plastic notched material. Furthermore, a new fatigue model is proposed in the following sections based on the advantages of M -integral and A_D .

3 FATIGUE MODEL BASED ON M -INTEGRAL AND ITS EXPERIMENTAL IMPLEMENTATION

3.1 Fatigue model via the M -integral

It has been demonstrated that the M -integral is inherently related to $CTPE$ regardless of the detailed damage characterizations (Chen, 2001a, b; Ma et al., 2001), which provides the driving force of defects evolution. Based on this, we define ΔM (the M -integral range per load cycle, that is, the difference between the M -integral corresponding to the maximum load and the minimum load for per load cycle) as the fatigue driving force. According to the A_D , the fatigue damage evolution rate is defined as dA_D/dN (the growth of equivalent damage area per load cycle). Therefore, the notch fatigue model of elastic-plastic material with a central notch is given as

$$dA_D/dN = \lambda(\Delta M)^n \quad (2)$$

where λ and n are material parameters determined by experiments.

3.2 Relationship between M -integral and the Change of the Total Potential Energy ($CTPE$)

In order to measure the value of M -integral effectively and conveniently, an experimental method is described as below.

Recently, Ma et al. (2001) studied the relationship between the M -integral and $CTPE$, which can be expressed as:

$$M = 2CTPE \quad (3)$$

For the specimen with circular notch subjected to remote load, $CTPE$ is as follows:

$$CTPE = \frac{1}{2} \int_{-\pi}^{\pi} [\sigma_{\theta}(\theta)u_{\theta}(\theta) + \sigma_r(\theta)u_r(\theta)]d\theta \quad (4)$$

where $\sigma_{\theta}(\theta)$ is the circumferential stress on the elastic integration path, $u_{\theta}(\theta)$ is the circumferential displacement of the elastic integration path under internal load $\sigma_{\theta}(\theta)$, $\sigma_r(\theta)$ is the radial stress on the elastic integration path, and $u_r(\theta)$ is the radial displacement of the elastic integration path under internal load $\sigma_r(\theta)$. Actually, the stress equivalent relationship of the specimen with circular notch can be decomposed according to the principle of superposition, as shown in Figure 5.

Figure 5. The stress equivalent relationship of the specimen with circular notch according to the principle of superposition. (a) the notched specimen under remote load; (b) the non-defective specimen under remote load; (c) the notched specimen under internal load (blue area: plastic zone; red line: integration path).

It can be proved that the plate with circular notch can be equivalent to the combination of the flawless continuum under the same remote load and the plate with circular notch under the internal load of the same magnitude acting on the elastic integration path (Wang, 2004). Therefore, the total work of the remote load per unit thickness in the notched specimen can be written as

$$\frac{1}{2}\sigma Lu = \frac{1}{2}\sigma Lu_1 + \frac{1}{2}\int_{-\pi}^{\pi} [\sigma_{\theta}(\theta)u_{\theta}(\theta) + \sigma_r(\theta)u_r(\theta)]d\theta \quad (5)$$

where L is the width of the specimen, u is the remote displacement of the notched specimen under remote load, as shown in Figure 5(a), u_1 is the remote displacement of the non-defective specimen under the same remote load, as shown in Figure 5(b). Comparing Eq. (4) and Eq. (5), it can be found that the second term on the right side of Eq. (5) is the $CTPE$. So the $CTPE$ is equal to the difference of external force work between the notched specimen and the non-defective specimen with the same size. Therefore, the M -integral can be obtained as

$$M = 2CTPE = \sigma L(u - u_1) \quad (6)$$

The detailed process to measure $CTPE$ is depicted in Figure 6. Firstly, the load-displacement curve L_0 is obtained by applying monotonic increasing uniaxial load p to the non-defective specimen as shown in Figure 5(b). Secondly, fatigue tests are carried out for the notched specimen as shown in Figure 5(a). The maximum fatigue load is p_{max} , and the minimum fatigue load is p_{min} . Finally, the load-displacement curve L_N after N fatigue cycles of the notched specimen is recorded by a uniaxial tensile test. According to the physical significance of $CTPE$, the area enclosed by the curves L_0 , L_N , $p=p_{max}$ (shaded by blue lines in Figure 6) is $CTPE$. The area enclosed by the curves L_0 , L_N , $p=p_{max}$, $p=p_{min}$ (yellow shadow in Figure 6) is named as $\Delta CTPE$. Therefore, the ΔM of notched specimens after N fatigue cycles can be calculated as:

$$\Delta M = 2\Delta CTPE \quad (7)$$

Figure 6. The detailed process to measure the M -integral and ΔM : the graph of $CTPE$ and $\Delta CTPE$.

3.3 Experimental procedure: Material, specimens and equipment

In this section, a series of fatigue tests have been carried out to validate the effectiveness of the proposed notch fatigue model based on the concept of M -integral. The experiments are implemented with No. 45 steel. The mechanical properties of No.45 steel are measured by uniaxial tensile tests, which shows a typical elastic-plastic behavior. In details, the elastic modulus is 195.6GPa while the yield strength is 344.4MPa. Specimens are particularly designed for the fatigue tests. In the center of the specimen, the circular notches with various radius (0.5mm, 1.0mm, 1.5mm, 2.0mm, and 2.5mm) are prefabricated as the initial notch.

MTS-880/25T electro-hydraulic servo universal testing machine is employed in this experiment to provide the cyclic loading. Experiments are performed in the force control mode with the various maximum load (p_{max}) of 22kN, 24kN, 26kN, 28kN, 30kN and 32kN, the loading ratio of 0.1, and a sinusoidal waveform at a frequency of 20Hz. All experiments are carried out at room temperature.

4 RESULTS AND DISCUSSIONS

The relationship between fatigue damage evolution rate and fatigue driving force is discussed for the notch fatigue test of No. 45 steel. This paper conducts experiments for different applied stresses and several hole radii. Each test is repeated twice, and finally a total of 60 groups of fatigue tests have been carried out.

In experiments, through observation of specimens by high-definition camera, it is found that the fatigue process can be divided into two stages: (i) the stage of the formation and growth of plastic zone accompanying the initiation of microcracks (Stage I) and (ii) the stage of macrocracks propagation and finally sudden fracture (Stage II), as shown in Figure 7. From Figure 8, when the crack length reaches 1.0 mm, it indicates that the macrocrack initiates, which is defined as the turning point of Stage I and Stage II. The corresponding number of cycles (N_C) when macrocrack initiates in each specimen is recorded. The first stage accounts for about 90% of the total fatigue life, and the second stage accounts for about 10% of the total fatigue life. In the following paragraphs, the fatigue process of the central notched elastic-plastic material will be described uniformly by the aid of the M -integral and A_D .

Figure 7. Fatigue process of the central notched elastic-plastic material. (a) the formation and growth of plastic zone; (b) the initiation of macrocrack; (c) the growth of macrocrack; (d) the sudden fracture.

Figure 8. Photos at the macrocrack initiation time.

As discussed in Section 2, the A_D can be calculated after obtaining M -integral experimentally, then the relationship between A_D and N can be given, further we can get the relationship between dA_D/dN and ΔM . The turning point of A_D is written as A_{DC} , when macrocrack initiates from the physical phenomenon. According to the N_C of each specimen, the corresponding A_{DC} is calculated.

The logarithmic operations of dA_D/dN versus ΔM are made and the results are presented in Figure 9. According to the N_C mentioned above, this paper divides the relation between dA_D/dN and ΔM into two stages. The first stage $n < N_C$, that is, when there is no macrocrack (crack length < 1.0 mm); The second stage $n \geq N_C$, that is, after the appearance of macrocrack. We define dA_D/dN corresponding to N_C as $(dA_D/dN)_C$, which is the turning point of damage evolution rate between the first and second stages. It can be seen from that the damage evolution rate dA_D/dN shows a logarithmic linear relationship with ΔM , which has the following three characteristics:

Figure 9. dA_D/dN correlated with ΔM : (a) $R=0.5\text{mm}$; (b) $R=1.0\text{mm}$; (c) $R=1.5\text{mm}$; (d) $R=2.0\text{mm}$.

1) The relationship between dA_D/dN and ΔM is a two-stage logarithmic linear relationship, denoting that there is a unified relation between the fatigue damage evolution rate dA_D/dN and fatigue driving force ΔM for notched elastic-plastic specimens.

2) The intercept λ of $\lg(dA_D/dN)-\lg(\Delta M)$ curve correlated with applied stress σ of elastic-plastic specimens with different magnitude of initial notch is shown in Figure 10(a)(b), and the intercept λ correlated with initial hole radius R is shown in Figure 10(c)(d). It can be found that λ does not change significantly with the increase of σ both in Stage I and Stage II, while λ is linearly related to the initial hole radius R . Therefore, it can be considered that λ is only related to R , but not to σ . The slope n also satisfies this law.

Figure 10. The slope n and intercept λ of $dA_D/dN-\Delta M$ curve correlated with σ and R : (a) $\lambda_1-\sigma$ curve in Stage I; (b) $\lambda_2-\sigma$ curve in Stage II; (c) λ_1-R curve in Stage I; (d) λ_2-R curve in Stage II.

3) The turning points of two fitting lines are not fixed value, but its distribution seems to meet a certain rule. The $(dA_D/dN)_C$ and ΔM corresponding to the initiation of macrocrack of all specimens are plotted in one diagram, as shown in Figure 11. It is found that there is a good logarithmic linear relationship between $(dA_D/dN)_C$ and ΔM . Therefore, we define the turning point from the physical phenomenon, and mathematically show that the turning point satisfies the simple mathematical law, i.e., the logarithmic linear relationship between the $(dA_D/dN)_C$ and ΔM .

Figure 11. The turning point $(dA_D/dN)_C$ correlated with ΔM of all specimens.

By substituting the fitting formula of n and λ changing with R in Figure 10 into Eq. (2), we can get the fitting formula of $dA_D/dN-\Delta M$, shown as below:

$$\begin{cases} \lg(dA_D/dN) = -18.62R - 2.87 + (10.45R + 2.55) \lg(\Delta M) & (\text{Stage I, } dA_D/dN < (dA_D/dN)_C) \\ \lg(dA_D/dN) = -4.64R - 8.01 + (2.66R + 0.56) \lg(\Delta M) & (\text{Stage II, } dA_D/dN > (dA_D/dN)_C) \end{cases} \quad (8)$$

where $\lg(dA_D/dN)_C = 0.86\lg(\Delta M) - 10.64$.

5 CONCLUSIONS

In present work, an innovative fatigue model is proposed for the notched elastic-plastic material based on the concept of M -integral. The main conclusions are as follows:

1) Two new parameters, the equivalent damage area (A_D) and the M -integral range (ΔM) are introduced to characterize the damage level of notched elastic-plastic material. dA_D/dN is defined to characterize the fatigue damage evolution rate of elastic-plastic material. ΔM is termed as the driving force of fatigue damage evolution.

- 2) The fatigue tests of No. 45 steel with circular notch show that the notch fatigue damage evolution of elastic-plastic material can be divided into two stages from the initiation and aggregation of microcracks to the growth of macrocracks. And $(dA_D/dN)_C$ is the turning point, which has a logarithmic linear correlation with ΔM . At whole stage (Stage I and Stage II), the relationship between dA_D/dN and ΔM keeps logarithmic linear correlation. The slope n and intercept λ of $\lg(dA_D/dN)-\lg(\Delta M)$ curve has linear correlation with the initial notch radius R , but not with applied stress σ .
- 3) The proposed fatigue model of the notched elastic-plastic material is verified and can accurately describe the damage process including the formation of plastic zone, the microcrack initiation and the macrocrack growth. The significance of the research is to put forward a standard which can be applied to evaluate the damage level and predict fatigue lifetime of the notched elastic-plastic material or structure.

ABSTRACT: This paper presents a study on seismic response of a metro station, constructed with cut-cover and jacking method, in Shanghai. As the station structure constructed by the combined structures of jacked caisson and culvert frames on both sides, differences in stiffness would induce unknown seismic effects. Shaking table tests, at geometric scale of 1/20, were carried out to investigate the seismic performance of the station structure, with flexible connection or rigid connection. The test results showed that the flexible connection, pipe-jacking portion at the end of frame portion with the larger mass has larger peak accelerations. Using the rigid connection, the overall circumferential-joint extensions of caisson portion is larger than that of the flexible connection.

1 INTRODUCTION

The urban subway plays an important role in improving travel efficiency. Besides the Daikai Station, many subway stations suffered great damage by Osaka-Kobe Earthquake in 1995 which indicated that dynamic performance of underground structures should be paid particular concern.

Previous research has established that shaking table test is an effective method to study the dynamic characteristics of underground structures. Numerous authors have treated this subject, including Iwatate *et al.* (Iwatate *et al.*, 2000) and Yang *et al.* (Yang *et al.*, 2003).

So far, however, there has been little discussion about dynamic performance of subway station with the connection between frame-structure and jacked caisson. Composite construction

Figure 1. Overview of the model experimental setup.

method subway station with open-cut frame at both ends and underground pipe jacking in the middle has stiffness mutation problem. In this paper, shaking table tests were performed to investigate the influence of joint stiffness of pipe jacking structure and frame structure on the seismic performance of the station. The prototype station of the tests is Jing'an Temple station of Shanghai rail transit line 14.

2 SHAKING TABLE TEST

2.1 Test apparatus and scaling relations

The shaking table tests were studied with the help of the shaking table system at Tongji University. The size of the shaking table is 10m long and 6m wide in plane, which can produce three dimensional motion, namely, transverse, longitudinal and rotational. The maximum permissible acceleration of the shaking table was 1.5g with the maximum proof mass of 140t, where g is the gravitational acceleration. The frequency of the input motion ranged from 0.1 Hz to 50 Hz.

As depicted in Figure 1, the rigid model container used in shaking table tests was installed on the shaking table by high-strength bolts. Fifteen horizontal H-steel layered frames made up main structure of the container. The external dimensions of the container are 10m long, 6m wide and 2m tall with the internal operation space size of 9.5m in length, 5.5m in width, and 2m in height. To mitigate boundary effect, energy absorption material is stuck to the inside of lateral wall.

Taking account of the size and capacity of the shaking tables (combined), an $S_l = 1/20$ geometry scale factor was selected for the experiments. The other scaling relations were derived through combination of the Vaschy-Buckingham Π theorem, dimensional analysis (Funglsang & Ovesen, 1988) and dynamic equilibrium (Fung, 1977). Firstly, based on the hyperbolic model proposed by Konder (Konder, 1963), the nonlinear stress-strain response of soil could be expressed by Equation1:

$$\sigma_1 - \sigma_3 = \frac{\varepsilon}{a - b\varepsilon} \quad (1)$$

where σ_1 and σ_3 are major and third principle stress, respectively; ε is the strain; a and b are constants. Therefore the similarity ratio of strain can be derived as 1. Assuming the soil as a continuous medium, based on Hooke's law and stress-strain relation (Kramer, 1996), the dynamic equilibrium in the x-direction can be written in terms of displacements:

$$\rho \frac{\partial^2 u}{\partial t^2} = (\lambda + G) \frac{\partial \varepsilon}{\partial x} + G \nabla^2 u \quad (2)$$

where λ and G are the Lamé's constants; and ∇^2 is the Laplacian operator; ρ , u and t are density, displacement and time, respectively. Equation 2 indicated the relationships of similitude ratios of density, acceleration, displacement and shear modulus. It could be written as:

$$S_\rho S_a = \frac{S_G}{S_l} \quad (3)$$

where S_ρ , S_a , S_G and S_l are similitude ratios of density, acceleration, shear modulus and geometry, respectively.

In this study, the similitude ratios of density, shear modulus and geometry are basic scale factors, considering the limitation of model container and experimental materials. They are set to $S_l = 1/25$, $S_\rho = 1/2.5$, and $S_G = 1/63.3$, respectively. Table 1 presents the main similitude relations of the synthetic model soil, obtained by applying the Vaschy-Buckingham Π theorem.

2.2 Model soil and model structure

The prototype soil profile is multi-layered. Accurate simulation of prototype soil is quite complicated and does not fall within the scope of this work. Regarding the prototype soil as

Table 1. Scaling relations of model soil to prototype soil.

Physical quantities	Similitude relations	Scale factor
Displacement	S_l	1/25
Density	S_ρ	1/2.5
Shear modulus	S_G	1/63.3
Acceleration	$S_a = S_l^{-1} S_\rho^{-1} S_G$	1/1
Time	$S_t = S_l S_\rho^{1/2} S_G^{-1/2}$	1/5
Frequency	$S_f = S_l^{-1} S_\rho^{-1/2} S_G^{1/2}$	5/1

Figure 2. Station structure: (a) overview of frame-structure part; (b) interior view of the pipe jacking structure; (c) overview of the pipe jacking structure; (d) rigid connection in the tests; (e) flexible connection in the tests.

deposit as a single model soil layer, the prototype soil's average density, equivalent shear wave velocity and equivalent shear modulus are available. The model soil should satisfy the similitude relations of Equation 3. Considerable work was undertaken to test the properties of different kinds of synthetic model soil. Key properties of the model soil are summarized as follow: density $\rho = 860 \text{ kg/m}^3$ and maximum shear modulus $G_0 = 4.47 \text{ MPa}$.

The station structure of model consists of frame-structure part and jacked caisson part. Both of the two parts meet the requirement that the relative stiffness of prototype station structure and prototype soil should be the same as the relative stiffness of model structure and model soil:

$$A_s^m = A_s^p S_l^2 S_E / S_f \quad (4)$$

where A_s^m and A_s^p are area of reinforcement for model and prototype sections, respectively; S_l , S_E and S_f are similitude ratios of geometry, elastic modulus and tensile strength.

As depicted in Figure 1, the Frame A part is 3.5m long in longitude direction and the Frame C part is 1.0m long in longitude direction, which are both 1.432m in width and 1.153m in height. As for the pipe jacking structure of the model, it is the combination of steel pipe sections which meet the requirement of relative stiffness. Every steel pipe section is 0.1m long in longitude direction.

As depicted in Figure 2d and e, two kinds of connection methods are adopted in the tests. The rigid connection shaped like flange plate is made up of carbon textile and epoxy resin while foamed rubber is used to fill the gap between frame-structure part and jacked caisson part in flexible connection.

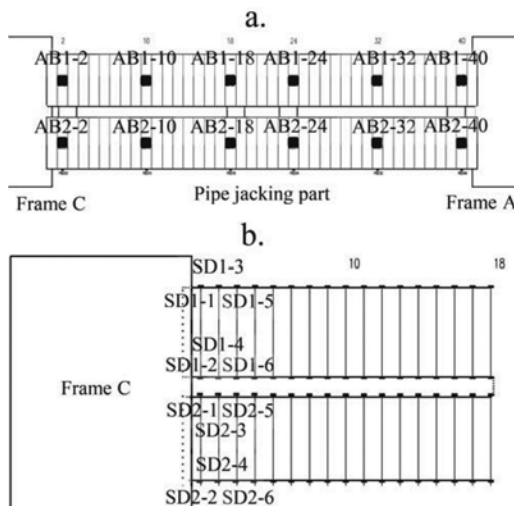

Figure 3. Shaking table model layout: (a) top view of the acceleration sensors in pipe jacking part and (b) top view of the circumferential-joint extensions sensors.

2.3 Instrumentation

Acceleration sensors and strain sensors are used to examine the dynamic response of soil and station structure throughout a series of tests. The sensors consist of three components: acceleration sensors in the soil, acceleration sensors in the station structure and sensors of circumferential-joint extensions.

A series of acceleration sensors are arranged in the soil at equal heights along the burial depth to measure the soil acceleration response. Every pipe in pipe jacking part is made up of 41 steel pipe sections. The pipe section nearest to the frame A is numbered 1 and is numbered in turn to the ring furthest from the Frame A, numbered 41. As depicted in Figure 3a, at the top of the six key sections of the pipe jacking part the pipe ring acceleration points are placed, numbered AB1-2, 10, 18, 24, 32, 40 and AB2-2, 10, 18, 24, 32, 40. The first digit represents the number of the pipe the sensor is on and the second digit represents the number of the pipe section the sensor is on.

Strain gauge based displacement sensor are arranged on both sides of the pipe joints to measure the circumferential-joint extensions, numbered SD1-1, ..., SD1-80 and SD2-1, ..., SD2-80. As depicted in Figure 3b, the first digit represents the number of the pipe in which the sensor is located, the second digit represents the position of the circumferential-joint in which the sensor is located, alternating the numbering on both sides of the tube ring starting from 1.

Table 2. Input motions applied to the models in model scale.

No.	Case ID	Earthquake motion	Amplitude (g)	Excitation direction
1	WN-0.05	White noise	0.05	Longitude (X)
2	SH-0.1X	Artificial wave	0.1	Longitude (X)
3	SH-0.1Y	Artificial wave	0.1	Transverse (Y)

Figure 4. (a) Artificially synthetic earthquake wave and (b) its Fourier spectra (model scale with PGA = 0.1g).

2.4 Input motions

Seismic motions are imposed in both transverse and longitudinal directions. Two kinds of earthquake sequences are employed in shaking table tests as summarized in Table 2. One is the white noise motion, and the other one is the artificially synthetic earthquake waves (representative of the construction site). The artificially synthetic earthquake excitation is illustrated in Figure 4, along with its Fourier spectrum.

3 TEST RESULTS

3.1 Transfer function of the model soil

One-dimensional site response based on the wave method can be used to inversely extrapolate the bedrock response from the surface recorded seismic response, i.e. the transfer function (TF). According to the assumption of a linearly elastic homogeneous site, the transfer function is only related to the site stiffness and damping ratio. The transfer function can therefore be used to verify the validity of the shaker test design. As depicted in Figure 5, the test result and the 1D analytical solution are in good agreement over a wide frequency range. Test result is the transfer function of free field, recorded by acceleration sensor of model ground surface in Case WN-0.05. The 1D analytical solution (Kramer, 1996) is computed by:

$$F(\omega) = 1 / \sqrt{[\cos\left(\frac{\omega H}{v_s}\right)]^2 + \left(\zeta \frac{\omega H}{v_s}\right)^2} \quad (5)$$

where ω is the frequency; H is the depth of model ground; v_s is the shear wave velocity; ζ is the damping ratio which is usually considered as 0.05.

Figure 5. Transfer function of tests results and analytical solution of damped ($\zeta = 0.05$) elastic soil on rigid base.

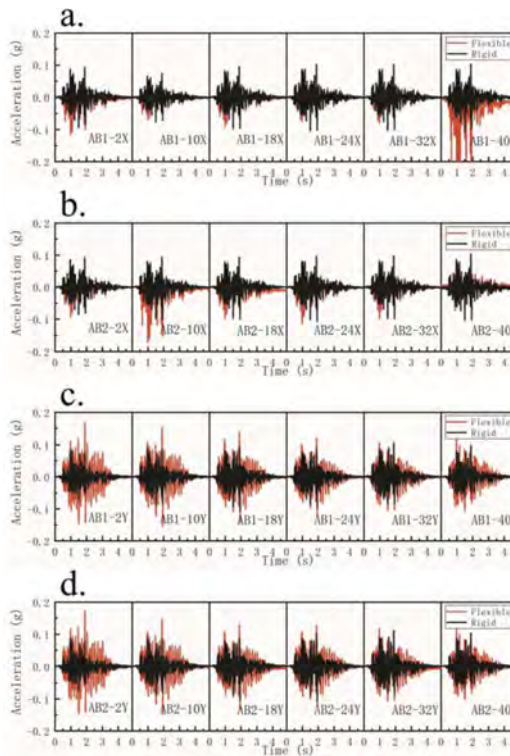

Figure 6. Time history of experimentally measured jacked caisson acceleration for different input motions: (a) acceleration sensors on pipe #1 for artificially synthetic earthquake wave in longitude direction; (b) acceleration sensors on pipe #2 for artificially synthetic earthquake wave in longitude direction; (c) acceleration sensors on pipe #1 for artificially synthetic earthquake wave in transverse direction; (d) acceleration sensors on pipe #2 for artificially synthetic earthquake wave in transverse direction. ‘Flexible’ is for flexible connection and ‘Rigid’ is for rigid connection as previously mentioned, respectively.

3.2 Acceleration of jacked caisson part

The two types of connection with different stiffnesses lead to different dynamic responses of the jacked caisson part. Figure 6 presents the time history of jacked caisson acceleration. With a flexible connection, the peak acceleration of the pipe due to motion input along the longitude direction is essentially at the same level, while the peak acceleration is inconsistent when motion input along the transverse direction. As depicted in Figure 7, the peak acceleration near Frame A is smaller than that near Frame C when motions are input along transverse direction. For artificially synthetic earthquake wave SH-0.1Y, the peak acceleration of sensor AB1-40 is 0.127g while the peak acceleration of sensor AB1-2 is 0.164g. The peak acceleration of sensor AB1-2 is 29% greater compared to that of sensor AB1-40. There is no significant trend in peak acceleration for the station model with rigid connections.

In combination with the above analysis, the motion input along the transverse direction when a flexible connection is used will cause the pipe to produce an uneven distribution of peak acceleration along longitude direction. It may be caused by the uneven quality of the frame at both ends. Inputting motions in transverse direction, the overall peak acceleration of the pipe is greater than that in longitude direction. It suggests that the stiffness of station structure in longitude direction is greater than that in transverse direction. Rigid connection could reduce the peak acceleration of pipe compared to flexible connection, with all other conditions being equal.

Figure 7. Peak acceleration of key sections in pipes: (a) rigid connection is adopted and (b) flexible connection is adopted.

3.3 Circumferential-joint extension

Figure 8 presents the maximum of circumferential-joint extension in the condition with case ID SH-0.1Y. When using a flexible connection, the overall circumferential-joint extension is generally small, with a maximum value of 0.008 mm. The maximum of peak circumferential-joint extension of all pipe sections increases to 0.172 mm while the overall circumferential-joint extension also increases with the adoption of rigid connection. In the rigid connection test, many mutation points of peak circumferential-joint extension occur in the middle part of pipe. Regardless of whether a flexible or rigid connection is adopted, the peak circumferential-joint extension near the Frame-A end is greater overall than the peak circumferential-joint extension near the Frame-C end.

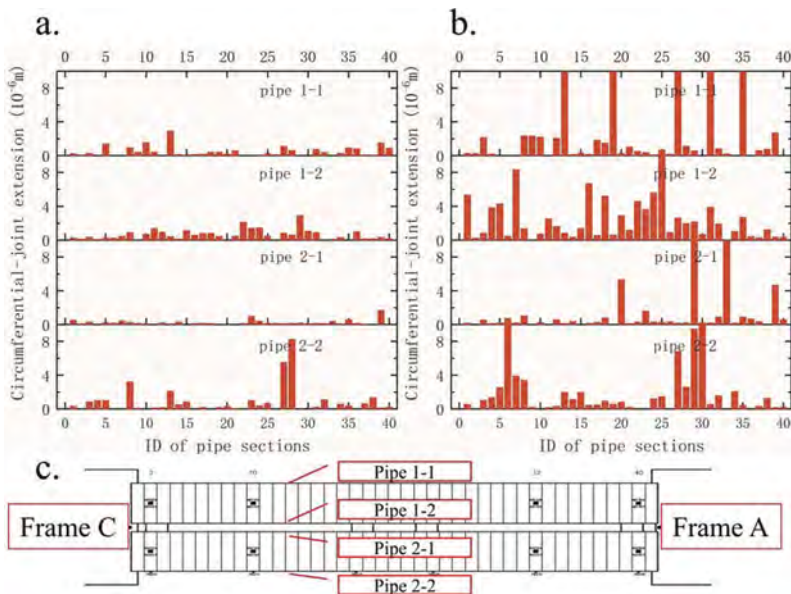

Figure 8. Maximum of circumferential-joint extension: (a) flexible connection is adopted and (b) rigid connection is adopted.

4 CONCLUSIONS

In this study, the behavior of a metro station with combined construction method in soft soil was investigated by performing shaking table tests on a scaled model. From the results of the shaking table tests, the following conclusions were obtained:

- (1) When a flexible connection is adopted, the peak acceleration of the pipes increases when the seismic wave is input in transverse direction compared to when it is input in longitude

direction. With the adoption of flexible connection, when ground vibrations are input in transverse direction, the peak acceleration of pipes is higher at the end with the higher mass due to the different masses of the frame structure at the two ends of the jacked caisson part. With the adoption of rigid connection, The peak acceleration of the pipes is evenly distributed along the longitudinal direction, and the different seismic wave input directions have little effect on the peak acceleration of the pipes.

- (2) With the adoption of flexible connection, the peak circumferential-joint extension is much smaller than that with the adoption of rigid connection. Due to the asymmetrical mass of the frame at both ends, the stiffness of the jacked caisson has a smaller degree of sudden change when using a flexible connection, reducing the maximum of peak circumferential-joint extension. Whether a flexible or rigid connection is used, there is a phenomenon that the maximum of peak circumferential-joint extension is greater on the side with the greater mass of the frame and less on the side with the smaller mass, which is more obvious when a flexible connection is used.

The behavior of a metro station with combined construction method in soft soil was very complicated because of stiffness mutation and different forms of soil-structure interaction. Hence, further improvements in analysis of acceleration and circumferential-joint extension should be attempted in future studies.

Robustness of RC girder bridges: The case of half-joint bridges

P. Martinelli, M. Colombo & M. di Prisco

Department of Civil and Environmental Engineering, Politecnico di Milano, Milan, Italy

ABSTRACT: Considerable research efforts have been made on the progressive collapse resistance of buildings. This effort is much more limited in the case of bridges, where robustness criteria are just as, or even more important than in buildings. Existing studies dealing with the robustness of bridges, although appreciable, often are limited to qualitative considerations that can provide designers with valuable pointers when designing new bridges. It is equally important to assess not only the safety but also the robustness of existing bridges through reliable metrics that can be used in the prioritization of interventions by the managing authority. According to this aim, this paper applies a selected measure of robustness to a particular type of reinforced concrete (RC) girder bridge, namely half-joint bridges. The Annone viaduct, which collapsed in 2016 after the passage of a heavy truck, is used as a case study.

1 INTRODUCTION

In the last decade, considerable research efforts have been made on the evaluation of the progressive collapse resistance – or equivalently in enhancing the structural robustness – of buildings with a particular focus on reinforced concrete frame buildings. Looking at the bridges, this research effort is much more limited and robustness criteria are just as, or even more important than in buildings. Existing studies on the robustness of bridges, although appreciable, are often limited to qualitative considerations that can provide designers with valuable indications for the design of new bridges. The dramatic series of bridge collapses that occurred in Italy in the last years has highlighted the need for urgent treatment of the worldwide infrastructural heritage, which consists mainly of reinforced concrete (RC) and precast concrete structures. In this regard, it is equally important to assess the safety and robustness of existing bridges. The robustness of existing bridges can be assessed through reliable metrics that can be used in the prioritization of interventions by the managing authority. In this context, the paper applies a measure of robustness available in the literature to a particular type of RC girder bridge, namely half-joint bridges. A simple methodology based on the notional removal of critical elements is applied for quantifying the structural robustness. Half-joint bridges represent a not insignificant amount of the Italian (and European) infrastructural stock and they are considered among the most critical infrastructures. The Annone viaduct, an RC half-joint bridge that collapsed in 2016 after the passage of a heavy truck, is used as a case study. The bridge was built in the early 60s in northern Italy and it consisted of a central suspended span and two side spans having a cantilever scheme, for a total length of 56.10 m.

2 BACKGROUND ON ROBUSTNESS INDICATORS

Objective measures of robustness are required to assess safety against progressive collapse, estimate losses, and decide whether a level of robustness is acceptable or not. Furthermore, a quantitative measure of robustness is useful for prioritizing maintenance and repair work on existing structures. Several indicators for measuring robustness are available in the literature,

some of them formulated in deterministic terms, others in probabilistic or risk-based terms. A comprehensive selection of robustness measures proposed in the literature can be found in Adam et al. (2018). To date, there is no unanimous consensus on a univocal measure of robustness. This limits the adoption of robustness indicators on a large scale.

Deterministic measures of robustness are typically based on the consequences of an assumed initial damage in the structure. In particular, such measures quantify the change in structural properties, such as stiffness or strength, having in common one basic idea: the comparison between the intact and the damaged structure. Although there are no specific robustness indicators for bridges, a careful analysis of the metrics available in the literature allows some indicators to be favoured over others based on the type of collapse mechanism (Starossek 2017).

Among the deterministic indicators of robustness that can also be calculated using linear elastic material behaviour, the ‘reserve-based measure’ R_r proposed by Starossek (2017) is considered particularly suitable for the study of half-joint bridges. It is based on the redistribution of forces following the failure of a structural element. This measure of robustness is called a ‘reserve-based measure’ because the redistribution of forces is only possible when the structure has reserves of bearing capacity. Let us consider a beam suspended on rods in the intact initial configuration of Figure 1a. The load applied to the beam induces stresses in the rods. Assume a local failure in the rod j . When the rod j is removed (Figure 1b), the force in the rod k increases by the quantity ΔF_k . The maximum dynamic force in the rod k F_{kj} ($F_{kj} = F_k + \Delta F_{kj}$) can be compared with the bearing capacity of the rod ($F_{k, ult}$). The index R_r can then be expressed as:

$$R_r = 1 - \max_{k,j} \frac{F_k + \Delta F_{kj}}{F_{k,ult}} \quad (1)$$

Positive values of the index R_r indicate robustness as failure does not propagate. Negative values of R_r indicate progressive collapse and lack of robustness. The maximum value of R_r , in this formulation is of the order of $1 - \phi$ where ϕ represents the average resistance safety factor.

Figure 1. Example of a beam suspended on rods to illustrate the index R_r (adapted from Starossek 2017).

Although the index R_r is referred to by Starossek (2017) as a measure of robustness, it is perhaps mainly connected to structural redundancy since it shows the ability of the system to redistribute loads after damage to a single or a few members. The terms structural robustness, redundancy, and static indeterminacy are often used as synonymous in the literature but they denote different properties of the structural system. The fundamental difference between these terms is addressed in Biondini et al. (2008) where multiple examples are given as well. It has been also demonstrated that the degree of static indeterminacy is not a consistent measure of structural redundancy (Frangopol & Curley 1987; Biondini et al. 2008). Although structural

robustness strongly depends on redundancy and alternative load paths may enhance structural redundancy, the latter does not necessarily lead to increasing structural robustness (Biondini 2009, André 2020). In fact, the redistribution of internal actions on the damaged system may promote the evolution of damage reducing robustness.

3 CASE STUDY DESCRIPTION

3.1 *Geometry*

The bridge case study is the Annone overpass, a precast concrete structure built in the 1960s and collapsed in 2016 due to the shear failure of a half-joint during the passage of a heavy truck. The bridge was located in Annone, a small town in the province of Lecco (northern Italy), and designed as a second category bridge according to Circular 14 February 1962 n.384 (1962). The bridge consisted of a central suspended span (drop-in) and two side spans having a cantilever scheme, for a total length of 56.10 m and a total width of 7.4 m. The two side spans were simply supported on the abutments and on the intermediate walls each having a cantilever of about 2.80 m at the end. The central beams were simply supported on the two lateral beams employing half-joints thus reproducing a statically determinate condition. The span of the central beams was equal to 19.0 m. The geometric details of the bridge are here omitted but can be found in di Prisco et al. (2018, 2023). Five prestressed prefabricated beams (PC beams in the following), with a spacing between their axes of 1.35 m and disposed along the longitudinal bridge direction, supported a continuous cast in situ RC slab. The RC top slab was clamped at the abutments. RC transversal beams – five in the central span and four in the side spans – were cast in situ in the orthogonal direction. A schematic plan view of the central span is shown in Figure 2a together with the nomenclature of the 10 half-joints (R1 – R10), while a vertical section of the bridge is illustrated in Figure 2b.

3.2 *Load configuration*

This section describes the nominal applied loads on the elements of the central span due to their self-weight and live loads according to the NTC 2018 (Infrastructure Ministerial Decree, 2018). For the sake of brevity, bending moments and shear forces at mid-span are omitted and only the load acting on the half-joints is evaluated.

Regarding the central span, the overall self-weight of the bridge, including safety barriers, pavement, curbs, beams, and RC slab, was equal to 1690 kN, a value higher than that assumed by the designer, set to 1521 kN. The dimension of conventional lanes, the load positions, and the amplitudes are described in Figure 3 according to NTC 2018 (Infrastructure Ministerial Decree, 2018). Two load configurations are assumed to maximize the load on supports R1-R5 (symmetrical load with respect to the mid-span can be assumed to maximize the load on supports R6-R10): (i) lane 1 loaded according to the diagram in Figure 3 and (ii) lanes 1 and 2 both loaded according to the diagram in Figure 3. The first load configuration is schematized in Figure 2a as the load area highlighted in green – and half of the light grey area – resulting in a total live load of 1132 kN, a combination of concentrated and distributed loads. The second load configuration is schematized in Figure 2 as the load area highlighted in green, grey, and red, for a total live load of 1693.5 kN.

It should be emphasised that these live loads are significantly higher than those envisaged in the design phase. The bridge was in fact designed following the provisions of Circular 14 February 1962 n.384 (1962) as a bridge of second category. Even assuming that the distance between two subsequent vehicles is equal to zero, the maximum overall live load applied on the central span is equal to 88 t. This load must be increased with a dynamic amplification coefficient that depends on the bridge span and that can be considered equal to 1.284 if the span between the central piers is considered resulting in a maximum live load of 113 t (1109 kN vs 1693.5 kN).

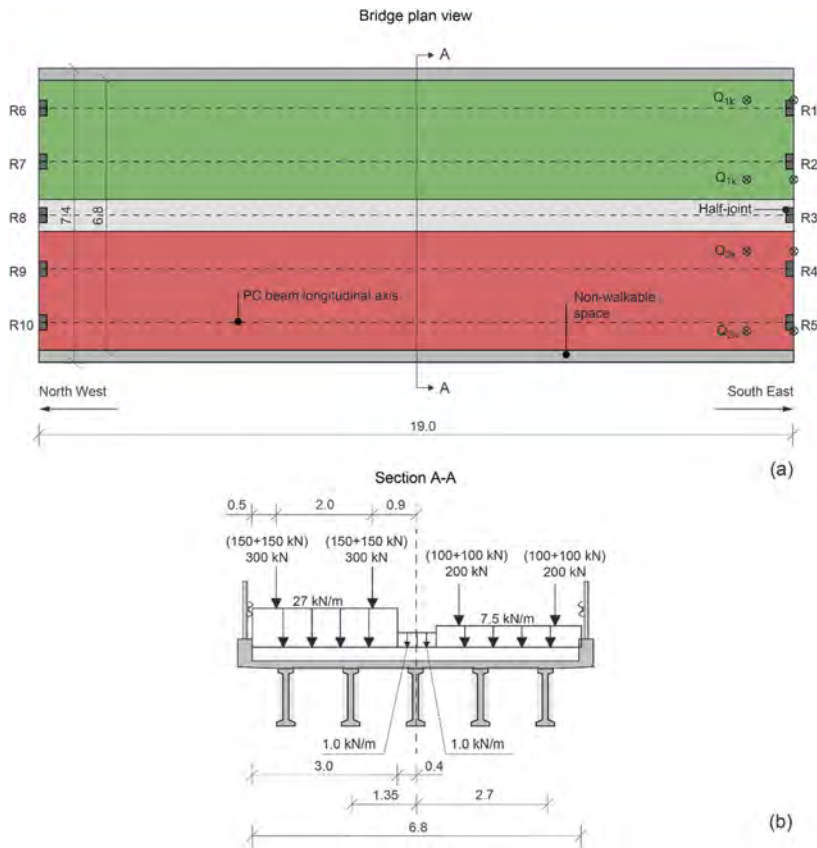

Figure 2. Loads on the central suspended span according to NTC 2018 (Infrastructure Ministerial Decree 2018): (a) plan view and (b) vertical cross-section.

Figure 3. Dimension of conventional lanes and loading scheme according to NTC 2018 (Infrastructure Ministerial Decree 2018).

3.3 Half-joint resistance

Equation (1) involves calculating the ultimate capacity of the half-joints ($F_{k,ult}$), which are considered the critical element of the entire system. The estimation of $F_{k,ult}$ is based on the strut-and-tie models presented in di Prisco et al. (2023) which reproduced the half-joint geometry

and reinforcement details. On this last aspect, an as-built reinforcement situation with nominal bar diameters is assumed. The ultimate load for each half-joint is then estimated at 578.5 kN.

4 FINITE ELEMENT MODELS

The robustness quantification is carried out using linear elastic finite element (FE) models. The basic – intact – model used in this study is the same as that adopted in di Prisco et al. (2023) and named ‘num. 2A’. This FE model is a 3D simplified model in which the side spans are not reproduced. This model is therefore only used to conduct analyses on the bridge central span. The side spans are assimilated to elastic constraints for the central span according to the loading scheme shown in Figure 4a. Such a loading scheme provides a stiffness k equal to 6.06E7 N/m. Values of elastic constants for PC beams, transversal RC beams, and top RC slab are here omitted but are given in di Prisco et al. (2023).

Elastic constraints (translational springs in the Y direction) are applied to the ends of the beams of the central span as shown in Figure 4b. A 3D mesh view of the simplified FE model is shown in Figure 4c. Two types of 3D finite elements are used for different regions of the bridge: the top RC slab is discretized with shell-type elements, while the longitudinal and transversal beams are discretized as linear beam-type elements.

Figure 4. Simplified FE model: (a) lateral span loading scheme used for estimating the stiffness (k) of half-joints (b) details of the boundary conditions and (c) mesh view (adapted from di Prisco et al. 2018).

5 NOTIONAL REMOVAL APPROACH FOR HALF-JOINT BRIDGES

Design from actions resulting from unspecified hazards can be treated with a notional damage scenarios approach. According to the draft version of the *fib* Model Code 2020 document, notional damage scenarios can include (i) notional deterioration scenarios or (ii) notional removal scenarios.

In case (i), the geometrical and/or material properties of one or more structural elements are notionally reduced and the structure is checked for disproportionate consequences.

In case (ii), structural elements are notionally removed and the structure is checked for disproportionate consequences, for example by conducting an alternative load path design. Columns (one or more), panels/walls or nominal wall length (one or more) and any other elements judged vital to the structural performance are among the structural elements that can be notionally removed.

Notional removal scenarios – usually considered to be related to the failure of a connection or structural member due to an unidentified hazard – have been largely applied to evaluate the robustness of buildings (see for example Rodriguez et al. 2021 and Martinelli et al. 2022, among the others). The notional removal scenarios strategy is here applied to the bridge under

study by removing the half-joints, considered to be the most critical elements of the entire bridge (di Prisco et al. 2023). It is worth mentioning that the notional removal scenarios approach herein adopted is more conservative than the notional deterioration scenarios approach.

The scenarios that will be considered include the removal of a single half-joint at a time. Given the symmetry of the loads described in §3.2 with respect to the centreline of the bridge, it will be sufficient to consider the loss of the half-joints R1-R5 (loss of half-joint R1, loss of half-joint R2, etc.).

6 RESULTS AND DISCUSSION

The simplified FE models described in §4 allow the computation of the index R_r (Starossek 2017) with the load configurations described in §3.2. Figure 5 shows the reactions in half-joints R1-R5 in the case of intact situation and for the half-joint loss scenarios described in §5. Figure 5a considers the loads on lane 1, whilst Figure 5b considers the loads on both lanes 1 and 2. As one would logically expect, the reaction in the removed half-joint is nil. The most severe condition occurs when the end half-joint R1 in lane 1 is removed. In this condition, the adjacent half-joint R2 registers the maximum reaction. For both load configurations (Figure 5), another severe load condition compared to the intact condition is the loss of the half-joint R2. When loads are applied on both lanes (Figure 5b), another severe load condition compared to the intact condition is the loss of the other end half-joint R5. The loss of centre half-joints allows a more homogenous redistribution of reactions, making these scenarios less critical than the loss of end half-joints.

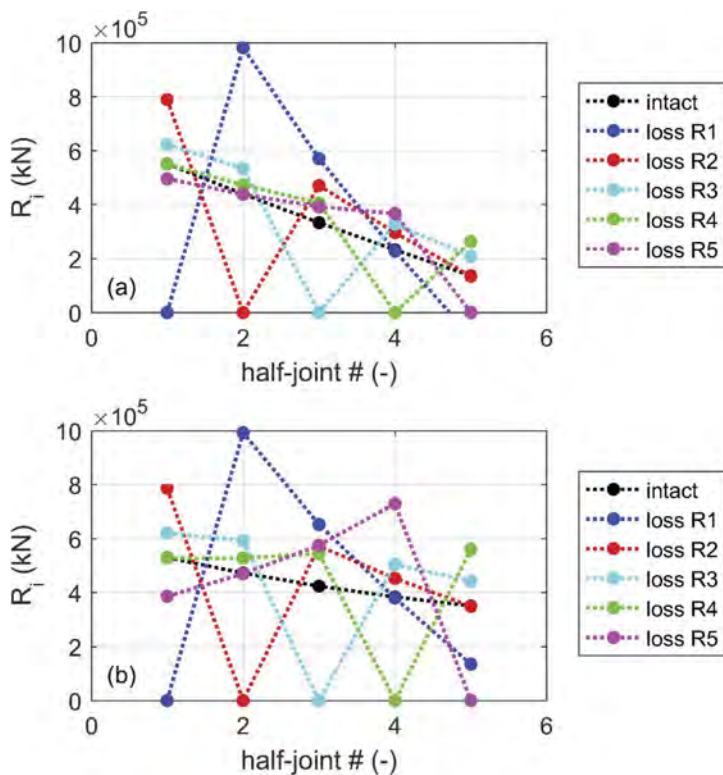

Figure 5. Reactions in half-joints R1-R5 in case of intact situation and for several half-joint loss scenarios: (a) loads on lane 1 and (b) loads on lanes 1 and 2.

Figure 6 shows the index R_r , calculated with Equation (1) for several half-joint loss scenarios. Regarding loads applied on lane 1 only, positive values of R_r are obtained when half-joints R4 or R5 are removed. Looking at the load configuration where loads are applied on both lanes, positive values of R_r are obtained only when half-joint R4 is removed. In both load situations and in agreement with the results of Figure 5, the most unfavourable situation is the loss of the half-joint R1.

While the results in Figure 6 show a lack of robustness for most of the scenarios considered (negative values of R_r), it should be remembered that the unit load multiplier ($\alpha = 1$) applied to the load configurations described in §3.2 is very severe. Concerning the load configuration involving loads on both lanes, the ratio between the live loads calculated according to Circular 14 February 1962 n.384 (1962) – and for which the bridge was designed – and according to NTC 2018 is 0.66. Applying a load multiplier equal to this ratio ($\alpha = 0.66$), Figure 7 compares the values of R_r for loads applied on lanes 1 and 2 and load multipliers $\alpha = 1$ and $\alpha = 0.66$. The two curves show very similar trends but with higher values of R_r for $\alpha = 0.66$. This case shows how the loss of central half-joints R3 or R4 – with positive values of R_r – does not lead to a propagation of failure. The most unfavourable situation is the loss of the end half-joint R1.

Figure 6. Index R_r (Starossek 2017) for loads applied on lane 1 only and loads applied on lanes 1 and 2.

Figure 7. Index R_r (Starossek 2017) for loads applied on lanes 1 and 2 and load multipliers $\alpha = 1$ and $\alpha = 0.66$.

7 CONCLUSIONS

In this paper, a selected measure of robustness – typically adopted for buildings – is applied to a particular type of reinforced concrete (RC) girder bridge, namely half-joint bridges.

A simple methodology based on the notional removal of half-joints – which represent the critical elements for this type of bridge – is applied. The analysis of the structural system under notional removal scenarios is herein executed through linear static analyses where dynamic effects are neglected. The Annone viaduct, an RC half-joint bridge that collapsed in 2016 after the passage of a heavy truck, is used as a case study. Using two of the heaviest load combinations in accordance with the current standard NTC 2018, the following conclusions can be drawn.

The results obtained show greater robustness when central half-joints are removed compared to when end half-joints are removed. In the former case, the loss of a half-joint is followed by a redistribution of actions in the adjacent Gerber saddles that do not propagate the initial damage. Conversely, the loss of an end half-joint results in an absence of robustness for both load configurations considered. This result is in line with the prescriptions adopted for some bridges whereby the transit of exceptional heavy trucks must take place in the centre of the carriageway. This requirement was also foreseen for the Annone bridge, but it was unfortunately disregarded by the heavy truck that then triggered first the rupture of the half-joint R1 and then the collapse of the entire bridge.

Research on imaging technology of concrete bridge bottom apparent disease detection based on machine vision

S.G. Cao, X.Y. Li, Y. Pan, J.L. Fu & H. Tian

College of Civil Engineering, Tongji University, Shanghai, China

Key Laboratory of Road and Bridge Detection and Maintenance Technology of Zhejiang Province, Hangzhou, Zhejiang, China

Zhejiang Provincial Engineering Research Center for Intelligent Operation and Maintenance Technology of Highway Bridge and Tunnel, Hangzhou, Zhejiang, China

ABSTRACT: At present, the inspection of the beam bottom apparent diseases mainly depends on the visual inspection and special inspection carried by the inspection vehicle. Such methods cannot form a standardized and digital data management of the apparent diseases, also it cannot guarantee the personal safety of the inspectors. The imaging principle of optical camera was introduced and a standardized imaging strategy for beam bottom scanning based on optical camera was proposed in this paper. The strategy has been verified on the bridge and can meet the requirements of concrete apparent disease detection in the specification. The results show that two standardized imaging modes, physical fixed focus and dynamic zoom, were proposed. According to the two imaging modes, the relationship between camera operating parameters was analyzed. The standardized imaging mode provides the calculation basis for the design and selection of the beam bottom apparent disease detection equipment. Based on the idea of grid division of beam bottom area, two basic scanning strategies in longitudinal and transverse directions were proposed. The transverse scanning method was recommended for the surface inspection of the bottom of the variable cross-section continuous box girder bridge. The apparent disease detection and imaging technology based on machine vision can facilitate the management of process parameters and the preservation of results, also it can provide reference for the rapid detection of apparent diseases at the bottom of other bridges of the same types.

1 INSTRUCTIONS

At present, the inspection of apparent diseases of concrete continuous box girder bridges mainly depends on the visual inspection and special inspection carried out manually by inspection vehicles. Such methods cannot form standardized and digital data management of apparent diseases, and cannot guarantee the personal safety of patrol inspectors. The whole inspection strategy is time-consuming and laborious, which directly limits the development of cutting-edge technologies such as artificial intelligence and the Internet of Things in bridge management and maintenance technology (He et al. 2017). At the same time, due to the change of continuous beam bridge height and the high difficulty of management and maintenance inspection, the workload of disease detection and management has increased (Xie et al. 2003, Xuan & Shen 2007).

In order to solve the defects of traditional manual visual inspection methods, a feasible method is to use automatic imaging equipment to replace the detection workers to detect the apparent diseases. At present, airborne equipment that has begun to take shape includes unmanned aerial vehicles (Hallermann & Morgenthal 2014), autonomous cruise vehicles (Zhao et al. 2020), robots (Wang et al. 2021), underwater detectors (James 2000), cable climbing robots (Xu et al. 2021), etc. For example, cable climbing robot can replace manual automatic scanning of cable surface diseases. Aerial camera UAV can take pictures of the top of

the high bridge and the bottom of the deep tower from the air, avoiding the risk of artificial aerial work. The airborne equipment used for disease detection attracted more and more attention from researchers at home and abroad.

Based on the needs of rapid detection of continuous beam bridges, the characteristics of the detection scene and the imaging strategy of the airborne visual system for rapid detection of apparent diseases of concrete continuous beam bridges are studied in this paper. The scanning method of bridge bottom disease is proposed based on the camera photography and image mosaic technology. So, in the acquisition of disease photos, the imaging principle of the camera, lens selection, and focus mode are introduced. In terms of image splicing requirements, the longitudinal and transverse scanning modes of bridge bottom diseases are introduced. Finally, a transverse scanning method based on optical camera is proposed. And the site verification is carried out relying on the Hangzhou Jiangdong Bridge.

2 IMAGING PRINCIPLE OF OPTICAL CAMERA

The basic principle of camera imaging is based on the principle of convex lens imaging (see in Figure 1). The convex lens is replaced by a photographic objective, and the optical image of the object is obtained through an array type light sensitive element. The main parameters of the optical camera are as follows:

- (a) Resolution. It refers to the number of pixel points of each image collected by the camera, which corresponds to the number of pixels arranged on the target surface of the light-sensitive chip (i.e. photoelectric sensor, CCD). The commonly mentioned camera pixels (such as 5 million, 8 million, etc.) refer to the resolution.
- (b) light-sensitive chip (CCD) size. The size of each pixel and the resolution determine the size of the CCD target. The size of the CCD target surface includes the size of horizontal width (V) and vertical height (H).
- (c) Field of view(FOV). It refers to the actual viewing angle range corresponding to the image taken by the camera, including horizontal width (V) and vertical height (H).
- (d) Working distance(WD). The distance from the lens to the object is also called object distance.
- (e) Lens focal length(f). Focal length refers to the distance from the main point to the focus after lens optics. The focal length of the lens determines the image size, field angle, depth of field and perspective of the picture.

Figure 1. Convex lens imaging principle (AB-object, ab-image, O-optical center, F-object focal length, F'-image focal length, f-focal length, u-object distance, v-image distance).

The physical quantities f , u and v in Figure 1 meet the formula (1):

$$\frac{1}{u} + \frac{1}{v} = \frac{1}{f} \quad (1)$$

For each type of camera and lens, its resolution and CCD target size are determined, and there is a certain recommended working distance range. According to the accuracy required by the target, the above parameters of the camera can be inversely calculated and selected or customized according to the actual product model. Modern cameras are divided into zoom and fixed focus.

Among them, f , u and v of zoom camera are variable, while only u and v of fixed focus camera are variable. However, in the case of actual photography, a clear image can be formed when the formula (1) is not strictly satisfied. At the imaging position before and after the focus, the foreground dispersion circle and the background dispersion circle can be formed according to the light gathering and dispersion. It can be seen that if you want to obtain higher imaging accuracy, the field of vision will inevitably be reduced. In other words, fast detection equipment cannot obtain a large range of objects at a time with high imaging accuracy at a long distance.

3 ANALYSIS OF STANDARDIZED IMAGING STRATEGY OF OPTICAL CAMERA

A major disadvantage of traditional manual detection is that the working parameters of the camera are often unknown when shooting disease images, so it is necessary to record the morphological characteristics of the disease through manual measurement. The advantage of processing disease images based on computer vision is that as long as the relationship between camera image coordinate system and world coordinate system is established through laboratory calibration, the relationship between pixel size and actual physical size can be accurately obtained. Therefore, in order to realize the standardized detection of diseases based on optical sensors and computer vision, it is necessary to carry out overall planning and analysis research from the following aspects:

- (1) Acquisition. According to the characteristics of the disease, the imaging parameters are formulated on the basis of the optical principle to achieve the accuracy required for quantitative evaluation;
- (2) Storage. Standardized storage management for disease images according to the component and location of the disease;
- (3) Processing. Quantitative processing and description of sequential disease images through panoramic splicing or positioning control points;
- (4) Recognition. For quantitative disease images, it use computer vision technology to extract structural disease features, and then identify disease information in unknown images;

The lens of an optical camera can be divided into a fixed focus lens and a zoom lens. For a fixed focus lens, because its focal length is fixed, it is necessary to take an image at a relatively fixed working distance to get a clear picture, and its imaging accuracy is a fixed value. For zoom lens, the focal length can be adjusted within a certain range (i.e., zoom magnification), the working distance can be adjusted within a certain range and the imaging accuracy will change accordingly. Based on this, two standardized imaging modes can be formed:

- a) Physical focusing. Through the method of physical or mechanical constraints, the camera can always shoot with the same attitude (i.e. fixed distance, fixed focus) in the process of shooting at the beam bottom, and then a series of standard images with the same imaging parameters are obtained.
- b) Dynamic zoom. The imaging parameters are not strictly constrained, but the camera attitude parameters are captured and stored for each imaging. In the subsequent image processing, the algorithm is used to analyze, normalize and adjust, and then the standard images are obtained.

4 ANALYSIS OF BEAM BOTTOM SCANNING STRATEGY FOR AIRBORNE EQUIPMENT

4.1 Camera lens selection

The Chinese Code for Maintenance of Highway Bridges and Culverts (JTG 5120-2021) provides the inspection methods and relevant provisions for various diseases, such as cracks, honeycombs, segregation, water seepage, whitening and calcification, concrete damage and exposed reinforcement. The Standard for Evaluation of Technical Conditions of Highway Bridges (JTG/T H21-2011) is the evaluation standard for various diseases of concrete bridge superstructure, such as honeycomb, pitting, peeling, corner loss, cracks. For the description

and measurement requirements of apparent diseases in the above specifications, the imaging accuracy of the visual method is determined to be 0.1mm/px. The actual physical size represented by each pixel in the image is 0.1mm. Based on this imaging accuracy, the camera lens and corresponding working parameters (resolution, pixel size, field of view, working distance, lens focal length) are preliminarily determined according to the above optical camera imaging principle, physical focusing and optical zoom mode.

(1) Physical focus mode

After the fixed focus lens has determined the model of the camera's photosensitive chip, it is necessary to select the corresponding model lens according to the imaging accuracy requirements to adapt the camera for work. At present, the common size of the camera sensor chip is shown in Table 1.

Table 1. Dimensions of conventional photosensitive chip.

Chip type	Length (mm)	Width (mm)	Diagonal (mm)
1/6"	2.3	1.73	2.878
1/4"	3.2	2.4	4
1/3"	4.8	3.6	6
1/2.5"	5.76	4.29	10.18
1/2"	6.4	4.8	8
1/1.8"	7.2	5.3	8.9

According to the parameters in Table 1 and the imaging accuracy requirements of 0.1mm/px, The physical size range of the actual field of view represented by the 4k (3840×2160) resolution image is 384mm×216mm. From this, the relationship between camera lens and working parameters is shown in Table 2. The focal length of lenses in Table 2 is listed in the common focal length models (2mm~100mm). The focal length can also be customized according to requirement. In practical use, within the range of clear imaging, the working distance of the camera is less than or equal to the median value in the table which can meet the accuracy requirements.

Table 2. Relation between lens focal length and camera working distance.

Focal length (mm)	Working distance (mm)					
	1/6"	1/4"	1/3"	1/2.5"	1/2"	1/1.8"
2	249.711	180	120	100.6993	90	81.50943
2.4	299.6532	216	144	120.8392	108	97.81132
2.6	324.6243	234	156	130.9091	117	105.9623
2.8	349.5954	252	168	140.979	126	114.1132
3	374.5665	270	180	151.049	135	122.2642
3.1	387.052	279	186	156.0839	139.5	126.3396
3.6	449.4798	324	216	181.2587	162	146.717
3.9	486.9364	351	234	196.3636	175.5	158.9434
4.2	524.3931	378	252	211.4685	189	171.1698
4.3	536.8786	387	258	216.5035	193.5	175.2453
5	624.2775	450	300	251.7483	225	203.7736
6	749.1329	540	360	302.0979	270	244.5283
8	998.8439	720	480	402.7972	360	326.0377
12	1498.266	1080	720	604.1958	540	489.0566
16	1997.688	1440	960	805.5944	720	652.0755
25	3121.387	2250	1500	1258.741	1125	1018.868
35	4369.942	3150	2100	1762.238	1575	1426.415
50	6242.775	4500	3000	2517.483	2250	2037.736
75	9364.162	6750	4500	3776.224	3375	3056.604
100	12485.55	9000	6000	5034.965	4500	4075.472

(2) Dynamic zoom mode

A typical 4k industrial camera movement is shown in Figure 2. It includes a photosensitive module and an optical zoom module. Its maximum resolution is 3840×2160 , 30 times optical zoom can be achieved, and the focus range is 6.9 mm~207 mm. According to the calibration results, the zoom magnification and the corresponding maximum working distance can be determined when the camera meets the requirements of imaging accuracy.

Figure 2. Industrial camera movement.

4.2 Scanning strategy of the beam bottom

For beam bottom scanning, due to objective hardware conditions, it is impossible to obtain a large range of images at a time with high imaging accuracy over a long distance. Therefore, in the process of taking photos of apparent disease images, it is inevitable to patrol and take photos of the beam bottom area in multiple groups. Therefore, the beam bottom area can be meshed and decomposed, and the coordinate system can be established along the bridge direction and across the bridge direction. The precision of single imaging determines the granularity of grid division. The higher the precision, the smaller the field of view, and the denser grid.

In traditional manual detection, due to the lack of standardization limit in shooting, the captured images often cannot be positioned on the bridge. Pictures and text records are formed for statistical summary when cracks are observed. In practice detection, the inspector can only roughly estimate the segment where the disease is located according to the moving position of the bridge inspection vehicle, and then shoot and describe the location. Therefore, the final retained image data are only sporadic images. Based on the requirements of standardized imaging, image panoramic splicing and disease location, it is necessary to specify the scanning path of equipment at the beam bottom.

For panoramic image mosaic and disease location, the relative coordinates of images are necessary information. In order to organize and calculate the position relationship between images, it is advantageous and necessary to decompose the beam bottom scanning task into several groups of ordered subtasks. As shown in Figure 3, it is a strategy for longitudinal bridge scanning zone division, and Figure 4 is a strategy for transverse bridge scanning zone division.

For the scanning detection work under the longitudinal bridge navigation belt division, the single navigation belt detection area is large. However, the detection personnel need to adjust the position repeatedly on the bridge deck. Also, the occupation of the bridge deck area is large and it takes a long time. In contrast, the scanning detection work under transverse bridge navigation belt division will gradually advance the detection area along the longitudinal bridge direction, and the occupation of the bridge deck area is in the process of dynamic progress.

Figure 3. Diagram of longitudinal bridge scanning navigation belt division.

Figure 4. Diagram of transverse bridge scanning navigation belt division.

At the same time, longitudinal scanning and transverse scanning also put forward different requirements for the adaptability of airborne equipment and variable cross-section. As shown in Figure 5, for the scanning detection work under the longitudinal bridge scanning navigation belt division, it needs to go through a significant height change when each navigation belt works. For example, the beam height is 3.5m-5.0m, and the height difference is 1.5m. For the physical focusing imaging mode, the device is required to travel along the beam bottom surface and adapt to the change of beam height through the adjustment of mechanical structure during the travel. For the optical zoom imaging mode, in order to maintain the standardization of image sequences, it is necessary to constantly adjust the magnification of the optical zoom. Otherwise, there will be constant changes in the field of view as shown in Figure 5, which also means constant changes in imaging accuracy.

Figure 5. Change of section height in the navigation belt under the longitudinal bridge scanning navigation belt division.

On the other hand, for the scanning detection work under transverse bridge scanning navigation belt division, the beam height change amplitude of each navigation belt detection work is relatively small, mainly from the height difference change within the field of view.

In general, for the variable cross-section beam, the transverse scanning method with high degree of subdivision is conducive to building the standardized imaging conditions of the equipment. At the same time, it can also relatively save the construction space of the bridge deck and it has obvious advantages compared with the longitudinal scanning method. Therefore, the transverse scanning method is recommended for the surface inspection of the bottom of the variable section continuous box girder bridge.

5 CASE STUDY

5.1 Engineering introduction

The Hangzhou Jiangdong Bridge is located in Zhejiang province of China. The bridge with a total length of 3552.66 meters has eight lanes and a single carriageway with a net width of 15.50 m. It is a fully closed and fully overpass expressway. The main bridge structure is a space cable self-anchored suspension bridge, and the approach bridge structure is a prestressed concrete continuous beam bridge. According to the 2016 regular inspection report, the concrete beams of the approach bridge appear to have coating peeling, cracks and other defects. Among them, the largest crack width of the 30th span of non-navigable which connects with the steel box girder is 0.8mm, and cracks of 0.2mm. The number of cracks with a width of 0.2mm or more accounts for 34% of the total number of cracks, which seriously threatens the safety of bridge operation. The management and maintenance department once repaired the surface, and strengthened the side webs outside the box with steel plates. However, it found that there were new longitudinal and transverse cracks on the outer bottom and web of the box in the recent inspection. The pressure of the management and maintenance department is high. So, a convenient and fast detection method is urgently needed to provide technical support for bridge management and maintenance.

5.2 Imaging of beam bottom disease detection

The on-site inspection is divided into three stages:

- (1) Erection of cableway system. The traction cableway is pulled through the beam bottom by unmanned aerial vehicle. The cableway system through the beam bottom is built to carry the beam bottom scanning device.
- (2) Erection of bridge deck walking system. Namely, the bridge deck support, walking device and power supply equipment supporting the cableway system are quickly erected on site;
- (3) Beam bottom scanning. The scanning device at the bottom of the beam is equipped, and the apparent image acquisition task starts after the control terminal is connected.

According to the transverse scanning method in Section 4.2, the transverse scanning navigation belt (as shown in Figure 6) is obtained. It is spliced to form a panoramic image of the beam bottom through image correction (as shown in Figure 7). The Figures 6 and 7 only verify the above process, and describe a small part of beam bottom disease photos. After scanning the apparent diseases at the beam bottom, a panoramic mosaic image which can be subsequently used for disease identification is formed.

Figure 6. Transverse scanning navigation belt of beam bottom.

Figure 7. Panoramic splicing of beam bottom.

The whole process of panoramic mosaic image based on computer vision is automatically carried out based on artificial intelligence algorithm. The whole process of data acquisition and disease identification is digitalized and automated, and the images are easy to call and storage. The image diseases based on the transverse scanning method are basically consistent with the results of manual inspection. The apparent disease detection and imaging technology based on machine

vision can facilitate the management of process parameters and the preservation of results. The degree of digitalization has obvious advantages over manual detection. It can provide a reference for the rapid detection of the apparent diseases at the bottom of other bridges of the same type.

6 CONCLUSIONS

The imaging principle of optical camera is introduced, and the standardized imaging strategy of optical camera and the scanning strategy of airborne equipment under the beam bottom are studied. Combined with the requirements of concrete apparent disease detection, a transverse scanning imaging strategy for the beam bottom is proposed and verified on the Jiangdong Bridge. The conclusions are as follows:

- (1) Two standardized imaging modes, physical fixed focus and dynamic zoom, are proposed. The corresponding camera working parameter relationship is analyzed and calculated according to the two imaging modes, which provides a calculation basis for the subsequent design and selection of airborne equipment.
- (2) Based on the idea of grid division of beam bottom area, two basic scanning strategies in longitudinal and transverse directions are proposed. The transverse scanning method is recommended for surface inspection of the bottom of the variable section continuous box girder bridge.

Semi-probabilistic methods for the assessment of existing concrete structures: An overview

Lorenzo Casti & Franziska Schmidt

Université Gustave Eiffel, Champs-sur-Marne, France

Fabio Biondini & Nisrine Makhoul

Politecnico di Milano, Milano, Italy

ABSTRACT: Life-cycle assessment of the residual performance of existing structures usually involves a wider spectrum of uncertainties compared to a standard approach for designing new structures. The main differences are related to the modification of structural capacity and demand in time, f.i. due to aging and structural deterioration processes. Furthermore, climate change has a significant impact on this evolution. In order to account for these aspects, full probabilistic approaches are often exploited for assessing existing structural systems. However, these methodologies are time-consuming and may require significant knowledge and expertise for numerical implementation. Therefore, the development of semi-probabilistic methodologies for existing structures considering the impact of climate change, including proper validation and calibration for incorporation in design codes and standards, is nowadays of essence. This paper provides an overview of recent accomplishments and available literature regarding semi-probabilistic code formats for the assessment of existing reinforced concrete structures, including insights on how to incorporate climate change effects on these methodologies.

1 INTRODUCTION

The evaluation of the residual performance of structural systems, such as bridges and infra-structural facilities, is currently a key issue since a large stock of existing structures is approaching the end of the design service life (Fabio Biondini & Frangopol 2016, 2018). The exploitation of conservative simplified approaches tailored for design of new structures may lead, in several cases, to expensive and unnecessary repairs due to the intrinsic differences with the assessment of existing systems (JRC 2015). Moreover, although existing constructions may not fulfill actual requirements for new design, in many cases these systems may still have adequate levels of performance for a target service life.

Structural design may be addressed as a decision problem involving uncertainties, in which the structural resistance $R=R(t)$ is required to be larger than the demand $E=E(t)$ over time t . The uncertainties involved in this problem are modified during the lifetime of the system, mainly due to aging and structural deterioration, leading to a decay of the resistance and possible evolution of the demand, related either to changes in loadings or internal stress redistributions. Furthermore, climate change is observed to have an impact on both structural loading (Mishra & Sadhu 2022), e.g. snow load or wind speed, and structural capacity (Nasr et al. 2021), e.g. enhancing deterioration mechanisms such as chloride- and carbonate-induced corrosion. In this context, it is important to properly assess the performance of existing structures considering the long-term evolution of environmental parameters (Retief 2022).

Following the international standards ISO 13822 (2001) and ISO 2394 (2015), the decision process regarding both the design of new structures and assessment of existing systems should be based on probabilistic evaluations which may be carried out at different levels of detail, from risk-informed decision-making to semi-probabilistic design. The latter methodology usually involves the lowest level of detail; nonetheless, it represents an important guidance for engineers to deal with common design situations and uncertainties within a reasonable range

of time and complexity. Several international design standards, e.g. Eurocodes (CEN EN1990 2002), AASHTO (2020) and ASCE 7-22 (2022), exploit the so-called load and resistance factor design (LRFD) format (Ravindra & Galambos 1978) for new structures providing, for a selected parameter a , the reference design values a_d through characteristic values a_k and partial safety factors γ . Reliability requirements are defined in order to determine a_k and γ , usually referring to this procedure as code calibration.

This paper provides an overview of recent accomplishments on the calibration of semi-probabilistic code format focusing on the assessment of existing structures. Firstly, a discussion of different methodologies for calibration is presented. Secondly, the semi-probabilistic code format is addressed based on research studies specifically dealing with the assessment of existing Reinforced Concrete (RC) structures. Finally, an insight into recent code calibration methodologies accounting for climate change effects on structural safety is also presented. The benefits and drawbacks of the methodologies discussed are addressed with emphasis on possible incorporation of long-climate prediction impacts on structural capacity and demand models.

2 BACKGROUND ON SEMI-PROBABILISTIC CODE FORMAT CALIBRATION

Code calibration may be described as the determination of the values of all parameters in a given code format (ISO 2394 2015), and it has been performed following different methodologies, based on past experiences, judgment, fitting, or a combination of these. In a broader sense, the calibration approach may be considered as a decision problem involving risk and uncertainties.

In ISO 2394 (2015), three different decision methodologies are defined for the design and assessment of structures considering different levels of detail. The risk-informed decision represents the highest level of detail (Level 4). In this case, the decision-making process should explicitly consider economic and safety consequences, as well as the modeling of uncertainties, aiming to maximize the expected utility. Although this approach is very powerful and flexible, it is not usually applied in engineering practice due to complexity and time constraints. Furthermore, in the context of code regulation, standardization and replicability are important aspects which may be archived exploiting simplified methodologies. Indeed, a simpler alternative is represented by reliability-based decision (Level 3). This approach relies on the satisfaction of predefined reliability requirements, which can be based on experience or on formal calibration through the Level 4 approach. The requirement may depend on the consequences and the cost of the specific decision implementation, although the consequences are not explicitly treated in the reliability considerations. Similarly, a reliability-based decision problem can be afforded involving simplified uncertainties representation and reliability computation (Level 2). Eventually, the semi-probabilistic approach corresponds to the lowest level of detail (Level 1).

The semi-probabilistic approach relies on the satisfaction of the safety deterministic criterion stating that the design resistance must be larger than the design demand. The design values are generally determined through the multiplication or division of the characteristic values by the partial safety factors, which are calibrated in order to meet the prescribed reliability requirements. This approach is proposed by several national and international design standards, such as the Eurocodes (CEN EN1990 2002), when dealing with common situations in terms of uncertainties and consequences. It should be noted that the described approaches, even if related to a different level of detail, are strongly interconnected; indeed, higher-level methodologies should be compliant and used in order to calibrate the lower levels. The different levels of decision-making strategy are reported in Table 1.

Consistently, semi-probabilistic code format calibration is usually based on reliability considerations where a given level of safety, measured by the reliability index β , should be assured by the definition of the reliability elements of the code, e.g. partial safety factors γ and combination factors ψ . The purpose of calibration of a semi-probabilistic code format, in addition to the formulation of a safe, economically efficient and simple tool for the design of ordinary structures, is to optimally select the parameters of the code by maximizing the benefits for the society. In this context, code calibration for a semi-probabilistic design is usually formulated as an optimization problem, which should be solved in order to retrieve the required reliability-based design factors.

Table 1. Levels of decision methodologies according to ISO 2394 (2015), based on Baravalle & Köhler (2016) and Köhler & Baravalle (2019).

Approach	Applicability	Objective	Norm
Risk-Informed (Level IV)	Exceptional design situations with respect to uncertainties and consequences.	Maximization of the expected utility for the decision maker.	Guidelines, e.g. ISO 2394 (2015).
Reliability-Based (Level III and II)	Unusual design situations with respect to uncertainties.	Fulfillment of reliability requirements.	Probabilistic codes, e.g. JCSS (JCSS 2001).
Semi-Probabilistic (Level I)	Usual design situations with respect to uncertainties and consequences.	Achievement of deterministic design criteria.	Semi-Probabilistic codes, e.g. EN1990 (2002).

Furthermore, appropriate treatment of uncertainties and the consequent selection of probabilistic models is fundamental in the calibration procedure. Indeed, structural engineering models are associated with a certain level of uncertainty, affecting both the structural demand and capacity. The Joint Committee on Structural Safety (JCSS) provides guidelines for the appropriate characterization of uncertainties, categorizing three main sources of uncertainty (intrinsic physic, parameter and model uncertainty), and suggesting the probabilistic models for the basic random variable (JCSS 2001), although the selection should always be tailored to the peculiar case study.

3 REVIEW ON SEMI-PROBABILISTIC CALIBRATION FOR EXISTING STRUCTURES

3.1 *Semi-probabilistic format calibration*

Calibration of the structural standards is currently a critical research issue, especially concerning existing structures. Indeed, for the aforementioned case, the semi-probabilistic format should be able to incorporate the potential updated information on geometry, loadings, materials and the different reliability requirements, in order to avoid non-effective decisions (Diamantidis 2001). Furthermore, the built environment is experiencing a change in environmental conditions which are likely not anymore the ones considered during the design; these climatic changes are reported to not have a negligible impact on both the evolution of structural capacity and demand. For this reason, code calibration of semi-probabilistic design format accounting for the actual evolution of the structural performance in a changing climate is fundamental.

Code calibration has been systematically researched in the past decades, e.g. by Cornell (1969), Ravindra et al. (1978), Thoft-Christensen & Baker (1982), Faber & Sørensen (2003), Madsen et al. (2006) and Ditlevsen & Madsen (2007). Based on this research, a standardization, specifically regarding reliability-based calibration, for semi-probabilistic design code is reported in ISO 2394 (2015). Among others, the selection of a target reliability β_T is a fundamental assumption in reliability-based calibration. In Baravalle & Köhler (2017) and Köhler et al. (2019) a discussion regarding the selection of β_T according to different strategies, addressing the benefit and drawbacks of each methodology, is presented. The definition of target reliability level for existing structures considering economic optimization and the marginal life-saving costs principle is addressed by Sýkora et al. (2017). Furthermore, Baravalle & Köhler (2019) proposed a comprehensive approach to code calibration of the reliability target through all levels of design. This article provides a background regarding the selection of the target reliability defining an extension of existing approaches for code optimization. A framework for reliability-based calibration of the load partial safety factor is proposed by Köhler et al. (2019). In this study, a generic limit state is considered for the calibration of the load safety factors of the Eurocodes. The results indicate that the partial safety factors proposed in the code are higher for permanent loads and lower for live loads. It is also observed that the reliability target assumed in the Eurocodes is higher than the average reliability level implied by the current safety factors.

A risk-based calibration problem is formulated by Köhler & Baravalle (2019), where economic considerations are explicitly considered in the optimization problem through the definition of a minimum expected cost. This is observed to be more consistent with respect to reliability-based optimization for which the definition of a generally accepted reliability target is observed to be hardly achievable.

In the approach proposed by Arrayago et al. (2022), the calibration of reliability indices and partial safety factors is based on First Order Second Moment (FOSM), considering both US and EU frameworks, and eventually compared with the results obtained exploiting First Order Reliability Methods (FORM). The results show that this simplified formulation is sufficiently accurate for the definition of reliability indices and partial safety factors, and it may provide a reference to the specification committees in the calibration process. Nevertheless, it is important to highlight that the comparison between the FOSM and FORM developed in the research involves only steel structures subjected to gravity and wind loads and it is limited to a specific sensitivity factor assumed for the calibration.

3.2 Assessment of existing RC structures

A comparison of semi-probabilistic vs full-probabilistic safety formats for RC structures based on limit states and partial factors of Eurocode 2 (2005) are presented in Biondini et al. (1999). The application of proper probabilistic models to the non linear analysis allows to assess the actual safety level with reference to the computed random distributions of structural response. The results include information about the large scattering of the reliability index, the sensitivity of the structure to the production control of higher level and the capacity of plastic adaptation under the applied load distributions. Semi-probabilistic approaches explicitly addressing the assessment of existing structures can be found in the *fib* Bulletin N°80 (2016). The described methodologies consider the residual service life, information from in situ and laboratory tests, measurements of variable actions, and reduced target reliability levels according to both economical and human safety criteria, focusing on standard RC structures. Specifically, two methodologies devoted to the recalibration of the partial safety factors for existing structures are presented: the design value method (DVM) and the adjusted partial factor method (APFM). The DVM, which has been introduced in the ISO 2394 (2015) and then adopted in the Eurocodes (CEN EN1990 2002), provides formulas for the calibration of partial safety factors of both material resistances and actions, exploiting appropriate probabilistic models derived by from the prior knowledge, test results, and observations related to the existing structure under investigation. The APFM (Caspelle & Taerwe 2012) is a simpler approach that allows to update the partial safety factors defined by Eurocodes for new structures, by means of “adjustment coefficients”.

The application of DVM and APFM has been performed in the past years for different RC structures by several researchers. In Sýkora et al. (2013), the DVM is applied to the pier and the slab of an existing RC bridge subjected to permanent and traffic loading. The results show that the semi-probabilistic format recommended for structural design in current codes may lead to conservative results and non-optimal decisions concerning rehabilitation of existing RC bridges. Caspele et al. (2013) exploited the DVM and APFM for the assessment of an existing RC beam and a short column subjected separately to wind and imposed variable loads, providing a framework for the application of the latter methodology. Gino et al. (2020) use the methodologies proposed in *fib* Bulletin 80 (2016) in order to evaluate the residual safety and performance of an existing prestressed RC bridge. The obtained outcomes are eventually compared with the results obtained based on the Eurocodes (CEN EN1990 2002), showing that recalibration of partial safety factors accounting for updated information may avoid expensive and not useful interventions. Nevertheless, the authors highlighted the absence of a definition for the probabilistic models to update partial safety factors for prestressing and imposed deformations in *fib* Bulletin 80 (2016) and the need of further research on this issue. The DVM and APFM methodologies are applied in Orcesi et al. (2021) for the assessment of two different existing RC bridges. The study illustrates the procedure for the application of the methodologies and provides a discussion regarding the assumption involved in both the approaches. It is evidenced that major simplifications rely on the consideration of

statistical uncertainty associated with the new measurements only in the estimate of characteristic values of basic variables and the assumption of standardized sensitivity factors or types of probabilistic distributions.

An important limitation common for the aforementioned studies regards the detrimental processes affecting RC structures, e.g. corrosion, which are assumed to be negligible. Moreover, no explicit consideration concerning the impact of climate change for the calibration of resistance and demand partial safety factors is addressed. In the context of calibration of partial safety factors for the assessment of existing RC structures subjected to corrosion-induced deterioration, preliminary considerations are undertaken by Tanner et al. (2011). In this paper, the uncertainties related to the resistance models for corrosion-damaged RC beams are estimated, showing how the partial safety factor for resistance should be incremented in the case of existing structures affected by corrosion. Nonetheless, the results obtained are not exploitable for the direct calibration of partial safety factors since more refined modeling should be devoted to characterize the resistance of deteriorating structures. An explicit formulation for the calibration of partial safety factors considering chloride-induced corrosion in RC structures is reported in Holicky et al. (2008). The research compares the partial safety factors obtained accounting and neglecting deterioration for different reliability targets, highlighting how the reliability level over time is strongly influenced by detrimental processes and, consequently, the calibration of partial factors. In this case, the limitation relies on the fact that the obtained results are significantly dependent on the model used. Consequently, more advanced corrosion modeling should be exploited, implementing the impact of climate change on the initiation and propagation phases, as well as more refined load modeling considering different ratio between permanent and variable loading. The calibration of the partial safety factors for the assessment of anchorage capacity in existing RC structures under corrosion is addressed in Blomfors et al. (2019). In this study, the partial safety factors are calibrated for different levels of corrosion, and considering the presence or the absence of stirrups. The obtained results are verified by exploiting Monte Carlo simulation for several design situations. The discussed methodology may, in principle, be extended to the calibration of partial safety factors for existing structures subjected to chloride-induced corrosion or carbonate-induced corrosion. Nevertheless, further research is needed for the quantification of the sensitivity factors in deteriorating structures.

The Technical Specification CEN/TS 17440 (2020) focuses on the assessment of existing structures suggesting the exploitation of the partial safety factors format of the Eurocodes (CEN EN1990 2002) as the initial method for the verification of the structural safety. In Lara et al. (2021), the assessment of an RC beams of an existing industrial building is performed, following the indication of the technical specification CEN/TS 17440 (2020) and applying both the DVM and APFM to compare the results with the outcomes of a full probabilistic analysis. The comparison shows that DVM incorporates the updated information more accurately than APFM. Furthermore, the full probabilistic assessment is reported to be in good agreement with the results obtained from DVM and APFM.

The assessment of existing structures may require the evaluation of the structural capacity at the system level exploiting nonlinear finite elements analyses (NLFEAs). In this context, Pimentel et al. (2014) propose the application of the global resistance safety factor approach into the semi-probabilistic format. The proposed methodology, which is consistent with the guidelines provided in the Swiss Standard for existing structures (SIA 2010; Brühwiler et al. 2012) and CEN EN1992-2 (2005), relies on the application of the partial safety factors to the overall system resistance. The main assumptions deal with the selection of a lognormal probability density function for the resistance and the estimation of the coefficient of variation. It is shown that the global resistance safety factor format may be more accurate than the partial safety factor, even at the member level. Nevertheless, the assumed lognormal distribution is not always adequate for the analysis. A discussion about a semi-probabilistic approach compliant with NLFEAs for the assessment of existing RC structures using different safety formats is presented in Castaldo et al. (2019). Methods for the assessment of uncertainties and estimation of the coefficient of variation of the resistance of RC structures are also presented in Novák et al. (2022).

3.3 *Insight into calibration considering climate change*

Calibration of a semi-probabilistic design format has been usually performed under the assumption of a stationary climate. Nowadays, climate change is extensively reported in the Intergovernmental Panel on Climate Change assessments (IPCC 2022), and its impact on structural demand and resistance is recognized in a large number of studies (Nasr et al. 2021; Mishra & Sadhu 2022). Consequently, design codes should incorporate considerations regarding climate change when calibrating the semi-probabilistic format in order to appropriately estimate structural safety and performance. Recent studies have tried to perform code calibration explicitly considering climate change.

Target structural performances have been investigated in terms of resilience and sustainability under climate change effects and other hazards (ASCE 2018). In Hong et al. (2021), a reliability-based design code calibration is performed in the context of possible implementation in the National Building Code of Canada (NBCC), focusing on the definition of design wind load, design snow load, and companion load factors. In the study, the stationary extremes derived from observed meteorological data and the nonstationary climate change effects are considered. Based on the performed analysis and the results from the climate change modeling results, sets of load scaling factors accounting for climate change effects are calibrated for different regions in Canada. Despite the calibrated load factors for climate change effects are specifically addressed to the Canadian environment and climate change effects may significantly vary from region to region, the proposed calibration procedure for nonstationary extremes is amenable to generalization. An extensive review of available information on climate change to identify methodologies and tools that would help the civil engineering profession to address the impacts of climate change on the life-cycle structural safety of structures and infrastructure facilities is currently ongoing within a SEI/ASCE special project (SEI/ASCE 2022).

In the context of European Standardization, the work proposed in Arnold & Kraus (2022) focused on the calibration of semi-probabilistic code formats considering the evolution of climate. In this research, FORM methodologies are extended to a nonstationary approach incorporating the reliability index and sensitivity factor and exploited for calibration. A practical application is presented involving a simply supported beam subjected to snow action in order to describe the proposed framework. The drawbacks of the work rely on the uncertainties involved in climate projection and on the selection of the time window which may significantly influence the results.

4 CONCLUSIONS

In this paper, recent research advances addressing the assessment of existing RC structures based on a semi-probabilistic approach are discussed. The aim of the study is to provide an overview of the current state-of-the-art for semi-probabilistic format code calibration and application, aiming at future implementation of the climate change impact on these methodologies.

The concepts of decision-making in engineering and calibration are introduced. A review of several studies is proposed concerning:

1. General calibration strategies for the semi-probabilistic code format applicable to different types of structures and analyses.
2. Methodologies for the definition of semi-probabilistic code key elements, as safety factors, for existing RC structures.
3. Calibration of the semi-probabilistic code format considering the impact of climate change on structural safety.

The review highlighted the significant amount of research advances in these fields, but also that further research is needed to appropriately calibrate semi-probabilistic formats for the assessment of existing RC structures subjected to detrimental processes such as corrosion. Moreover, the changes in current and future climate are affecting structural systems, and in general the built environment, influencing both structural capacity and demand. Further developments are needed also along these lines of research in order to provide semi-probabilistic methodologies for the assessment of RC structures subjected to detrimental processes in a changing climate. Eventually, although some studies analyzed the non-stationary

evolution of climate and its impact on environmental actions, more steps for the characterization of uncertainties and the definition of basic assumptions are needed for the consequent calibration of semi-probabilistic design codes.

ABSTRACT: In order to investigate the fatigue crack propagation properties of rib-to-deck weld joint toe and root details for orthotropic steel decks, the suspension bridge with the 1688 m main span of the Nizhou bridge in Nansha bridge project was selected as the engineering background and the digital fatigue tests of these details were carried out based on extended Finite Element Method (XFEM) and numerical fracture mechanic theory, which could reflect the actual stress characteristic. The welding residual stress field simulation was carried out for the orthotropic steel deck manufacturing process. The residual stress result shows that there is a large residual tensile stress in the welding area of the rib-to-deck toe and root details, and the peak value of the Von-Mises stress at the rib-to-deck joint is close to the yield stress of Q345 steel. A multi-scale whole bridge finite element model was established considering construction condition for the orthotropic steel deck construction process. The fatigue crack propagation could be simulated by XFEM coupling with welding residual stress field, live load and dead load stress field. The results of fatigue crack propagation behavior display that the fatigue crack at the weld root is led by mode I, which could keep in the plane during the crack propagation. And the fatigue crack at the weld toe is mix mode I-II-III crack led by mode I, which cannot keep in the plane during the crack propagation, but slightly deflection.

1 INTRODUCTION

The orthotropic steel decks are widely applied in modern bridge construction due to their excellent mechanical properties, construction convenience and attractive shape. However, the fatigue cracks often appear in the orthotropic steel decks shortly after opening to traffic because of their complex structure, inevitable welding defects during the bridge deck manufacturing process, dead-load stress introduced during the construction process and live load stress during operation process. Hence it is necessary to investigate the orthotropic steel decks fatigue character. The physical fatigue tests based on stress analysis method are widely used in the fatigue problem researches, which has been gotten kinds of research achievement and could display of test phenomena intuitively. With development of finite element theory, digital twin simulation (Yeratapally et al. 2020) is applied in the steel bridge fatigue characteristic research, which could overcome the defects of manpower-consuming and time-consuming for conventional physical fatigue test.

The digital fatigue test based on normal conventional finite element method is often used in bridge researches. Kiss and Dunai (Kiss and Dunai 2002) based on FEM software CRAXIM to achieve cyclic loading and establish two-level stress analysis models. The actual bridge fatigue life assessment was based on the fracture mechanics method. Wang (Wang et al. 2019) established the three-dimensional fracture mechanics model to evaluate the fatigue life of a riveted steel bridge before and after reinforcement, considering the coupling effect of fatigue and corrosion, and the results show that the method could evaluate the fatigue life evaluation of riveted steel bridge.

Calculation consuming will be expensive and the residual welding stress could not be considered because of element remeshing. While extended finite element method (XFEM) (Belytschko and Black 1999; Moës et al. 1999) could solve remeshing problems by introducing the enrichment function into the conventional finite element displacement function. Based on

DOI: 10.1201/9781003323020-476

the extended finite element method, Nagy(Nagy et al. 2015) established a segmental model of orthotropic steel deck, and studied the fatigue crack propagation characteristics and fatigue life of the easily fatigue-sensitive details at the top deck plate. The results show that the load sequence seems to have an important influence on the crack propagation, but does not affect the crack size in the final stage. Wang et al.(Wang et al. 2020) studied steel bridge web gaps and orthotropic steel decks' typical fatigue details' fracture mechanic properties. They took a series of digital fatigue test based on XFEM and digital fracture mechanics, considering welding residual stress. Multi-scale digital fracture mechanic models of the rib-to-diaphragm detail of a cable-stayed bridge were established.

However, large-size cracks are used in the existing research, so it is difficult to reflect the actual situation at the initial crack growth stage. Thus, it cannot completely simulate the whole process of crack propagation. Moreover, the residual stress is calculated using a small-scale FEM model, which is not consistent with the actual welding situation in the factory.

In this paper, the rib-to-deck detail of Nizhou suspension bridge was selected as the engineering background, and the muti-scale digital fatigue test models were established. The welding residual stress was simulated for the factory welding process, and rational boundary conditions in the thermal-stress analysis were put forward. Based on the numerical fracture mechanics theory and extended finite element method (XFEM), different propagation stage fatigue propagation behavior of these two details was revealed. Research results are beneficial in investigating the the fatigue crack propagation mechanism

2 ENGINEERING BACKGROUND AND FINITE ELEMENT MODEL

A suspension bridge with the 1688 m main span of the Nizhou bridge in Nansha bridge project was selected as the engineering background as shown in Figure 1 (a). The height of the main girder is 3,5m, and the width of transverse direction is 49.7m as shown in Figure 1 (b). Q345qD is used in this steel bridge. The thickness of steel deck is 18mm; the longitudinal stiffener ribs adopt closed trapezoidal cross section with the section parameters of 300 mm × 280 mm × 8 mm as shown in Figure 1 (c). This steel box girder is a fully welded structure, and the partial penetration fillet weld joints are used in of rib-to-deck details.

Figure 1. Structural dimensions of steel deck (Unit: mm): (a) bridge elevation; (b) girder cross section; (c) U-rib detail drawing.

In order to consider the dead stress caused by bridge construction process, the muti-scale whole bridge model was established. The tower and girder were established by girder elements, the cables were simulated by truss elements. Shell elements was used to simulate the flat steel box girders sub-model. And local sub-model was established by shell elements which is connected with concerning detail directly. The concerning fatigue detail was established by solid elements as shown in Figure 2. In the rib-to-deck detail model, the deck plate length and width are 600mm × 400mm, and the height of the U-rib is 280mm. And in order to match small-size of fatigue cracks and improve the computational efficiency, the transition grid

method was applied in the meshing process; as shown in Figure 2, the grid size was transitioned from 1mm to 15mm. Considering the fatigue crack size is far smaller than the solid model, the transition grid method is selected in the digital fatigue simulation, and this meshing result will be also used in the welding process simulation.

Figure 2. Multi-scale whole bridge element model.

3 WEDLIGN PROCESS SIMULATION

The influence of residual welding stress on fatigue performance at joint details cannot be neglected. Some research results show that there exists large residual stress in rib-to deck details (Wang et al. 2013). Therefore, it is necessary to research the residual welding stress at this typical detail in the orthotropic steel deck. However, small-scale solid models were often used to simulate the residual welding stress in most research, which could partially illustrate the residual stress distribution, but the constraints will be much strong. Hence, whether the boundary conditions are correct determines whether the residual welding stress distribution could be rational.

3.1 Welding simulation finite element model

The sequential coupled thermal analysis method is applied in this paper (effect of only temperature field on stress field). In order to simulate the actual welding process, the segmental steel deck sub model and the welding solid sub-model were established in this paper, as shown in Figure 2.. The dimension of the segmental steel deck model is the same as the actual welding process, which could provide a relatively exact boundary condition for the sub-model as shown in Figure 3.

Figure 3. FEM model of welding stress analysis for steel deck.

3.2 Welding analysis methodology

The welding process simulation is divided into two steps by thermal-stress sequential coupling method. In the first step, a thermal analysis model is established to simulate the arc heat transferring to the weld joint. In the second step, residual stress is calculated based the thermal analysis to simulate welding thermal stress.

The initial environmental temperature was set to 20 °C, the absolute zero is - 273.15 °C, and the Stefan-Boltzmann constant is $5.67 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$. CO2 gas-shielded welding is adopted in rib-to-deck welding. In order to realize the dynamic simulation of temperature filed, double ellipsoidal heat source model(Goldak et al. 1984) was adopted. And Fortran language was used to compile

program to achieve moving heat source loading. The heat source parameters could be inputted like: thermal energy, moving speed, and time. The thermal parameters can be seen at Table 1.

Table 1. Parameters of weld heat source model.

Parameters	Value	Unit
melting width	10	mm
penetration depth	18	mm
Front axle length	3	mm
back axle length	5	mm
coefficient f_f	0,6	
coefficient f_r	1,4	
Welding speed	5	mm/s
Voltage	35	V
Current	350	A

3.3 Residual welding stress analysis

Residual welding stress cloud atlas of rib-to-deck detail after welding process is shown in Figure 4. During the welding process, the stress at melted welds is small, but the stress of the weldments around the weld pool is close to the yield stress of the steel. After welding cooling process, the stress along X-direction and Z-direction of weld joint around the weld pool is close to the yield stress of Q345.

Figure 4. Residual welding stress along X-direction and Z-direction cloud atlas (Unit:Pa).

The local coordinate system is defined for the weld joints. Along the x-direction, the distribution curves of different residual welding stress components are drawn at top, middle and bottom surface of deck, as shown in Figure 5. The longitudinal residual stress σ_z and the transverse residual stress σ_x are both the largest at top surface and the lowest at bottom surface. Although the thickness of deck plate is only 14mm, the stress distribution also shows a significant difference along the deck thickness direction. This means that the closer to the welding heat source, the greater the welding residual stress. And the peak values of σ_z and σ_x both appear at 143mm and 155mm for the bottom surface where the positions are the weld toe position and weld root position,

Figure 5. Residual stress distribution of rib-to-deck in half section.

respectively. In the approximate 50mm range near the weld toe and root, longitudinal residual stress σ_z change rapidly, and the peak value of σ_z reaches to the yield stress of Q345. transverse residual stress σ_x is uniformly distributed along the x-direction, and the maximum is 168MPa for the top surface. Therefore, weld root and weld toe of rib-to-deck could be prone to fatigue detail.

4 FATIGUE CRACK PROPAGATION SIMULATION

4.1 Fracture mechanics parameters

Extend finite element method was applied as the calculation tool, and crack dynamic propagation was accomplished based linear elastic fracture mechanics theory. There are three fracture modes of metal, and two or three mix fracture mode are common in real engineering. Therefore, it is necessary to apply fracture criterion considering three fracture mode. Mixed-mode fracture criterion is expressed as(Wu and Reuter Jr 1965):

$$\left(\frac{\Delta K_I}{\Delta K_{th}}\right)^2 + 1.9\left(\frac{\Delta K_{II}}{\Delta K_{th}}\right)^2 + 2.1\left(\frac{\Delta K_{III}}{\Delta K_{th}}\right)^2 = 1.0 \quad (1)$$

where ΔK_I , ΔK_{II} , and ΔK_{III} stand for the SIF ranges of Mode I, II, and III cracks, respectively.

According to the relationship between energy release rate G and stress intensity factor K , mixed-mode fracture criteria can be expressed in the form of energy release rate(Wu and Reuter Jr 1965):

$$\frac{G_I}{G_{th}} + 1.9\frac{G_{II}}{G_{th}} + 2.1\frac{G_{III}}{G_{th}} = 1.0 \quad (2)$$

where G_I , G_{II} , and G_{III} stand for the strain energy release rate of Mode I, II, and III cracks; G_{th} = the threshold of energy release rate. In order to directly use the strain energy release rate calculated by VCCT improving the working rate.

Based on liner elastic fracture mechanics, the Paris formula for the expression of crack propagation is presented in Eq(3)(Paris and Erdogan 1963).

$$\frac{da}{dN} = C \cdot \Delta K^m \quad (3)$$

where C, m refers to material constants; a refers to crack length; N refers to loading cycles; $\Delta K = Y \cdot \Delta \sigma \cdot \sqrt{\pi \cdot a}$; Y refers to the modified factor; $\Delta \sigma$ refers to stress range. According to the BS7910(British Standards Institution 2019), the material constant of the Paris formula in this paper $C=1.28 \times 10^{-12}$ mm \cdot cycle; $m=3.0$.

In the digital fatigue test, the crack propagation rate is calculated by the energy method, which is expressed as follows(Paris and Erdogan 1963):

$$\frac{da}{dN} = c_1 \cdot \Delta G^{c_2} \quad (4)$$

where c_1 and c_2 refer to material constants; ΔG refers to strain energy release rate amplitude. When the crack tip meets $G_{th} < \Delta G$, cracks begin to grow; G_{th} refers to the energy release rate threshold.

The maximum tangential stress criterion(MTS) is applied to determine the fatigue crack propagation direction, the expression is shown as(Erdogan and Sih 1963):

$$\theta = \cos^{-1}\left(\frac{3K_{II}^2 + \sqrt{K_I^4 + 8K_I^2 K_{II}^2}}{K_I^2 + 9K_{II}^2}\right) \quad (5)$$

Where θ is measured with respect to the crack plane.

4.2 Modeling methodology

In order to simulate initial defect introduced by welding process, the initial crack should be inserted in the typical detail at digital fatigue test. Half ellipse shape cracks were adopted in models of other details. Dimension of the half ellipse shape and the quarter ellipse-shaped crack was $a_0/c_0 = 0.5\text{mm}/1.0\text{mm}$ in this paper as shown in Figure 6 (where a_0 is the length of an elliptical semi-short axis and c_0 is the length of the elliptic semi-long axis). To simulate live load caused by fatigue vehicle, fatigue load model III in JTG D64 (Ministry of Transport of the People's Republic of China 2015).

Figure 6. Fatigue crack insertion position.

4.3 Crack propagation analysis of rib-to-deck weld joint detail

Initial cracks size at rib-to-deck weld toe and root were assumed as $a_0/2c_0=0.5\text{mm}/2\text{mm}$. Initial crack plane surface was parallel to the direction of deck thickness. The propagation trend of crack planes in rib-to-deck weld toe is shown in Figure 7. The crack at weld toe propagated along the weld joint and plate thickness direction. The crack size propagated to $a/2c=5\text{mm}/18.5\text{mm}$ after 2.7 million cycle of loadings. Although the long and short axial ratio of semi-elliptical cracks $a/2c$, has been changed during the propagation process, the semi-elliptical shape could be remained basically. The cracks in the propagation process cannot keep in the plane surface, but a slightly deflection as shown in Figure 7. And the crack propagation direction even appeared transverse direction of bridge propagation trend after 2.7 million cyclic loading, which is a phenomenon seriously affecting the safety of bridge use. It was believed that fatigue cracks were mixed-mode cracks with the crack propagation, and the crack plane deflection was caused by the cracks of Mode II and Mode III. Hence, residual welding stress not only make crack grow but also change the propagation direction of the fatigue crack.

Figure 7. Fatigue crack propagation in the weld toe of deck plate.

In order to judge the fatigue crack mode, the cumulative strain energy release rates of G_I , G_{II} , and G_{III} are calculated as shown in Figure 8. Because Mode II and Mode III were pretty close, the proportional curve of G_{III}/G_I is only drawn to analyze another two Mode cracks' influence, and red dotted line is represented the trend of G_{III}/G_I as shown in Figure 8. At crack propagation initial stage, Mode I was the leading position, and influence of Mode II and Mode III could be ignored. The G_{III}/G_I reached 10% after 1.5 million cycles, and the effect of Mode II and Mode III crack on fatigue crack propagation direction can not be neglected. Between 2.2 million and 2.7 million loading cycles, the proportion of G_{II} and G_{III} increased sharply. At 2.7million cycles, G_{II}/G_I and G_{III}/G_I were about 26.3% and 21.4%. Therefore, the influence of Mode II and III cracks at the crack propagation in the rib weld toe of rib-to-deck detail cannot be ignored during the crack propagation. They will not only affect the fatigue crack propagation rate but also crack propagation direction at this detail.

Figure 8. The cumulative strain energy release rate in weld toe of deck plate.

Fatigue crack grown from the deck weld root of rib-to-deck detail is another fatigue mode, also detected in actual bridges. The fatigue propagation behavior differed from the crack initiating from the deck weld toe. Figure 9 illustrates the propagation process of cracks initiating from the deck weld root under a given initial crack condition. The cracks mainly propagated along the long axis of the semi-ellipse cracks. They propagated to the inside of the weld when the propagation trend was along the deck thickness direction. The crack plane was kept in the plane during the propagation process, which indicated that the dominant type of fatigue crack in the weld root of rib-to-deck detail was the I-mode crack. Crack propagation rate and direction was controlled by Mode I crack at this detail.

Figure 9. Fatigue crack propagation process in weld root of deck plate.

The cumulative strain energy release rate curve during the crack propagation process is shown in Figure 10. The cumulative strain energy releasing rate G_I of Mode I cracks was dominant during the whole crack propagation process. The increasing rate of these three types strain energy release rate between 0 to 5.8 million cycles was relatively slow. The increase rate G_I of Mode I between 5.8 million to 7 million cycles loading was fast which reached to 102 N/mm at about 2million loading cycles, while the increase rates G_{II} and G_{III} were still slow. G_{II}/G_I and G_{III}/G_I were about 2.4% and 2.7% at the end of 7 million cycles. Hence, the influence of Mode II and III cracks could be ignored during the crack propagation process at this detail.

Figure 10. The cumulative strain energy release rate at the rib-to-deck weld root.

5 CONCLUSIONS

Digital fatigue test was selected to simulate the fatigue crack propagation at rib-to-deck detail. In this paper, the multi-scale whole bridge model was established, and properties analysis of fatigue crack propagation properties considering the residual welding stress was set.

1. A rational boundary of residual welding process was put forward. The welding process analysis was shown that there existed large residual stress at rib-to-deck detail. Von-Mises residual stress reached to the mental yield stress of Q345. Hence, the residual stress of rib-to-deck detail could not be neglected.
2. The fatigue crack propagation state and cumulative strain energy release rate analysis result shows that the crack at the weld toe of the rib-to-deck is led by mix mode I-II-III led by mode I, while the influence of mode II and mode III cannot be neglected. And the crack will not keep in plane at the crack propagation due to the existence of mode III.
3. The crack at the weld root of the rib-to-deck was led by mode I, while the influence of mode II and mode III is little. And the crack will keep in plane at the crack propagation. The fatigue crack propagation behavior of these two details are consistent with those obtained by experiments.

Nonstructural performance improvements for seismic resilience enhancement of modern code-compliant buildings

M.R. Joo & R. Sinha

Indian Institute of Technology Bombay, Mumbai, India

ABSTRACT: Rapid recovery of functionality after disaster is an important attribute of resilient infrastructure. Modern code-compliant buildings are designed based on life-safety principles and may experience severe damage during earthquakes leading to loss of their use for long periods. Contributors to occupancy and functionality losses should be first identified for enhancing performance and developing resilience-based design guidelines. This study assesses economic, reoccupancy, and functionality losses and subsequent recovery for an archetypical building, considering performance of structural and nonstructural components under a probabilistic performance-based earthquake engineering framework. The study provides deeper understanding of the root causes of functional vulnerability of code-compliant buildings and opportunities to reduce. The contribution of various components to loss of immediate occupancy and functionality is evaluated and implications of various nonstructural improvements on different component-level and building-level resilience metrics are assessed. The study illustrates the necessity of explicit nonstructural design options to enhance seismic resilience of buildings.

1 INTRODUCTION

Recent disasters, including major earthquakes, have demonstrated their potential to set back decades of progress and investment in an instant. Buildings form an important backbone of built infrastructure to support community functioning. Modern buildings are designed following life-safety-based standards using perspective specifications that do not provide an explicit understanding of performance during earthquakes. They have been found to perform better in collapse prevention and life-safety objectives and thus reduce the risk of casualties (Molina Hutt *et al.* 2016, 2022, Du *et al.* 2021, Joo and Sinha 2022, 2023, Joo *et al.* 2022, Terzic and Kolozvari 2022). However, high social expectations (higher performance than code goals, continued functionality after earthquake, etc.) are associated with modern code-conforming and engineered buildings. Experience shows that substantial damage is experienced by various structural and non-structural components which leads to uneconomical repairs, building demolition, occupancy and functionality losses, loss of essential services, long-term societal disruption (Du *et al.* 2021, Joo and Sinha 2023, Joo *et al.* 2022, Terzic and Kolozvari 2022). Such evidences reflect lack of resilience characteristics. The communities take significantly long to recover to pre-earthquake condition, which adds to the indirect seismic losses.

Conventional assessment and design approaches focus on structural performance and loss estimation immediately after an earthquake and do not consider post-event parameters to quantify recovery. The performance is indicated by response parameters, annualized losses, or collapse risk. Performance-based earthquake engineering (PBEE) framework (Moehle and Deierlein 2004, FEMA P-58-1 2018) provides avenues for explicit quantification of performance using various metrics of interest for effective decision making. Several studies (Goulet *et al.* 2007, Molina Hutt *et al.* 2016, del Gobbo *et al.* 2018, Cardone *et al.* 2019, Du *et al.* 2021) employed performance-based approaches to estimate direct and indirect losses. Goulet *et al.* (2007) used PBEE approach to evaluate the seismic response of a low-rise reinforced concrete (RC) structure using collapse risk and economic losses. Cardone *et al.* (2019) assessed the efficacy of various retrofit strategies for RC buildings to reduce expected annual loss. Gobbo *et al.* (2018) evaluated the performance of Eurocode-8 compliant braced RC frame buildings in terms of repair cost.

Rapid recovery is an important attribute of resilience and missing from current code provisions. Functional recovery bridges the gap between design provisions and community resilience (EERI 2019) and thus requires serious consideration for incorporating recovery-based performance objectives in design, assessment, and retrofitting methods for essential facilities. FEMA P-58 (2018) methodology integrates procedures for performance-based design of buildings and enables estimation of direct losses and repair times of various building contents based on their damage levels. While PBEE approach can be extended to quantify recovery and estimate building downtime, a very limited number of studies (Molina Hutt *et al.* 2016, 2022, Du *et al.* 2021, Joo and Sinha 2022, Terzic and Kolozvari 2022) attempted to consider post-earthquake scenario and assess repair or recovery time. Molina Hutt *et al.* (2016) utilized FEMA P-58 approach and evaluated the performance of a tall building using financial losses and downtime as performance metrics and compared different resilience strategies. Du *et al.* (2021) compared seismic performance of RC frame structures with and without structural enhancements using decision variables including repair times. Terzic and Kolozvari (2022) evaluated the functional recovery of a tall building and revealed the need to develop design requirements to improve post-earthquake functional performance of buildings.

Past studies (Du *et al.* 2021, Molina Hutt *et al.* 2022) have focused on improvement of building performance using various structural retrofits. Damage to non-structural systems, essential to a building's operations, can require expensive repairs and lead to unacceptable downtime. Controlling nonstructural damage is essential to maintain post-earthquake occupancy and functionality (Gebelein *et al.* 2017) and only limited number of studies (Molina Hutt *et al.* 2016, Joo and Sinha 2023) have considered nonstructural performance improvements. Therefore, a need exists to quantify the contribution of nonstructural components to occupancy and functionality losses and subsequent recovery. Identifying contributors of occupancy and functionality losses of important buildings forms a basis to understand the post-disaster scenario and opportunities for performance improvement during future events and development of resilience-based design guidelines.

In this study, seismic resilience assessment of an archetypical building, representing state of design and existing construction practices, is conducted to identify components and quantify their contributions to occupancy and functionality losses. Two seismic hazard levels: design basis earthquake (DBE) and maximum considered earthquake (MCE) are considered. The study benchmarks the performance of a midrise RC archetypical commercial office building. It considers component-level damage, building reoccupancy and functionality losses and their subsequent recovery under a probabilistic PBEE framework in line with the requirements of decision-making. The damage probability of each system contributing to occupancy and functionality loss is assessed. The study reveals that high building functionality losses is expected due to a design-level seismic event, which is mainly attributed to extensive damage experienced by various nonstructural building contents. Increasing deformation capacity of various non-structural components is a useful approach for resilience enhancement, as its implementation is comparatively simpler. Therefore, a range of improved non-structural components with high resilience to earthquake damage are explored for improved building performance to minimize the reoccupancy and functionality losses and downtime in expected future events. Their implications on various resilience metrics including economic, reoccupancy, and functionality losses as well as reoccupancy, functional recovery and full recovery time are evaluated. The study illustrates advantages of considering different non-structural design and installation options to build a seismic resilient system for better performance in the wake of future disasters. Contribution of each improved element in reducing the probability of occupancy or functionality loss and the overall effects on building recovery time and recovery trajectories are also presented. The study advocates that performance of non-structural components should be considered by design standards to enhance resilience of buildings and ensure rapid functional recovery. The results provide key indicators of resilience enhancement that enable various stakeholders to contribute to improving building functional performance and recovery.

2 METHODOLOGY

Building-specific resilience assessment was conducted in accordance with the probabilistic PBEE frameworks (FEMA P-58-1 2018, ATC 138-3 2021) for which various steps are outlined

in Figure 1. The details about the selection of archetypical building, structural and non-structural components, ground motion selection, structural modeling and analysis, damage and loss assessment procedure, and functionality loss and subsequent recovery approaches are presented in the subsections below.

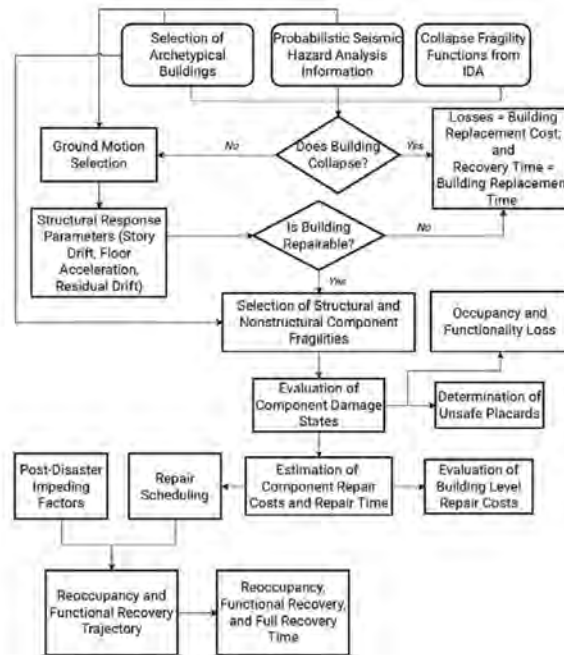

Figure 1. Resilience assessment methodology adopted in the current study.

2.1 Design of archetypical building and selection of components

A special RC moment frame archetypical building (ID-2215), representing a typical commercial building and designed as per Indian standards for New Delhi, India (seismic zone IV), is selected from a suite of archetypes (Badal and Sinha 2019). It represents the state of design and construction scenario for a typical midrise RC structure. The design has given due consideration to existing building stock in the region and can therefore be used to represent the behavior and seismic performance of a class of buildings. The material and geometric characteristics, design load scenarios, member design, and detailing are provided elsewhere (Badal and Sinha 2019). The building is 7 stories high, has 9×3 bays spanning 8.2 m in each direction, typical regular story height of 3.9 m, and first story height of 4.5 m due to foundation depth. The floor area of 1815.48 m^2 is constant across all the levels. The building replacement cost, used for the estimation of direct economic losses in case of collapse or irreparable damage (see Figure 1), was estimated based on the building footprint area. A building replacement time of 910 days (about 2.5 years) was used to represent the recovery time in case of collapse or irreparable damage.

The component fragilities for the RC structural members were obtained from FEMA P-58 fragility database (FEMA P-58-3 2018) based on the closest match of properties with structural design of members. Quantities of structural components were based on architectural and structural design details of the building. Non-structural components were selected based on a review of the inventory of structural and architectural drawings of several real buildings in India, literature survey (del Gobbo *et al.* 2018, Du *et al.* 2021) and recommendations from the normative quantity estimation tool (FEMA P-58-3 2018). The component details, quantities, and dispersion are available in Joo (2022) and other details, including different damage states and corresponding consequence functions, can be referred from the fragility database (FEMA P-58-3 2018).

2.2 Structural analysis and ground motion selection

A two-dimensional structural model employing concentrated plasticity approach and incorporating P-delta effects using *PDelta* nonlinear geometric transformation of the members and a leaning column frame was developed in OpenSees (McKenna *et al.* 2000) to simulate the nonlinear behavior of RC frames under earthquakes. Considering capacity-based shear design for the building, the nonlinearity of beams and columns was modelled using zero-length nonlinear flexural hinges at each end with hysteretic behavior defined using the modified Ibarra-Medina-Krawinkler model (Ibarra *et al.* 2005). The key points and cyclic deterioration parameters for defining backbone curve are derived using semi-empirical relationships (Panagiotakos and Fardis 2001, Haselton *et al.* 2016) and secant stiffness to 40% of yield moment is used as initial stiffness. The effects of longitudinal reinforcement bond-slip behavior, finite beam-column joints, and foundation flexibility are also considered (Joo *et al.* 2022).

Seismic hazard estimation for the selected site in New Delhi, India (28.61°N, 77.21°E) was from a recent probabilistic seismic hazard analysis (Raghukanth 2020). Two intensity levels based on widely used probability of exceedance (POE) - 10% POE in 50 years (DBE) and 2% POE in 50 years (MCE) were selected for the analysis. The site and building-specific conditional mean spectra (Baker 2011) for DBE and MCE intensity levels were developed at analytical fundamental period (T_1) of 2.55 s and used as a target spectra. Twenty pairs of recorded ground motions were selected and scaled at each hazard level to match the arithmetic logarithmic mean of the ground motion suite with the target spectrum. The selection was based on minimum mean squared error between the target spectrum and the scaled ground motion spectrum over the period range of $0.2T_1$ to $2T_1$ (del Gobbo *et al.*, 2018; FEMA P-58-1, 2018). Further details about the selection and scaling parameters are available Joo *et al.* (2022).

2.3 Damage and loss assessment procedure

Damage states and consequent repair costs and repair time of various building components were evaluated in accordance with FEMA P-58 (2018) approach (see Figure 1). Various uncertainties in structural response, damage states, repair cost, impeding time, and repair time are incorporated utilizing 5000 realizations of Monte Carlo simulations. Building collapse fragility functions obtained using incremental dynamic analyses are taken from Badal and Sinha (2022). Component fragility functions from FEMA P-58 fragility database (FEMA P-58-3 2018) are used to relate the response parameters to damage states. The damage results are converted into loss values (repair costs and repair time) using probabilistic consequence functions defined for each component damage state and aggregated for building-level loss estimation (see Figure 1). For each realization, the building is first examined for collapse. If the building does not collapse, it is further evaluated for reparability based on residual drift ratio and building irreparability fragility curve (see Figure 1). For a repairable building, the damage states, and consequences (repair cost, repair time) are evaluated for each component as shown in Figure 1.

2.4 Functionality loss and recovery assessment approach

The damage assessment results are utilized to evaluate the building's occupancy and functionality immediately following an earthquake and until it fully recovers in accordance with the post-earthquake functional recovery framework (Cook *et al.* 2022). The damage states experienced by the components were utilized to assess system-level operational performance, and building-level performance states. The framework used a series of fault trees to correlate component damage to system operation and building function. For a building to be occupiable, the building safety, story access, and user safety of a particular space were verified. The building's functionality was assessed as a function of reoccupancy and user and occupancy-specific functionality requirements.

The repair time obtained from FEMA P-58 analysis is only one contributor of overall downtime (see Figure 1). Various impeding factors delaying the start of repair works, construction constraints, worker allocations, repair priorities and repair optimization are also considered to estimate recovery time (Cook *et al.* 2022). To estimate the time until damaged components are repaired and building function is restored, a building repair schedule

determines repair sequence and work allocation of each building components, instead of only those components affecting function. The entire procedure, including the fault trees to access the functionality of subsystems, repair scheduling algorithm, and impeding factors are available in literature (ATC 138-3 2021, Cook *et al.* 2022). The FEMA P-58 and ATC-138-3 (Beta) methodologies, implemented in SP3 software (SP3 2022) are used in the current study.

3 NON-STRUCTURAL PERFORMANCE IMPROVEMENTS

In this study, resilience assessment of an archetypical building was carried out to understand and identify various vulnerable components and corresponding pathways or strategies for improving component-level as well as overall building resilience. The building (referred to here as baseline model) consists of a bare RC frame as structural system and other typical non-structural components which were assumed to be designed and installed without seismic design considerations, as per typical industry practices in India. Different performance metrics, quantifying scenario losses and recovery times were evaluated and are discussed in subsection 4.1. Various vulnerable non-structural components, contributing significantly to building functionality loss (> 5% realizations at DBE or 10% realizations at MCE) were identified and replaced with improved non-structural components with better seismic performance. The enhanced components can withstand significantly larger deformations or accelerations before reaching a particular damage state which result in less damage to the components for same demand parameters. Major modifications in the building performance model (improved model) and their component fragilities from FEMA P-58 database are listed below:

1. Stairs were assumed to have seismic joints that accommodate drift (C2011.001a).
2. Suspended ceilings with vertical as well as lateral support (C3032.003a-d) were considered.
3. Independent pendant lighting was presumed to be seismically rated (C3034.002).
4. Motor control center was either hard anchored or vibration isolated with seismic snubbers/restraints (D5012.013c).
5. Potable water piping and bracing fragilities of higher (D, E, or F) seismic design category (D2021.013a-b) were considered.
6. Sanitary waste piping and bracing fragilities of higher (D, E, or F) seismic design category (D2031.023a - b) were considered.
7. Heating ventilation and air conditioning (HVAC) fan was either hard anchored or vibration isolated with seismic snubbers/restraints (D3041.103b)
8. HVAC air handling unit was either hard anchored or vibration isolated with seismic snubbers/restraints (D3052.013b).

The improvements in scenario economic, reoccupancy, and functionality losses and subsequent recovery time are detailed in the subsection 4.2.

4 RESULTS AND DISCUSSIONS

4.1 *Baseline model*

Table 1 shows the performance assessment results for the baseline model. The average repair cost ratio, referred to as scenario expected loss (SEL) for DBE and MCE events was 3.5% and 12.4%, respectively, of the building replacement cost. The estimated repair time, in days, based on FEMA P-58 floor-wise parallel and series repair scheduling, respectively, are 6 and 22 at DBE and 21 and 75 at MCE. The archetypical building is immediately reoccupiable after DBE event while taking 102 days after an MCE event. However, functional recovery is achieved only after 174 days and 234 days at DBE and MCE, respectively. The expected (median) time to full recovery to pre-earthquake condition is 207 days and 291 days at DBE and MCE, respectively.

The major contributors to loss of building reoccupancy at DBE level are stairs and interior falling hazards while stairs, red tag, interior falling hazard, and damage to exterior enclosure majorly contribute to occupancy loss at MCE, as shown on the left sides of dashed lines in Figure 2a. Other major components contributing to functionality loss at DBE, in addition to

those resulting in reoccupancy loss include HVAC ventilation, heating, cooling, and exhaust elements, elevators, and sanitary plumbing (see right side of the dashed line, Figure 2a). While, at MCE, the major contributors include HVAC ventilation, heating, cooling, and exhaust elements, elevators, interior space, sanitary plumbing, potable water piping, and electrical equipment (see right side of the dashed line, Figure 2b). The potential of each system to result in building reoccupancy or functionality loss at DBE and MCE can be obtained from the percentage of realizations in which each system affects occupancy, functionality, or both (see Figure 2).

Reoccupancy or functionality of any structure is dynamic and evolves over time due to repairs being carried out in the post-earthquake phase. Figures 3a and 3b, respectively, show the probability of building reoccupancy and functionality over time at DBE and MCE. The reoccupancy and functional recovery trajectories for the baseline model at DBE and MCE are almost parallel (see Figure 3) with different values suggesting that the governing components are same for the two levels but with different damage levels. The governing components for reoccupancy are stairs and for functionality, HVAC elements (see Figure 2). The significant building functionality loss over time reveals a need to focus on recovery-based design philosophies and guidelines and nonstructural performance in design and assessment.

Table 1. Scenario losses, repair time, and recovery time assessment results.

Intensity Level	Model	Scenario Expected Loss (%)	Repair Time (Days)		Median Recovery Time (Days)		
			Parallel	Series	Reoccupancy	Functional Recovery	Full Recovery
10 % in 50 years (DBE)	Baseline	3.5	6	22	0	174	207
	Improved	2.6	5	18	0	0	150
2 % in 50 years (MCE)	Baseline	12.4	21	75	102	234	291
	Improved	10.7	20	69	3	3	261

DBE = Design Basis Earthquake, MCE = Maximum Considered Earthquake

Figure 2. Percentage of realizations for different systems leading to occupancy or functionality loss at (a) DBE (10% in 50 years) and (b) MCE (2% in 50 years).

4.2 Non-structural improvements

The non-structural performance improvements listed in section 3 were undertaken to investigate their potential in reducing scenario economic and functionality losses and downtime. Table 1 presents the loss values and recovery time for the improved model for both scenarios. SEL reduced from 3.5% to 2.6% and 12.4% to 10.7% at DBE and MCE, respectively. Marginal reduction of repair time was also observed. Median building reoccupancy time sharply reduced from 102 days to 3 days at MCE. Functional recovery was also achieved much faster as the median time reduced from 174 days to 0 days at DBE and 234 to 3 days at MCE. The

full recovery time reduced from 207 days to 150 days and 291 days to 261 days at DBE and MCE, respectively. The substantial improvement in reoccupancy and functional recovery implies considerable resilience enhancement with use of enhanced nonstructural components.

The improvement in individual performance (probability of leading to occupancy/functionality loss) at DBE and MCE can be seen in Figure 2. The stairs and HVAC system show significant reduction in probability of occupancy/functionality loss from 14% to 0.5% and 86% to 5.6% at DBE. Similarly, improved stairs, HVAC systems, elevators, sanitary plumbing play a major role to reduce occupancy or functionality losses at MCE (see Figure 2). The percentage of realizations reduced from 58% to 12% for stairs, 34% to 11% for elevators, and 97% to 19% for HVAC components. The improvements for other elements are also shown in Figure 2. Figure 3 shows significant improvement in building reoccupancy and functionality over time after earthquake.

Figure 3. Variation of probability of (a) reoccupancy and (b) functionality, over time in the post-earthquake phase for baseline and improved model.

5 CONCLUSIONS

The study presents resilience assessment of modern code-complaint archetypical building to identify their contributors to reoccupancy and functionality losses and identifies opportunities to improve performance by enhancing capacity of vulnerable nonstructural components. The study considers an archetypical building that was designed, modeled, and analyzed for DBE and MCE scenarios. Damage, functionality loss, and subsequent recovery assessments were conducted in accordance with PBEE approaches. The results identify the various components that lead to functionality loss and the impact of improving their performances. Some of the key conclusions from the study are given below:

- The unacceptably long downtime for code-compliant buildings calls for considering non-structural performance in design approach and emphasizes the need to advance recovery-based design philosophies.
- Damage to conventional stairs is a major contributor of reoccupancy loss at both DBE and MCE scenarios and therefore require improved seismic design considerations.
- HVAC elements are the major contributors to extended functionality loss at DBE as well as at MCE. These elements should either be designed for higher demand parameters or/and buildings should be designed with well-ventilated systems to allow desired functionality without HVAC in the post-disaster phase.
- The use of resilient nonstructural components enables a significant reduction in overall losses and downtime, attributing to major reduction in damage to stairs, HVAC elements, elevators, and other exterior and interior components.
- The reduction of reoccupancy time from 102 days to 3 days at MCE, and functional recovery time from 174 days to 0 days at DBE and from 234 days to 3 days at MCE illustrate the significance of nonstructural improvements in resilience enhancement.

ABSTRACT: A combined highway and railway steel truss bridge with upper stiffening was taken as an engineering background to explore solution of improving fatigue performance of bridge deck. For highway orthotropic steel deck in upper layer, a layer of ultra-high performance fiber reinforced cementitious composite material (UHPFRC) was composited on deck plate by gluing corrugated steel plate shear connector (CSPC). The stress intensity factor (SIF) amplitude of rib-to-deck detail was analyzed based on linear elastic fracture mechanics. Numerical fracture mechanics results reveal SIF amplitude at the crack tip is lower than the threshold of crack propagation. For railway bridge deck in lower layer, a UHPFRC layer combined with deck plate was proposed. Fatigue stress for rib-to-deck detail under multi-field coupling effect was analyzed. Results show that fatigue stress amplitude was reduced by about 40% compared with steel deck without pavement.

1 INTRODUCTION

Orthotropic steel bridge decks have become the most widely used structures in modern large and medium span steel bridges due to its light weight, high bearing capacity and recyclability, etc. (Wang & Feng 2009, Conner & Fisher 2006, Xiao et al., 2006). However, the fatigue problem of orthotropic steel bridge deck is remarkable due to residual tensile stress, initial imperfection caused by the welding of a large number of connecting welds, long-term traffic load and environmental corrosion. The rib-to-deck detail subjected to high transverse bending moments under wheel load and simultaneously affected by welding method, penetration rate is the most prone to fatigue cracking position in orthotropic steel bridge deck, which reduces durability of pavement (Wang et al., 2017). Fatigue cracks in rib-to-deck detail located on the top of the steel girder are also the most difficult cracks to repair in steel bridge deck. Moreover, the pavement of steel bridge deck is prone to fatigue and durability damage problems such as cracking, rutting, sliding delamination under traffic and environmental loads.

Therefore, the design of new bridges should conform to the concept of higher durability, easy maintenance and long life to adapt to the characteristics of high speed, heavy load, large traffic volume and special environment of modern traffic (Duan et al., 2015). Composite steel bridge deck which improves the cooperative bearing capacity, increases the local stiffness of the steel deck and reduces the stress concentration is a significant method to solve the problem of fatigue cracking of steel bridge deck and the lack of durability for pavement. Duan et al. proposed to replace part of the traditional asphalt concrete pavement with ultra-high

performance fiber reinforced cementitious composite material (UHPFRC) to form UHPFRC composite steel bridge deck (Duan et al., 2020).

UHPFRC has fine strain strengthening characteristics, bending ability and fracture resistance (Brühwiler 2019). Thus, the crack width control ability and fatigue resistance of UHPFRC layer are enhanced, which satisfies the technical requirements of cooperating with the steel bridge deck and improving the stress state of pavement layer. Extensive researches of fatigue performance of UHPFRC composited steel bridge deck have been carried out. Dieng et al. carried out the full-scale tests and finite element analysis to study the application of UHPFRC as the pavement of OSD (Dieng 2013). The results showed that UHPFRC overlay reduce the stain at the weld root of rib-to-deck connection by 60% compared with OSD without pavement. Chen investigated the fatigue behavior of UHPC-orthotropic steel composite deck in hogging bending and evaluated the fatigue strength of cracks in the low portion of rib web and fatigue damage of the short headed studs (Chen 2019). Ma conducted fatigue analysis of UHPFRC composite deck considering the bridging degradation of cracked UHPFRC and the bond stiffness degradation at UHPFRC-steel interface (Ma 2021). Domestic and foreign scholars have carried out a large number of studies on composite layer design. Shear stud is the most common combination design. However, welding studs will cause a large number of welding fatigue details in where fatigue cracking is likely to occur under coupling of residual stress, heavy traffic and initial crack. Cold connection composite design adopted epoxy bonding and cold bonding shear connector avoid fatigue vulnerable welded details, reduce the technical difficulty of replacing the composite layer and become the research focus of long-life composite steel bridge deck in recent years. Wang developed the UHPFRC-steel composite bridge decks with cold-connectors to improve the local stiffness of the steel deck and avoid or reduce the welded shear connector, therefore, increasing the interface stiffness of UHPFRC composite steel decks (Wang et al., 2017). WANG proposed a modified steel strip-UHPFRC composite deck to increase the tensile strength at the bottom of UHPFRC (Wang & Shao 2020). Parametric static test and fatigue test were carried out and S-N curve of the steel strip-UHPC composite members was proposed.

The above literature review shows that improving the fatigue resistance and durability of steel bridge deck is necessary to ensure structural safety. The design method and research of UHPFRC composite steel bridge deck still need further research to provide technical support for the application. A cross-scale digital fatigue analysis model was established to study the fatigue performance of bridge decks of a steel truss bridge under the coupling of vehicle load, dead load, residual stress and initial crack. The thermal-solid coupling numerical model was used to simulate the welding process and calculate the welding residual stress field. For highway steel deck, a composite layer of UHPFRC with adhesive cold bonding corrugated steel plate shear connector was proposed. And the SIF amplitude of rib-to-deck detail was analyzed. For railway bridge deck, fatigue stress amplitude for rib-to-deck detail was analyzed.

2 FINITE ELEMENT MODEL OF BRIDGE STRUCTURE

A combined highway and railway steel truss bridge with upper stiffening in which upper highway and lower railway all laid on orthotropic steel bridge deck integrally connected with chord top plate was taken as the engineering background to investigate the fatigue performance of the UHPFRC combined with cold bonding connectors for composite bridge deck.

The cross section of this ten-span continuous steel truss with a length of 1410m is shown in Figure 1(a). The center distance and height of main truss are 30.5m and 12m, respectively. The height of the upper stiffening chord is 32m. The thickness of the deck is 16mm to 20mm. The geometrical dimension of the longitudinal U rib is 300mm×280mm×8mm with a spacing of 600mm. As shown in Figure 1, the conventional OSD was designed as a 70mm thick asphalt pavement. The UHPFRC overlay was reinforced with steel meshes where 30mm thick of asphalt was applied to protect the UHPFRC layer. In order to provide a great connection between steel plate and UHPFRC, the cold bonding corrugated steel plate was used at the OSD-UHPFRC overlay interface. The material properties of UHPFRC and epoxy resin refer

to previous test study (Duan et al., 2017). The multi-scale continuous steel truss bridge finite element was established as shown in Figure 1(b). The full-scale steel truss bridge was modeled using beam element. A five panel lengths main girder segment all modeled by shell element was established. The solid elements were used for the steel deck segment sub model, rib-to-deck sub model, asphalt layer, UHPFRC layer and cold bonding corrugated steel plate shear connector. The cohesive element was used for epoxy layer.

Figure 1. Background and finite element model.

3 NUMERICAL FATIGUE SIMULATION OF UPPER BRIDGE DECK

3.1 Numerical simulation of residual stress

It was found by fatigue stress test that the welded details in the compressive stress zone which indicated that the influence of residual stress on fatigue performance at joint details cannot be neglected. Zhao and Berg estimated and analyzed the welding residual stress of a U-rib stiffened plate. The results showed that residual stress near the weld seam was closed to material yielding stress. Considering the actual welding sequence, material parameters and construction technology of bridge deck, the thermal-stress sequence coupling method was used to simulate the welding residual stress. The solid sub-model as shown in Figure 2 was determined. The horizontal length and longitudinal width of deck are 600mm and 200mm respectively. And the thermo-dynamic parameters refer to previous studies (Zhao & Wu 2012).

Double ellipsoidal heat source model was used to realize the dynamic simulation of temperature filed. Figure 3 shows that the shape of the molten pool and the size of the weld during the welding process are relatively close, indicating that the parameters refer to existing research results.

Figure 2. Rib-to-deck sub model.

The Von mises stress after cooling around the weld joint were large and closed to yield stress of steel material. The edges at the top surface, middle section and bottom surface of the deck plate were selected as paths to analyze stress. In Figure 4, the transversal and longitudinal residual stress were plotted at three paths. The transverse stress which was perpendicular propagation direction of cracks initiated at the weld toe and weld root of the deck and had a significant effect on fatigue performance of the fatigue cracks. The transverse and longitudinal

Figure 3. Result of welding numerical simulation.

residual stress values of the deck changed dramatically in the transverse range of about 60mm at weld joint. The maximum of transverse stress was 405MPa and the maximum of longitudinal stress exceeded 350MPa.

Figure 4. Residual stress distribution of rib-to-deck weld in 1/2 section.

3.2 Fatigue load model

The fatigue load model III of the Chinese specification for the design of highway steel bridges was used as the loading model to analyze the fatigue performance of the composite bridge deck as shown in Figure 5. Load positions changed by applying Fortran programming and axle load was converted to equivalent surface load. Each axel load was 120kN and the contact area of wheel landing was 200mm×600mm so that the single wheel equivalent surface pressure was 0.5MPa. There were eight transversal loading cases named HLC1 to HL6 with 150mm transverse spacing as shown in Figure 6. Longitudinal loading cases TLC1 to TLC250 were adopt. The longitudinal speeds of vehicle were 120mm/s, 60mm/s and 10mm/s. The vehicle velocities were 60mm/s and 10mm/s when the wheel arrived area of 240mm and 120mm away from the crack, respectively.

Figure 5. Fatigue load vehicle.

Figure 6. Transverse loading case of a rib-to-deck plate connection between crossbeam.

Figure 7. Longitudinal loading case.

3.3 Analysis of stress intensity factor

There are two type typical cracks in rib-to-deck detail, namely fatigue cracks D1 and D2 initiating from the deck-side weld toe and weld root respectively of rib-to-deck welding joint. A half ellipse was used to simulate the initial crack, with a size of $a_0/2c_0=0,5\text{mm}/2\text{mm}$, where a_0 and c_0 were length of major and minor axe respectively. Digital fracture parameter analysis of the two typical fatigue cracks were carried out under coupling effect of dead load stress field, live load stress field and welding residual stress field. Crack would propagate when the magnitude of the stress intensity factor ΔK is greater than the threshold ΔK_{th} . Fatigue crack propagation threshold of $63\text{MPa}\cdot\text{mm}^{1/2}$ in BS7910 was adopted in this paper. Cracks in steel bridge deck are often mixed mode cracks. The mixed mode fatigue crack propagation criterion was shown in Eq 3.1 (Jin & Li 1978). And The equivalent stress intensity factor K_e could be determined by Eq 3.2 (Jin & Li 1978).

$$(K_I + K_{II})^2 + \frac{1}{1 - 2\nu} K_{III}^2 = K_{IC}^2 \quad (3.1)$$

where K_I , K_{II} , and K_{III} are stress intensity factor of crack tip of Mode I, Mode II, and Mode III; ν is Poisson's ratio; and K_{IC} is critical stress intensity factors of modes I crack.

$$K_e = \sqrt{(K_I + K_{II})^2 + \frac{1}{1 - 2\nu} K_{III}^2} \quad (3.2)$$

Figure 8 shows the stress intensity factors of crack D1 versus the locations of the wheel load. It was found that the crack was mixed mode cracks led by mode I. The SIF of the crack modes II and III was 17.9% and 23.6% lower than crack mode I at case LLC-154, which indicated that cracks modes II and III could not neglect. Thus, equivalent SIF K_e must be considered to predict the crack growth at the detail. Figure 8(d) provides the maximum equivalent SIF of the conventional OSD compared with the UHPFRC-steel composite bridge decks. The maximum equivalent SIF ΔK_e at crack tip of crack D1 for the conventional OSD was $84.3\text{MPa}\cdot\text{mm}^{1/2}$, which denoted that ΔK_e was higher than the threshold ΔK_{th} proposed in BS7608. It can be noticed that the crack will propagate under the effect of live loads combined

with the welded residual stresses and dead load. Consequently, the composite bridge deck was applied to arrest the fatigue crack propagation in the typical detail. It was found that adopting the composite bridge decks with cold bonding connectors reduced the maximum equivalent SIF to $36.2\text{MPa}\cdot\text{mm}^{1/2}$. The equivalent stress intensity factors were lower than the recommended ΔK_{th} proposed for this detail. It denoted that adopting the composite bridge decks with cold-connectors could stop the fatigue crack propagation.

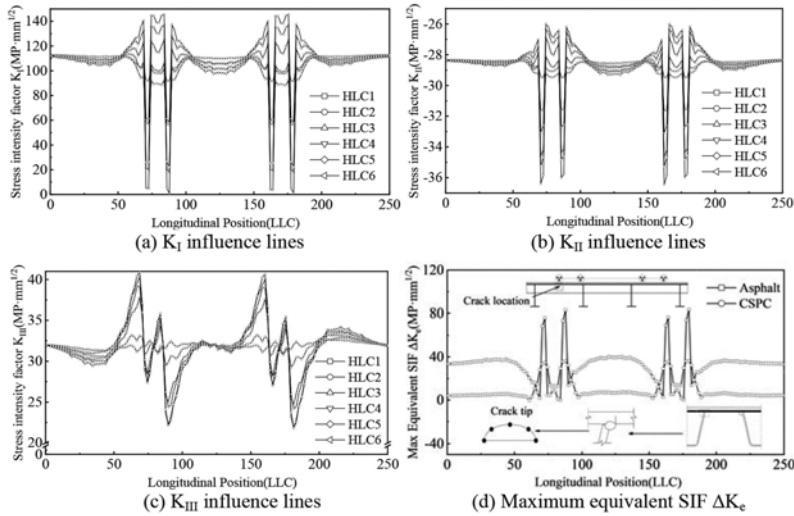

Figure 8. SIF of crack D1 in rib-to-deck detail.

Figure 9 shows the stress intensity factors of crack D2 versus the locations of the wheel load. It was found that the crack mode I was mainly propagated and cracks modes II and III could not neglect. The maximum equivalent SIF ΔK_e was $73.0\text{MPa}\cdot\text{mm}^{1/2}$ for conventional OSD calculated at crack tip of D2, which means that the crack will propagate. Figure 9(d) shows that by adopting the UHPFRC-steel composite bridge decks with CSPC, ΔK_e was $23.8\text{MPa}\cdot\text{mm}^{1/2}$. Compared with ΔK_{th} , it could be found that adopting the composite bridge decks with CSPC could arrest the fatigue crack propagation.

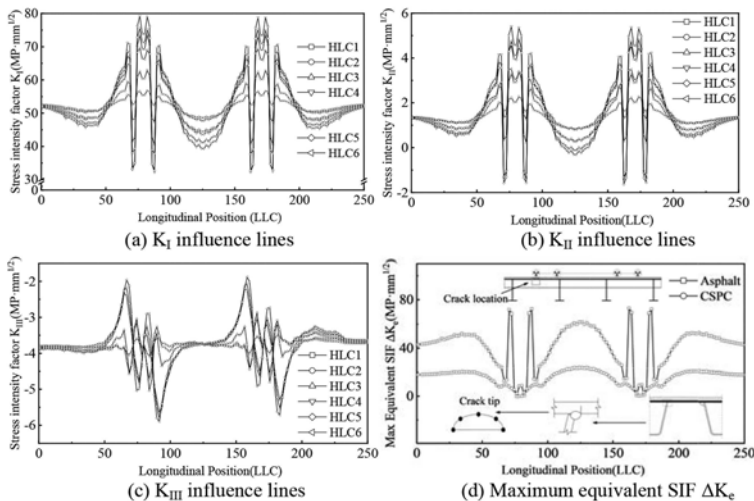

Figure 9. SIF of crack D2 in rib-to-deck detail.

4 NUMERICAL FATIGUE SIMULATION OF LOWER BRIDGE DECK

Urban railway is laid on lower bridge decks. The train is a B-type metro vehicle with a length of 19.52 m, a vehicle distance of 12.6 m, an axial spacing of 2.2 m, and a maximum axle load of 145 kN. The longitudinal speed of train was 150mm/s and there were 148 longitudinal cases realized by Fortran programming. The stress variations at two points D3 and D4 which are located at deck-side weld toe and weld root separately of rib-to-deck welding joint were studied when the steel bridge deck was paved with UHPFRC and without pavement under effects of train load, dead load and welding residual stress.

Figure 10. Stress change under train load and residual welding stress.

Figure 10 gives the stress time history curve. The stress at rib-to-deck detail was symmetrically distributed, and the stress peaked when the axle are near the detail. The stress amplitudes at D3 and D4 were 46.4 MPa and 58.8 MPa respectively when the bridge deck had no pavement layer. The stress amplitudes at D3 and D4 were 26.8 MPa and 35.1 MPa respectively when UHPFRC layer was used. It could be seen that the stress amplitudes at D3 and D4 were reduced by about 42.2 % and 40.3 % respectively by using UHPFRC layer compared with no pavement.

5 CONCLUSIONS

Fatigue cracking of orthotropic steel deck and pavement damage are typical engineering problems. UHPFRC layer with cold bonding connector is possible solution for typical engineering problems of fatigue cracking in orthotropic steel deck and pavement durability problem. This paper takes the UHPFRC-steel composite bridge decks with cold bonding connectors as the research object. A cross-scale digital fatigue analysis model was established to study the fatigue performance of UHPFRC composite bridge decks of a steel truss bridge under the coupling of vehicle load, dead load, residual stress and initial crack. The following conclusions can be drawn:

1. The welding process analysis was proved the existence of large residual stress at rib-to-deck detail. Residual stress reached to the mental yield stress, and thus the residual stress of rib-to-deck detail could not be neglected.
2. For highway steel deck, UHPFRC-steel composite bridge decks with cold bonding corrugated steel plate shear connector reduced equivalent SIF amplitudes below the threshold at

crack tip of crack initiating from the deck-side weld toe of rib-to-deck welding joint, so did the crack initiating from the deck-side weld root. It denoted that fatigue crack propagation will be stopped.

3. For railway steel deck, the stress amplitudes in rib-to-deck detail was reduced by about 40% when UHPFRC layer was used.
4. This research was concentrated on the fatigue performance simulation of UHPFRC composited deck for steel truss girder bridge. In the future, experimental tests for the UHPFRC-steel composite bridge decks under the wheel load should be carried out, and in-site monitoring during in-service stage are needed to analyze the performance of the composited deck.

Redundancy, importance, and robustness analyses for damage scenarios of bridges

S. Sarmiento, J. González-Libreros & G. Sas
Luleå University of Technology, Sweden

I. Björnsson & S. Thöns
Lund University, Sweden

ABSTRACT: Bridges are an important part of the traffic infrastructure, which are subjected to high safety requirements and economic consequences in case of functionality failure. Therefore, it is needed to consider potentially substantial direct and indirect risks during service life, i.e., the need for risk and robustness analyses. Over the last decades, various quantitative performance criteria have been developed but their interrelation and compatibility has hardly been systematically studied. This paper contains a proposal of a novel and complementary formulation of interrelations between reliability- and risk-based robustness, importance, and redundancy indicators. The classification, derivation, and exemplification of the interrelations between these indicators are presented and formulated for two case studies of a pre-stressed concrete bridge considering different hazard scenarios namely overloading and chloride attack. The analyses and applications lead to the identification of interrelations between the reliability based robustness, redundancy and importance indicator indicators and with the risk based robustness indicator.

1 INTRODUCTION

During the services life, bridges are exposed to several environmental conditions that might contribute to their deterioration and therefore the decrease of their safety level. Existing structures were designed under the assumption that the failure of their critical element induces the failure of the overall structural system. This, for some cases, leads to an underestimation of the structural system capacity since the contribution of secondary elements is not considered, ignoring the ability of the structure to redistribute loads (known as redundancy), and the capacity of withstanding additional load despite the failure of one of its elements (known as robustness) (Ghosn et al. 2010).

Through the years, several authors have proposed and further improved, different indicators aimed to quantify the redundancy, robustness, and element importance of existing structures. For example, Frangopol & Curley (1987) who introduced an indicator based on the reliability index, which was later modified by Feng et al. (2020) by incorporating the concept of progressive collapse probabilities. Similarly, Ghosn & Moses (1998) proposed reliability-based redundancy and robustness measures. Indicators expressed in terms of failure probabilities were developed by Rabi et al. (1989), which were later modified by Lind (1995). Later, Baker et al. (2008) introduced a risk-informed robustness measure to account for failure consequences, for which Faber et al. (2017) introduced a probabilistic characterization. Additionally, Praxedes et al. (2022) develop a new risk-based robustness index aimed to account for the full spectrum of risk. Other researchers have expanded the scope of these measures by adding damage progression, optimization, and combinatorial principles, among others (e.g., Biondini et al. 2008, Straub & Kiureghian 2011, Cavaco et al. 2013). Biondini (2009) is an example of a key study on the evaluation of robustness of structural subjected to continuous degradation in which a methodology for life-time assessment of concrete structures is used together with time-variant analysis.

Despite the large number of contributions in this area, there are hardly any studies, which analyze jointly such indicators nor document their interrelations. Therefore, this paper contains a first step towards a classification, derivation, and exemplification of interrelations between reliability- and risk-based robustness, importance, and redundancy indicators. The objective of this proposal is to facilitate the general understanding, and differences between the information that the indicators provide. The quantification of the indicators requires the implementation of reliability, and risk analyses, introduced in Section 2 together with the classification, derivation and illustration of the interrelation of the indicators under study. The exemplification is performed through for two case studies of a pre-stressed concrete bridge which represent two relevant damage scenarios. The description of the example application is presented in Section 4, followed by the analysis of the results and discussion in Section 5. Finally, the conclusions are presented in Section 6.

2 METHODOLOGY

2.1 Reliability and risk analyses of damage scenarios

Initially, the modeling of failure scenarios is performed by considering the critical element(s) of the system, i.e., the elements most probable to fail first due to the identified exposure(s). This paper considers two of the most common sources of damage to multibeam bridges: overloading and chloride attack (see e.g., Ghaffary & Moustafa 2020). These two exposures are studied separately to compare the structural system's element and system behavior. Given the exposure, two different failure scenarios are modeled, namely Scenario 1 (s_1) and Scenario 2 (s_2), for overloading and chloride attack, respectively.

Two system states and one element state are analyzed to determine the robustness of a determined structure. The first system state corresponds to the intact structure which represents the structure under analysis subjected to normal loading, before being exposed to any hazard. The element state corresponds to the analysis of the critical element(s) due to a determined exposure, and the second system state corresponds to the damaged structure which represents the case in which the critical elements have failed and are discarded as a part of the structure.

After obtaining the failure scenarios, the reliability analysis is performed, which aims to quantify the safety level of a determined structure. This safety level is commonly expressed in terms of the reliability index (β) and its associated probability of failure ($P(F)$). The failure event F with random variables resistance R and load S is then defined as:

$$F: g(\mathbf{X}) = R - S \leq 0 \quad (1)$$

$g(\mathbf{X})$ is the limit state function, and \mathbf{X} is the vector of random variables.

In this paper, a metamodel-based reliability analysis is performed to obtain the values of P (F) and β . This methodology is an iterative process that consists of obtaining points from the random space using the Latin Hypercube Design (LHD) to assess the value of $g(\mathbf{X})$ at each point and then, by a Gaussian interpolation, a new limit state function is obtained denominated as $\hat{g}(\mathbf{X})$. With the new limit state function, the Monte Carlo simulation (MCs) is used to calculate $P(F)$, and β . The process described previously is repeated until a convergence criterion is satisfied, and in each iteration is enhanced by using a learning function. More details regarding the implemented methodology can be found in Sarmiento et al. (2022).

The values of $P(F)$ and β are obtained for the different failure scenarios mentioned above, i.e., the intact system, the critical element(s), and the damaged system. Therefore, three different limit state functions are formulated and shown in Equation 2. The limit state function of the intact system $g_{F_S}(\mathbf{X})$ works for both scenarios since it is the case of the structure in normal conditions. $g_{F_l}(\mathbf{X})$ and $g_{F_S|F_l}(\mathbf{X})$ are different for s_1 and s_2 since the critical element(s) might be different for each one, and thus different damaged systems are obtained.

$$F_S: g_{F_S}(\mathbf{X}) = R_S - S \leq 0, F_l: g_{F_l}(\mathbf{X}) = R_l - S \leq 0 \text{ and } F_S | F_l: g_{F_S|F_l}(\mathbf{X}) = R_S(F_l) - S \leq 0 \quad (2)$$

where R_S is the intact system resistance; R_l is the resistance of the critical element l ; and $R_S(F_l)$ is the system resistance given failure F_l of the critical element l .

Finally, a risk analysis is conducted to obtain the risk-based robustness indicator. In structural engineering risk is set up as the product of the probability of failure $P(F)$ and the corresponding failure consequence C_f (see e.g., Faber 2008), which is normally expressed in terms of costs, i.e., a monetary value. The values of risks provide a measure of what probability different ranges of consequences will occur (Faber 2008). Risk can be classified into direct and indirect, which are normally related to the probability of local damage and to the failure of the overall system, respectively (Baker et al. 2008, Faber 2008). Direct (R_{Dir}) and indirect (R_{Ind}) risks can be calculated using Equation (3). Different types of consequences can be considered when performing structural risk analysis, and they can also be classified as direct and indirect consequences, as shown in Equation 3. C_{Dir} is associated with the costs related to the failure of the critical element(s), whereas C_{Ind} is the additional consequences that are not counted as direct (Faber 2008).

$$R_{Dir} = P(F_l) \cdot C_{Dir} \cdots \text{and} \cdots R_{Ind} = P(F_l) \cdot P(F_S|F_l) \cdot C_{Ind} \quad (3)$$

where $P(F_l)$ is the probability of failure of the critical element(s), $P(F_S|F_l)$ is the conditional probability of the system failure F_S due to the critical element F_l , C_{Dir} is direct consequences of failure, and C_{Ind} indirect consequences of failure.

2.2 Redundancy, importance, and robustness analyses

In bridge engineering, importance, redundancy, and robustness are important concepts related to the safety and performance of a bridge system. Various reliability-based, or risk-based indicators relating to redundancy, importance and robustness characteristics can be found in the scientific literature. Importance refers to the significance of a component or element in maintaining the overall structural integrity (e.g., Straub & Kiureghian 2011), meanwhile redundancy is related to the existence of alternative load paths, so that if one element fails, the load is transferred to other elements in the system (e.g., Dusenberry et al. 2022). Furthermore, robustness refers to the ability of the system to maintain its structural integrity without excessive changes in system capacity, reliability, or performance during the occurrence of adverse events (e.g., Starossek & Haberland 2010 and Baker et.al. 2008). Despite the different meanings of the redundancy, importance and robustness indicators, it is observed that there is a common basis in reliability element and system analysis subjected to a damage or element failure scenario.

For an overview, Table 1 contains a denotation, formulation, and a classification of the redundancy, importance and robustness indicators. The denotation is harmonized for consistency with the definition of the indicators. The indicators classification shows that the indicators include (1) either ratios or differences of probabilities and reliabilities or both, differences, and ratios (Table 1).

The robustness contains by sums aggregated direct and indirect risk for hazards, component damage states and system failure states (see e.g., Faber 2008). In this paper a reformulation is introduced with consideration of single hazard, damage, and failure scenarios s and rewrite robustness index as:

$$I_{rob}(s) = \frac{P_{Dir}(s) \cdot C_{Dir}(s)}{P_{Dir}(s) \cdot C_{Dir}(s) + P_{Ind}(s) \cdot C_{Ind}(s)} \quad (4)$$

where $P_{Dir}(s)$ and $C_{Dir}(s)$ are the direct probability and consequences, respectively, related to $R_{Dir}(s)$, and $P_{Ind}(s)$ and $C_{Ind}(s)$ are the indirect probability and consequences, respectively, related to $R_{Ind}(s)$.

If $P_{Dir}(s)$ and $P_{Ind}(s)$ are associated with the probabilities defined in Equation 3 it can be established that:

$$P_{Dir}(s) = P(F_l(s)) \text{ and } P_{Ind}(s) = P(F_l(s)) \cdot P(F_S(s)|F_l(s)) \quad (5)$$

The scenario-wise formulation of Equation 4 facilitates the introduction of a probability ratio $Q_P(s)$ as:

$$Q_P(s) = P_{Ind}(s)/P_{Dir}(s) \quad (6)$$

The robustness index can then be rewritten as:

$$I_{rob}(s) = C_{Dir}(s)/(C_{Dir}(s) + Q_P(s) \cdot C_{Ind}(s)) \quad (7)$$

Replacing Equation 5 into Equation 6, $Q_P(s)$ can be simplified as:

Table 1. Redundancy and robustness index summary and their classification.

Indicator denotation	Formulation	Ratio	Diff.	Rel.-based	Risk-based	Reference
System and component reliability difference	$\Delta\beta_u = \beta_S - \beta_I$		X	X		Ghosn & Moses (1998)
Damaged system and component reliability difference	$\Delta\beta_d = \beta_{F_S F_I} - \beta_I$		X	X		
Component importance ratio	$IR_S = P(F_S)/P(F_I)$	X		X		Rabi et al. (1989)
Damaged system importance ratio	$IR_d = P(F_S F_I)/P(F_S)$	X		X		
Reliability difference ratio	$\beta_r = \beta_S/(\beta_S - \beta_{F_S F_I})$	X	X	X		Frangopol & Curley (1987)
Importance difference ratio	$RI = (P(F_S F_I) - P(F_S))/P(F_S)$	X	X	X		
Single element importance	$SEI = P(F_S F_I) - P(F_S)$		X	X		Straub & Kiureghian (2011)
Direct risk to total risk ratio	$I_{rob} = R_{Dir}/(R_{Dir} + R_{Ind})$	X	X	X	X	Baker et al. (2008)

$$Q_P(s) = \frac{P_{Ind}(s)}{P_{Dir}(s)} = P(F_S(s)|F_I(s)) \quad (8)$$

In this study, complementary formulations of the indicator I_{rob} are derived with the objective of creating an interrelation between the risk-based robustness index and the reliability-based redundancy/robustness indicators. Equations 9-11 show how the re-formulation of Equation 6 can be obtained using IR_d , IR_S , RI , and SEI since they are calculated based on the probabilities of failure. It is considered that the failure of the intact system $P(F_S)$ is independent of the scenario.

$$Q_P(s) = \frac{P(F_S(s)|F_I(s))}{P(F_S)} \cdot \frac{P(F_S)}{P(F_I(s))} \cdot P(F_I(s)) = IR_d(s) \cdot IR_S(s) \cdot P(F_I(s)) \quad (9)$$

If using the indicator RI , $Q_P(s)$ can be re-written as:

$$Q_P(s) = P(F_S) \cdot (RI(s) + 1) = IR_S(s) \cdot (RI(s) + 1) \cdot P(F_I(s)) \quad (10)$$

or in function of SEI :

$$Q_P(s) = SEI(s) + P(F_S) \quad (11)$$

It is also possible to express the reliability-based indicators in function of the factor $Q_P(s)$, by re-arranging Equations 9-11, and for the indicators $\Delta\beta_d$ and β_r as:

$$\Delta\beta_d(s) = -\phi^{-1}(Q_P(s)) - \beta_I(s) \quad \text{and} \quad \beta_r(s) = \beta_S/(\beta_S + \phi^{-1}(Q_P(s))) \quad (12)$$

The expressions above can be illustrated by evaluating the indicators for different $Q_P(s)$ values, which can be obtained by considering the domain $0 \leq I_{rob} \leq 1$, and relevant consequences values. Figure 1 displays an illustration of the indicators, for different values of $Q_P(s)$ considering the values of the consequences ($C_{Dir}(s) = 9.2 \times 10^5$ and $C_{Ind}(s) = 1.8 \times 10^8$) and probabilities ($P(F_I) = 2.28 \times 10^{-6}$ and $P(F_S) = 5.41 \times 10^{-11}$) obtained in Sarmiento et al. (2022).

When the coefficient Q_P , i.e., the probability of system failure given element failure $P(F_S(s)|F_i(s))$, increases, the robustness index I_{rob} decreases linearly. The damaged system and component reliability difference $\Delta\beta_d$ also decreases, but with different inclinations, i.e., partly exponential, and partly linear following the inverse standard normal CDF. The reliability difference ratio β_r behaves similar to $\Delta\beta_d$, but with a smaller amplitude. The SEI , IR_d and RI indicators increase with increasing Q_P values, linearly for low Q_P and exponential for higher Q_P . Both IR_d and RI yield in the same numerical values due to a very small $P(F_S)$. The value of the indicators IR_S and $\Delta\beta_u$ are 2.37×10^{-5} and 2.42×10^8 , respectively, and they remain constant for different Q_P since they are independent of $P(F_S(s)|F_i(s))$.

Structure's failure probabilities are usually very small; therefore, indicators defined by probability ratios tend to be either really small or high (e.g., IR_d and RI) making their interpretation more difficult. When an interrelation between the different robustness and redundancy indicators exists, an easier comparison and interpretation can be obtained. For instance, it is observed that a value of $IR_d = 3.2E+09$ in Figure 1 corresponds to $Q_P \approx 1.75E-01$ and therefore a value of $I_{rob} \approx 0.23$ (or $\beta_d \approx 3.65$) is obtained, which can be interpreted as a low robustness level (value far from $I_{rob}=1.0$).

Figure 1. Variation of importance, robustness, and redundancy indicators for different values of q_p , where ir_d and ri have the same numerical values, i.e., follows the same curve.

3 EXEMPLARY REDUNDANCY, IMPORTANCE AND ROBUSTNESS QUANTIFICATION

The classification and derivation of the interrelations between the redundancy, importance, and robustness indicators (Section 3) are formulated and exemplified for two case studies of a pre-stressed concrete bridge considering overloading (s_1) and chloride attack (s_2). The geometry of the structure analyzed is presented in Figure 2. It is considered that the structure under normal conditions is subjected only to traffic loads, which are represented through the design truck HL-93 (AASHTO, 1965). For s_1 the structure is subjected to an unexpected overload located at the weakest point of the bridge superstructure, i.e., the mid-span of the external girder. Therefore, the damaged system considers the failure of one of the external girders by removing this element from the FEM.

Figure 2. The geometry of a. the transversal section of the superstructure and b. the beam and reinforcement configuration of the section at mid-span.

For s_2 the structure is subjected to chloride ingress through the concrete surfaces, which leads to reinforcement corrosion (pitting corrosion). Given the normal loads of the structure, i.e., the traffic loads, the critical section is the same as s_1 . For the reinforcement in this section, due to the high concentration of stresses, corrosion propagates faster leading to an earlier failure. Therefore, the damage system is represented by removing the two rebars and four prestressing cables from the external girder, since they are located at the same distance to the bottom concrete surface.

The structure capacity is assessed using Nonlinear Finite Element Analysis (NLFEA), and to develop the FE models of both scenarios, the software ATENA Studio v.5.9 is implemented. The capacity of the four tendons and two bars system is obtained analytically, using the expressions in Tu et al. (2019) to obtain its reduced resistance due to the transversal area reduction. The probabilistic parameters for the reliability analysis are listed in Table 2. The probabilistic models are based on standards (CEB-FIP 1993, JCSS 2000) and previous studies (Akgul & Frangopol 2004, Nowak & Collins 2012, Dias-da Costa et al. 2019). Correlation between concrete properties is modelled, and the correlation coefficients were taken from Strauss et al. (2009). The formulations for I_{rob} and $Q_P(s)$ described in Equations 4-5 can be obtained for the case study if considering the $P_{Dir}(s)$ and $P_{Ind}(s)$ as described in Table 3, for both s_1 and s_2 .

Table 2. Random variables and probabilistic parameters.

Scenario 1 and Scenario 2				Scenario 2			
Variable	Distribution	Mean	COV	Variable	Distribution	Mean	COV
f_c (MPa)	Log-normal	38.16	0.18	D (m ² /s)	Normal	$2.5 \cdot 10^{-2}$	0.18
f_t (MPa)	Weibull	2.77	0.18	C_s (%)	Normal	$2.5 \cdot 10^{-2}$	0.18
E_c (MPa)	Log-normal	$3.34 \cdot 10^4$	0.15	C_{cr} (%)	Normal	$4.0 \cdot 10^{-3}$	0.23
G_f (N/m)	Weibull	140.61	0.2	M_R	Log-normal	1.2	0.05
A_{ps} (m ²)	Normal	$4.96 \cdot 10^{-4}$	0.0125	M_A	Log-normal	1.0	0.05
DL (kN)	Normal	15.81	0.1				
P_e (kN)	Normal	429.33	0.05				
P_{ve} (kN)	Gumbel	134.1	0.25				

Table 3. Direct and indirect probabilities for the analyzed scenarios.

	$P_{Dir}(s)$	$P_{Ind}(s)$		$P_{Dir}(s)$	$P_{Ind}(s)$
S_1	$P(F_{beam})$	$P(F_S F_{beam}) P(F_{beam})$	S_2	$P(F_{T,B})$	$P(F_S F_{T,B}) P(F_{T,B})$

f_c is the concrete compressive strength, f_t the concrete tensile strength, E_c the concrete modulus of elasticity, G_f the concrete fracture energy, A_{ps} the prestressing tendons' transversal area, DL the death load (self-weight of the structure), P_e the prestressing effective force, P_{ve} the vehicle load, D the diffusion coefficient of chloride, C_s the surface chloride content, C_{cr} the critical chloride content, M_R the resistance uncertainty factor, and M_A the analysis uncertainty factor.

where F_{beam} represents the failure of the external beam, $F_{T,B}$ the failure of the tendons and bars system, and F_S the failure of the system.

4 RESULTS AND DISCUSSION

The results obtained through the reliability analysis are presented in Table 4, which show that the reliability of the intact system is considerably higher than the reliability of the critical element for both scenarios. The damaged system for s_1 has a higher reliability $\beta_{FS|FI}$ since no material degradation is considered in contrast to s_2 , where, additionally to the failure of tendons and bars on the external beam, also degradation of the remaining reinforcement due to chloride attack is considered.

Figure 3 Shows, by building upon Figure 1, the indicators according to Table 1 for a range of Q_P . The values of Q_P and indicators are highlighted with the vertical line at $Q_P \approx 1.31E-02$ for s_1 , and $Q_P \approx 2.5E-02$ for s_2 . It is worth noticing that the indicators IR_S and $\Delta\beta_d$ are not

illustrated since they remain constant due to their independency on $P(F_s(s)|F(s))$. Table 5 contains the individual values of the indicators.

Table 4. Reliability results.

	β_t	β_S	$\beta_{F_S F_t}$	$P(F_t)$	$P(F_S)$	$P(F_S F_t)$
s_1	5.04	6.46	2.22	2.3×10^{-6}	5.4×10^{-11}	1.3×10^{-2}
s_2	4.02	6.46	1.95	1.8×10^{-5}	5.4×10^{-11}	2.5×10^{-2}

Table 5. Indicators values obtain from a reliability and risk analysis.

	$\Delta\beta_d$	IR_d	I_{rob}	IR_S	RI	SEI	β_r	$\Delta\beta_u$
S_1	-2.8	2.4×10^8	0.8	2.4×10^{-5}	2.4×10^8	1.3×10^{-2}	1.52	1.42
S_2	-2.1	4.6×10^8	0.62	3.0×10^{-6}	4.6×10^8	2.6×10^{-2}	1.43	2.44

All shown indicators are sensitive to a change of Q_P . For increasing values of the damaged system failure probability ($Q_P = P(F_s(s)|F(s))$) the indicators I_{rob} , $\Delta\beta_d$ and β_r experience a linear decrease. This decrease is due to a higher loss on the system's reliability after the failure of the critical element. In contrast, indicators SEI , IR_d and RI increase exponentially, as the importance of the failed element becomes higher with an increasing damaged system failure probability.

Figure 3. Variation of the indicators in function of the coefficient Q_P .

The indicators β_r , SEI , IR_d and RI coincide for the evaluated Q_P values for both scenarios since the intact system failure probability ($P(F_S)$) is the same. The indicators I_{rob} and $\Delta\beta_d$ have different values for s_1 and s_2 because they depend on the critical element failure probabilities ($P(F_t(s))$), which are different for s_1 and s_2 . The negative $\Delta\beta_d$ values indicate that the system reliability given element failure is lower than the critical element reliability. Thus, lower values of $\Delta\beta_d$ can be interpreted as lower reliability-based robustness levels. In contrast, higher values of IR_d represent higher failure probability after the failure of the critical element, i.e., an increase in reliability-based vulnerability. Lower values of I_{rob} are obtained when the indirect risks, i.e., risks associated with the system's failure, have a bigger influence on the total risks, which represents lower risk-based robustness levels.

The increase on values reflect an increase difference of the system failure probability before (intact) and after (damaged) the element's failure. Thus, higher SEI values represent a higher probabilistic-based importance of the critical element on the system. The indicator RI provides a normalized version of SEI ; therefore, a higher probabilistic-based importance of the element is also reflected through higher RI values. The indicator β_r is higher for lower differences between the system reliability before and after the failure of the element, and therefore higher β_r reflects better reliability-based redundancy levels.

The indicator IR_S is another probabilistic-based measure of the element importance, and its value provides the ratio between the intact system and element's failure probability. Therefore, values closer to one represent equal failure probabilities, thus, lower redundancy levels. A relation between the reliabilities of the intact system and the element is also provided by $\Delta\beta_u$. The indicator gives the difference between both reliabilities in a way that higher $\Delta\beta_u$ values, i.e., higher intact system's reliability in comparison with the element's reliability, represent higher reliability-based redundancy levels.

5 CONCLUSIONS

This paper presents a summary and classification of the available reliability- and risk-related redundancy, importance, and robustness indicators. Also, it contains the development of new complementary formulations of interrelation between the different indicators. A case study of a prestressed concrete bridge is used to exemplify, illustrate, and compare the derived formulations.

Based on the analyses presented it can be concluded that the studied indicators provide different structural performance measures, such as reliability-based robustness and redundancy ($\Delta\beta_d$, IR_d , β_r and $\Delta\beta_u$), importance (SEI , IR_S and RI) and risk-based robustness (I_{rob}). Furthermore, an interrelation of robustness, redundancy and importance indicators can be derived with the introduction of the indirect to direct failure probability ratio Q_p for which the indicators $\Delta\beta_d$, IR_d , β_r , SEI , RI and I_{rob} show to be sensitive. The derived formulations provide a way of translating the values of the reliability-based indicators into the risk-based robustness index I_{rob} . This translation allows an easier comparison and a better understanding for indicators such as IR_d , IR_S and RI . With an example application, the robustness, redundancy and importance indicator calculation and their interrelation are illustrated and the identified interrelations of the reliability based indicators and the risk based robustness indicators are exemplified.

ABSTRACT: Composite cable-stayed bridge is more and more widely used, which fills the economic gap between traditional concrete cable-stayed bridge and steel girder cable-stayed bridge. This paper studied the behavior of composite truss girder with thicker concrete, based on a composite truss girder cable-stayed bridge with thicker concrete at side span. The multiple scale models of the whole bridge were established to investigate the distribution of normal stress of concrete and steel truss under dead load and live load. The finite element results showed that the stress of concrete is main compressive stress, and the distribution of stress of cable section concrete is uneven with obvious shear lag phenomenon. The stress of lower chord at the pier's top section is large. As the thickness of concrete increases, the stress distribution becomes more uniform, and the thickness of concrete is recommended to be 40 cm ~ 50 cm.

1 INTRODUCTION

The composite truss girder comprises a steel truss girder, bridge deck, and shear connectors with a strong spanning capacity. The concrete slab is connected through the shear connectors with the upper chord of the truss and the steel cross beam, respectively. The composite truss girder takes full advantages of the tensile properties of steel and the compressive properties of concrete to improve the material utilization and bearing capacity, which has the characteristic of light weight, less steel consumption, and strong spanning ability. The concrete slab in composite truss girder is beneficial to increase the stiffness of the main truss, improve traffic conditions and reduce the engineering cost. Concrete slab not only plays the role of bridge deck, the main truss horizontal and vertical connection, but also assists the main truss in bearing shear force. On the one hand, the concrete slab bears and transmits the bridge deck load, on the other hand, it forms a stable spatial structure with the main truss, which makes the lateral bending stiffness and torsional stiffness of the bridge larger. The composite structure is suitable for bridges with larger spans. The composite girder cable-stayed bridge structure is a kind of cable-stayed bridge structure first proposed by German bridge designer Leonhardt in 1980. It combines the advantages of concrete cable-stayed bridges and steel cable-stayed bridges, and has strong economic advantages.

Many scholars have studied the structural behavior of simple composite girders. Wang et al. (2008) studied the performance of high strength steel and concrete composite girders through numerical simulation, considering parameters of the geometrical dimension of concrete slabs, transverse reinforcement ratio, and material strength. The numerical analysis results showed that the longitudinal slip was affected by material strength, the width of the concrete slab, and transverse reinforcement during the in-elastic stage. Machacek & Cudejko (2009) investigated the longitudinal connection of the steel truss and concrete slab through parametric studies, finding that the greater the concrete slab dimensions, the greater the values of longitudinal shear.

At the whole bridge scale, Li et al. (2013) studied the influence of concrete shrinkage and creep on deformation, internal force, and stress of composite cable-stayed bridges through numerical simulation. The simulated results showed that the shrinkage and creep of concrete cause stress redistribution. Additional tensile stress is produced in the concrete slab, and the main beam undergoes axial compression deformation. Jin et al. (2010) established a finite element model to study the deck response and the stress state of truss joints of truss composite girder cable-stayed bridge under dynamic load, considering the influence of geometric nonlinearity and material nonlinearity.

There are many scholars have studied the shear lag effect in composite girders. Johnson & Lewis (1966) studied the effective width at the limit state of the continuous composite girder under uniform load. Macorini et al. (2006) calculated the effective width of a composite girder under long-term impact using the finite element method, considering the shrinkage and creep of concrete. Pedro & Reis (2010) established the whole bridge model of a composite cable-stayed bridge, and analyzed the mechanical performance at the end of the construction and service stages. Wang et al. (2022) carried out finite element analysis on composite cable-stayed bridges and then calculated the distribution of effective width coefficients of the whole bridge. The results showed that cable spacing and bridge width have a great influence on the effective width. Giaccu et al. (2022) proposed a calculation method for the effective width of the composite girder considering the combined axial force and bending moment through a finite element model of a whole composite cable-stayed bridge.

The mechanical properties of simple system composite structure girder bridges and composite girder cable-stayed bridges with bridge deck thicknesses of 25 cm~30 cm have been further studied. However, there are few studies on the mechanical performance of composite truss girder structures in a cable-stayed bridge with a concrete deck thickness of 40 cm on average. Therefore, it is necessary to carry out some research on it. In this paper, based on a composite truss girder with a thicker concrete deck at the side span in a cable-stayed bridge, the main span is 930 m, a finite element model is established to study the behavior of composite truss girders with a thicker concrete deck.

2 NUMERICAL ANALYSIS

2.1 *Bridge description*

In this paper, the research object is a composite girder cable-stayed bridge with two diamond-type towers and two parallel strand cables, as shown in Figure 1. The full length of this bridge is 1650m. Three auxiliary piers are installed in each side span, so the bridge has nine spans ($3 \times 84 + 108 + 930 + 108 + 3 \times 84 = 1650$ m). The main span girder is a steel composite truss girder with an orthotropic steel deck, while the side span is a steel composite truss girder with a thicker concrete deck. The length of the side span is 360 m, and the total width is 29.8 m. The truss girder comprises N-shaped main truss, transverse truss, secondary crossbeam, a longitudinal girder, and bottom laterals. The standard girder length of the main truss is divided into 7.5 m and 10.5 m. The height of the main truss is 7.98 m, and the thickness of the concrete slab is 46.8 cm. The steel truss girder and the concrete slab are connected through shear connectors. The standard cable distance is 15 m, and the cable distance in the dense cable area of the side span is 10.5 m. Q420 steel is used for the upper and lower chord of the main truss, Q345 steel is used for the rest chords, and C55 concrete is used for the deck of the side span.

2.2 *Finite element model*

The full bridge finite element model was established through Midas Civil to determine the rational completion cable force of the bridge. The results showed that the 3# auxiliary pier is the most unfavorable position where the stress is largest under the dead and live loads. Then, a multiple-scale model was built to study the structural behavior of the composite truss girder with thicker concrete near the 3# auxiliary pier. In the finite element analysis, to improve the

(a) Elevation of the cable-stayed bridge

(b) Standard cross-section of the main girder at side span

Figure 1. The general layout of the cable-stayed bridge (unit: cm).

calculation efficiency, the solid element (C3D8R) with reduced integration was used to simulate the concrete slab, the shell element (S4R) was selected for the main truss girder, and the truss elements (T3D2) was chosen for the reinforcement in the concrete slab as well as the cables. The towers and the rest girders are simulated by the beam element (B31) to improve the calculation efficiency. The elastic modulus of concrete is 3.6×10^4 MPa, and Poisson's ratio is 0.2. The elastic modulus of the steel truss girder is 2.06×10^5 MPa, and Poisson's ratio is 0.3. The finite element model is shown in Figure 2. Ignoring the interface slip between the concrete slab and the steel girder, the "Tie" command simulates the connection between the concrete slab and the steel truss girder without considering the nonlinear effect. To simplify the model, the longitudinal and transverse slopes of the bridge are not considered.

The dead load accounts for a large proportion of the total load in a cable-stayed bridge, and the live load is also one of the bridge load forms which acts on the slab directly. Therefore, it is significant to study the structural behavior of the thicker concrete under dead and live loads. Highway-I lane load was used to calculate the effect of live load. According to the code (China's Ministry of Transportation 2015) provisions on live load, lane load consists of concentrated force and uniform load. Four lanes were considered in this paper. The uniform load of the load is 10.5 kN/m, and the concentrated force is 360 kN. The transverse reduction coefficient of the lane is 0.67, and the longitudinal reduction coefficient is 0.94. The sidewalk was not considered.

Figure 2. Finite element model.

3 RESULTS ANALYSIS

3.1 Analysis of concrete

The stress of cable section and pier's top section is more complex. So three typical sections are studied. S1 and S3 are the cable sections, while S2 is between the two cables, and S3 section is at the top of 3# auxiliary pier. Because of the large thickness of the concrete deck, it is necessary to select the upper, middle, and lower sections along the thickness direction to analyze the stress distribution along the thickness direction, as shown in Figure 3(a). The distribution of normal stress of concrete slab under dead load and live load is indicated in Figure 4. It can be seen that the distribution of normal stress of concrete is symmetrical along the central axis of the bridge. And the stress level of the concrete section is not large. The normal stress of three sections changes obviously at the position of small stringers. The stress fluctuation in cable anchor sections (S1, S3) is serious, while the stress changes greatly along the thickness direction in the S2 section. Obviously, there exists a significant shear lag effect in the concrete slab. Due to the large negative bending moment at the top of the pier, the compressive stress of the S3 section is smaller than that of the other two sections, and there even exists tensile stress which does not exceed the limitation.

Figure 3. Normal stress nephogram of typical sections.

The concrete thicknesses of 250 mm, 300 mm, 400 mm and 500 mm are selected to study the influence of concrete thickness on stress distribution, and the normal stress of concrete in S3 section is shown in Figure 5. The normal stress of concrete with 250 mm thickness is the largest and the distribution is the most uneven. When the thickness of concrete is 500 mm, the normal stress

Figure 4. Distribution of normal stress of concrete.

is smaller and the distribution is more uniform. Figure 6 shows the distribution of normal stress on the upper surface and the lower surface of the concrete with different thicknesses at the pier's top section. It can be seen from the figure that with the increase in thickness, the stress distribution of concrete is more uniform and the stress degree of the concrete slab decreases. This is because as the concrete thickness increases, the stiffness of the structure becomes larger. On the one hand, thicker concrete can play a role of pressure, on the other hand, the stress level is lower and the stress distribution is more uniform. Therefore, it is suggested that the concrete thickness can be larger in the design of cable-stayed bridges and 400 mm ~ 500 mm thick is recommended.

Figure 5. Distribution of normal stress of concrete with different thicknesses.

3.2 Analysis of steel truss girder

The steel truss girder is the essential component that takes most loads of the bridge. The Mises stress of the upper and lower chords of three typical sections under dead load is shown

Figure 6. Comparison of normal stress of concrete with different thicknesses.

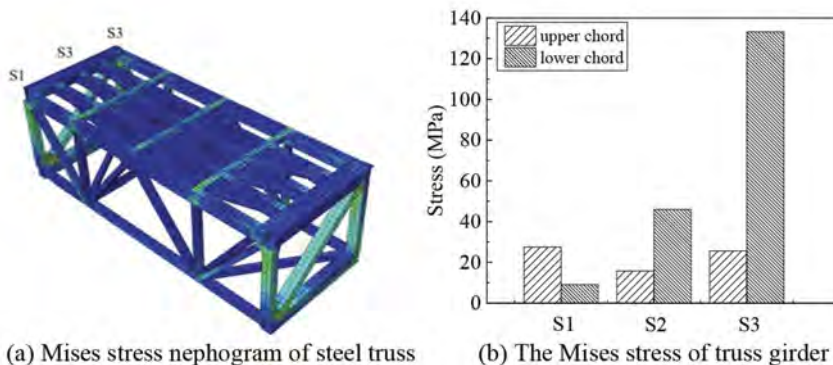

Figure 7. Distribution of Mises stress of truss girder.

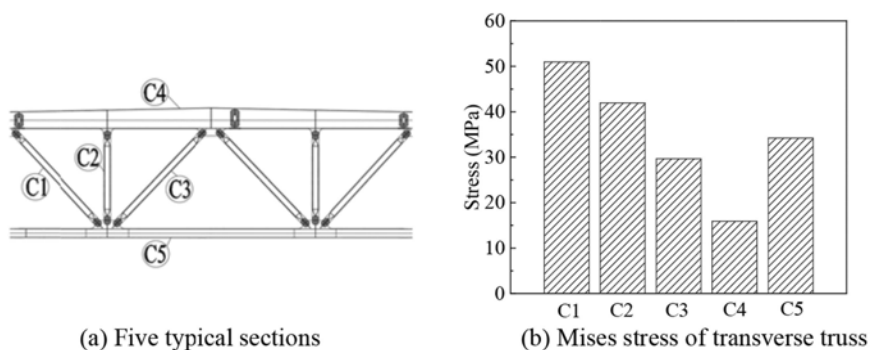

Figure 8. Distribution of Mises stress of transverse truss section.

in Figure 7. It can be seen that the stress of the upper chord at three typical sections is similar, and the stress of cable anchor sections (S1、S3) is slightly greater than that of the non-cable section (S2). In addition, the closer, the lower chord is to the auxiliary pier, the greater the stress is. The stress of the lower chord of S3 located at the top of the auxiliary pier is much larger than the other sections.

The main transverse truss section of the pier's top section is shown in Figure 8(a). Two diagonal belly poles, vertical belly poles, upper chord, and lower chord are numbered C1 ~ C5 respectively. The Mises stress of each member of the transverse truss is shown in Figure 8(b). The stress of diagonal belly poles near the main truss is the largest, and the closer to the central axis of the bridge, the smaller the stress is. The upper chord stress of the transverse truss is smaller than the lower chord stress, only half of the lower chord stress.

4 CONCLUSIONS

The structural behavior of the composite truss girder with the thicker concrete deck at the side span in a cable-stayed bridge was studied in this paper by simulation. The conclusions were summarized as follows:

- (1) In the cable-stayed bridge, the concrete slab is mainly subjected to compressive stress. The small stringers greatly influence the stress distribution in the concrete.
- (2) The shear lag effect in the concrete slab is prominent. The distribution of normal stress of thicker concrete slab along the thickness direction is also non-uniform.
- (3) The normal stress degree of thicker concrete is smaller and more evenly distributed. Considering the side-span ballast and the normal stress distribution, the concrete thickness of 400 mm ~ 500 mm is recommended in this paper.
- (4) The stress of the truss girder at the auxiliary pier is large, especially the lower chord. For the main transverse truss, the stress of diagonal belly poles near the main truss is the largest.

ABSTRACT: The Italian built heritage is characterized by an extensive use of timber as building material, realizing floor and roof structures of palace, churches and buildings. Conservation and restoration are needed for the safeguard of the timber-built heritage. However, given the lack of knowledge about the mechanical capabilities of the ancient structural members, often the blind removal takes place. In this context a research program for the mechanical characterization of ancient timber elements through an experimental campaign is ongoing at the University of Calabria, through a cooperation with the University of Naples Federico II, the University of Florence and the National Research Council. In particular, 18 ancient timber members are studied through the application of innovative survey methods, visual strength grading, non-destructive, destructive and long-term bending tests. In this paper a first part of the experimental work concerning survey, visual strength grading and non-destructive tests on 8 specimen is presented.

1 INTRODUCTION

In Italy most of the built-up consists of masonry buildings that are generally characterized by timber floors and roofs structures. Timber was already used in advanced systems since the Roman times (Stellacci and Rato, 2021). In southern Italy, during the Borbone reign, it even realized the first example of anti-seismic construction technique (Ruggieri, 2022). Furthermore, since the ancient times timber was widely used for medium and large span structures in churches and prestigious buildings (Faggiano et al., 2018). The conservation of the architectural heritage is a policy of protection, recently also raised to a social relaunch of territorial context as the Italian inner areas (Rossitti et al., 2022). At the same time, since Italy is heavily exposed to seismic and hydrogeological risks, conservation also aims at reducing the vulnerability of the built-up. Further to the structural function, also the authenticity, both ideal and material, in a condition of sufficient safety (ICOMOS, 1999; Tampone and Ruggieri, 2016) should be conserved.

Interventions on existing structures need adequate knowledge of material and structure characteristics, as well as of survey and diagnostic techniques. Therefore a preliminary assessment aiming at defining history, geometry and mechanics of timber structures is required (Cruz et al., 2015). In particular ancient timber is usually affected by defects, irregular geometries and degradations that influence the behavior, so that the lack of knowledge often directs the design choices towards the replacement of members, causing economic, cultural and environmental losses.

Inspired by this motivation a research program for the mechanical characterization of ancient timber members is ongoing at the University of Calabria, through a cooperation with the

University of Naples Federico II, the University of Florence and the National Research Council. In particular, the experimental campaign aims at the *in-situ* determination of the mechanical properties of timber members through the application of smart non-destructive technologies. In particular the following methods and techniques are included: visual strength grading, also aided by laser scanner acquisitions, non-destructive tests, like stress waves propagation, vibration and drilling resistance tests, destructive bending tests and long-term bending tests.

The first part of the experimental work regarding the survey, visual strength grading (VSG) and non-destructive test (NDT) on 8 specimens (ID: 2, 7, 9, 10, 11, 13, 17, 18) is herein presented.

2 VSG AND NDT FOR MECHANICAL CHARACTERIZATION OF ANCIENT TIMBER MEMBERS

2.1 *The sample features*

The 18 timber specimens in structural dimensions are part of the rafters extracted from the roof trusses of the XIX century building, the lyceum gymnasium Bernardino Telesio, in the historic center of Cosenza (Italy; Ruggieri and Serra, 2019). The specimens date back approximately to the mid eighteenth century, since after the Cosenza earthquake (1854) the roof was reconstructed. In 2020 the timber trusses were replaced and the 18 rafters were deposited at the “DINCI” Laboratory for tests on materials and structures of the University of Calabria, in Rende (Cosenza).

Rafters have an average 4.00 m length with an approximately square cross section, with an average size of 20 cm. The sample timber species identification was performed through the visual analysis: most of the members (13) are in Corsican Pine (*Pinus nigra* subsp. *laricio* (Poir.) Maire); the others (5) in Chestnut (*Castanea Sativa*). In particular Corsican Pine (PNL) is characterized by resinous and rounded knots having modest dimensions, as well as by differentiated heartwood in the transversal cross section; while Chestnut (CS) is characterized by large and elliptical knots, porous rings and the typical flaming appearance of the grain on the tangential section.

Figure 1. a) Timber trusses extracted from the lyceum gymnasium Bernardino Telesio, Cosenza (Italy); b) Timber rafters stored in the DINCI Laboratory, Rende (CS); c) Survey of two rafters with laser scanner.

2.2 *Sample survey*

Visual inspection and size measurement were carried out, they being fundamental steps in the assessment of historic timber structures. Visual inspection provides information about the overall state of conservation of the structure, as well as the presence of any sign of mechanical damage or decay, whereas size measurement aims at defining geometry and main dimensions of timber members. In general these analyses are performed through on-site observation and traditional survey techniques. However, thanks to the technological progress, innovative survey techniques are spreading. Indeed, laser scanners and photogrammetry have been recently used (Riggio et al., 2015; Nocetti et al., 2021; Abraldes et al., 2022) for the evaluation of wooden elements: from morphological, geometric and mechanical aspects to visual and degradation aspects. Therefore, as part of the experimental campaign, both 3D acquisition methodologies were applied, in order to generate three-dimensional models useful for the mechanical characterization of the study specimen. In particular, the accurate geometry of the specimens was surveyed, allowing the determination of volumes, as well as attention was paid to the restitution of textures useful for carrying out visual classification (VSG) even remotely.

2.3 Visual Strength Grading (VSG)

For the on-site mechanical characterization of timber members the visual strength grading (VSG) approach was firstly applied. It allows to attribute a strength grade to the members according to the visual criteria defined by regulations (Piazza and Riggio, 2008). Grading rules take into account macroscopic features of timber, such as size of knots, slope of grain and presence of shake. In Italy two national standards are available for VSG: UNI 11119 providing procedures for the on-site classification and UNI 11035 used for newly sawn structural timber, although it is used also for ancient timber. According to UNI 11119 three visual grades (I, II, III) can be assigned both to Corsican Pine and Chestnut, whereas according to UNI 11035 three (S1, S2, S3) and only one (S) visual grades can be respectively assigned to Corsican Pine and Chestnut. Both standards provide a strength class, in terms of allowable stresses (UNI 11119) or characteristic values (UNI 11035), as function of the assigned visual grade.

During the experimental campaign 8 rafters were graded according to the aforementioned standards. VSG was performed considering only the macroscopic characteristics located in the middle third of each member, since this part mostly affect the bending behavior of the member. VSG was performed both in laboratory and in-remote, using the high-resolution images acquired with photogrammetry survey (Figure 2). The latter methodology was found to be advantageous as it allowed the research group to share information and work even remotely.

More in detail, the 3D acquisition methodologies applied were phase-difference ToF laser scanner (LS) survey and close-range photogrammetric (P) survey, for which FARO Technologies, Inc. Focus Plus 150 laser scanner and a Fujifilm X-T2 nonmetric camera combined with Fujifilm XF 18-55 f/2.8-4R LM OIS lens were used, respectively.

The laser scanner survey was carried out for all the specimens under daylight ambient light conditions, in two stages: point detection and HDR frame acquisition. Scan registration and point cloud orientation operations were performed using SCENE software by FARO. After the cleanup actions, a point cloud of about 13 million points, with a density of 1.75 points/mm² was obtained for each specimen. The clouds were then processed to obtain meshes in Geomagic Wrap 2021 by 3D Systems, Inc. The cloud was sampled to make the point density homogeneous. The resulting meshes possessed approximately 10 million triangles per specimen.

The close-range photogrammetry was applied in conjunction with Structure from Motion software, only for specimens 16-P, 17-P, which were surveyed individually under daylight ambient light conditions. An average of 420 frames per specimen were taken. Photogrammetric processing was done using Metashape Professional produced by Agisoft LLC. Point clouds of about 45 million points per specimen with a density of 13.1 points/mm² were obtained. Meshes generated have approximately 10 million polygons. The 3D models were textured with high-definition.

Figure 2. High-definition 3D model obtained by laser scanning and photogrammetry: a) Model textured; b) Point Cloud; c) Model Wireframe.

2.4 Non-Destructive Techniques (NDT)

Non-destructive techniques (NDT) are complementary to VSG. They are frequently used in professional practice and research fields, in order to collect information, principally about the state of conservation and the mechanical properties of timber members. The most common techniques can be grouped in three different categories: probing, acoustic and vibration techniques (Llana et al., 2020). Probing category includes drilling resistance method (Nowak et al., 2015; Faggiano et al., 2011), needle penetration, screw withdrawal and core drilling tests. Acoustic methods are based on the propagation of stress waves through material in order to

estimate the timber member stiffness. Generally, two types of waves are used: sonic stress waves for frequencies within the audible range and ultrasonic stress waves at frequencies above 20 kHz (Dackerman et al., 2014). Vibration methods are based on natural frequency of timber member, which is directly related to the stiffness. Both acoustic and vibration methods are used to estimate the dynamic modulus of elasticity (MOE_{dyn}) from which static modulus of elasticity (MOE) can be derived through linear regression laws (Nocetti et al., 2010; Brunetti et al., 2013).

In this work drilling resistance, acoustic and vibration tests were carried out on the sample (Figure 3). Moisture content (MC) and mass were also measured. For each specimen a single MC measurement was taken on transversal face, through the hygrometer Hydromette CH 17 GANN, with a 60mm electrode length. Drilling resistance test was carried out using the Resi PD 400 Resistograph®. The penetration length and the average resistance to drilling (R_m) are the outputs provided by the device. For each specimen two measurements transversal to the grain were taken at each face, near the specimen end. The R_m measure was evaluated excluding the zones of the chart with no resistance. The device FAKOPP Microsecond timer® was used for acoustic test. It measures the time of flight of an acoustic stress wave induced by a hammer excitation. For each specimen five measurements were carried out using different sensor placement arrangements: one direct measurement (parallel to the grain) and four indirect measurements (one for each specimen face, placing sensors on the face with a same angle orientation (about 60°). During the test the length between sensors was measured in order to obtain the stress wave speed (SWS) through the time of flight (TOF) evaluated by the device. In the end, vibration test was conducted using the VISCAN Portable® Microtec device. It measures the natural frequency of vibration in the longitudinal direction of a timber piece by a laser interferometer exciting the specimen with a hammer (Berti et al., 2015). For each timber rafter one measurement was done in longitudinal direction.

Figure 3. Application of NDTs: a) the drilling resistance (DRM); b) acoustic; c) vibrational methods.

3 RESULTS

3.1 Visual Strength Grading (VSG)

Through visual inspection mechanical cracks were detected at the head of 4 members, probably caused by an excess of compressive stress at the joint between rafters and tie-beams. Other typical aspects of ancient timber noticed are the irregular geometry of the cross section (waned and distortions) along the specimen length, double piths (on 4 specimens), iron stain discoloration on CS members, sign of superficial decay due to insect attacks (*Cerambycidae*, *Hyloterpes bajulus*; *Anobium*, *Anobiidae*), ring shakes at the member ends for most of the specimens. It is worth to notice that for VSG, defects as ring shakes, double piths and insect attacks are not taken into account, they being outside the specimen middle third. Moreover, geometrical irregularities were also not considered, because they would be very penalizing for the specimens, they being a widespread peculiarity of ancient timber structural members of the Mediterranean area.

The main geometric features of the specimens have been extracted from the 3D models generated through LS and P survey (Table 1). Given the irregular geometry of the specimens, the size of the cross section have been referred to a nominal section. Furthermore volume measured with both LS and P survey methods led to similar values, ranging from 132 dm³ to 193 dm³. Textured 3D models obtained from P survey has been used for VSG.

In order to assign a strength grade to the specimens, quantitative evaluations were carried out. For Chestnut specimens 2, 7, 9, large knots are inside the middle third, specimen 10 only shows insect damage also inside the middle third. Thus, three specimens (2, 9, 10) are classified as grade III (UNI 11119), while specimen 7 as grade II. According to UNI 11035 specimen 7 falls into

grade S, while specimens 2, 9,10 are not classifiable as timber structural members, since they show defects above the prescribed limits. Corsican Pine specimens 7, 13, 17 are characterized by a grain slope up to 14%, specimen 18 has knots with diameter larger than 70mm. Thus, according to UNI 11119 three rafters (13, 17, 18) are classified as grade III and specimen 7 as grade II. At the same time specimens 13, 17, 18 are graded as S3 and specimen 7 as S2 according to UNI 11035.

3.2 Non-destructive methods (NDT)

In general, the moisture content (MC) of the specimen is higher than the normal content: the average value of MC is about 14.6% (maximum value is 23% for specimen 7). This is the consequence of unprotected storage of material until it was transported to the laboratory. The density ρ is similar for both wood species, being in average approximately equal to 600kg for CS and 550kg for PNL (maximum value is 723kg/m³ for CS specimen 2). A slight data dispersion is recorded for CS (COV:17%) than PNL (COV:12%). Higher value of density for CS are probably due to the widespread presence of large knots.

In Table 1 the average value of the drilling resistance measures (R_m) are shown. It is apparent that for CS R_m values are higher (R_m :27.0%) than for PNL (R_m :21%). The higher value is for specimen 2 (R_m : 34.1%), it being closely related to the high density of the member. From drill charts it is also apparent that rafters 7, 9 and 18 belonged to very old trees, since they have a large number of rings. The acoustic tests and vibrational tests results are also given in Table 1. It is apparent that for both wood species stress wave speed (SWS) is directly proportional to density. The mean value of SWS is equal to 4,392 m/s for CS and to 4,264m/s for PNL. However, the values are much more dispersed for PNL (COV:17%) than for CS (COV:4%). The dynamic elastic modulus (MOE_{dyn}) calculated has average values equal to 11,600 MPa for CS and 10,500 MPa for PNL. Again, a greater dispersion characterizes PNL (COV:47%) as respect to CS (COV:26%).

With regards to vibrational tests, it is noted that for the whole sample frequencies are quite close and equally distributed, with an average value of 531Hz for CS and 511Hz for PNL. Unlike the acoustic test, for CS sample the average value of MOE_{dyn} is lower than for PNL (10,400 MPa and 11,100MPa, respectively). MOE_{dyn} values obtained from acoustic and vibration techniques vary by a maximum of 10%. Only for the CS specimens 2 and 10 there is a variation ranging from 20% to 25%. Also, in this case for PNL specimens MOE_{dyn} is statistically more dispersed than Chestnut (COV:51% versus 17%). Furthermore, it is worth to notice that for specimen 7 the MOE_{dyn} values are not affected by the high MC values. This is probably due to the good characteristic of the member that has been graded as II and S2 in VSG.

Table 1. Strength grading and non-destructive test results.

Wood Species	Density Kg/m ³		DRM		Acoustic test				Vibrational test			
			R_m		SWS		MOE_{dyn}		Frequency		MOE_{dyn}

4 CONCLUSIVE REMARKS

In this paper the first part of a larger experimental campaign is showed. The work involved the application of innovative survey method, visual strength grading and non-destructive test on a sample of ancient timber members. The following conclusive remarks can be drawn:

- Innovative survey methods are effective methods to support the assessment of ancient timber members. Photogrammetry has produced 3D models with extremely precise and accurate geometry (useful for section extraction, volume measurements, etc.) and characterized by high resolution texture, which makes the technique more suitable for carrying out the VSG (useful for measuring knots, slope of the grain, etc.). 3D models, generated from data acquired by laser scanner adopted, resulted in less detailed meshes than photogrammetry, but there were no appreciable differences in volume and section measurements; texture quality proved to be unsuitable for visual analysis (due to the colorimetric characteristics of the specimens and ambient brightness). The computational and time burdens of acquisition by laser technique are lower than those by photogrammetric technique. The photogrammetry returns a textured model more suitable for carrying out the VSG. Visual strength grading performed on textured model is an effective methodology for working in a team even remotely. However, the survey of wane and cracks is a more time-consuming operation than standard Visual Inspection;
- Typical aspects of the ancient timber (double pith, biological decay, ring shake, mechanical damage) were identified through visual inspection, as well as LS and P. However, the criterion that considerably limits the VSG of ancient timber is the presence of wane. Indeed, this criterion has not been considered in the present work; large knots and slope of the grain have been the most recurrent defects respectively for Chestnut and Corsican Pine;
- From the application of NDT, it has been found that R_m and SWS are strictly correlated to timber density both for Chestnut and Pine. At the same time frequency seems to be not density dependent. Furthermore, for each specimen different values of MOE_{dyn} were determined by means of the application of acoustic and vibrational tests. However, in most cases the relative variation is less than 10%. A greater dispersion of MOE_{dyn} has been found for Corsican Pine. It is probably due to the heterogeneity of the quality of the material. Furthermore, for specimen 7 (PNL) MOE_{dyn} value was not affected by the high MC. This is probably due to the good characteristic of the member, as shown by the VSG results.

ABSTRACT: Many existing bridges now have a life of more than 50 years and the recently occurred failures underline the need for many of these structures to be assessed and, if required, retrofitted, in order to avoid catastrophic collapses. The Applied Element Method is herein used to show as advanced numerical modelling that accounts for as-built structural details, construction stages, material deterioration effects and structural modifications over time, have the potential to predict the failure mechanism and study the sensitivity of complex structural schemes to external actions. To this end, the collapse of the Polcevera viaduct in Genoa (August 2018), and of the historical multi-span arch bridge of Capriogliola (April 2020) are reproduced. Comparisons between numerical results and evidence, indicate that an accurate knowledge of the as-built structural details and conservation may permit to point out potential criticalities and analyse the robustness of existing bridges to avoid the premature end of their life.

1 INTRODUCTION

After the Second World War the Italian government announced the need for (re-)constructing the infrastructural system of the country, introducing guidelines to regulate material and construction demands that promoted the use of affordable materials such as concrete. Therefore, many of the existing arch bridges, both in masonry and concrete, that were destroyed during the war were then rebuilt mainly using concrete. The evolvement from a national emergency situation to a new economic and commercial development stimulated and pushed for the introduction of innovative techniques, construction methods and structural systems. Prestressed concrete technology would have still been regarded as being in its infancy at the time, however, skilled designers such as Levi, Cestelli-Guidi, Pizzetti, Oberti and Zorzi started nonetheless to apply it to relatively long-span bridges (Iori & Poretti 2009). Solutions to problems related to creep, temperature variations, strand relaxation, redistribution effects in statically indeterminate structures, nonlinear and ultimate response, were only intuitively considered, and sometimes simply overlooked. Between 1956 and 1964 the 760 km “*Autostrada del Sole*” linking Milan to Rome and Naples was designed and built, with a total of 853 bridges and viaducts (in addition to 572 overpasses) and 38 tunnels needing to be constructed. It was only years later, with the development of dedicated software, that it became possible to model most of the aforementioned complex time-dependent effects.

Today, the road network of Italy counts around 839,629 km with approx. 60,000 bridges and viaducts, and is managed by four main operators. Almost 40-50% of these bridges have reached

their design life (ANAS 2021), which was typically between 50 and 100 years, and the majority are reinforced concrete (RC) and precast concrete (PC). In addition, the lack of government-enforced universal guidelines for the conservation of such complex infrastructural system, and thus the heterogeneity of the strategy adopted by each operator, has undoubtedly not contributed to an optimum management of the road network. Indeed, the critical condition of this aging infrastructure has recently been propelled onto the international stage due to the collapse of the Polcevera viaduct in Genoa, in August 2018, and is also well epitomized by the fact that a complete registry of existing bridges is currently still missing. Since then, however, further local and global failures of other Italian bridges of varying typologies, dimensions, and relevance have occurred, including the bridge of Capriogliola (Massa e Carrara, Italy), of significant historic value and strategic importance, which collapsed into the Magra river in April 2020. Considering the limited 2-year timespan from 2018 to 2020 alone, a relatively large number of local and global bridge failures have been reported in Italy (see Figure 1), which is quite alarming and highlights the need for an urgent assessment and rehabilitation of the road infrastructures.

Figure 1. Reported bridge failures in Italy in the 2-year timespan between 2018 and 2020. (Red coloured dots indicate failures reported by national media).

Thus, as underlined in recent guidelines e.g., CNR (2021), research is still strongly needed to investigate resistance, robustness and potential progressive collapse scenarios of deteriorated bridges, considering the interaction between continuous damage due to material degradation and discontinuous damage due to accidental events. As such, the present work aims to provide a contribution to a better understanding of the sensitivity to various external loadings (both standard and exceptional, due to natural and anthropic hazards) and input data (e.g., as-design vs. as-built structural details) of two structural scheme typologies; the arch bridge used in Capriogliola and the cable-stayed system adopted for the Polcevera viaduct. Use is made of the relatively innovative Applied Element Method (AEM, Meguro & Tagel-Din (2002)) structural modelling and analysis approach (as implemented in the computer program ELS (ASI 2020)), which has been shown to be capable of accurately modelling the response of bridge structures from their elastic behaviour up to debris distribution (e.g., Malomo et al. (2020)).

2 THE RC CABLE-STAYED BRIDGE OVER THE POLCEVERA RIVER: 51 YEARS OLD

2.1 Overview of its history

The viaduct over the Polcevera river in Genoa, Italy, was built between 1963 and 1967 and is widely known as Morandi bridge, taking the name of its designer, Riccardo Morandi. The complete viaduct had a total length of about 1100 m, with each of its twelve support points being

numbered sequentially from the Savona end (Figure 2), with piers 9, 10 and 11 constituting the so-called “balanced systems” passing over the Polcevera valley and railway tracks below.

The original design of the entire viaduct is described in e.g. Morandi (1967), being then revisited, in particular for what concerns its construction and loading history, in the work by Orgnoni et al. (2023a, b). As is common for structures of this type, the Polcevera viaduct was object of a number of maintenance operations during its lifetime (Rosati et al. 2020), among which, e.g., the substitution of the original steel guardrails with New Jersey barriers, the enlargement and strengthening of sidewalks in combination, and also addition of new asphalt layers.

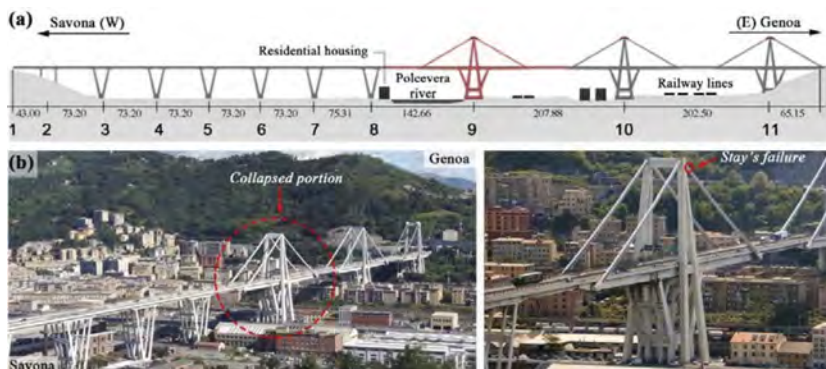

Figure 2. (a) Longitudinal schematic of the viaduct, (b) pre-collapse photos of the bridge and of pier 9.

2.2 The collapse in 2018, after 51 years of operativity

It was the balanced-system number 9 (shown in Figure 2) that collapsed on the 14th of August 2018. As is often the case in the aftermath of a structural collapse, the identification of the triggering event behind the observed stay failure remains an open question, with various qualitative hypotheses having been thus far formulated and discussed. Initial studies by Calvi et al. (2019) and Malomo et al. (2020) suggested the failure of one of its stays as a likely initiator of the observed collapse, an hypothesis that was subsequently confirmed by video footage (la Repubblica 2019) that clearly showed that the failure mechanism initiated with the occurrence of a rupture at the top end of the SE stay (see Figure 2). Subsequent forensics studies by Rosati et al. (2020) identified a number of previously unknown construction defects (e.g. heavily cluttered and congested layout of stays’ cables) and consequent (non-visible) material deterioration, underlining the noticeable mismatch between as-designed and as-built structural details. Pinho et al. (2023) have shown the influence of such construction defects on the residual capacity of the ruptured stay, highlighting as their combination with equally unforeseen exceptional load scenarios (such as e.g. impact of a falling coil and/or strong differential thermal effects) on the specific day of the collapse, could have indeed triggered the observed collapse.

2.3 Collapse analysis through the AEM-based model

The developed AEM bridge model shown in Figure 3 consisted in the assembly of approx. 100,000 elements for a total of 600,000 degrees-of-freedom. It was built based on pre-collapse building inspections, thus accounting for the as-built bridge geometry such as e.g. the twist of the antenna around its vertical axis and the stays in their catenary shape. The model featured a precise definition of acting loads, geometry, materials, and state of conservation at the time of the collapse (Scatarreggia et al. 2022a).

A number of numerical modelling studies, referenced throughout the present manuscript, have been carried out on this bridge by means of linear and nonlinear models, all reciprocally cross-validated, to investigate the impact of construction errors on the bridge conservation and stress-strain state at the time of the collapse, as well as the potential triggering factor of the stay’s failure. The results in Figure 4, taken from Scatarreggia et al. (2022a), show in particular

that the AEM model with as-built details (also including material deterioration) led to a failure mechanism noticeably different with respect to that obtained in initial studies by e.g. Calvi et al. (2019). Indeed, the model with the as-built details duplicated the collapse of the bridge portion in the immediate moments after the stay failure (see the comparison between numerical and as-observed counterpart in Figure 5), a result that could not be obtained in the earlier preliminary work by e.g. Calvi et al. (2019) and Malomo et al. (2020), where the actual as-built construction details, loading history and state of conservation were not yet fully known.

Figure 3. Mesh discretization (Δ indicates the average smallest and larger mesh dimension) adopted for various bridge parts, reinforcement details and restraints adopted in the AEM model.

Figure 4. Frames of the collapse simulation induced by a stay failure, considering both the initially assumed (top) and as-built (bottom) structural details assumptions.

3 THE MULTI-SPAN RC ARCH BRIDGE OF CAPRIGLIOLA: 71 YEARS OLD

3.1 Overview of its history

The multi-span arch bridge over the Magra river, was first built in 1908, as a link between the two municipalities of Caprigliola and Albiano Magra, in Tuscany, Italy (see e.g. Ceradini

(1951)). It was designed by the Italian engineer Attilio Muggia, one of the Italian pioneers in the field of reinforced concrete. At that time, with its 260-m length, constituted by five 51-m spans, the bridge had the record of the longest bridge ever built worldwide. Unfortunately, it was bombed during the Second World War, and it thus had to be rebuilt between 1945 and 1949.

Figure 5. Comparison between the observed (top) and numerical collapse (below).

The new design was inspired by the engineer Robert Maillart, consisting of five variable-thickness slender RC arches that were supported on the existing original piers (Figure 6). It involved the change from a fixed-arch static scheme to a three-hinges arch bridge, as well as an increase of permanent loads due to carriage enlargement to meet the increase of traffic with respect to the time of its first construction. The static scheme change aimed at achieving a theoretically permanent state of compression in the arches, which would be a statically favourable characteristic, and deemed appropriate by the designers to manage potential settlements of the original foundations of the bombed bridge. Subsequently, during the 90's, to adapt the bridge to the road traffic of the twentieth century, the carriageway was enlarged by about 2 m (from 8 m to 10 m) and its thickness increased by about 0.35 m (as estimated from the post-collapse remains).

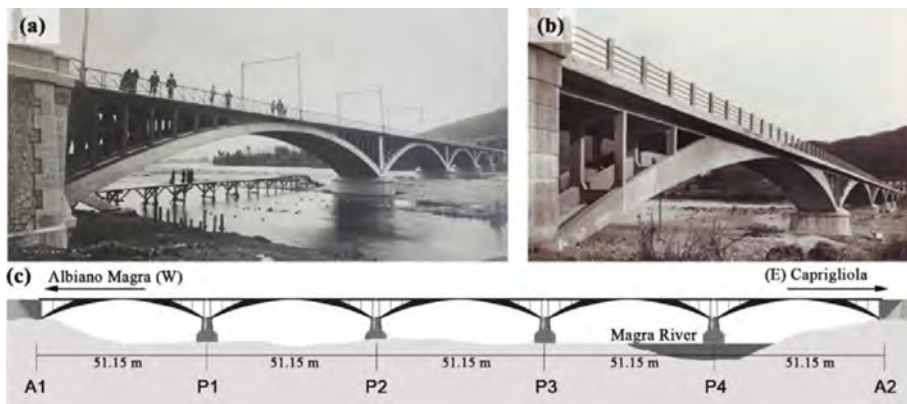

Figure 6. (a) Bridge over the Magra river built in the early '900, (b) bridge rebuilt in 1940's, and (c) schematic of the whole rebuilt bridge.

3.2 The collapse in 2020, after 71 years of operativity

On April 8th, 2020, around 10:20 am, after 71 years of operativity, the bridge suddenly collapsed (see Figure 7). Although the bridge was generally crossed by more than 2,000 vehicles per day, there was little traffic on that occasion due to travel restrictions in place due to the COVID-19 pandemic, and only minor injuries to two truck drivers were recorded. According to an eyewitness, who was driving on the bridge a few seconds before the event, localized damage, not well identified, would have spread rapidly starting from the Capriogliola side, causing a progressive domino-type of collapse.

Figure 7. Post-collapse debris distribution: (a) top view, (b) global perspective view from the South.

Similarly to what happened after the collapse of the Morandi bridge, many qualitative hypotheses were formulated on the possible underlying collapse causes, among which (as described in Scattarreggia et al. (2022b); i) materials degradation, ii) foundations subsidence, iii) excessive loading, iv) a slow slope slippage on the Capriogliola side. However, to date, the actual cause, or, perhaps better and as usually happens, the contributing causes to the collapse are still unknown. Notwithstanding, from a preliminary analysis of Figure 7 it is readily possible to note that the residual rotations, with respect to the transversal axis of the bridge, of pier P2 and P3 towards abutment A2 are a clear indication that the progressive collapse of the bridge could not have started from the side of abutment A1, given that the piers could only have rotated towards the direction from where arch support became absent, and would suggest that something must have instead occurred on the opposite side, i.e. on Capriogliola side.

3.3 Collapse analysis through the AEM-based model

The AEM-based numerical model consisted of an assembly of approx. 100,000 elements for a single bridge span, shown in Figure 8 below. The model has been cross-validated using traditional 3D and 2D FE models, i.e. a 3D model in MidasFEA (MIDAS IT 2021), which eigenvalue analysis results were compared with onsite dynamic characterisation tests, and a 2D model in VecTor2 (VecTor Analysis Group 2020), as shown in Scattarreggia et al. (2022b). The analyses carried out indicated that the vertical load capacity of the bridge was well above the stresses induced by today's traffic loads, and hence notwithstanding the fact that the construction of the additional slab in the 90's had led to a considerable increase in stresses close to the pier-arch connections (+50%), the bridge was still capable of supporting a vertical load significantly higher than that acting at the time of the collapse. The potential deterioration of

the steel and concrete materials, hypothesized both independently as well as in combination, was not a critical factor for the collapse of the bridge under the action of vertical loads (assumed to be uniformly distributed).

Figure 8. (a) AEM model of a single bridge span, with the nomenclature of main constituting components, and (b) comparison between original drawing reinforcement details and numerical counterpart.

On the contrary, small settlements/rotations at one end of an arch potentially induced on the piers in the riverbed by the erosive action of the river water, or near an abutment due to the thrust of slow slope slippage present on the Capriogliola side, would have had the potential to generate localized damage at critical sections near the pier-arch connection capable of inducing the failure. Such failure potential would have been further increased by the unintended variations in the height of the throat of RC hinges, which would have considerably reduced their rotational capacity compared to what it should have been for a 3-hinged arch bridge (theoretically iso-static), leading to a concentration of damage in correspondence of the critical section at pier-arch connection. Figure 9(a) shows the scenario following a failure in the span on the Capriogliola side at the most stressed section as inferred from the analyses considering small displacements/rotations of the pier/abutment on the Capriogliola side (as potentially induced by the recorded slow slope slippage). The final configuration of the debris predicted by the model (at 7.5 seconds in Figure 9(a)) is compatible with that observed on site (Figure 9(b)).

Figure 9. (a) Predicted progressive collapse mechanism of the entire bridge as triggered by a failure close to the pier-arch connection potentially caused by slope slippage at the abutment A2 and (b) observed debris.

4 CONCLUSIONS

The AEM seems to be a computational efficient numerical analysis method to study the response of quite complex and large RC bridge structures taking into consideration as-built

structural details as well as changes in loading and materials during the life of the structures. The application to the cable-stayed Polcevera viaduct and to the arch bridge of Capriogliola highlighted the criticalities of such bridge typologies. For what concerns the Morandi bridge, the innovative idea by Morandi of introducing only four main post-compressed stays, seemingly ingenious and effective, when combined with construction errors (that became known only after the collapse) and the consequent (non-visible) material deterioration throughout its life rendered the structure more vulnerable to potential exceptional load scenarios. In the case of the Capriogliola bridge, the idea of changing the initial fixed arch scheme into a three-hinges arch configuration, theoretically appropriate to render the bridge less sensitive to imposed foundation movements, when combined with initially unforeseen changes in the arch hinges throats and the years long slow slope slippage behind one of the abutments did inevitably render the bridge more susceptible to the type of complete collapse that was observed.

Digital fatigue test of flange-web welded details in guideway girders

C.S. Wang, X.G. Zhou, Y.Z. Wang & M.Y. Yang

Department of Bridge Engineering, College of Highways, Chang'an University, Xi'an, China

ABSTRACT: In order to investigate the long-term fatigue performance of the flange-web welded details of the guideway under eccentric loads, the digital fatigue tests of the flange-web welded details are carried out by using the extended finite element method (XFEM) and fracture mechanic theory. The results show a large welding residual tensile stress approaching to the yield stress of Q345 steel at the flange-web weld toes. Out-of-plane distortion will increase the local stress of steel structure under live load. The fatigue crack at the web is a mixed Mode I-II-III composite crack dominated by Mode I crack. This research determines the effect of residual tensile stress on distortion-induced fatigue behavior of this detail and the fatigue crack type under coupling actions. The design and construction of the guideway should avoid eccentric setting web, and the welding residual stress of fatigue-sensitive detail parts should be reduced by ultrasonic impact treatment.

1 INTRODUCTION

Fatigue cracks usually initiate at the weld in steel bridges, which can be divided into two types, including load-induced fatigue cracks and distortion-induced fatigue cracks, of which about 90% of fatigue cracks are caused by secondary stress due to out-of-plane distortion at fatigue details (Connor & Fisher 2006). Full-scale fatigue test proves that the fatigue life of vertical stiffener web gaps in steel girder bridges is affected by distortion ratio and nominal stress ratio (Wang et al. 2022). A new type of rubber-tyred tram transit system consisting of a rubber-tyred tram and guideway girder bridge is gradually being used in China. The guideway is composed of two I-girders connected by a transverse connection system. The running wheel of the rubber-tyred tram runs on the flange of I-girders because of lacking deck. Under the action of live loads, the distortion will cause high local flexural stresses and lead to the initiation and propagation of fatigue cracks at the flange-web welded details of the I-girder as shown in Figure 1.

Figure 1. Out-of-plane distortion at the flange-web welding detail.

With the development of fracture mechanics theory and extended finite element method, the numerical simulation of fatigue crack propagation has made great progress. XFEM eliminates the need to remesh during simulated crack growth, greatly improving the solution efficiency

(Belytsehko & Black 1999; Stolarska et al. 2001). XFEM reflects the discontinuity of the crack through the special enriched functions, increasing the degree of freedom of element nodes around the crack (Moës et al. 1999). Compared with the traditional finite element method, XFEM can well simulate the mixed-mode cracks propagation of steel bridges (Wang et al. 2020). Based on the theory of linear elastic fracture mechanics (LFEM), Xiao et al. (2008) analyzed the fatigue stress under vehicle loads and estimated the life of the rib-to-deck joints in orthotropic steel decks. Zhan et al. (2017) simulated fatigue crack growth and evaluated the total fatigue life of components based on the XFEM. It was found that the crack propagation behavior and the predicted total fatigue life are consistent with the fatigue test results. XFEM has also been successfully applied to simulate fatigue cracking in steel bridges due to out-of-plane distortion (Mahmoud & Miller 2016; Wang et al 2017). Mahmoud and Miller (2016) used XFEM to explore the fatigue mechanism induced by out-of-plane distortion and determined the effectiveness of XFEM in simulating high-cycle fatigue crack growth.

The existence of welding residual stress has an important role in the fatigue crack propagation behavior in steel bridges. Barsoum (2009) confirmed that fatigue life predictions agree well with experimental results when residual stress is considered in crack propagation analysis. Wang et al. (2020) used the extended finite method of coupled welding residual stress field to numerically simulate the fatigue crack propagation of the I-girder web gap. The results show that the shape and propagation direction of the fatigue crack is consistent with the physical fatigue test results.

This paper researches the fatigue damage mechanism of flange-web welding details. The stress distribution of the flange-web welded detail is calculated considering the secondary stress caused by the out-of-plane distortion under fatigue loads. The welding residual stress field of fatigue details was obtained by simulating the flange-web fillet weld welding process. Fatigue crack propagation simulation under multi-field coupling is carried out to investigate the fatigue crack propagation mechanism of the flange-web weld toes under eccentric loads.

2 FATIGUE SIMULATION MODEL

Three-span continuous guideway girder is established based on the tram test line under construction. Flange-web welding fatigue detail is selected as the research object at the middle of the side span, as shown in Figure 2. For the full-bridge shell model, the total length is 89.9 m, with 2 intermediate supports (29.6 m+30 m+29.6 m). For the entity sub-model, the size of the fillet welds is 8×8 mm, and the dimensions of the flange and the web are 380×200×26 mm and 200×200×12 mm, respectively. Shell-solid coupling constraint is adopted between the solid sub-model and the full-bridge shell model, and the boundary conditions of the full-bridge model are shown in Figure 3.

Figure 2. Three-span continuous guideway girder (Unit: mm).

The wheel track of the rubber-tyred tram is 1380 mm, and the wheelbase is 4200 mm. In operation by 4 vehicles as a group, the wheelbase between adjacent vehicles is 3800 mm.

Figure 3. Boundary conditions of guideway girder.

The running wheel's load area is 195 mm × 130 mm on the guideway girder's flange plate, and the fixed axle load $P = 60$ kN. The fatigue load model adopts the vehicle formation in fixed personnel operation. Figure 4 gives the wheel load distribution of the rubber-tyred tram. And Figure 5 shows the relative position of the axle to the fatigue detail for longitudinal loading case 8.

Figure 4. Fatigue load model (Unit: mm).

Figure 5. Longitudinal loading conditions (Unit: m).

3 FATIGUE CRACK PROPAGATION MECHANISM ANALYSIS

3.1 Live load stress analysis

The out-of-plane distortion of the flange-web welding details occurs below the load position, which causes large bending stress. Eight longitudinal working conditions are set up, and eight axles are applied to the flange plate above the fatigue details in turn (Figure 5). The stress component of the P1 path under live load is shown in Figure 6(a). Four paths are selected to characterize the stress field distribution caused by out-of-plane distortion under the most unfavorable conditions, as shown in Figure 6(b).

The stress extraction path is selected from the 1/2 section of the solid model. The starting point of the P1 path is the toe of weld 2 at the web, and the starting point of the P2 path is the toe of weld 2 at the flange plate. Similarly, the starting point of the P3 and P4 paths is the toe of weld 1. In the x -direction, the secondary stress caused by distortion drives tensile stress outside the web and compressive stress inside the web. The x -direction stress component is -49 MPa and -25 MPa at the starting point of P1 and P2, respectively. Without distortion, the x -direction stress component is -30 MPa at the weld toe.

3.2 Welding residual stress analysis

The welding residual stress is calculated by the thermal-stress sequential coupling method. For the thermal analysis, boundary conditions are not required to establish, and DC3D8 eight-node

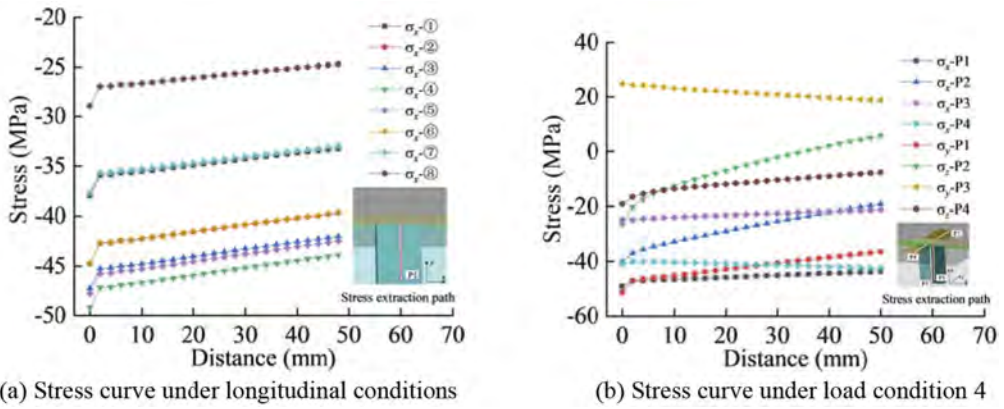

Figure 6. Live load stress distribution under longitudinal conditions.

linear hexahedron heat transfer elements are used to calculate the welding temperature field at the heat transfer analysis steps. In the thermo-mechanical analysis, the boundary conditions of the solid model are shown in Table 1. And the welding residual stress field is calculated by C3D8R eight-node linear hexahedron elements. The weld formation is simulated by model change in the welding process. The element size of the weld area is about 2 mm and away from the weld area is 4 mm. The thermal physical parameters of Q345 steel are shown in Figure 7.

Table 1. Thermal-force analysis model boundary condition.

Location	Constrain state	
	Weld 1	Weld 2
S1	$U_x = U_y = 0$	$U_x = U_y = 0$
S2	$U_x = U_y = 0$	$U_x = U_y = 0$
S3	$U_z = 0$	$U_z = 0$

Figure 7. Material properties of Q345.

The web and flange of the guideway girder are connected by double-sided fillet welds, weld 1 on the inner side of the web and weld 2 on the outer side of the web. The welding heat source adopts the double ellipsoid heat source model, and the welding temperature field is shown in Figure 8. The temperature of the grey part is greater than the melting point of the steel (1450 °C) during the welding process. After welding, the temperature of the solid model is cooled to 20 °C.

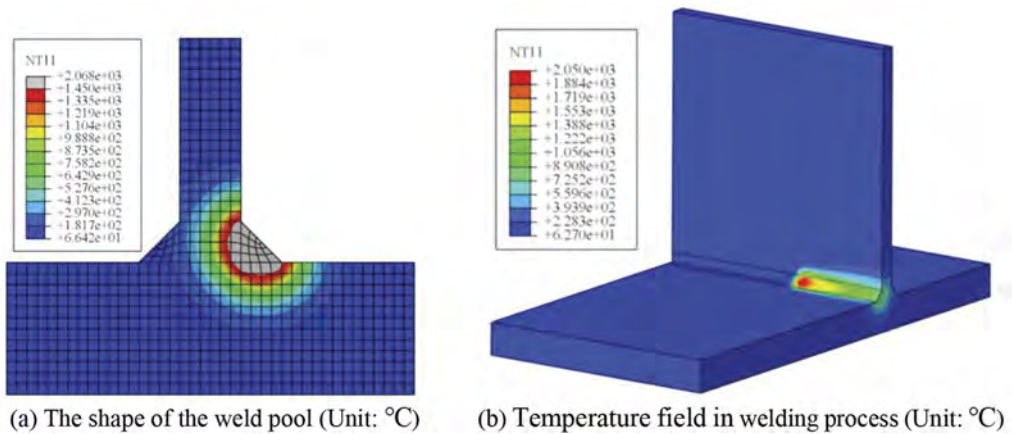

Figure 8. Welding temperature field.

In thermo-mechanical analysis, the welding temperature field is acted as a temperature load to the welding residual stress model with defined boundary conditions. After the welding is completed, there is a large welding residual tensile stress near the weld, which is close to the yield strength of the steel. And the Von Mises stress is shown in Figure 9(a). To accurately obtain the residual stress field distribution at the flange-web weld, the P1, P2, P3 and P4 stress extraction paths are selected for residual stress analysis, as shown in Figure 9(b). The x -direction stress component is 372 MPa and -49 MPa at the starting point of P1 and P2, respectively. In addition, the toe of weld 2 was mainly under cyclic compressive stress during the cyclic loading. Therefore, the flange-web welded details are vulnerable to fatigue cracking at the toe of weld 2.

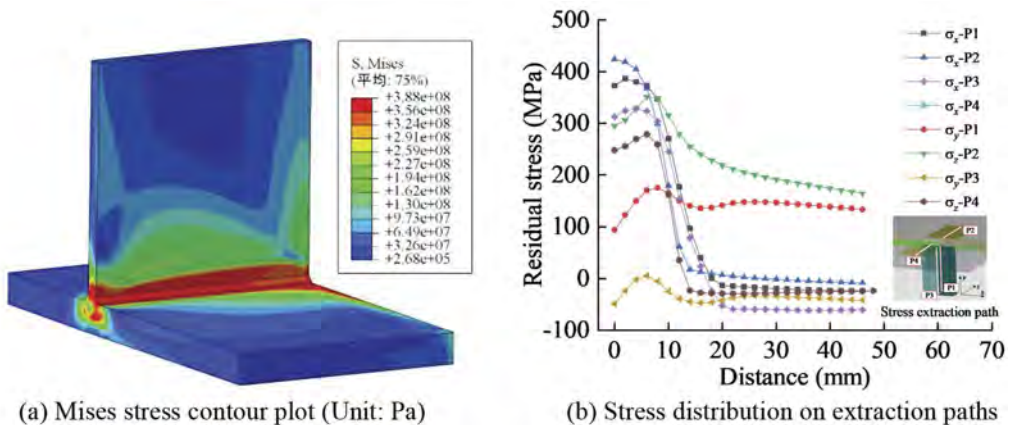

Figure 9. Welding residual stress distribution.

3.3 Fatigue crack growth analysis

When the residual stress is not considered, the weld toe is in a compressive state under vehicle load. In contrast, after the introduction of welding residual stress, this place is in a tension-tension state. As a result, fatigue cracks initiate and propagate there.

The crack propagation process in fatigue numerical simulation is characterized by strain energy release rate, calculated by the virtual crack closure technique (VCCT) (Shivakumar 1998). The classical Paris law is rewritten in the numerical fatigue simulation, and the fatigue crack propagation criterion is defined:

$$\frac{da}{dN} = c_1 \Delta G^{c_2} \quad (1)$$

where c_1 and c_2 are material parameters; ΔG is the strain energy release rate range. When $G_{th} < \Delta G < G_{pl}$, the crack will propagate stably under Paris law. Where G_{th} is the threshold of strain energy release rate; G_{pl} is the upper limit of strain energy release rate.

The initial fatigue crack size was assumed as $a_0/2c_0 = 0.5 \text{ mm}/2 \text{ mm}$, and the propagation path of the crack is shown in Figure 10. Figure 11 displays the variation in crack length on the web and flange surfaces during fatigue loading. When the initial fatigue crack begins to expand, the fatigue crack growth direction is deflected by 90 degrees. After 1.1 million times of fatigue loading, the fatigue crack propagates along the web simultaneously in the direction of the upper and lower flange plate. Until 1.6 million fatigue loadings, the fatigue crack penetrates the welds on both sides of the web, and the crack tip is semi-elliptical in the cross-section of the flange plate. The flange is penetrated by fatigue cracks during the 1.9 millionth fatigue loading. As shown in Figure 10(d), after 2.5 million cycles, the fatigue crack propagated to 70 mm, 48 mm and 96 mm in the web, top and bottom surfaces of the flange plate, respectively.

Figure 12 and Figure 13 show the cumulative strain energy release rates G_I , G_{II} and G_{III} in crack propagation process in the web and flange plate, respectively. As can be seen from Figure 12, mode I was the dominant crack mode, and G_{II}/G_I and G_{III}/G_I were respectively 0.07 and 0.15, with crack propagating along the web. As illustrated by Figure 13, G_{II}/G_I and G_{III}/G_I were respectively 0.07 and 0.15, with cracks propagating in the flange plate. And fatigue cracks in the flange plate Mode I.

4 CONCLUSIONS

Digital fatigue tests are conducted to investigate the mechanism of distortion-induced fatigue at flange-web welded details in guideway girder, based on XFEM and linear elastic fracture mechanics. The welding residual stress field and live load stress field are calculated. According to the analysis results, the following conclusions can be drawn:

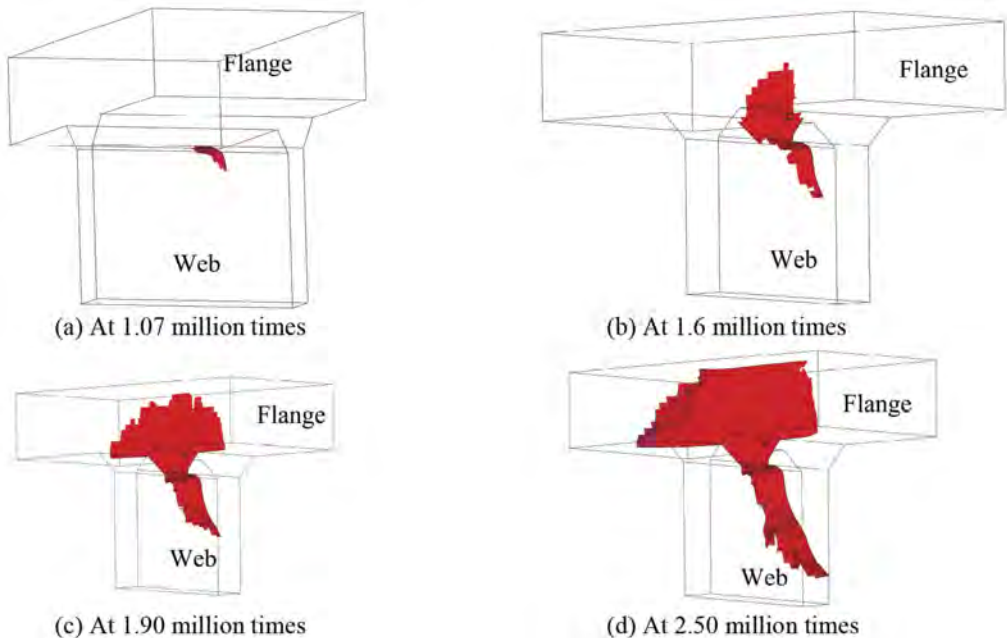

Figure 10. Propagation behavior of the crack.

Figure 11. Fatigue crack length on web and flange surfaces.

Figure 12. Cumulative strain energy release rate of crack propagation at web.

Figure 13. Cumulative strain energy release rate of crack propagation at the flange.

- (1) Fatigue cracks of flange-web welded details propagating at the web and flange plate are Mode I leading mixed-mode cracks of Modes I, II and III and Mode I, respectively. And the out-of-plane deflection occurs during the fatigue crack propagation at the web.
- (2) There is welding residual stress at the flange-web weld toes, and the von Mises stress peak is close to the yield stress of steel. After coupling the residual stress field, the compressive-compressive stress cycle caused by vehicle load is transformed into a tensile-tensile stress cycle in the fatigue details, which leads to the initiation and propagation of fatigue cracks. In the manufacture of guideway girders, the welding sequence should be optimized to reduce the welding residual stress, or the ultrasonic hammering technique should be used to hit the weld toe at fatigue details to reduce the influence of welding residual stress.
- (3) The distortion affects the local stress distribution of the steel bridges. The design of the guideway should avoid eccentric setting web or decrease the distance of adjacent vertical stiffeners to reduce out-of-plane distortion.

3-D segmentation of concrete spalling in point cloud using unsupervised clustering and plane fitting

Y. Zhang

Aalto University, Espoo, Finland

B. Xia

Silo AI, Helsinki, Finland

ABSTRACT: Spalling is one of the typical damage types of concrete structures. Concrete spalling occurs with local concavity and volume loss, leading to a certain range of load capacity reduction. Recently, with the rapid development of structural health monitoring and non-destructive inspection technologies, it becomes possible to perform high-resolution measurements and capture rich details of civil structures. By using laser scanners, Lidar scanners, or photogrammetry techniques, dense point clouds of structural faces can be reconstructed. Those dense point cloudscan describe both global and local geometries of structures in detail, which can be further used for damage assessment. However, the researches on identifying and localizing structural damage on concrete structures based on PC processing are still limited. Therefore, in the article, we propose a method to segment concrete spalling in 3-D point clouds of concrete structures. Unsupervised clustering methods are used to segment the point cloud into several classes that represent different faces of the target structure or structural member. Then a plane is fitted to each class of the point cloud using the Least Squares method. Based on the distances from the points to the corresponding fitted plane, a threshold can be determined, and the points that are far off the plane can be identified and localized. Those identified points can be used to present concrete spalling damage. To validate the proposed method, an experiment was conducted on a reinforced concrete beam. The result shows that the volume loss of the concrete beam was successfully identified and localized. Using a distance threshold, the points of damage can be segmented from the point cloud. Therefore, the feasibility of the proposed method was fully demonstrated.

1 INTRODUCTION

Spalling is one of the most common types of damage on concrete structures. Spalling describes the cracked and delaminated areas of concrete. It is mainly caused by corrosion or oxidization of reinforcing rebar, freeze-thaw cycling, subpar quality concrete, improper curing, etc. Spalling leads to local volume loss and reduces the load-bearing capacity of concrete. It can spread on concrete structures and accelerate degradation. Therefore, spalling greatly affects the health state of concrete structures. Concrete with severe spalling damage had become a threat to public safety. To address this challenge, structural health monitoring (SHM) (Boller et al., 2009) and non-destructive testing (NDT) (Dwivedi et al., 2018) technologies can be used for acquiring information and analysing the health state of concrete structures.

Recently, SHM and NDT technologies have greatly powered the management and maintenance of civil structures. The advanced sensing technologies enable monitoring structural behaviours with enriched information, for instance, vibration (Zhang et al., 2019), image (Zhang and Li, 2022; Zhang et al., 2022), strain, temperature, and point cloud data of

structures can be acquired for further analyses. Long-term monitoring can accumulate large scale of monitoring data which provides a solid foundation for data-driven modelling methods, especially, machine learning (ML) and deep learning (DL) (LeCun et al., 2015; Goodfellow et al., 2016). These data-driven methods can be used for establishing mappings or functions to make predictions. The sensing technology and data-driven methods provide full potential for digging deeper into the concrete spalling issue.

The existing literature mainly discusses the detection and evaluation of concrete spalling using 2-D image processing and DL modelling (Cha et al., 2017). Deep learning models were trained by labelled images to output bounding boxes or segmented images. Areas with concrete spalling in image data are pointed out with bounding boxes or pixels with different colours. Such a method can perform a fast examination with satisfactory detection accuracy. However, researches on spalling quantification or quantitative analyses of spalling still remain insufficient.

As concrete spalling is generally with apparent volume losses, depth information is of great significance to analyse the damage. The commonly used methods that are based on 2-D image data cannot acquire depth information. Thus, a 3-D point cloud has great advantages to deal with depth-related issues, like quantitative analysis of concrete spalling. Indeed, acquiring point cloud data has become simplistic nowadays. Despite the expensive laser scanners for industrial applications, lidar scanners on portable devices or even photogrammetry techniques are quite handy tools to scan objects and generate point cloud data. Such a technological advance can also benefit the detection and evaluation of concrete spalling.

Overall, this article presents a method to perform 3-D segmentation of concrete spalling using point cloud processing, unsupervised clustering, and plane fitting. Those identified points can be used to detect concrete spalling damage in a rapid manner and provide the potential for further analyses.

2 METHODOLOGY

2.1 Overview of the proposed method

An overview of the proposed spalling segmentation method for point cloud data is shown in Figure 1. Point clouds can be generated in multiple approaches as mentioned in the introduction, for instance, laser scanning, Lidar scanning, photogrammetry (Mikhail et al., 2001), etc. In this study, photogrammetry was chosen because of its convenience and simplicity. Photos taken by ordinary commercial cameras are capable to be directly used for generating 3-D point clouds of the objects in the photos via the structure from motion (SfM) algorithm (Ullman, 1979; Özyeşil et al., 2017).

Raw point clouds generated by the above methods normally contain large numbers of points which represent the desired objects, backgrounds, and noises. To make the raw point clouds feasible to be clustered, applying pre-processing to the point clouds is necessary. The pre-processing includes cropping, down-sampling, and noise reduction. The cropping operation removes the undesired parts and leaves only the structure in the point cloud. Down-sampling reduces the number of points in the cloud, so that the computational speed can be significantly improved. Noise reduction can remove the outliers in the point cloud.

Figure 1. Flowchart of the proposed method.

The processed local point cloud with the region(s) of concrete spalling is clustered into several classes to represent different faces. Unsupervised learning algorithms, such as k -means, DBSCAN, etc., can be used for clustering. Then each cluster of the point cloud is fitted to a plane. Finally, by evaluating the distance from each point in the cloud to the fitted plane with a threshold, the points that are further away from the plane can be identified. As the points in the spalling regions are generally far off the fitted plane, the proposed method can achieve remarkable performance in detecting the points of spalling in the cloud of concrete structures.

2.2 Point cloud pre-processing

Voxel down sample can effectively reduce the number and the density of the point cloud. The algorithm has two steps. The points are embedded into voxels, and then each voxel outputs a point by averaging the coordinates of the embedded points in the voxel.

Statistical outlier removal algorithm removes the points that are further away from their neighbour points compared to the mean value of the entire point cloud. Two parameters of the algorithm are the number of neighbour points and the standard deviation of the mean distances across the point cloud.

2.3 Gaussian mixture model

Gaussian mixture model (GMM) is an efficient and powerful clustering algorithm (Press et al., 2007). It implements the expectation maximization (EM) algorithm (Dempster et al., 1977) for fitting and mixing Gaussian models. Then the fitted models can be used for clustering the data into a specific number of classes. To achieve robust performance, an initializer such as k -means (Hartigan & Wong, 1979), k -means ++ (Vassilvitskii & Arthur, 2006) can be used to initialize the weights, means, and precisions of the GMM. As GMM is a standard method, detailed descriptions are omitted in this article.

2.4 Plane fitting

Plane fitting of points is achieved by using the Least Squares method. Planes can be defined as Equation (1), in which the normal to the plane is $\langle A, B, C \rangle$. Equation (1) can also be simplified to Equation (2). Fitting 3-D points to a plane is calculating the optimal a , b , and c , which can be defined as an optimization problem described in Equations (3-6). In Equations (4), (6) and (7), x_i , y_i , and z_i are the coordinates of each point. The solution of a , b , and c for plan fitting can be finally obtained using Equation (7).

$$Ax + By + Cz + D = 0 \quad (1)$$

$$z = ax + by + c \quad (2)$$

$$a, b, c = \operatorname{argmin}(L) \quad (3)$$

$$L = \sum_{i=1}^n (ax_i + by_i + c - z_i)^2 \quad (4)$$

$$\begin{cases} \frac{\partial L}{\partial a} = 0 \\ \frac{\partial L}{\partial b} = 0 \\ \frac{\partial L}{\partial c} = 0 \end{cases} \quad (5)$$

$$\begin{pmatrix} \sum x_i^2 & \sum x_i y_i & \sum x_i \\ \sum x_i y_i & \sum y_i^2 & \sum y_i \\ \sum x_i & \sum y_i & n \end{pmatrix} \begin{pmatrix} a \\ b \\ c \end{pmatrix} = \begin{pmatrix} \sum z_i x_i \\ \sum z_i y_i \\ \sum z_i \end{pmatrix} \quad (6)$$

$$\begin{pmatrix} a \\ b \\ c \end{pmatrix} = \begin{pmatrix} \sum x_i^2 & \sum x_i y_i & \sum x_i \\ \sum x_i y_i & \sum y_i^2 & \sum y_i \\ \sum x_i & \sum y_i & n \end{pmatrix}^{-1} \begin{pmatrix} \sum z_i x_i \\ \sum z_i y_i \\ \sum z_i \end{pmatrix} \quad (7)$$

After that, the distance between each point to the fitted plane is calculated based on Equation (8). A threshold is manually assigned to evaluate whether the point is out of a plane. The out-of-plane points are then identified and localized as the points at the region(s) of concrete spalling.

$$d = \frac{|ax_0 + by_0 - z_0 + c|}{\sqrt{a^2 + b^2 + 1^2}} \quad (8)$$

3 EXPERIMENT SETTINGS

To validate the proposed method for 3-D segmentation of concrete spalling in a point cloud, an experiment was conducted on a reinforced concrete beam. One photo of the beam is shown in Figure 2. The length of the beam is 82 cm. Concrete volume loss is on one edge of the beam, as shown in Figure 3. The length of the damage is about 5 cm, and the depth of the damage is about 1 cm. Over 100 photos of the beam were taken from different perspectives for generating the 3D dense point cloud of the beam.

Figure 2. Photo of the concrete beam.

Figure 3. Spalling on the beam.

4 RESULTS

The 3-D dense point cloud of the scene was generated using an unordered photo set and the SfM algorithm, as shown in Figure 4. This procedure was realized using the Meshroom software (Griwodz et al., 2021). As the number of points is very large and the density of the point is too high, pre-processing was performed on the raw point cloud.

Figure 4. 3-D model of the scene generated by SfM.

The cropping operation was performed manually using MeshLab software (Cignoni et al., 2008). Then, voxel down sample and noise reduction were performed in Python environment and Open3D (Zhou et al., 2018). The parameters were determined by several rounds of trial and error. Figure 5 shows the cleaned local point cloud after the pre-processing. The point cloud describes three faces of the beam, because photos of the bottom face could not be taken and no point on the bottom face was generated in the 3-D reconstruction. The volume loss is presented clearly on the point cloud.

Figure 5. Cleaned local point cloud at the damage region.

The points in the local point cloud were then clustered into 3 classes for representing the three faces of the beam via the GMM algorithm which is included in the scikit-learn package (Pedregosa et al., 2011). The number of components is 3 because of the 3 faces. The covariance type is “tied” which means that all components share the same general covariance matrix. To achieve a robust performance of GMM clustering, the k -means algorithm was used as the initializer to initialize the weights, the means, and the precisions. The covariance type is tied, which means all components share the same general covariance matrix. The clustering result is shown in Figure 6, in which the points were accurately clustered based on the faces even at the damage region and edges, demonstrating the effectiveness of the GMM algorithm for this task. For structures with simpler geometries, directly using the k -means algorithm for clustering is also feasible, as proved in the article (Nakamizo and Nishio, 2022).

Figure 6. Result of clustering.

As the damage is at the edge of the beam, only the yellow and green point clusters are involved in the damage, as shown in Figure 7. Plane fitting and distance evaluation were performed on these two clusters respectively. Using the green cluster in Figure 8 as an example, the damage is clearly profiled.

Figure 7. Two faces involved in the damage.

Figure 8. One of the two faces involved in the damage.

Implementing the plane fitting algorithm as introduced beforehand, a plane was accurately fitted to the green points, as shown in Figure 9. A side view of the green points and the corresponding plane was shown in Figure 10 to provide additional information about the result. The points at the damage region are out of plane clearly in Figure 10.

Subsequently, after several rounds of trial and error, a threshold of 1.5 mm was assigned to identify and localize the points at the damage region. Figure 11 shows the result of point segmentation, in which the points at the spalling region are successfully identified and marked with red colour.

Repeating the same procedure on the yellow point cluster and summarizing the results for each point cluster, the final result of the point segmentation at the spalling region was obtained, as shown in Figure 12. The result was demonstrated in three different perspectives in the subplots, and very high accuracy of point segmentation was achieved. Even though the depth of the concrete damage is about 7 mm which is relatively shallow, the remarkable point segmentation result can be achieved. In most other engineering cases which have concrete damage deeper than 7mm, better point segmentation results are expected.

Figure 12. The final result of the point segmentation at the spalling region.

5 CONCLUSIONS

In this article, a simple yet efficient method for segmenting the points of spalling in the point cloud of concrete structure was proposed. The method combines GMM clustering, plane fitting, and distance evaluation. Through an experiment on a concrete beam, the effectiveness and feasibility of the proposed method were demonstrated.

As this research is in its beginning phase, currently the method includes several manual steps, such as cropping the raw point cloud and parameter tuning. The limitation of the method is that the distance threshold needs to be determined manually by trial and error. In our future work, the proposed method will be updated with more automatic processes and less manual intervention.

ABSTRACT: The integral joint of steel truss girder is widely used in the construction of modern large-span suspension bridges due to its advantages of simple course of manufacture and installation. However, the complex cross-section geometry and the inevitable existence of welding residual stress during the welding process, which would cause fatigue problems under the long process of cyclic vehicle loading. A framework for fatigue assessment of integral joints of steel truss girder in large-span suspension bridge is thus presented in this study. The main features of the framework include multi-scale finite element bridge model, vehicle induced stress, the simulation of complex welding residual stress field, and the crack propagation simulation of fatigue-prone details of integral joints. Based on the Linear Elastic Fracture Mechanics (LEFM) and Extended Finite Element Method (XFEM), the digital fatigue test was carried out. According to the digital fatigue test results, the cracking growth mode of fatigue-sensitive details of integral joints in steel truss girder were determined, and the fatigue damage characteristics of fatigue-prone details were analyzed. The results indicate that the developed framework is applicable and the Mixed-mode crack propagation law was identified in fatigue-prone details, and the fatigue growth life will be overestimated irrespective of the welding residual stress.

1 INTRODUCTION

In recent years, the steel truss girder is widely used in long-span highway or railway suspension bridges due to its light weight. The fully-welded integral joint are commonly used in steel truss girder for it can be prefabricated in the factory and simple installation. However, this kind of welded integral joints generally have complex cross welds, and large welding residual stress will exist around the fatigue details during the welding process. Under the superimposed of cyclic load and welding residual tensile stress, the fatigue cracks easily initiated and propagated in integral joints (Wang et al. 2013), which greatly affects the durability of long-span suspension bridges.

At present, the *S-N* curve method is mainly used to assess the fatigue life of integral joints (Cai et al. 2017, Liu et al. 2019, Wei et al. 2017), such as the nominal stress method, hot-spot stress method, effective notch stress method, etc. Both methods all ignore the initial crack of integral joints, and cannot describe the fatigue crack growth stage. Many studies have shown that the fracture mechanics evaluation method can be effectively used for the research on fatigue crack growth of steel bridges (Wang et al. 2019, Wang et al. 2020), overcoming the

deficiency that the traditional S-N curve method cannot consider the initial defects existing in actual structures. The fracture mechanics evaluation method can generally be divided into numerical methods and analytical methods. Because of simple application and avoiding complex analytic solution, the numerical method shows broad application prospects. Belytschko and Black (1999) of Northwestern University in the United States put forward a numerical solution method in 1999 - the Extended finite element method (XFEM). This method describes the discontinuous displacement of the crack surface and crack tip by adding displacement expansion terms during the crack growth simulation.

In this paper, the fatigue crack growth law of a out of plane deformation fatigue detail of a suspension bridge steel truss girder integral joint is studied. Based on the linear elastic fracture mechanics method (LEFM) and XFEM, the crack propagation law is analyzed by introducing an initial fatigue crack at the hot-spot. In addition, based on the sequential coupling principle, a refined numerical model was established to consider the welding residual stress. By comparison, the influence of welding residual stress on fatigue crack growth law and fatigue crack growth life was discussed, and the effectiveness of the numerical simulation method was verified.

2 CASE STUDY

A Double deck steel truss suspension bridge was selected for analysis, and the overall layout of the bridge is shown in Figure 1. The upper deck is a two-way 6-lane expressway with a total width of 33.5 m; the lower deck of the main bridge is a two-way 4-lane urban road with a total width of 25.0 m. Through stress characteristic analysis and fatigue sensitive details identification, the mid-span and short suspender area is selected for fatigue assessment.

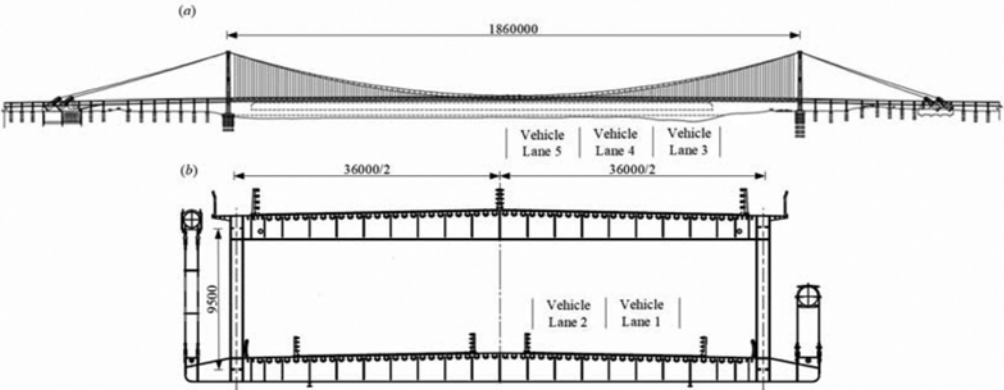

Figure 1. The layout of the bridge (Unit: mm): (a) bridge elevation; (b) cross section of stiffing girder.

3 FINITE ELEMENT ANALYSIS

3.1 Multi-scale bridge model

In order to display the characteristics of the whole bridge and the local fatigue detail geometric, a multi-scale finite element model is established. Firstly, the BEAM/TRUSS element is used to simulate the whole bridge except for the segmental double-layer steel truss girder, then the SHELL/SOLID element is used to establish the segmental double-layer steel truss girder. On the one hand, the fatigue detail geometry can only be simplified as a node when used SHELL element to simulate it. On the other hand, using SOLID elements to simulate all the double deck steel truss girder will lead to too many elements, which will affect the calculation efficiency. In order to accurately resolve the stress distribution around the fatigue details in

the integral joint and consider the calculation efficiency, a local area including fatigue details is selected in the segment model and the local area is established by using SOLID element, as shown in Figure 2(c). The shell element is used to simulate the remaining part of double deck steel truss girder. The selected fatigue detail for analysis are far away from the boundary area of the multi-scale model to ensure that the stress distribution of fatigue details is reasonable. To clarify the crack growth law at the fatigue detail, an elliptical initial crack is inserted at the hot-spot, and the crack length a is 0.5 mm, the crack depth c is 1.0 mm, as shown in Figure 2(d).

Figure 2. Multi-scale FEM of the suspension bridge (Unit: mm).

3.2 Welding process simulation

During the welding process simulation, the sequentially coupled thermo-mechanical analysis was adopted to predict the temperature history and welding residual stress distribution of the fatigue detail. The temperature field was calculated first, and then the temperature history of each node was imported as the initial state for the thermal stress analysis to obtain the distribution of WRS. A local refined three-dimension finite element model, including the fatigue detail was established, as shown in Figure 2(c). The 8-node hexahedral element DC3D8 and C3D8R were used to calculate the temperature history and WRS, respectively. The geometry and node number of the FEM are consistent, and only the element type is changed. The mesh size around the thermomechanical coupling region is set as 2mm and the symmetrical constraints is used in the thickness direction of all plates. As the material of the steel truss girder is Q420qd, the thermal performance parameter of Q390 high strengthen steel (Sun et al. 2016) was selected for conservative estimate the distribution of WRS. The welding wire material and the base metal are taken as the same material. To simulate the actual multi-layer welding situation, the multi-layer multi pass weld was simulated, and a cooling step is set between two adjacent welds to ensure a suitable interlayer temperature.

3.3 Fatigue loading

The FLM 2 is a double-truck model in Chinese design code for steel bridges (Ministry of Transport of the People's Republic of China 2015) to the fatigue design of members and connections, in which the longitudinal distance between two successive trucks is no less than 25.7 m, recommended in the specification. The spacing between two successive trucks is defined as the length between the last axle of the prior truck and the first axle of the rear truck. To obtain the stress response of the fatigue detail under truck loading, the FLM 2 was

used as the fatigue design loads in this paper, and the longitudinal distance between the two successive trucks was assumed as 25.7 m. The contact area between tires and pavement is defined as 0.35 m × 0.75 m considering the diffusion effect of asphalt pavement along the 45 degree angle.

4 MAJOR RESULTS AND DISCUSSION

4.1 Distribution of weld residual stress

In the thermal analysis, the heat source model will directly affect the accuracy of the temperature history as well as the WRS. A commonly used volumetric heat source model with a double ellipsoidal distribution proposed by Goldak et al. (1984) was applied to simulate the welding heating process. The heat source is expressed as follows:

$$q(x, y, z, t) = \frac{6\sqrt{3}f_f Q}{a_1 b c \sqrt{\pi}} e^{-3(z-vt-z_0)^2/a_1^2} e^{-3x^2/b^2} e^{-3y^2/c^2} \quad (1)$$

For the rear heat source:

$$q(x, y, z, t) = \frac{6\sqrt{3}f_r Q}{a_2 b c \sqrt{\pi}} e^{-3(z-vt-z_0)^2/a_2^2} e^{-3x^2/b^2} e^{-3y^2/c^2} \quad (2)$$

where f_1 and f_2 are constants of the heat deposited in the front and rear quadrants; Q is the heat input per unit time; v is the welding speed; t is the welding time; z_0 is the position of the heat source in the z -direction at the beginning. The heat source model geometric parameters a_1 , a_2 , b and c are independent and they can have different value.

To ensure complete penetration of weld during the welding heating process simulation, the heat source parameters were modified according to the melting pool geometry. Figure 3 shows the temperature field simulation results during welding process of the fifth and seventh weld. It can be seen from Figure 3 that the temperature in the weld area is the highest, and the molten pool geometry is basically consistent with that of the weld during welding process simulation, which demonstrates the selected heat source parameters are reasonable.

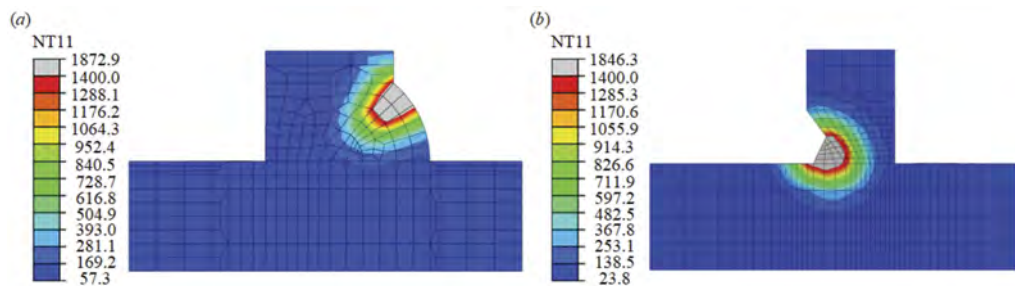

Figure 3. Simulated molten pool geometry and temperature contours (Unit: MPa): (a) $t = 2485.6$ s (welding process of fifth weld pass); (b) $t = 14525.5$ s (welding process of seventh weld pass).

After welding temperature field calculation, the temperature simulation results of each node are imported as the initial state to predict the WRS. The von Mises stress distribution results after the sixth weld cooling and final weld cooling are shown in Figure 4. It can be seen from the Figure 4 there is a large tensile WRS near the weld, and the maximum Mises stress is close to the yield strength of the steel Q420qd. In order to further analyze the WRS distribution at the fatigue crack growth location, the WRS distribution on different paths in the weld area is

extracted, as shown in Figure 5. It can be seen that the residual stress value near the corner continuous weld is about 100 MPa, and the WRS away from the corner weld increases gradually.

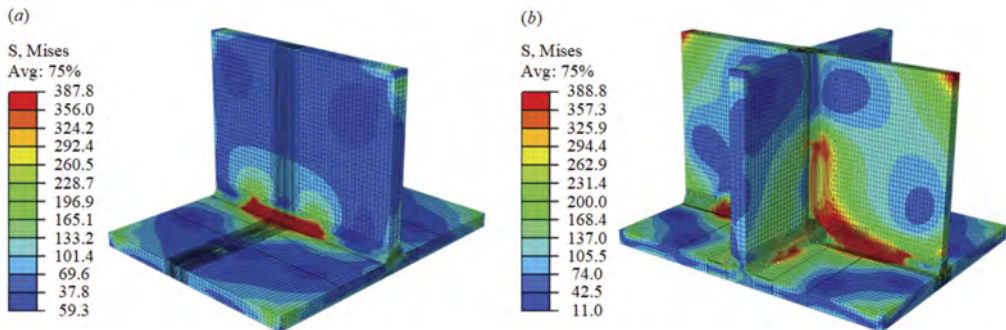

Figure 4. The simulated distribution of WRS (Unit: MPa): (a) after cooling of the sixth weld; (b) after final weld cooling.

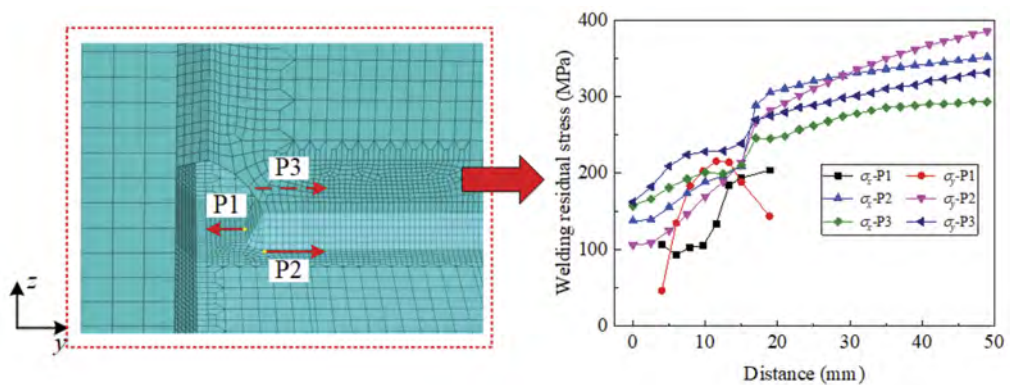

Figure 5. Distribution of WRS along extraction path during the simulation.

4.2 Stress response of typical fatigue detail

Various load conditions were designed to determine the most unfavorable loading conditions of FLM 2, as shown in Table 1. The stress responses at the fatigue details under different loading conditions without considering WRS are calculated respectively, as shown in Figure 6. It can be seen that the stress history presents a multi-peak distribution law. When the fatigue load truck is close to the fatigue detail position, the stress of the fatigue detail is maximum. Under all loading conditions, the stress amplitude of fatigue details under load case 5 is the largest and the maximum stress amplitude is 30.5 MPa.

4.3 Digital fatigue test results

Because physical fatigue test is expensive, digital fatigue test based on fracture mechanics method has been widely used in recent years. The existing research shows that Pairs model can well describe the crack growth law. To more accurately evaluate the crack growth rate of the selected fatigue detail, the Pairs model was adopted here, as shown in Equation 3.

Table 1. Designed load scenery of FLM 2.

Load cases	FLM 2 loading lane
Case 1	Vehicle lane 3
Case 2	Vehicle lane 1 and 3
Case 3	Vehicle lane 3 and 4
Case 4	Vehicle lane 1, 3 and 4
Case 5	Vehicle lane 1, 2, 3, and 4
Case 6	Vehicle lane 1,3, 4, and 5
Case 7	Vehicle lane 1
Case 8	Vehicle lane 1 and 2
Case 9	Vehicle lane 1, 2 and 3

Figure 6. Stress time-history of fatigue detail without considering WRS.

$$\frac{da}{dN} = C(\Delta K)^m \quad (3)$$

where da/dN is the fatigue crack growth rate; C , m are the material constants; ΔK is the range of stress intensity factor.

4.3.1 Crack growth behaviors

In order to clarify the crack growth type at the hot-spot under cyclic FLM 2 loading, an energy based approach was adopted to calculate the deflection angle of the crack surface, the more detail of this method can be found in reference (Erdogan & Sih 1963). Figure 7 shows the fatigue crack growth path under the load case 5. It can be seen from the figures that, without considering the residual stress, the crack surface deflects along the length and depth direction during the crack growth process under cyclic load. After considering the WRS, the crack propagation trajectory basically does not change, indicating that the influence of residual stress on the crack growth type is negligible.

Further analysis shows that after the FLM 2 is loaded in 8.3 million cycles, the crack propagates about 9 mm and 24 mm along the depth respectively with and without considering the WRS. It is conservatively estimated that the crack growth rate will increase about 2.7 times considered the WRS.

4.3.2 Cumulative strain energy release rate

In order to further determine the crack growth law at the hot-spot, the cumulative strain energy release rate at the crack tip is compared, and the cumulative strain energy release rate is shown in

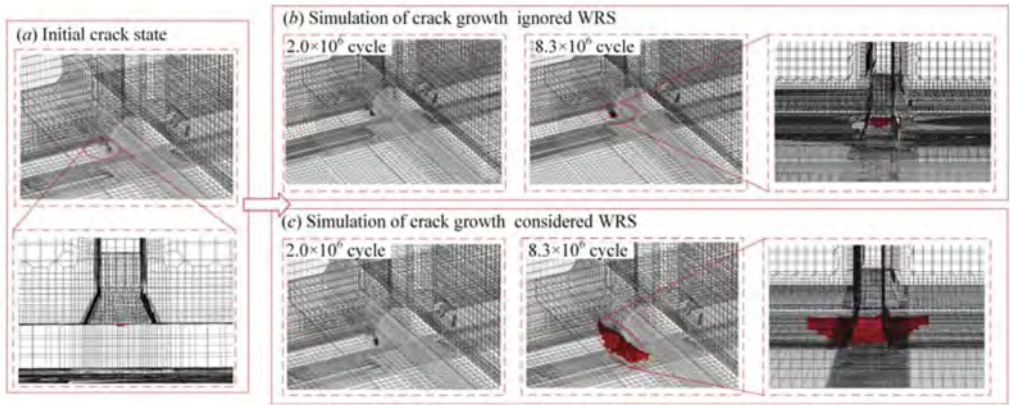

Figure 7. Comparison of crack growth simulation with and without considering WRS.

Figure 8. It can be seen that ΣG_I is far greater than ΣG_{II} and ΣG_{III} during the crack growth process. The value of $(\Sigma G_{III}\Sigma G_I)_{max}$ and $(\Sigma G_{III}\Sigma G_{II})_{max}$ without considering WRS is 4.8% and 5.8%, respectively. The value of $(\Sigma G_{III}\Sigma G_I)_{max}$ and $(\Sigma G_{III}\Sigma G_{II})_{max}$ with considering WRS is 15.4% and 23.5%, respectively. After considering the WRS, the strain energy release rate are significantly increased, The value of ΣG_I is much greater than that of ΣG_{II} and ΣG_{III} . To sum up, the crack growth mode is a mixed mode dominated by mode I with and without considering WRS.

Figure 8. Cumulative strain energy release rate during the crack growth simulation: (a) without considering WRS; (b) considering WRS.

5 CONCLUSIONS

In this study, a framework for fatigue assessment of integral joints of steel truss girder in large-span suspension bridge has been proposed, including the multi-scale FEM model, vehicle induced stress, complex welding residual stress and crack growth simulation. Based on the LEM and XFEM, the full-scale digital fatigue test of integral joint of steel truss girder was carried out, and the main conclusions are summarized as follows:

- (1) To meet the actual welding process, the multi-layer multi pass weld was simulated. Based on the WRS simulation results, it was obtained that the WRS near the fatigue detail is about 100 MPa, which is about 23.8% of the yield stress of main truss material.

- (2) In full-scale digital fatigue test, the influence on crack growth rate is that ΣG_{III} is greater than ΣG_{II} , and ΣG_I is much larger than ΣG_{II} and ΣG_{III} . It can be concluded that the crack growth type is a mixed mode dominated by mode I with and without considering WRS.
- (3) During the most unfavorable cyclic loading condition of FLM 2, it is conservatively estimated that the crack growth rate will increase about 2.7 times considered the WRS, which indicated that the influence of welding residual stress on fatigue crack growth life cannot be ignored.

Life-cycle and evolution of tunnel equipment

G. Nodiroli, M. Katterbach & P. Klaus

Lombardi SA Ingegneri consulenti, Bellinzona-Giubiasco, Switzerland

D. Tillet

Lombardi Ingénierie SAS, Lyon, France

ABSTRACT: The equipment and systems of a tunnel are essential for the safe use of this particular transport route. These systems are often all but invisible for the user and only play a role in certain specific circumstances (in the event of unexpected incidents inside the tunnel). The equipment and systems in question have evolved enormously over the years and made a significant contribution to ongoing safety improvements (PDCA) and the avoidance of potential tragedies. The tunnel is a special environment where an incident such as a fire can suddenly endanger the lives of users and the integrity of the structure. The human factor remains the element that is the most difficult to control, while electromechanical devices have benefited from ongoing and favorable technological development. Today's devices and systems offer increased availability thanks to the introduction of redundancy concepts and deteriorated functionality, and contribute to a safer, less-interrupted management of tunnels.

1 INTRODUCTION

A tunnel has a different value depending on the perspective used to evaluate it. On an economic level, the tunnel may represent an investment that is amortised over the years, while from a sociological perspective a tunnel represents a communication route that shortens distances. On an engineering level, the construction of a tunnel is a technological challenge and the solution to an otherwise difficult if not impossible communication route. Tunnelling evolves over time, requirements change, technology advances rapidly and the expectations of generations change; what was done in the past is no longer accepted, and this also applies to tunnelling. Despite a very conservative approach to tunnel design and operation, it is now possible to apply innovative structural, equipment and functional solutions that bring a general benefit to the overall sustainability of this object. In addition to benefiting from technology directly, the tunnel can benefit from the indirect technological evolution of the users, vehicles that are becoming less polluting, intelligent and interconnected with time.

2 TECHNOLOGICAL EVOLUTION OF EQUIPMENT AND VEHICLES

The technological evolution of tunnel equipment draws on a number of wide-ranging aspects that, when taken together, facilitate the definition of a general evolutionary concept. The evolution of electromechanical equipment inevitably entails the evolution of materials and equipment, a reduction in energy consumption, the development of control and surveillance systems, which have seen major changes over the past few decades, and the evolution of modes of transport, which has also been significant over the same time frame.

2.1 *Evolution of materials and equipment*

The major link between the worlds of industry and tunnels is without question ventilation. Ventilation is a crucial installation when it comes to tunnel safety and, generally speaking, for any underground infrastructure. The evolution of this equipment has not been especially significant; capacities have increased and weights have been reduced, but the biggest change has been in the way these installations are managed. Without ventilation, it would be impossible to use these tunnels for road traffic – and it is often this very same ventilation that determines the degree to which usage is possible. Today, the ventilation can be controlled using sensors capable of measuring the speed and quality of the air very precisely, as well as the exact position of a fire, and all this extremely quickly and reliably. This information, rounded off by the intelligent and distributed control systems, facilitates the management of complex ventilation scenarios, including real-time management of various types of ventilators and associated equipment (dampers, motorized valves, etc.), all while operating a closed-loop control (PID-type controller) that adapts based on the data collected at a given moment inside the tunnel.

2.2 *Evolution of energy consumption*

Tunnels are major consumers of electrical energy, which is mainly necessary for lighting and ventilation (if present) and sometimes for air conditioning systems. Over the past few years, the greatest progress associated with the consumption of electricity has been achieved thanks to the LED technology used in lighting the tunnel and its auxiliary tunnels. Aside from lighting technology, another major development is associated with managing the intensity of the light generated by the lighting fixtures. The result of this is that it is now possible to adjust the setting of each lighting point individually via the control systems. It is now therefore possible to manage the equipment by optimising the energy to be consumed as part of an environmentally responsible approach so as to increase the sustainability of the tunnel.

2.3 *Evolution of the control and surveillance systems*

As with all systems in various fields of application, the tunnel has seen significant development in its control and surveillance systems. In just a few decades, technology has progressed from relay-based to intelligent automated systems. The various subsystems interact with one another in a coordinated way and react automatically to specific incidents (reflex-action concept).

All the information from the different systems is accessible at various levels, meaning that the complete functionality of the tunnel can be verified and managed from a distance, for example with remote video streams. The time required to alert the command centre of an incident is reduced to a minimum and is completely automated. The evolution of the control and surveillance systems has been facilitated by the processing power of the controllers used, the increasingly effective and secure communication networks, and digitisation, which now has an impact on almost all areas. The image below (Figure 1) shows in general terms how the field of application of the controllers (PLC) has been integrated with that of the computers to ultimately converge into integrated architecture. Even if it is possible to assert that the level of automation and surveillance attained thus far is high, development in other areas clearly demonstrates that this evolution is not complete, increasingly guiding us to intelligent interconnected systems and management of an ever-growing volume of data. Artificial intelligence, for example, is continuing to develop for Automatic Incident Detection (AID) systems in conjunction with real-time analysis of video images of the tunnel.

2.4 *Evolution of data processing*

Today, tunnel control and surveillance systems are able to access a lot of the data provided by modern sensors and actuators. However, the tendency to focus on the operational data that directly influence traffic management and infrastructure safety remains. Operating and auxiliary data provided by many sensors and actuators are recorded in databases within the various

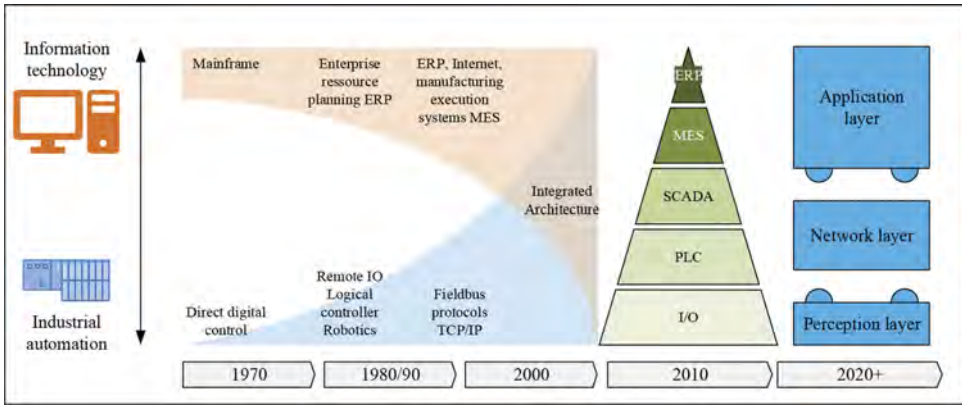

Figure 1. IT-IA convergence and system architectures.

installations' controllers and can be exported as tables or charts using the controller's own software. Recent developments in the processing of data have been moving towards the provision of all this information on an open, flexible platform where the various systems can interact with one another based on these data (Internet of Things – IoT). This platform allows us to access data and to implement applications that target a precise goal while using a program that is independent of the nature and type of controller, sensor or actuator. For example, opacity data from smoke detectors can be used to determine possible alarms inside the tunnel, data on the accumulation of dirt can be used to evaluate maintenance requirements, and measurements of opacity in time and space (provided by several detectors in different locations) facilitate the management of airflows within the tunnel associated with a specific incident. These three applications access data present on a single platform. Over time, it will be possible to add additional information to the platform and to create new applications without compromising what has already been achieved. The architecture of the Internet of Things is represented in a simple format in Figure 2 using two models of three and five layers (Figure 2).

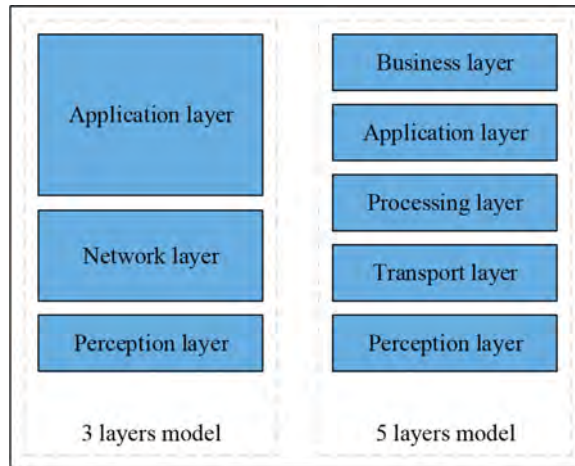

Figure 2. Architecture of IoT (three layers and five layers).

2.5 Evolution of modelling – BIM

The arrival of digitisation to the field of construction now offers the possibility of reproducing each individual component of a tunnel in a 3D model, but the use of this and the resulting innovation of processes represent the main challenge now both for engineers and the project

owner. Currently, a tunnel is represented using construction plans, usually in two dimensions. For the oldest structures, these exist exclusively in paper format. In practice, the representation of a tunnel consists of a significant number of documents in various formats that are then used in different ways depending on requirements. The evolution of digitisation has meant that it is increasingly common to use the “Building Information Modelling” (BIM) method within the context of design. This is a shared knowledge resource for information on a structure and represents a reliable basis for decisions throughout its life cycle – from the initial design and detailed development to implementation, maintenance and, ultimately, demolition. As for the management and maintenance of the installations, the BIM model may be extended during the object’s construction phases to include all relevant information on the installations, components, and operating and security systems. It is therefore possible to create an object’s digital twin, which can be used for management, training, inspection and maintenance activities.

Figure 3. BIM and IoT for tunneling life cycle management.

2.6 Evolution of vehicles

The evolution of vehicles for transporting goods and people is a topical subject that will give rise to significant changes in mobility over the short and medium term. Over the past few years, technology has facilitated a considerable reduction in harmful vehicle emissions and there is a clear prospect of ultimately achieving zero emissions for all vehicles in circulation. Regarding the tunnel, this change will require the modification of sanitary ventilation and various air quality sensors. In addition, the new vehicles behave in a different way to traditional combustion engine vehicles in the event of an incident, and the technological evolution of batteries and new fuels will likely lead to an increase in the potential energy of vehicles in transit and thus a different approach to managing the installations and response strategies of emergency services in the event of a fire.

Another central aspect associated with the technological evolution of vehicles concerns the level of automation in assisted driving. Here, we expect to reach the maximum level with completely autonomous guidance without a driver by 2050. The impact on safety inside the tunnel is significant. On the one hand, it is possible to eliminate human error while driving. On the other, it will be possible to evacuate the tunnel quickly and safely if a problem occurs within it. Several considerations can be raised in this respect:

Is it possible to equip the tunnel in a way that increases the effectiveness of assisted-driving systems (for level-four automation in particular)?

Once all vehicles are fitted with autonomous driving systems, will it be possible to dispense with or reduce certain installations within the tunnel?

It is clear that a major change in mobility towards a completely autonomous system will not happen in the immediate future. We will therefore face these developments and the associated maintenance of the tunnels and their operating and safety equipment progressively over the years to come.

3 MANAGEMENT OF THE TUNNEL'S LIFE CYCLE

The overall availability of the tunnel depends on a number of factors and, in specific cases, a lack of availability could lead to a temporary interruption of operation. The electromechanical equipment has little effect on the overall service life of a structure, but the correct management of these installations can improve day-to-day management, increase safety levels and limit facility closures. Moreover, the configuration and efficiency of the equipment facilitates the more efficient and sustainable use of a tunnel, with equipment that can be modified depending on a careful analysis of the general state of the construction.

Compared to the past, we now have a lot of data originating from various sources that determine the functional parameters of a structure. The challenge is therefore to find a platform (middleware) for data convergence where it would be possible to extrapolate the required information using adapted applications (predictive maintenance approach). In the following illustration, a platform (middleware) is shown that collects all data from various sources and makes them available to applications with a range of functionalities.

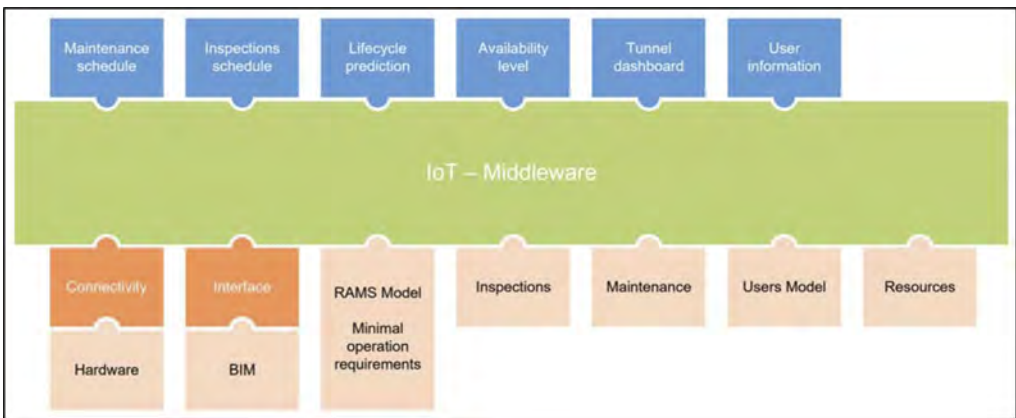

Figure 5. Example of an IoT model for tunnels.

3.1 *Source data*

Primarily, the following information (non-exhaustive list) can converge within the platform (middleware):

- Data from all devices installed in the tunnel, sensors and actuators, generally referred to as hardware.
- BIM model of the infrastructure that, aside from construction information, also contains hardware components.
- RAMS model (reliability, availability, maintainability and safety) defining the main parameters associated with the condition of the equipment when it comes to its reliability, availability, maintainability and degree of safety.
- Data originating from inspections and the condition of components.
- Feedback once maintenance has been conducted (use of a CMMS-type system – computerised maintenance management system).
- User model.
- Resources available for any management and maintenance activity for the construction.

3.2 *Basic platform (middleware) for data management*

Within IT projects, there is a very high risk that the predefined objectives will not be achieved or that there will simply be a delay. To implement a data management platform, it is therefore necessary to refer to existing models that are undergoing development and that can be expanded, improved and made more efficient without giving up what has already been implemented during previous phases. Today, we refer to these platforms in general terms as an “Internet of Things”. These platforms all have the basic characteristics for implementing a tool to manage a tunnel, a section or a full communication network:

- A database that can hold an unlimited number of different information types (data, documents, images, videos, etc.).
- Quick access to data.
- The possibility of expanding the information contained within the various data without compromising the existing data and without having to reconfigure the platform.

Generally speaking, it is necessary to have access to the data held on the platform without special restrictions while bearing in mind that the quantity and typology of the information will change over time depending on various technological developments. This type of platform thus facilitates the implementation of software without necessarily having to predict future uses of information during creation that are unknown at that point, with current availability and needs being the focus. This kind of approach is designed to avoid generating obstacles for the future evolution of applications.

3.3 *Applications*

The applications access the data stored in the middleware and codify the information necessary for the manager and owner of the infrastructure for the overall administration of the tunnel. The applications can be modified and expanded depending on requirements, and new applications can be implemented on the same platform in a fully independent manner. These applications may include the following functionalities (non-exhaustive list):

- Supporting maintenance, scheduling of servicing callouts, management of replacement parts, etc.
- Inspection planning.
- Prediction and planning of life cycles and various sections of the installation.
- Availability level constantly updated.
- Operational reliability level.
- Dashboard facilitating quick and complete access to all information related to the tunnel.
- Possible application allowing the provision of information to users.

4 LIFE CYCLE

A tunnel's life cycle is generally associated with the service life of the construction engineering infrastructure. During this time (which can be considered as lasting up to 100 years), the electromechanical equipment, which has an average life cycle of 20 years, requires refurbishment, rejuvenation and replacement work on several occasions. Preventive maintenance facilitates the extension of the service life and guarantees ongoing operation, but this is limited by specific components having conclusively reached the end of their service life.

In engineering, mathematical models are used to determine the parameters associated with a system's life cycle. These models are primarily used for design, but they can continue to be used to check on an ongoing basis that the system maintains its characteristics over time. Several approaches exist; the best known of these is RAMS (reliability, availability, maintainability and safety).

4.1 *RAMS analysis*

The abbreviation RAMS combines the key terms that characterise a system and its functionality.

Reliability is defined as the probability that a component or system will carry out its required function for a specified time provided that it is used within defined operational conditions. This is therefore the probability that it will not be subject to faults over time. Reliability is often associated with the quality of a product.

Availability is defined as the probability that a component or system will carry out its function at a given moment provided that it is used within defined operational conditions.

Maintainability is defined as the probability that a component or system will be able to be made operational again or repaired to a specified condition within a defined time frame provided that maintenance has been conducted in line with prescribed procedures.

As far as safety is concerned, a risk assessment helps to calculate the probability of harming people and structures. In general, this involves statistical indicators that provide probability values for which minimum threshold values are defined that must always be respected. In the event that these threshold values are not respected, it is possible to introduce specific measures that will have a positive impact on the calculation, making these values acceptable.

4.2 *Minimum operating conditions*

Minimum operating conditions define the minimum conditions with which a tunnel can be used, possible usage restrictions should optimal conditions not be respected and time limits within which anomalies must be corrected. Here, too, this involves a statistical analysis that limits the amount of time a component or system is unavailable. In extreme cases, a disruption could trigger a risk level that is too high to allow the tunnel to be used, forcing a temporary closure and bringing with it all the associated inconveniences. A tunnel may thus be allocated a nominal operational level, deteriorated levels and a closure level.

5 CONCLUSIONS

The tunnel is a special environment where an incident such as a fire can suddenly endanger the lives of users and the integrity of the structure. The human factor remains the element that is the most difficult to control, while electromechanical devices have benefited from ongoing and favourable technological development. Today's devices and systems offer increased availability thanks to the introduction of redundancy concepts and deteriorated functionality, and contribute to a safer, less-interrupted management of tunnels. At an operational level, it is possible to reduce the risk of fire by limiting the number of trips through a tunnel (typically for bidirectional tunnels) and carrying out checks on vehicles in transit (typically heavy-goods vehicles).

The life cycle of a tunnel is not only limited to its service life, but also considers the quality of service provided during this cycle. It is therefore important to be able to guarantee the correct

Figure 6. Different operating situations.

probability values derived from a RAMS analysis and to include information gained from inspections and maintenance within a comprehensive model that can provide the various stakeholders involved in management and administration with all information related to maintenance programmes, programmes concerned with updates and the replacement of components and systems, inspection programmes, and the overall forecasting of technical problems.

This information and these applications must form part of a communal platform that facilitates uniform access to the various levels based on this same information. The platform must be capable of evolving based on the technical development of equipment and users, meaning that it will be possible to keep up with IT developments employing opensource technologies that do not compromise portability and possible technological migrations. This platform includes various levels of specialisation – from the on-site maintenance supervisor to the control room operator, the infrastructure administrator, the head of security, the tunnel operator, the planners and executing companies, the mathematicians and safety engineers, the computer scientists, and the IT infrastructure managers. The management of a tunnel’s life cycle is not substantially different from the management of other types of structure in other fields. It is therefore possible to benefit from experience gained in other environments where managers have applied the concepts described above – in the generation and distribution of electricity (Smart Energy), for example, or in the field of manufacturing (Smart Manufacturing) in order to ultimately arrive at the Smart Tunnel.

SPERI, Engineering Design Firm, Roma, Italy

ABSTRACT: The assessment of existing structures is a crucial task upon which rely an efficient retrofit design. Bridges are ‘key elements’ of the infrastructural network, and ensuring their good serviceability is of paramount importance. In 2020, in Italy were enacted the ‘*Guidelines for the classification, risk management, safety evaluation and monitoring of existing bridges*’: the underlying philosophy is to deepen the analysis only on those bridges showing poor maintenance conditions. Prestressed concrete bridges with post-tensioned cables are one of the bridge typologies mostly affected by relevant structural issues and whose assessment is more complicated. In this research, a multiphase methodology is proposed, specifically to be applied to PT bridges. The method is organized in progressive levels of knowledges. The aim is to provide an answer about how to perform the safety assessment of these structures and how deep shall be the preliminary knowledge campaign to consider the PT bridge completely investigated.

1 INTRODUCTION

Bridges are crucial points in the infrastructural system, as their suboptimal functionality strongly affects the economic and social life of the community. The need to optimize the inspection and intervention procedures is, nowadays, a central issue especially in countries like Italy where several catastrophic events have occurred in recent decades. Since the Polcevera viaduct collapse (2018), both the professional and academic communities have been working on shared methodologies to optimize census and assessment; the overall effort led to the adoption of the ‘*Guidelines for the classification, risk management, safety assessment and monitoring of existing bridges*’ in 2020 (MIT CSLP 2020). The Italian Guidelines are organized into six deepening levels for the assessment. This multilevel approach allows to save resources and to optimize both inspections and interventions, since a lower risk level requires less analysis and a lower level of knowledge achieved for the infrastructure.

The first three assessment levels are required for all the structures: through Level 0 it is possible to carry out the census, Level 1 is devoted to the execution of in-situ visual inspections allowing to classify the infrastructures according to indications of Level 2. The Level 2 classification is the results of four different risks: the structural and geotechnical risk, the hydraulic risk, the seismic risk and the landslide risk. The so-derived ‘Attention Class’ allows the definition of a priority order of interventions and/or monitoring for considered infrastructures. All these evaluations can be performed by collecting data from the original documentation and

through only visual inspections. However, there are some situations where visual inspections only are not sufficient: this is the case of precast concrete bridges with post-tensioned cables (namely PT bridges).

PT bridges represent a consistent portion of the infrastructural system, especially of the highways' one. Their large number is due to the inherent advantages that this technology offered in comparison to the Reinforced Concrete (RC) one, as the possibility to gain longer spans using less materials, the easiness of construction phase thanks to the partial prefabrication and the repeatability of the static schemes. However, as the decades pass, the materials physiologically degrade, and the issue of inspection and evaluation becomes more and more urgent. The evaluation of the maintenance condition of a RC structure is relatively easy since the defectiveness is usually visible: the strong corrosion of rebars is often joined to the loss of the concrete cover or to a very serious degradation of it. On the other hand, PT structures may be affected by defects difficult to detect: for instance, since the steel cables are inside a duct, and the duct is inside the concrete section, with a cover usually thicker than that for ordinary reinforcement, it may be difficult to find corrosion defects on the cables. These situations may be defined as "*hidden defectiveness*" and in these cases a visual inspection cannot be sufficient to assess, even if in a preliminary evaluation, a PT bridge. The issue is complex being the hidden defects completely unknown and the critical questions are mainly two: how and where to perform inspections, i.e. which investigation technique shall be used and how many samples shall be analysed. The present research tries to give a general methodology to evaluate PT structures, from the preliminary to the accurate assessment.

2 THE MULTI-PHASE METHODOLOGY

The proposed methodology has been conceived referring to the Guidelines of the Federal Highway Administration (FHWA 2013), to the directions given by the Highways England in *CS 465 – Management of post-tensioned concrete bridges* (Highways England, 2020) and to the Italian Guidelines (MIT CSLP 2020).

The FHWA guidelines provide a method based on the adoption of destructive testing, which aims to assess the risk of PT bridges, and thus prioritize interventions and define a probable level of defectiveness. The determination of the number of samples to investigate is performed by assuming that the tests' results can be described with a hypergeometric distribution. The CS 465, on the other side, proposes a methodology for the management of inspections, monitoring and interventions on PT bridges carried out through a process including risk review, risk assessment and risk management. Suggestions are given about how to perform the tests, their best location and the most critical defects to be considered.

For PT systems, the Italian Guidelines 2020 proposes the so-called 'Special Inspections' (SI), giving indications about the mandatory information to collect, i.e. the individuation of the cables' trace, the localization of defects and their quantification and qualification, and how to perform the tests. Being the assessment of PT structures a relatively recent issue and lacking the knowledge about the technologies to employ and the way to perform an inspection campaign, more indications are needed.

A multi-phase methodology, following the approach of the Italian Guidelines and comprehensive of the suggestions given by FHWA and the Highways England, is then proposed (Figure 1). It works at subsequent levels of analysis: the more likely the presence of serious defectiveness, the more accurate the investigations. It means that it is not necessary to go through each phase for all the bridges, but only the most degraded ones need to be deeply assessed. The first two phases are mandatory for all the bridges: *phase 0* provides the knowledge of the structure and indications about the number of samples to investigate, *phase 1* provides for the overall assessment conditions through both non-destructive (ND) and semi-destructive (SD) testing, *Phase 2* consists in the deep analysis of the defectiveness individuated at the end of the phase 1 and, finally, *phase 3* is optional and contains suggestions for the global analysis of the bridge.

Two are the possible overall outcomes of the proposed procedure: (a) the classification of the bridge according to the LG as for all other bridge typologies or (b) the need for its accurate assessment. The classification shall be performed according to the Italian Guidelines, considering that the present methodology gives information only about the defectiveness level of the bridge. The accurate assessment is required only if the structure presents worrying defects. In the following, each phase will be discussed and deepened.

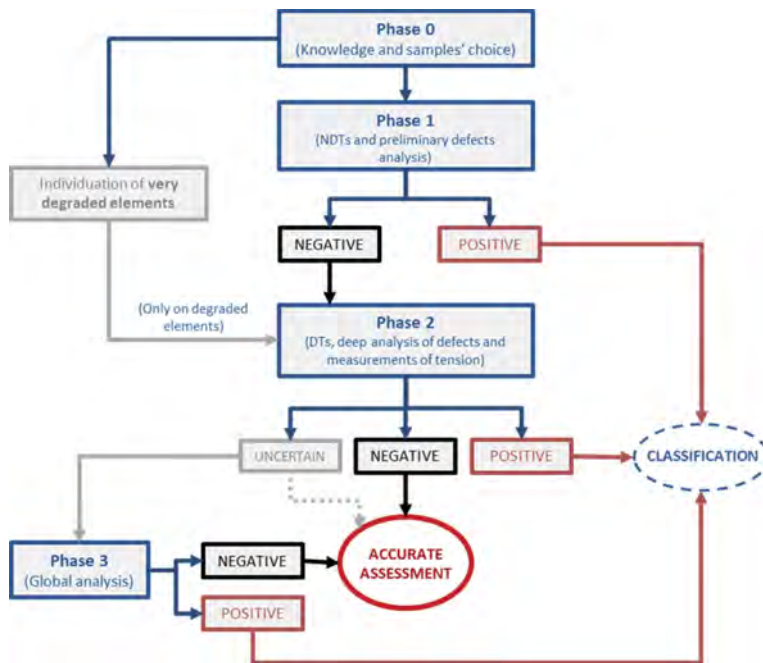

Figure 1. Logical flow of the proposed multi-phase methodology.

2.1 Phase 0: The knowledge

Phase 0 is devoted to the knowledge of the structure and can be divided into two main parts: (0a) the historical-critical analysis of the available documentation and (0b) the assessment of the conservation conditions through visual inspections. By completing these operations, all the required data to define the number of samples to investigate in the following steps, according to a method deriving from FHWA, are achieved. Besides, portions affected by high degradation - namely strong oxidation, or corrosion of the PT cables, if present - can be determined.

The historical-critical analysis (0a) is necessary to collect information about the type, the number and the trace of PT cables and relevant intervention/modifications after construction. In case of lack of original documents, on-site operations (geometrical surveys, non-destructive and/or destructive testing) shall be carried out: of course, the more unknowns, the more invasive will be the impact on the structure. Defectiveness (0b) shall be assessed according to Level 2 of the Italian Guidelines (MIT CSLP 2020), considering only beams and crossbeams belonging to the PT system, resulting in an overall defectiveness level strictly related to the one of each accounted component.

Once all the previous data are known, it is possible to proceed with the risk assessment, a necessary step to estimate the minimum number of samples to investigate. These two operations are based on the same hypothesis and follow the methodology proposed by the FHWA, with few integrations and adjustments required to match the Italian Guidelines.

To perform the risk assessment and therefore define the number of samples to investigate, it is necessary, as the FHWA proposes, to make some assumptions about the expected distribution of the defectiveness within the structure. The worst defect considered in this field is the one that may determine the corrosion of the cables; since the corrosion is most probable to occur in areas where the grouting is not complete, the investigations are focused on finding grouted/ungouted areas. Being these two outputs the only two possibilities and being the single investigation not able to provide the re-entry of the single test in the sample, the distribution can be described as hypergeometric.

The probability mass function of the hypergeometric distribution is then defined according to (1), being the main parameters n - the number of cables to be investigated, N - the total number of cables belonging to the same homogeneous group, k - the number of times in which the cables are ungrouted and $m = n/N \cdot 100$. By considering a homogeneous group of cables, in terms of geometrical and typological characteristics, the width N can be defined; by supposing a certain percentage of defective cables m (as described in the following) and by relating the probability of finding at least one defective cable ($k = 1$) to the concept of confidence in the outcome of the investigations and, therefore, establishing a confidence level, it is possible to determine the amplitude n of the sample to investigate.

The FHWA proposes to establish a probability/confidence level of 75%; being the planned investigations for Phase 2 ‘preliminary’, the same percentage is suggested to be adopted.

$$P(X = k) = \frac{\binom{m}{k} \binom{N - m}{n - k}}{\binom{N}{n}} \tag{1}$$

where m = defects present; n = number of cables to be investigated; N = total number of cables; k = times in which the cable is defective.

The assumed level m of defective elements depends on the risk level associated to the structure and on the structural impact associated to the tests to be performed. Three risk levels and three structural impact levels are then provided: *high*, *medium* and *low*. As showed in Figure 2, the risk level must be defined through the calculation of a probability index and of a confidence index, with values in the range 1÷5. The probability index depends on the presence of technical documentation, the length and type of PT cables and the actual defectiveness level of the structure, this last one defined as previously explained. The consequence index depends on the cost for restoring, the redundancy of the structure and its importance level, representing therefore a sort of exposure indicator.

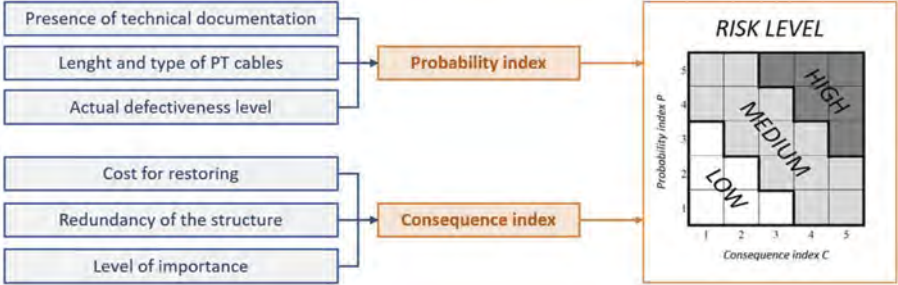

Figure 2. Definition of the risk level.

The number of samples deriving from the previous consideration must not include all the cables that present evident corrosion defects after a visual inspection. These samples must be deeply investigated directly by the analysis provided in the *Phase 2*.

In this context, one sample means one cable. A cable can be considered fully inspected if all the critical areas for the injection and therefore all the areas where the presence of defective grouting is most probable (Trejo et al. 2009), are investigated. Figure 3 shows the riskiest zone of a cable belonging to a simply supported post-tensioned beam: the anchorage zones, the midspan region and the zones in which there is a change in curvature. Finally, it is necessary to choose which sample to investigate. The suggestion is to investigate at most two cables for beam, to obtain a statistically significant result, and choosing the most defective beams belonging to the most defective spans.

Figure 3. Areas to investigate in order to consider a sample (a cable) fully inspected.

2.2 Phase 1: Preliminary analysis

Phase 1 is devoted to the (1a) preliminary analysis of the defects through non-destructive (NDTs) or semi-destructive (SDTs) techniques and (1b) the definition of the corrosion probability of the concrete matrix.

Figure 4. Individuation of cables' layout by using GPR technology (on site trace VS design trace).

The preliminary analysis of the defects (1a) aims to locate eventual deficiencies in the grouting. The definition of the cables' layout is then the preliminary necessary step and can be performed, for instance, through the Ground Penetrating Radar (GPR) technique (see Figure 4), strongly promoted and used by many researches (Terzioglu et al. 2018; Sławski, Kosno, and Świt 2016; Wai-Lok Lai, Dérobert, and Annan 2018). Of course, other possibilities can be explored if able to provide adequate and reliable results.

The individuation of defective grouting can be carried out by any test methodology of proven validity. In (Highways England 2020a) many proposals are given, such as the Impact Echo (IE), the Ultrasonic Echo (UE), the Ultrasonic Tomography (UT) and the X-rays scans. Even if in the academic and scientific world these technologies are well-known and widely tested (Giannopoulos et al. 2002; Sławski, Kosno, and Świt 2016; Terzioglu et al. 2018; Wai-Lok Lai, Dérobert, and Annan 2018), in the common practice there are still no consolidated procedures and protocols since the results of their application are often difficult to be interpreted and applied on-site. Keeping in mind the need for determining objective procedures and protocols for in-situ NDTs, the application of even more than one ND technique can be promoted (Terzioglu et al., 2018), or in combination with semi-destructive tests (e.g. endoscopic

investigations) more or less widely applied. Alternatively, it can be possible to apply only semi-destructive tests, but widely spreading them through the samples.

The definition of the corrosion probability (1b) can be performed preliminarily on the concrete matrix to evaluate the likelihood of occurrence of corrosive phenomena in the ordinary steel and in the metallic ducts. A high corrosion probability on these elements does not necessarily imply corrosion of the PT cables, as the opposite situation, but a low corrosion probability, together with the lack of ungrouted region, may indicate the good condition of the PT system. As suggested in (Highways England 2020b) the main factors to investigate, in this case, are: the width of the concrete cover, the depth of carbonatation, the concrete resistivity, the half-cell potential, the chloride, sulphate and alkali contents.

According to Figure 1, Phase 1 can give either ‘positive’ or ‘negative’ results. By adopting the classification of voids proposed by (Highways England 2020b) and reported in Table 1, a positive result means no voids or only small voids determined: namely, it is possible to consider that the structure, with the probability defined before, has no defects. On the other hand, if even one large void is found, or several medium voids and a high probability of corrosion is stated, it is not possible to consider the structure without defects and *Phase 2* becomes therefore necessary.

Table 1. Classification of voids according to (Highways England, 2020b).

Classification	Description
No void	Fully grouted
Small void	<50 mm length
Medium void	50-300 mm length
Large void	>300 mm length
UngROUTED	No evidence of grout

2.3 Phase 2: Deep analysis

Deep analysis of *Phase 2* is necessary when, from *Phase 1*, it is not possible to conclude that the structure has no deficiencies in the grouting, and/or when, from *Phase 0*, the presence of defects of oxidation/corrosion on the PT system is assessed by visual inspection. In-depth investigations must be then located in those areas emerged as defective from *Phase 1*, and/or on the degraded portions determined in *Phase 0*.

The primary objective is the damage evaluation in terms of cross-section reduction; therefore, samples through concrete excavation are required. If no corrosion/oxidation is stated after these operations, it is suggested to evaluate the corrosion probability of the grout by defining the cement content, the chloride ion concentration, the sulfate ion concentration, the alkalinity and the moisture content (Highways England 2020b). In addition, it is possible to evaluate the stress acting through the steel cable and/or the tensional state of the concrete cross-section, to indirectly assess the efficiency of the PT system and therefore exclude the presence of strong corrosion phenomena.

These evaluations can be performed in any way deemed effective by the current scientific literature. Some test methodologies can be suggested: for instance, to assess the stress acting through the wire/strand it is possible to perform the X-ray diffraction investigations, NDT usually adopted in the quality check of the manufacturing processes by the measure of residual stresses. Many researchers in last years confirm the reliability of this NDT (Carfagno et al. 1995; Morelli et al. 2021; Zanini, Faleschini, and Pellegrino 2022). The measure can be indirectly performed on the concrete section through the saw-cut method, which is basically a SDT relating the “released” deformation of the test area with the pre-existing tensional state; this methodology has been employed both on-site (Bagge, Nilimaa, and Elfgrén 2017;

Jakub Kral'ovanec, Moravčík, et al. 2021) and in laboratory (J Kral'ovanec and Moravčík 2021; Jakub Kral'ovanec, Bahleda, et al. 2021).

Figure 5. The picture in a) shows X-ray diffraction measurements on-site, while the picture b) shows the saw-cut method.

As well as for *Phase 1*, *Phase 2* can give either ‘positive’ or ‘negative’ results, but also the ‘uncertain’ condition is admitted. If no corrosion phenomena are detected and the probability of grout corrosion is negligible, it is possible to consider the structure, with the probability previously defined, not defective therefore going on with the classification according to Italian Guidelines. If corrosion phenomena are detected, or if large voids associated with a high corrosion probability are found, the accurate assessment of the structure is required. When the results of the investigations are difficult to interpret, or in any case, when the designer thinks that could be necessary, it is possible to go through the global analysis of the structure.

2.4 *Phase 3: Global analysis*

If the expert judgment is not able to completely exclude the presence of conditions that could compromise the safety of the whole structure or a part of it, or if there is the will of assessing the influence of certain detected damage on global behavior, it is possible to perform dynamic tests or static load tests. For this Phase too the final outputs can be positive or negative. Being these evaluations complex, it is not possible to generalize the cases in which it results a positive judgment instead of a negative one. The designer must have the responsibility in the assessment of the structure deriving from global analysis.

3 CONCLUSIONS

The present research aims to define a methodology for the design and execution of the in-situ inspection on precast concrete bridges with post-tensioned cables. This structural system is very complex to investigate as a consequence of the potential presence of hidden defectiveness: therefore, a multi-phase procedure organized into four different steps is proposed.

The procedure follows the same philosophy adopted by the Italian Guidelines, with the aim of optimizing time and economic resources for the inspection and the assessment of bridges: the higher the defectiveness, the deeper the evaluation and the more complex and reliable the tests’ methodologies required. For the methodology elaboration, reference has been also made to the indications provided by English and American Standards; in particular, the assumption for the determination of the number of samples to investigate is the same as the ones proposed by the FHWA. Many experimental campaigns are going to be planned and performed on existing case studies with the aim of validating the proposed procedure and providing in-depth indications about how to perform the accurate assessment of PT bridges.

Super resolution of multi-channel ground penetrating radar volume data by zero-interpolated 3D kirchhoff migration

T. Imai & T. Mizutani

Institute of Industrial Science, the University of Tokyo, Meguro-Ku, Japan

ABSTRACT: On-vehicle multi-channel Ground Penetrating Radar is attracting much attention in infrastructure maintenance field. Besides the key benefits of high-speed 3D subsurface data acquisition, basic problems such as data discontinuity due to use of multiple antennas and sparse observation that arises aliasing have been a problem. This study proposes easily applicable but effective method to solve these problems. For the first issue, calibration in each channel was done by improved Sparse Blind Deconvolution (SBD) method proposed in previous research. It was found that disuse of low-intensity frequency band provides better estimation of transmitted waves. For the second issue, super resolution method was proposed. It interpolates zeros in between sparsely observed data and then apply synthetic aperture processing. Zero insertion is an operation that restores high frequencies, which makes it possible to restore frequency components above the Nyquist frequency under certain conditions. The method was confirmed to be effective on real data.

1 IMPORTANCE IN PRE-PROCESSING OF GPR VOLUME DATA

Infrastructures has been deteriorating worldwide and increasing inspection costs has becoming a concern. Shifting from breakdown maintenance that waits for structures' life limit without any repairing to preventive maintenance that extends service life by regular inspection plays an important role in controlling long-term management costs. In order to achieve this, establishment of early damage detection technology is necessary. Nowadays, Ground Penetrating Radar (GPR) has attracting much attention for inspection of road infrastructures. It obtains subsurface information by emitting electromagnetic waves and observing their reflection. Since the technology is completely non-contact, non-destructive and fast, it enables efficient maintenance of infrastructures.

Mainly two types of GPRs are used for different purposes. The first one is a ground-coupled hand-held type used for close inspection (Liu, Lin, Cui, Fan, Xie, & Spencer 2020; Dinh, Gucunski, Tran, Novo, & Nguyen 2021). It offers high-resolution images, and is also used for exploration of back and sides of structures. The second one is an on-vehicle multi-channel type, which is a main target of this study. It drives at maximum 80km/h and achieve high-speed data acquisition. Also, antenna elements are aligned transversely to the driving direction, thus provides 3D subsurface information.

Besides the key benefits, there are several issues regarding on-vehicle multi-channel GPR (Yamaguchi, Mizutani, Meguro, & Hirano 2022; Liu, Shi, Li, Liu, Meng, Du, & Chen 2021). First issue is lack of data consistency and continuity in the transverse direction, since it utilizes different antenna elements transmitting slightly different waveforms. In general, calibration by frequency domain deconvolution of observed data using transmitted wave is done for removing the inconsistency. For estimation of actual transmitted electromagnetic waves, Sparse Blind Deconvolution (SBD) method was proposed by (Jazayeri, Kazemi, & Kruse 2019). This method iteratively calculates sparse reflectivity and transmitted waveform from observed data. There remains problem of zero-division in the algorithm, that has to be solved.

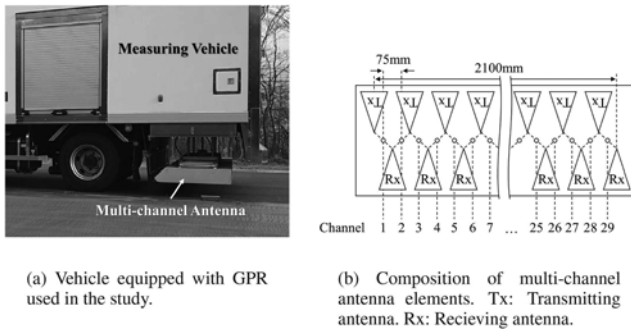

Figure 1. Equipment used for measurement and its composition.

Figure 2. Comparison of calibrated data by original SBD method (previous research) and improved SBD (proposed).

Another issue is that it records data in a sparse spacing with 7 cm in the longitudinal direction for high-speed inspection. This sparse observation induces phenomena well-known as aliasing, and under data with 7 cm spacing acquisition, high-frequency waves under wavelength of 14 cm cannot be observed. Objects installed within structures at just similar intervals are the rebars. Knowing the rebar spacing helps to determine the structural strength of RC bridge decks. Also, damages often appears in the vicinity of rebars, therefore many studies has been conducted focusing on detection of rebars in GPR images (Wang, Zhou, Slabaugh, Zhai, & Fang 2011; Abouhad, Dawood, Jabri, Alsharqawi, & Zayed 2017). However, rebars in bridge decks are usually placed in 10 to 30 cm intervals, and of course there remains a risk that the information on rebars cannot be accurately extracted under aliasing. One major approach of increasing the radar image resolution is synthetic aperture processing, known as the term migration in subsurface exploration field. It is a method to converge diffraction curves, or hyperbolic responses seen in GPR images to a points. Preliminary investigation showed that migration sometimes does not recover the image with sparse observation, therefore further study is necessary.

The objective of this study is to propose a pre-processing method for on-vehicle multi-channel GPR. Composition is as follows. In section 2, appropriate updating methods in SBD algorithm to avoid zero-division problem is proposed. Section 3 focuses on proposal of super resolution of GPR image for resolution recovery. Application results of the proposed methods to in-service data will be shown in Section 4.

2 CALIBRATION OF ANTENNAS BY SPARSE BLIND DECONVOLUTION

Multi-channel GPR utilized in this study is composed of 29 (or 25) channels using 30 (or 26) antenna elements (Figure 1). It acquires data by Stepped-Frequency Continuous Wave (SFCW) system. The frequency of electromagnetic wave used was 50 MHz to 3030 MHz by a step of 20 MHz. Transmitted electromagnetic waves are desired be having an one-sided and narrow peak,

Figure 3. Changes in the transverse (channel) direction cross section image when using different calibration filters and clutter removal method.

for example the sinc function, but often this condition is not always satisfied. Therefore, the inverse convolution in the frequency domain is performed by the following equation:

$$\hat{y}_c = \frac{\hat{y}}{\hat{w}} \quad (1)$$

where, y is observed wave, w is transmitted wavelet and y_c is calibrated wave. $\hat{\cdot}$ indicates the Fourier Transform.

For estimation of the wavelet, SBD can be used. Here is a brief overview of SBD. Convolution of wavelet $w = (w[0], w[1], w[2], \dots, w[L-1])^T$ and reflectivity $r = (r[0], r[1], r[2], \dots, r[L-1])^T$ can be written in a matrix form:

$$y = Wr \quad (2)$$

where $y = (y[0], y[1], y[2], \dots, y[L-1])^T$ and W is circulant matrix constructed from wavelet vector w . In SBD, the reflectivity r and the transmitted wavelet w are obtained by alternately solving the following two equations:

$$r = \arg \min_r \|y - Wr\|_2^2 + \lambda_r \|r\|_1 \quad (3)$$

$$w = \arg \min_w \|y - R w\|_2^2 + \lambda_w \|w\|_2^2 \quad (4)$$

where R is circulant matrix constructed from reflectivity vector r . The first term in equation (3) is the fidelity term and the second term is the l_1 regularization term to assume sparsity in the reflectivity r . It is known that optimization problem with l_1 regularization term can be solved iteratively by Split Bregman Algorithm (Goldstein & Osher 2009). Equation (4) contains l_2 regularization term for maintaining smoothness of the estimated wavelet, and has a closed-form solution of:

$$w = (R^T R + \lambda_w I)^{-1} R y \quad (5)$$

and re-written in the frequency domain as:

$$\hat{w} = \frac{\hat{r}^* \odot \hat{y}}{\hat{r} + \lambda_w}, \quad (\hat{r} = \hat{r}^* \odot \hat{r}) \quad (6)$$

Here, $*$ is Hermitian transpose and \odot is Hadamard product. The wavelet is updated by taking average of the estimation results in each observation. However, Above solution has a problem when applied to calibration by equation (1). The problem occurs when the specific frequency-band components of the observed signal \hat{y} is close to zero. In this case \hat{w} also becomes close to zero, which causes zero-division providing unstable calibrated signal \hat{y}_c . In this study, a minor but effective approach of disusing a low-intensity frequency band for wavelet update was implemented. Certain threshold was set and the frequency band with amplitude below that threshold were disused. Comparison of calibrated data by equation (1) using wavelets calculated

Figure 4. Comparison of ideal diffraction curves when changing the relative permittivity and the antenna height in the 2-layer model.

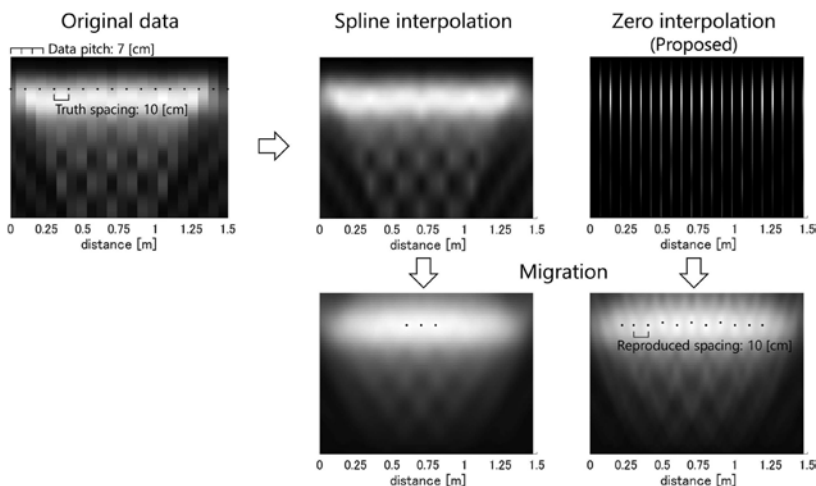

Figure 5. Simulation of super resolution.

by original method and the proposed disuse method is shown in Figure 2. Figure 2(a) calibrated by the original SBD method contains needless vibrations by poor estimation results in certain frequency band, while Figure 2(b) with the proposed method shows good estimation results.

Using the improved SBD method, Wavelets were estimated for each channel. Cross-sectional image of calibrated data in the transverse direction is shown in the center of Figure 3(b). Compared to the calibrated data using direct wave measured by an experiment (Figure 3(a)), it shows significantly clear image. The data was obtained from the RC bridge section, and rebar responses are recognized around 5 ns depth that were not visible in the left image. On the contrary to the favorable findings, slight clutter can be found in especially the edge of the center image. The clutter is stationary and it is presumed that this is attributed to reflection from the vehicle. Clutter was simply removed by subtracting only the components of variation in the transverse direction from the average image in the longitudinal direction (Figure 3(c)).

3 SUPER RESOLUTION OF GPR VOLUME DATA

3.1 Hyperbolic response with refraction

Electromagnetic waves are emitted spherically, and point-like objects are observed as hyperbolic diffraction curves in ground-penetrating radar images. Migration is an often-used

method for convergence of hyperbolic responses seen in GPR to a points, for improved visibility and resolution. Kirchhoff migration (Özdemir, Şevket Demirci, Yiğit, & Yilmaz 2014) is derived from the wave equation and can be applied as follows:

$$I(x, y, z) = \int \frac{\cos \theta}{r} \left(\frac{1}{c} E'(x, y, t = t_0) \right) dS \quad (7)$$

where E is observed signal and I is migrated image. t_0 represents the transmission time which is equal to the diffraction curve, and $\cos \theta$ indicates the radiant angle. To obtain appropriately converged images, accurate assumption of hyperbolic shape is required. Wave propagation using ground-coupled antennas can be explained by considering a two-layer model of air and soil (or concrete), and it can be formulated as follows:

$$f(x) = \frac{2}{c} \sqrt{(x - x_1)^2 + h^2} + \frac{2\sqrt{\epsilon_r}}{c} \sqrt{(x_1 - x_0)^2 + d^2} \quad (8)$$

$$\sin \theta_1 = \sqrt{\epsilon_r} \sin \theta_2 \quad (9)$$

where c is light velocity, ϵ_r is relative permittivity of the soil, d is the height of the antenna and d is the depth of the target object. (Persico, Leucci, Matera, de Giorgi, Soldovieri, Cataldo, Cannazza, & Benedetto 2015) stated that Snell's law (equation (9)) comes down to a quadratic equation and derived a closed-form solution.

They also made a qualitative discussion, stating that diffraction curves of objects at shallow depth does not change when observed by air-coupled GPR. This is explained by Fermat's principle of least time, where electromagnetic waves tend to pass the air layer than the soil layer. The theory support an important fact that relative permittivity of the propagating medium and depth of the object cannot be estimated from the diffraction curve. This disadvantage, however, inversely becomes an advantage in that migration can be applied using a single diffraction curve. In order to understand applicable limits, diffraction curves depending on various conditions were calculated. Since this study utilizes antennas with separated receiver and transmitter, diffraction curves were calculated by the following equation:

$$g(x; l) = f \left(\sqrt{\left(x - \frac{l_1}{2}\right)^2 + \left(y - \frac{l_2}{2}\right)^2} \right) + f \left(\sqrt{\left(x + \frac{l_1}{2}\right)^2 + \left(y + \frac{l_2}{2}\right)^2} \right) \quad (10)$$

where (x, y) is the longitudinal and transverse coordinate of antenna center and (l_1, l_2) is the distance of two antenna elements in each direction. Figure 4(a) shows changes of diffraction curves under conditions when apexes appear in the same reflection time. Two cases of relative permittivity $\epsilon_r = 4, 20$ are compared. When the depth of target is shallow around $0.1 \sim 0.2$ m, diffraction curves have almost no differences showing that migration can be applied using a unified curve.

Another important issue is undulation of data due to vehicle vibration. Changes in diffraction curves due to vertical displacement of the vehicle can have a effect on migration results. Diffraction curves under different antenna height conditions were compared. The curves showed less differences under the height variation of ± 3 cm (Figure 4(b)). According to the results, it is considered that the diffraction curve will be distorted by the same amount as the road surface variation in the image. For this reason, time-shifting of the A-scan signals for flattening the road surface reflection improves migration accuracy.

3.2 Kirchhoff migration for recovery from aliasing

Migration in discrete system is applied by similar processing of taking cross correlation with diffraction curve template. When data is sparsely observed, the data acquisition point is often not located directly above the point-like target object, and for this case, appropriate diffraction curve fitting cannot be implemented.

In this subsection, super resolution method for recovery of aliased GPR images based on zero-interpolated migration is proposed. The method is very simple: zeros are inserted in between sparsely observed data, then migration is processed. Simulation result of zero-interpolated migration compared with spline-interpolated migration is shown in Figure 5. Original data in the upper left figure expresses rebar response often seen in on-vehicle radar data image. It was produced by convolution of diffraction curve in 10 cm spacing, and sampled in 7cm pitch. Under this condition, apexes of diffraction curves are aliased and hard to recognize in the original data. The center and the right

Figure 6. Photo of the experimental field where Data1 was measured.

Table 1. Parameters of antennas used for migration.

	Channel	Long. Dist.	Trans. Dist.	Height
Data1	29	47.5 cm	7.5 cm	15 cm
Data2	25	47.5 cm	7.5 cm	15 cm

figures shows interpolated data and migration results. Black dots in the migration data represent the local maxima points. The spline interpolated migration image hardly restores the black dots, whereas zero-interpolated migration produces black dots in accurately 10 cm spacing.

Zero-interpolated migration can be interpreted from mathematical point of views. As seen in the f-k migration (Stolt 1978), the synthetic aperture processing of GPR images can be interpreted in the frequency domain. For example, the simplest migration method is convolution with a single hyperbola, which can be represented in the frequency domain by multiplication of the spectrum. If the image is subjected to aliasing, of course the spectrum after migration does not contain any true frequency components. Spline interpolation is also impossible to recover the true frequency components since it is essentially a method of interpolating the image with a low-order polynomial function. On the contrary, zero interpolation in the time domain is equivalent to repetition of spectrum in the frequency domain. This allows the aliased spectrum restored to its true frequency again, symmetrically with respect to the Nyquist frequency. However, excessive interpolation also accentuates unwanted high-frequency noise, and a low-pass filter must be applied after zero-interpolated migration. In Figure 5, a filter with a cutoff frequency of 1/15 [1/m] is applied for high-frequency noise removal.

4 APPLICATION TO MEASUREMENT DATA

Super resolution by zero-interpolated migration was applied to real measurement data. Two volume images of different bridge decks were prepared. The first one (Data1) was with known rebar spacing: main rebar in 15 cm; and distribution rebar in 30 cm and 15 cm. Photos of the experimental field where Data1 was taken is shown in Figure 6. The other data (Data2) was acquired by driving an in-service bridge. The truth rebar spacing is unknown for Data2. The data was calibrated by the proposed method explained in Section 2. Road surface was flattened by time-shifting and 4 times zero-interpolation was applied.

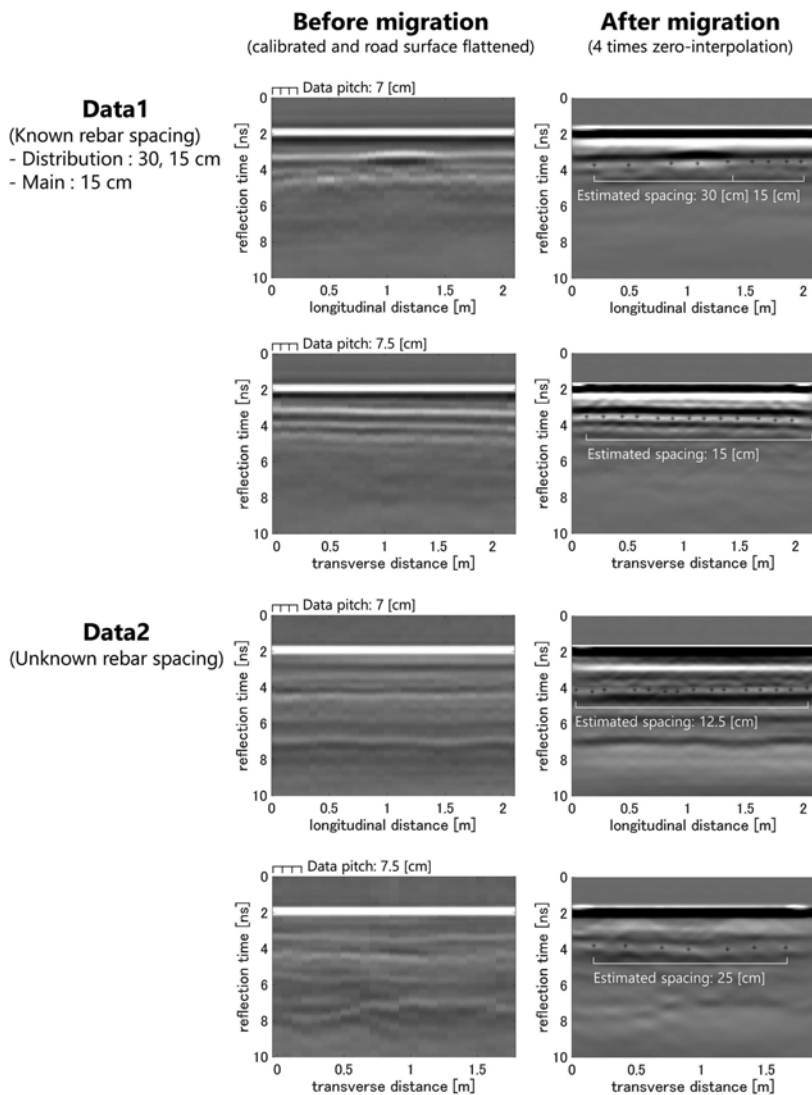

Figure 7. Super resolution of real volume data.

Precise calculation of diffraction curve requires distances of the Tx/Rx antenna elements in the longitudinal and transverse direction, and the height from the ground (equations (8) and (10)). The distance of the elements in the transverse direction is a known parameter and the height is obtained by actual measurement. Unknown parameter is only the distance in the longitudinal direction, and values that produces good migration result were chosen (Table 1). Relative permittivity was assumed to be 10 in the calculation.

Cross section images of original data and results of applying super resolution method is shown in Figure 7. While original images contain complex hyperbolic responses with unclear rebar apexes, super resolution provides easy-to-interpret images. Although these two sets of data may not have the same permittivity, the method worked well. This is based on discussion done in Section 3.1, and it could be concluded that the behavior of the real data follows the theory.

Black dots in the migrated images show local maxima points and only the depth that corresponding to the rebar response are extracted. For Data1, distribution rebars in the longitudinal

cross sectional image were seen in spacing of 30 cm and 15 cm; main rebar responses in the transverse image were recognized in 15 cm spacing. These were the same as the true rebar spacing, indicating that the migration worked effectively. Super resolution method also produced good results for Data2. Main rebars were seen in around 25 cm spacing with a little noise. Interestingly, distribution rebars appeared stably in a spacing of around 12.5 cm. The data was acquired at 7 cm intervals, which would normally not capture responses with a period of 14 cm or less, however this was overcome by super resolution.

5 CONCLUSION

In this study, mainly two methods regarding pre-processing of on-vehicle multi-channel GPR data were proposed. Both were easily applicable and strongly effective. Specifically, in Section 2, improvement of SBD method for calibration of data and maintaining smoothness in transverse direction images was introduced. Section 3 and Section 4 focused on recovery of true frequency component from aliased image. It was confirmed that the data acquired by on-vehicle GPR follows electromagnetic theory and possibility to avoid aliasing even in real data.

Also, various challenges remain. Firstly, clutter was removed by simple subtraction in the study, however, the mechanism is assumed to be complex and it needs to be solved comprehensively in conjunction with SBD and other methods. Secondly, there should be some limitations for recovery from aliased image and future study is needed for theoretical analysis. It would be also interesting to focus on engineering aspects that was not mentioned in the study such as automation of migration and rebar detection.

ACKNOWLEDGMENT

The authors are grateful to Mr. IGUCHI, Tatsuya, Mr. TAKEMOTO, Dai, and Mr. YAGISAWA, Kazuya from C.E.Management Integrated Laboratory Co.Ltd (C.E.O. SHIMODAIRA, Yuji) for designing and constructing the specimens.

Crack growth suppression effect of SFRC overlay for root-deck fatigue in orthotropic steel deck

M.J.B. Uaje

Tokyo Metropolitan University, Tokyo, Japan
University of the Philippines Los Baños, Laguna, Philippines

J. Murakoshi

Tokyo Metropolitan University, Tokyo, Japan

ABSTRACT: A previous study demonstrated after 10 million cycles of 50 kN wheel loads that reinforcing a partial OSD specimen with SFRC overlay suppressed the crack growth propagation. To analytically evaluate the crack growth suppression effect of SFRC pavement reinforcement, several finite element models were developed, and semi-elliptical cracks with an aspect ratio of 0.15 were introduced at the root of the rib-to-deck weld. Using the displacement-matching approach for calculating the stress intensity factor (SIF) at the crack tip, the results showed that reinforcing a 12 mm thick deck plate with a 75 mm thick SFRC pavement lowers the SIF to about the level of the threshold value, confirming the experimental results.

1 INTRODUCTION

The orthotropic steel deck (OSD) is a deck system composed of a thin deck plate typically 12 to 16 mm in thickness and supported by closely spaced longitudinal ribs. The rib commonly takes a “U”-shape because of its effective torsional properties. It is used as a common deck system for long-span bridges and urban viaducts; however, its complicated welding details resulting in concentrated residual stresses make it susceptible to fatigue. Furthermore, with the increase in traffic volume and vehicle weights, fatigue cracks have been found in existing OSDs in Japan (JSCE 2010), and other countries such as Humen Bridge in China (Ji et al. 2013) and Temse Bridge in Belgium (Nagy et al. 2015). Root-deck cracks, which are one of the observed fatigue cracks in 12 mm thick deck plates under severe traffic condition, initiate from the root of the rib-to-deck weld and propagates through the deck. Previous studies confirmed the formation of the stress concentration at the rib-to-deck weld root, and these demonstrated that the steel fiber reinforced concrete (SFRC) pavement was effective in improving the stress condition (Murakoshi et al. 2019, Uaje & Murakoshi 2022). The latter study also confirmed that in the case of 75 mm thick SFRC pavement reinforcement, the debonding of adhesive increased the critical stress by only 15%. Furthermore, fatigue testing of the same specimen demonstrated the occurrence of root-deck cracks after subjecting it to at least 1 million cycles of 50 kN wheel load directly above the U-rib (Murakoshi et al. 2019). The current study aims to analytically clarify the crack growth suppression effect of SFRC pavement by introducing semi-elliptical cracks at the weld root and comparing the stress intensity factor (SIF) using the displacement-matching approach.

2 FINITE ELEMENT MODEL

2.1 Specimen

The finite element model developed in this study is based on the partial OSD specimen shown in Figure 1. The partial OSD specimen targeted the root-deck cracks at the cross beam since both field surveys (JSCE 2010) and previous fatigue testing (Murakoshi et al. 2012) showed

cracks occurring at the intersection of the cross beam and the U-rib. The thickness of the deck plate, U-rib, and cross beam web is 12, 6, and 12 mm, respectively (Figure 1). The deck plate is welded to the U-rib with one-sided fillet welds of leg length 8 mm and 75% weld penetration. Taking advantage of the symmetry of the specimen, only one-fourth of the OSD specimen was modeled. The software used was MSC Marc 2018.1.0.

In the calculation of the root stress in uncracked models, the modeling of the adhesive did not affect the stress condition significantly; hence the modeling technique adopted was to neglect the adhesive in favor of faster calculation time (Uaje & Murakoshi 2022). In the current study, on the other hand, it was found that the difference between the two methods resulted in a 7-12% difference in the SIF; therefore, the adhesive was considered in the modeling.

2.2 Modeling parameters

To save calculation time, the finite element model was divided into solid and shell elements, as shown in Figure 2. The upper portion, where the area of interest was located, was modeled as three-dimensional, eight-node, first-order, isoparametric solid elements. The lower portion was modeled as four-node, thick shell elements. Table 1 shows the properties of the materials used in the finite element model. The yield point σ_{yield} of the SM490YB steel is 355 MPa.

Figure 1. Unpaved OSD specimen from fatigue testing of Murakoshi et al. (2019). Dimensions in mm.

Figure 2. Finite element model of the specimen. Dimensions in mm.

A simple support was provided 75 mm from the end (Figure 2), following the specimen shown in Figure 1. The appropriate boundary conditions were applied accounting for the symmetry of the specimen. In the previous study (Murakoshi et al. 2019), the wheel load was simulated by the application of two-50 kN uniform load at each U-rib over a contact area of 200 by 200 mm through a rubber plate. The finite element model in this study was in turn loaded by

Table 1. Material properties.

Materials	Young's modulus	Poisson's ratio
	MPa	
Steel	200,000	0.30
SFRC pavement	40,000	0.20
Adhesive	2000	0.20

a pressure load of 1.25 MPa as shown in Figure 2. The design live load of the deck plate is 140 kN (considering impact to one side of the design T-load), which corresponds to a pressure load of 1.4 N/mm², and the test load is generally close to this value.

2.3 Crack geometry

In the previous fatigue testing (Murakoshi et al. 2019), before reinforcing the OSD specimen, semi-elliptical cracks initiating from the weld root were introduced by subjecting it to a wheel load of at least 1 million cycles. The previous study collected the crack data and established a linear relationship between the crack aspect ratio alb and a , where a and b are the depth and half-width of the semi-elliptical crack respectively. The crack depth a is not the actual depth of the crack, but rather the projected depth to the vertical plane. The same study conservatively chose the crack aspect ratio $alb = 0.15$, which corresponds to deep cracks, for the analysis. To maintain compatibility with the previous study, the current study utilized the same crack aspect ratio.

Figure 3 shows the typical crack modeling in the current study. Seven types of cracked models with crack depths of 2, 3, 4, 5, 6, 7, and 8 mm were developed. Although the actual crack initiates diagonally from the root and changes direction throughout the deck thickness, the introduced cracks at the weld root model were developed with a vertical orientation for simplicity. The crack surface was generated from two coincident nodes. Each pair of nodes along the crack surface had the same coordinates but were treated as separate nodes by the software. The mesh size from the crack tip to 0.30 mm of the crack plane was 0.025 by 0.025 by 0.25 mm. From 0.30 mm to 1.00 mm from the crack tip, the mesh size was set to 0.025 by 0.050 by 0.25 mm.

2.4 Strain comparison

To establish some consistency between the analytical models with the actual specimen, the strain ranges were compared. The gauge locations from testing which are focused on in this study are shown in Figure 1. It should be noted that this location is of interest because the analytical results exhibited more critical values from this location rather than that of the weld root locations near the midspan of the specimen. Murakoshi et al. (2019) attached the 3 mm strain gauges 5 mm away from the inner surface of the U-rib. Figure 4 shows the strain comparison for the analytical and testing strain ranges from both the unpaved and paved cases across various crack depths. For the uncracked case of the unpaved specimen, it can be observed that the strain ranges were close. For the cracked cases of the unpaved specimen, there is a discrepancy although the consistency of the general trend can be argued. This discrepancy may be mainly due to the simplified modeling of the crack. Furthermore, a wide variation can be observed in the testing strain range itself for the crack depth of approximately 9 mm. For the paved case, there were only two data points of comparison with one data point being close to the analytical trend and another with a significant discrepancy.

2.5 Analysis cases

The analysis discussion is divided into three sections. In Section 4.1, the pavement considered is SFRC. Pavement thicknesses of 25, 50, and 75 mm were chosen; however, the common practice in Japan is to reinforce the deck plate with either 50 or 75 mm thick SFRC pavement. The 25 mm thick SFRC pavement was included only as a theoretical comparison. In Section 4.2, the pavement type is also SFRC, but the debonding of the adhesive was considered. The debonding was accounted for by setting the Young's modulus of the four 0.25 mm layers of adhesive to near 0. i.e.

10 MPa. In Section 4.3, the pavement considered is asphalt, as it is a common overlay, and was included in this study for comparison. Deck plate thicknesses of 12 and 16 mm were considered to account for both the old and new thickness requirements. In the current Japanese design code,

Figure 3. Typical crack modeling at the rib-to-deck weld with the crack surface exposed (8 mm deep crack model shown).

Figure 4. Strain comparison for analytical and testing strain ranges of unpaved and paved (75 mm thick SFRC) specimens.

the deck plate thickness requirement is 16 mm, but no scallop was specified as a structural detail (JRA 2017). Therefore, it should be noted that the 16 mm thick deck plate analytical model in this paper does not comply with the current design code in structural detail and is only a relative comparison of the effect of deck thickness. The 75 mm thick asphalt overlay is a common structural detail in bridges in Japan; hence, the results are presented for the same thickness. The disadvantage of asphalt for consideration of fatigue durability is its stiffness varies with temperature. In this study, three seasons were tested representing various temperatures, assuming the temperature for spring is the same for autumn. The Young’s modulus was set to 500, 1500, and 5000 MPa for summer, spring, and winter respectively, while the Poisson’s ratio for all cases of asphalt was set to 0.35 (Inokuchi et al. 2008).

3 STRESS INTENSITY FACTOR CALCULATION

3.1 Displacement-matching approach

Three modes exist to define the type of loading applied to a crack: Mode I, Mode II, and Mode III, which correspond to opening, in-plane shear, and out-of-plane shear respectively. Since a stress singularity tends to form at the crack tip, it is desirable to describe the crack tip condition by its amplitude, SIF. If the SIF K is determined, then all components of stress, strain, and displacement can be calculated, given the distance r from the crack tip, and angle θ from the horizontal at the opposite side of the crack. For Mode I, the SIF is defined by Equation 1 (Anderson 2005):

$$K_I = \lim_{r \rightarrow 0} \left[\frac{E u_y}{4(1 - \nu^2)} \sqrt{\frac{2\pi}{r}} \right] \tag{1}$$

where r is the distance from the crack tip; E is the Young’s modulus; u_y is the displacement perpendicular to the crack; and ν is the Poisson’s ratio. In lieu of obtaining the closed-form solution, the

SIF K_I can be obtained by calculating Equation 1 numerically. This study only focused on the Mode I SIF K_I , as the results demonstrated that it is the most dominant SIF. Hereon, this paper refers to the Mode I K_I as SIF, unless otherwise specified.

3.2 Crack-tip plasticity confirmation

To validate the applicability of Equation 1, the formation of crack-tip plasticity was examined. As the plastic zone at the crack tip becomes larger, the elastic analysis becomes more inaccurate (Anderson 2005). Hence, it would be desirable to confirm a minimal area of plasticity at the crack tip. Furthermore, the normal stress near the crack tip varies with $1/\sqrt{r}$, while the displacement near the crack tip varies with \sqrt{r} . In this section, it is demonstrated that all these conditions were met by the analytical model.

Figure 5a shows the relationship between the normal stress σ_{yy} in front of the crack tip (+x direction) and the distance from the crack tip for the unpaved 12 mm model with an 8 mm deep crack. In this section, the local coordinate system shown in Figure 5a is used. Taking the stress field for Mode I and the triaxial state due to plane strain, and substituting these equations to the von Mises yield criterion gives a normal stress at yield of $\sigma_{yy} = 887.5$ MPa for SM490YB, as outlined as well by Hattori et al. (2020). This means a normal stress above this value belongs to the plastic zone. As shown in Figure 5a, the plastic zone was formed up to about 0.09 mm from the crack tip. With respect to the crack dimensions (in this case, $a = 8$ mm; $b = 53.35$ mm), the plastic zone was relatively small. Furthermore, the singularity zone was confirmed to form up to 0.15 mm in front of the crack tip, as shown by the slope -1/2 on the logarithmic scale which corresponds to the normal stress varying with $1/\sqrt{r}$.

Figure 5b shows the relationship between the displacement perpendicular to the crack u_y of the crack-face node and its distance from the crack tip (-x direction). As shown, a singularity zone was formed up to 0.30 mm behind the crack tip. This zone was determined from the intersection with the line of slope 1/2 in the logarithmic scale, which corresponds to the displacement u_y varying with \sqrt{r} .

3.3 Stress intensity factor extrapolation

As the SIF is valid only to the crack-tip displacement field, the SIF should be taken only from the singularity zone. As shown in Figure 5b, the singularity zone for the 8 mm deep crack model reached up to 0.30 mm from the crack tip. For smaller cracks, the singularity zone had a longer range with the 2 mm deep crack model having the longest range of 1.20 mm. However, to maintain consistency across various models, the maximum range of 0.30 mm was considered for the calculation of the SIF.

In convergence studies by Anderson (2005), it was found that for the displacement-matching approach, the SIF should be extrapolated from crack-face nodes that are relatively close enough to the crack tip (i.e. singularity zone). However, Anderson (2005) stated that the inclusion of the first few nodes introduced some error with respect to the theoretical value. Therefore, in the current study, while taking the maximum range to be 0.30 mm from the crack tip, the range for SIF extrapolation was further narrowed by examining the consistency of the linearity between the argument of the limit in Equation 1 and the distance from the crack tip. Taking the range 0.125 to 0.30 mm resulted in a coefficient of determination R^2 of at least 0.96 for all sets of models including different pavement configurations. It should be noted that the closer the value of R^2 to 1.0, the greater the consistency of linearity is. Therefore, using the displacement-matching approach (Equation 1), the SIF was extrapolated from the range 0.125 to 0.30 mm from the crack tip.

4 ANALYTICAL RESULTS AND DISCUSSION

4.1 Effect of SFRC overlay thickness

Figure 6 shows the relationship between the SIF and crack depth for different thicknesses of SFRC pavement. It can be observed that the SIF increased across the crack depths except in the case of the unpaved condition wherein the SIF peaks at the 6 mm deep crack. This can be explained by the changing of the bending stress direction at the neutral axis in the deck plate. On unpaved models,

the neutral axis was located 5.9 mm from the bottom of the deck plate, as demonstrated by stress analysis on uncracked models. The neutral axis shifted to 8.8, 10.1, and 10.2 mm from the bottom of the deck plate for the 25, 50, and 75 mm thick SFRC pavement models respectively.

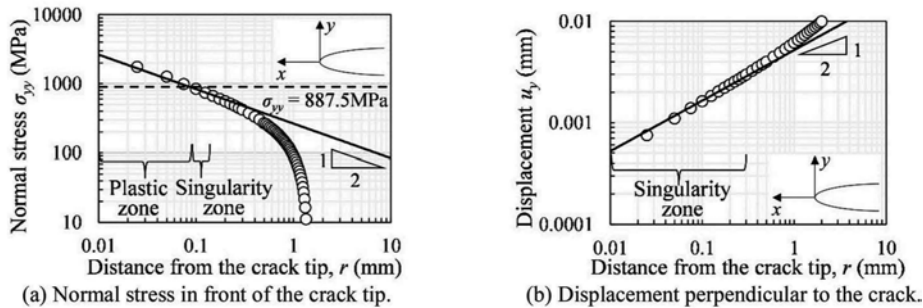

Figure 5. Crack-tip plasticity confirmation for the unpaved 12 mm thick deck plate model with an 8 mm deep crack.

In all cases of the uncracked models, the deck plate was in negative bending at the weld root location; hence, the weld root was in compression. However, it is assumed that there are residual tensile stresses resulting in net tension, which causes the crack to initiate.

Figure 7a shows the relationship between the SIF and SFRC pavement thickness for various crack depths. It should be noted that this figure shows the same data as Figure 6 but was reorganized to capture the influence of SFRC pavement thickness better. The other crack depths were removed as well for clarity. As the pavement thickness was increased, the SIF decreased. This is an expected behavior; since the SFRC pavement increased the rigidity of the deck system. Compared to the unpaved condition, the 50 mm SFRC pavement improved the SIF by at least 83% across the crack depths, while the 75 mm SFRC pavement improved the SIF by at least 88%. The Fatigue Design Recommendations for Steel Structures (JSSC 2012) states that the mean design threshold SIF, ΔK_{th} is equal to $76 \text{ N/mm}^{3/2}$ for the crack propagation design curve. A SIF below this threshold value means the crack is not likely to propagate. As shown in Figure 6, the SIF is below the threshold for crack depths of 2 to 3 mm ($\text{SIF} = 68 \text{ to } 73 \text{ N/mm}^{3/2}$). While the SIF for the model with crack depths 4 to 8 mm was above the threshold ($\text{SIF} = 77 \text{ to } 89 \text{ N/mm}^{3/2}$), it was still close; hence, theoretically, the crack may propagate, albeit very slowly. As for practical purposes though, it may be considered that the crack is not likely to propagate, as demonstrated by previous fatigue tests for 75 mm thick SFRC pavement reinforcement (Murakoshi et al. 2019). The previous fatigue testing showed that the remaining cracks (crack depth: 5.9 to 10.8 mm) did not propagate at 10 million cycles of 50 kN load after reinforcing the OSD specimen with SFRC pavement. The same study concluded that even for 50 mm thick SFRC pavement reinforcement (Analysis SIF for 8 mm deep crack = $128 \text{ N/mm}^{3/2}$), the cracks did not propagate. This further supports the argument that the propagation may be very slow for the 75 mm thick SFRC pavement reinforcement, and for practical purposes, sufficient to suppress the crack propagation.

4.2 Effect of adhesive debonding

Figure 7a shows the SIF of the base case wherein the Young's modulus of adhesive was set to full capacity. Figure 7b, on the other hand, shows the relationship between the SIF and SFRC pavement thickness of the case wherein the adhesive has debonded. The SIF of the debonding case increased by 60 to 87% across various crack depths and SFRC thicknesses. In particular, the SIF of the model with the 8 mm deep crack and 75 mm thick SFRC pavement increased from 89 to $153 \text{ N/mm}^{3/2}$, which is 101% higher than the threshold value ΔK_{th} . It is also above the SIF of the 50 mm thick SFRC pavement reinforcement (Analysis SIF = $128 \text{ N/mm}^{3/2}$) which did not show crack propagation in actual fatigue testing (Murakoshi et al. 2019). Therefore, there is no assurance in maintaining the crack suppression capacity of the 75 mm thick SFRC pavement if adhesive debonding occurs.

4.3 Effect of asphalt overlay rigidity

Figure 8a shows the relationship between SIF and asphalt rigidity for a 12 mm thick deck plate with a 75 mm thick asphalt overlay. The SIF was highest during summer and lowest during winter, which is an expected behavior based on stiffness across the seasons. For example, the SIF of a 75 mm thick asphalt on a 12 mm thick deck plate was at most 437 N/mm^{3/2} across crack depths during summer, at most 296 N/mm^{3/2} during spring, and at most 183 N/mm^{3/2} during winter, which are 475%, 290%, and 141% higher than the threshold ΔK_{th} respectively.

Figure 6. Relationship of SIF and crack depth for the 12 mm thick deck plate reinforced with SFRC pavement.

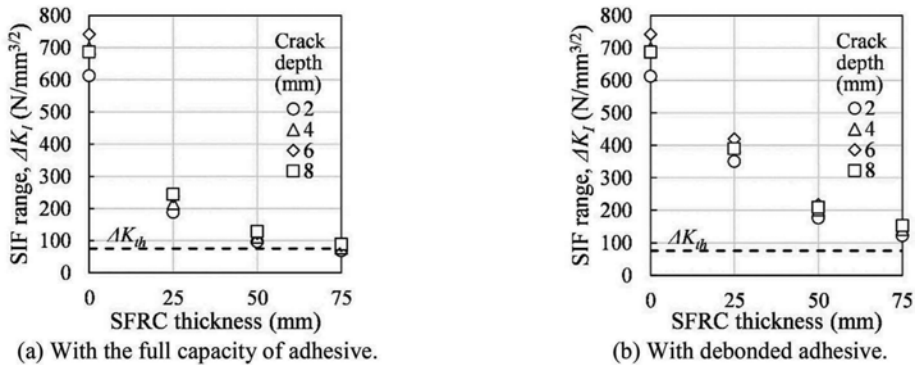

Figure 7. Relationship of SIF and SFRC pavement thickness across crack depths for 12 mm thick deck plate.

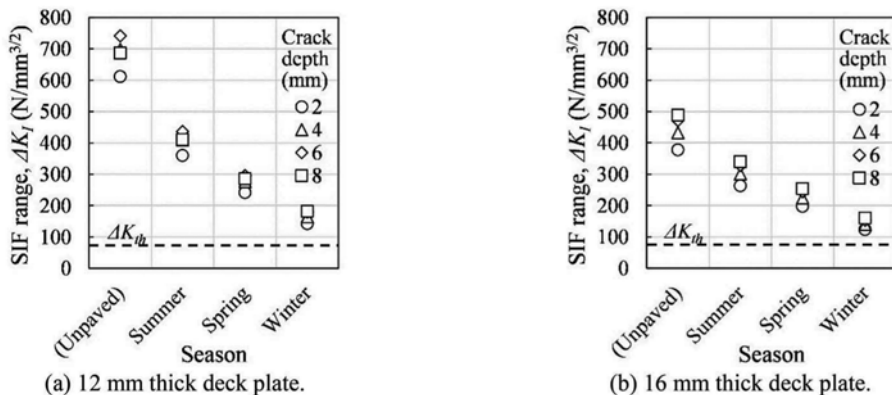

Figure 8. Relationship of SIF and asphalt rigidity for deck plate with 75 mm thick asphalt overlay.

Figure 8b shows the relationship between SIF and asphalt rigidity for a 16 mm thick deck plate with a 75 mm thick asphalt overlay. The SIF was at most $340 \text{ N/mm}^{3/2}$ during summer, at most $254 \text{ N/mm}^{3/2}$ during spring, and at most $161 \text{ N/mm}^{3/2}$ during winter, which are 347%, 234%, and 112% higher than the threshold ΔK_{th} . Hence, the SIF of the 75 mm thick asphalt in either the 12 or 16 mm thick deck plate during winter was still higher than that of the SFRC with debonded adhesive. In addition, this contribution from asphalt cannot be sustained during higher temperatures in other seasons.

5 CONCLUSIONS

Several finite element models were developed to analyze the crack suppression effect of SFRC pavement on a simply supported partial OSD specimen. Semi-elliptical cracks with an aspect ratio of 0.15 were introduced at the root of the rib-to-deck weld. A relatively small plastic zone, as well as a singularity zone, was confirmed at the crack tip, validating the use of the SIF for characterizing the stress condition. The SIF was then obtained from crack-face nodes 0.125 to 0.30 mm away from the crack tip using the displacement-matching method. The main results are enumerated as follows.

- (1) Reinforcing the OSD specimen with 75 mm thick SFRC pavement decreased the SIF to a level below the threshold ΔK_{th} for crack depths 2 to 3 mm, theoretically confirming that the crack is not likely to propagate. For crack depths of 4 to 8 mm, on the other hand, the SIF was still higher than the threshold, albeit close. Although theoretically the crack is likely to slowly propagate, previous fatigue testing supports that this is not the case. Therefore, for practical purposes, it can be considered that the crack still may not propagate.
- (2) The debonding of the adhesive that attached the SFRC pavement to the deck plate led to a 60 to 87% increase in the SIF across various crack depths and SFRC pavement configurations, making the SIF of the 75 mm thick SFRC pavement model significantly higher than the threshold value ΔK_{th} . Therefore, when the debonding of the adhesive occurs, a crack with any depth from 2 to 8 mm is theoretically likely to propagate.
- (3) The common deck detail of using an asphalt overlay helped in decreasing the SIF and was most effective at cold temperatures. However, even if a 75 mm thick asphalt overlay was used on either a 12 mm or 16 mm thick deck plate, the use of a debonded 75 mm thick SFRC pavement on a 12 mm thick deck plate still resulted in a lower SIF. Moreover, this contribution of asphalt weakens during higher temperatures, which makes it unreliable for crack suppression.

Refined perception and management of ring-wise deformation information for shield tunnels based on point cloud deep learning and BIM

Wei Lin, Xiongyao Xie, Biao Zhou & Pan Li

ABSTRACT: The performance maintenance of shield tunnels is of more and more significance with a great number of shield tunnels being put into service. The perception of deformation is an essential part of shield tunnel performance assessment because of the correlation between deformation and all kinds of affecting factors during service. While due to the nature of shield tunnels, the perception of deformation based on the traditional method requires costly effort. For the refined perception of ring-wise deformation, which includes segment rotation and segment dislocation, an automated workflow for processing and managing the point cloud of tunnel lining has been proposed based on deep learning and BIM. An end-to-end deep learning model based on PointNet++ has been trained for the segmentation of ring-wise shield tunnel point clouds. With the proposed data normalization and augmentation method, the accuracy of the deep learning model can achieve promising results. Based on the ring-wise deformation pattern, a robust and efficient optimization algorithm for deformation extraction has been designed. The fusion of accurate data from point clouds and semantic information from BIM models enables the automatic calculation of all types of ring-wise deformation. The proposed methods and workflow provide novel perspectives of digitalization in the life-cycle maintenance for shield tunnels.

1 INSTRUCTION

The structural performance of shield tunnels is influenced by complex geotechnical and structural evolution during the life cycle, resulting in the lasting structural deformation process since as-built (Xie *et al.* 2021, Chang *et al.* 2022). The shield tunnel is a type of prefabricated assembled and long linear underground structure, constructed by joining lots of segments and rings. Due to the structural nature of shield tunnels, the deformation can be depicted as longitudinal deformation and transverse deformation (Yu *et al.* 2019). For each ring of shield tunnels, transverse deformation is the main concern when assessing life-cycle structural performance (Yang *et al.* 2018). Given the significance of ring-wise transverse deformation, varieties of methods and corresponding instruments have been proposed for data acquisition, such as total station, laser convergence gauge, tilt sensor (Chang *et al.* 2022), and optical-fiber sensors (Wang *et al.* 2019). However, the transverse deformation derived by the above methods is incomplete. The ring-wise transverse deformation of shield tunnels includes convergence, dislocation, and rotation (Dong *et al.* 2020). The above methods are designed for one of the deformation patterns and usually rely on instruments installed on the tunnel lining. Hence the measured transverse deformations are isolated between different deformation behaviors and are distributed at limited locations, which will result in poor information for life-cycle maintenance.

The development of laser scanning technology enables the efficient acquisition of large point cloud data during the life cycle of shield tunnels, in which detailed three-dimensional space information is included (Xie and Lu 2017, Lin *et al.* 2022). The advantages of laser

scanning also include the non-contact and non-destructive data acquisition process (Menendez *et al.* 2018). The segmentation of point cloud data, however, remains to be inefficient and labor-intensive (Yi *et al.* 2019). The promising feasibility of applying DL (deep learning) in the segmentation of shield tunnel point clouds has been shown (Zhang *et al.* 2022). While the application cases of DL in the shield tunnel point clouds are usually component-based systems rather than end-to-end models. In contrast, end-to-end models have the advantage of excellent performance, simplicity, and optimization (Li *et al.* 2022).

Lack of semantic information is another main challenge for interpreting and managing point clouds in the life cycle of infrastructure (Soilán *et al.* 2021). The deformation information between segments is implicitly included in the point cloud data. Consequently, it is difficult to extract deformation information without point-wise semantic information. The lack of semantic information will also result in the low re-usability of point cloud data in historical deformation analysis (Krijnen and Beetz 2017). The appearance of BIM enables information management and data exchange in the life-cycle of shield tunnels (Hegemann *et al.* 2020). While most researches concerning BIM in the field of shield tunnels focus on the design and construction phase (Ninic *et al.* 2021). The registration of geometric and semantic information for point clouds and BIM models is of obvious significance for infrastructure life-cycle data management (Shu *et al.* 2022), which has not been completely solved yet.

Given the challenges in the perception and management of deformation information for shield tunnels, this paper aims to advance digitalization in the life-cycle maintenance of shield tunnels utilizing DL and BIM. Point cloud datasets were labeled and the corresponding data processing algorithm was proposed. The deformation extraction method was then proposed based on a two-stage optimization algorithm for the semantic-rich point clouds. At last, an integrated and automatic workflow based on the proposed methods and BIM was proposed for the refined perception and management of ring-wise deformation of shield tunnels.

Figure 1. Ring segmentation of original point clouds.

2 SEMANTIC SEGMENTATION OF POINT CLOUDS

2.1 Point cloud scanning and labeling

The terrestrial laser scanning was performed in a station interval of a metro line, which consists of two parallel circle shield tunnels, namely upline and downline, from Wuxi. The point clouds were scanned by a Leica ScanStation C10, of which the modeled surface precision is within 2 mm. The coordinate systems of point clouds scanned from different scanning stations can be aligned by mutual targets. The point clouds of each shield tunnel ring can be segmented from the original point clouds, taking point clouds of upline between Ring 119 and Ring 140 for example, as shown in Figure 1. The point clouds of single rings contain the points generated by varieties of objects, such as segments, tracks, walkways, pipes, and cables, as also shown in Figure 1.

For point clouds of single rings, point-wise semantic labeling has been carried out. The labeled point clouds shown in Figure 2 can be used as datasets for DL training and testing. Given the assembled structural nature of shield tunnels, the segmentation of different segments is of great significance for deformation perception. Hence, point clouds for different segments are labeled separately. There are many utilities in the shield tunnels, which will bring disturbance in the point clouds. For the perception of structural deformation, segments are the actual concerned objects. One task of DL is to distinguish the points generated by other objects so that these undesired points can be removed. So the points of other different objects are labeled as the same, i.e., undesired points.

Figure 2. The labeled ring-wise point cloud.

2.2 Data normalization and augmentation

Data labeling is time-consuming and labor-intensive work. The number of valid datasets for DL may be very limited. Data augmentation is an important technique to reduce overfitting and improve DL performance, of which the outstanding examples include the models named AdaPC, PointAugment, and PointMixup. One feasible and economic way for data augmentation is to generate new datasets by rotating the points of real datasets. It's noted that unreasonable augmentation methods will result in invalid datasets, even harmful. For ring-wise point clouds of shield tunnels, a data augmentation method considering global and local rotation is proposed, as shown in Figure 3. The coordinate systems of point clouds are not specified when scanning. Hence, for the easier design of data processing and better performance of the DL model, the data should be normalized before the augmentation procedure. The point clouds of rings will be transformed into a unified Cartesian coordinate system for understandable spatial description and normative coordinate operation. In the unified Cartesian coordinate system, the y-axis denotes the vertically upward direction, the z-axis denotes the tunneling direction in the horizontal plane, and the x-axis is determined by the right-hand rule. The origin is the barycenter of the tunnel ring. For the chosen point cloud, the unified coordinate system is uniquely associated with the tunneling direction. The tunneling direction (denoted as d in Figure 3) can be represented by the vector of the cylindrical axis from the shape fitting of the point cloud.

After the data normalization, the data augmentation can be implemented by a unified data processing program. According to the design of shield tunnels, the slope and alignment of rings will differ. In the step of global rotation, the points will be rotated at random degrees around the x-axis and the y-axis respectively to generate different slopes and alignments. Local rotation is proposed to increase the diversity in the positions of non-structural objects. The points of non-structural objects will be rotated at random degrees around the vector of tunneling direction. The proposed method for data normalization and augmentation ensures highlighting the local features rather than the nonsense global features of the point clouds in the DL models.

2.3 DL model training and testing

The architecture of the end-to-end point cloud DL network adopted in this paper is PointNet ++ (Qi *et al.* 2017), which is popular and influential for point cloud understanding (Agapaki

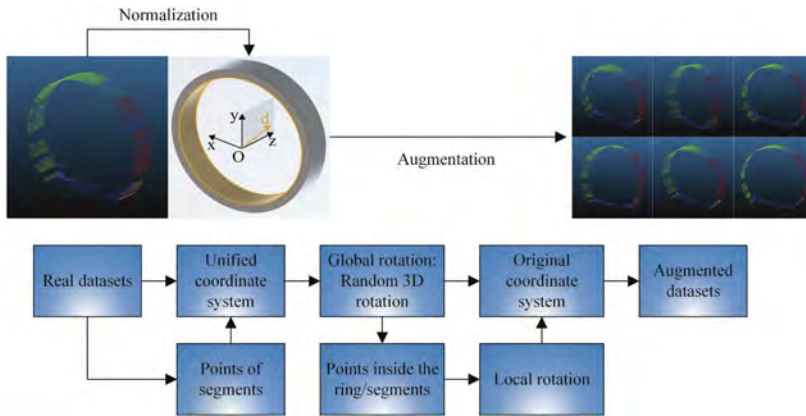

Figure 3. The workflow of the proposed data normalization and augmentation method.

Table 1. The number of points in the datasets.

Object	F	L2	B2	B3	B1	L1	Other objects
Number	3,136,410	7,498,800	3,693,890	925,909	3,389,710	8,618,730	11,885,100

Figure 4. The segmentation performance of the trained model.

and Brilakis 2020). The end-to-end point cloud DL model allows inputting point clouds directly into the network without unrolling or other extra data processing. The multi-scale grouping algorithm is adopted in the DL model.

The real datasets and the augmented datasets will be used together for the training and testing of DL models. Scanned point clouds were labeled as the real datasets and then were augmented. As shown in Table 1, the point clouds of 2193 rings, including 39,148,549 points, were prepared for the model training and testing. Given the 80:20 rule, 80% of the datasets are utilized for model training and the remaining 20% of the datasets are leveraged for model testing. The optimized network architecture parameters were determined by comparing preliminary tests. The accuracy and MIoU (mean intersection over union) are adopted to evaluate the segmentation performance of the DL model, as shown in Figure 4. The best accuracy and MIoU on testing datasets reached 96.0% and 92.8% respectively. Promising segmentation performance was achieved, which is the basis for deformation perception.

3 PERCEPTION OF RING-WISE DEFORMATION

3.1 Ring-wise deformation pattern

The ring-wise deformation patterns of shield tunnels include rotation, dislocation, and convergence. Rotation denotes the relative rotation between two adjacent segments. Dislocation

denotes the relative dislocation along the radius direction. Besides, the segments will deform under the structural effect of axial force and moment. Convergence denotes the comprehensive influence of the three factors on the actual diameters of the rings, which usually occurs in the form of ovalization (Nuttens *et al.* 2014). The interpretation of numerical simulation and model experiments demonstrates that the rotation and dislocation, i.e., the deformation patterns happening at joints, constitute the main part of ring-wise deformation (Wang *et al.* 2021). Hence, the convergence is mainly contributed by rotation and dislocation, which can be extracted from point clouds.

A ring-wise deformation pattern for shield tunnels is proposed considering the rotation, dislocation, and consistency of segments, as shown in Figure 5. Taking the six-segment ring for example, the deformation is determined by 12 parameters of the rotation and dislocation, which are constrained by the consistency of the segments. The proposed ring-wise deformation pattern allows the representation of arbitrary ovalization or convergence induced by rotation and dislocation.

Figure 5. The ring-wise deformation pattern of shield tunnels.

Figure 6. The workflow of the two-stage optimization algorithm for deformation extraction.

Table 2. The performance of the deformation extraction algorithm for the synthetic dataset.

Segment	F	L2	B2	B3	B1	L1	Maximum error
Ground truth of rotation/ $^{\circ}$	2.00	-0.30	0.40	0.20	-1.00	1.00	/
Extraction result of rotation/ $^{\circ}$	2.00	-0.31	0.40	0.20	-1.00	1.01	0.01
Ground truth of dislocation/mm	0.30	7.90	0.00	2.00	8.00	5.00	/
Extraction result of dislocation/mm	0.15	7.71	0.00	2.00	8.00	4.82	0.19

3.2 Deformation extraction algorithm

The high-resolution point clouds allow comprehensive descriptions of the deformation patterns. The point clouds with semantic information enable the automatic process of deformation extraction. The rotation and dislocation of each segment can be determined by the parameter fitting. Powered by the DL model and the deformation extraction method, an automatic perception method of ring-wise deformation is proposed. The workflow of the proposed algorithm for ring-wise deformation extraction is illustrated in Figure 6. A two-stage optimization method based on least squares is proposed for the fitting of 12 deformation parameters. The iteration of two-stage optimization is designed in the algorithm to ensure the overall accuracy of deformation extraction. Synthetic datasets generated by deformed ring

models with the designed deformation parameters were used to validate the performance of the deformation extraction. The performance of the proposed algorithm shows satisfying results, of which a case is listed in Table 2.

Figure 7. The parameters for modeling the ring-wise shield tunnels.

Figure 8. The codes and implemented results of parametric modeling and visual enhancement.

Figure 9. The management framework for data and information.

4 VISUALIZATION AND MANAGEMENT OF LIFE-CYCLE DEFORMATION INFORMATION

4.1 Parametric modeling of deformed shield tunnel rings

Due to the long-term behavior of life-cycle deformation, the models in the design and construction phase are not adequate to reflect the up-to-date deformation of shield tunnel rings. A parametric modeling method considering the rotation and dislocation of segments is proposed based on Revit and Dynamo. The demanded parameters for modeling the ring-wise shield tunnels are listed in Figure 7. The parameters can be classified into two types, namely static parameters and dynamic parameters. Static parameters reflect the inherent spatial properties of rings during the life cycle. While dynamic parameters reflect the up-to-date deformation information. For more elaborated models, the deformation behavior of the beam effect for segments can be further considered.

The proposed DL model and deformation extraction method can be coded as Python scripts and implemented in Dynamo. As a result, the proposed method can be embedded into the BIM environment, enhancing the level of automation and integration. Revit and Dynamo are also utilized to parametrically create and update BIM models of shield tunnel rings. Then, the ring-wise models can be defined automatically by static and dynamic parameters. The values of deformation are smaller than the size of shield tunnel rings, which brings difficulty

in observation. A visual enhancement algorithm was also proposed to explicitly display the deformation by RGB colors in the BIM environment. The proposed codes and implemented results in Revit are shown in Figure 8.

4.2 Management framework of point clouds and deformation information

Scanning data and deformation information are valuable digital assets in the life cycle of shield tunnels. A management framework combined with the BIM applications for data and information was designed to enhance data security and reusability, as shown in Figure 9. The semantic information is managed in the designed database. In the database, the historical deformation information is also stored so that the historical analysis will be convenient. The data and codes are integrated to model the deformed shield tunnel rings in Revit by Dynamo. The models can be uploaded to the cloud for remote management of shield tunnel performance.

5 CONCLUSIONS AND DISCUSSION

The data normalization and augmentation methods for ring-wise point clouds of shield tunnels are proposed to avoid the expensive effort of dataset scanning and labeling. Data normalization and augmentation will help reduce the demanded amount of scanning datasets. The segmentation performance of the end-to-end DL model trained by normalized and augmented datasets achieves promising results. The contribution of end-to-end DL in the workflow of deformation perception for the life-cycle maintenance of shield tunnels is illustrated. While the existing network architectures are not perfect and remain to be improved according to the characteristics of shield tunnel point clouds.

The ring-wise deformation pattern of shield tunnels considering the rotation and dislocation is analyzed. Based on the semantic-rich point clouds provided by the DL model, the deformation of each segment can be extracted based on the proposed two-stage optimization algorithm, which shows satisfying accuracy. The deformation behavior of the beam effect for segments can be further considered and extracted from point clouds. Despite the limitation, the proposed perception method of deformation is believed to be a promising supplement to existing measurement methods.

The data-driven parametric modeling is implemented by Dynamo with dynamic and static parameters as the input. The information supporting the life-cycle maintenance decision-making can be displayed in the models of deformed rings. In addition, a visual enhancement algorithm is proposed for the plain understanding of shield tunnel performance. The management framework of data and information ensures the level of automation in the workflow. For extension, the path for point clouds and deformation information to be expressed in the IFC framework should be further studied, for the unified information exchange.

The main interest of this paper is to explore the potential value of multi-discipline techniques in the life-cycle maintenance of shield tunnels. The practical application demonstrates that the life-cycle maintenance benefits from the digitalization of techniques adopted. Point clouds, DL, and BIM are believed to be the bases of the digital twin vision.

Structural model updating of an existing concrete bridge based on load testing and monitoring data

A. Agredo Chávez, J. Gonzalez-Libreros, L. Elfgren & G. Sas

Politecnico di Milano, Milan, Italy

ABSTRACT: The backbone of European infrastructure was built after the end of the second World War and has reached, or is near to, the end of its nominal design life. This issue urges the development of structural assessment procedures that can provide infrastructure managers the information to make decisions for repairing, upgrading, or replacement. In this paper, a methodology based on load testing and Structural Health Monitoring (SHM) for the assessment of a 65-year-old prestressed concrete bridge located in Northern Sweden is presented. The retrieved data is used to develop and calibrate structural models with different levels of data completeness. The SHM procedure includes the evaluation of material properties by diagnostics, definition of the layout and installation of the instrumentation, test execution, and data analysis. A preliminary structural model is developed based only on the original design parameters, and it is sequentially updated with monitoring data retrieved during a performed proof loading test of the bridge.

1 INTRODUCTION

The existing infrastructure and built environment represent approximately 50% of the national wealth in most countries within Europe (Plos et al. 2017). The economic impact of aging and deterioration processes on all such systems is exceptionally high (Biondini & Frangopol 2016, Bagge 2020). Therefore, the need of an adequate structural assessment procedure is fundamental when managing bridges' integrity along their life cycle and their impact in infrastructures networks, where a high level of decision-making is required for effective management of resilient lifelines (Capacci et al. 2022). Hence, it is necessary to go beyond the traditional visual inspection to properly assess the necessary intervention on the structure (Casas & Gómez 2013). To cope with the need of retrieving timely and continuous data to assess the structure, Structural Health Monitoring (SHM) employing non-destructive tests has risen as a promising technique for damage assessment, structural evaluation, structural model updating and model verification (Sanayei et al. 2015). Numerical methods for structural analysis provide a solid groundwork to predict the structural behavior under different loading conditions, nevertheless, when these predictions are compared with experimental data, it is frequently found that the degree of correlation is not satisfactory to allow the further use of the model with confidence (Mottershead et al. 2011). One of the approaches to reduce this discrepancy is to modify the modelling assumptions using experimental data to overcome model parameter errors to generate an improved numerical model. This validated numerical model is then used in further predictions for alternative loading arrangements and distinct structural configurations to complete an adequate structural assessment (Mottershead 1993).

Thus, seeking to define an innovative approach for bridge management, a series of on-site evaluation and testing on the integrity of a 65-year-old prestressed concrete bridge (see Figure 1)

were carried out. The Kalix bridge was a prestressed concrete box girder bridge located in Northern Sweden, and it was constructed by the balanced cantilever method.

Figure 1. The old Kalix bridge in the foreground with foundations of the new bridge behind.

Considering it had reached the end of its lifetime, the bridge is currently being dismantled (as of January 2023) after the construction of a new bridge. The new structure is aimed to carry the increase of traffic loads in the area and both bearing capacity and geometry have been upgraded accordingly (Gonzalez-Libreros et al. 2022). The retrieved data will be then used to calibrate a structural model where the estimation of material properties by means of several core extraction and a proof loading test were performed with the aim of evaluating the structural response of the bridge under serviceability loading conditions.

2 KALIX BRIDGE

2.1 Description of the bridge

The Kalix bridge was a five (5) span prestressed concrete bridge, with total length of 283.6 m and 13 m wide. The structure is a single-box-girder with variable cross-section, as shown in Figure 2. The bridge shows complete symmetry (geometry and supports) at midspan, where the bridge halves are joined by a pendulum bearing as described in section 2.3. The bridge was dimensioned according to the 1955 Swedish provisional regulations and the prestressing system was ruled by DIN 4227 (Deutsche Norm Vorgespannt), obeying the German standard code for this bridge typology, initially patented and by Dyckerhoff & Widmann AG (Dinges 2009).

Figure 2. Kalix bridge lateral view (half of the bridge) and cross section geometry in meters.

2.2 Concrete cores extraction

According to the technical drawings retrieved from the Swedish Bridge and Tunnel Management system (BaTMan), the design concrete compressive strength for the superstructure was 45 MPa. Nevertheless, an extensive campaign of core extraction was performed as part of the material characterization. This allowed refining the knowledge on material mechanical properties to better calibrate the numerical model and improving model parameters uncertainties.

The extraction of concrete cores followed the schematic procedure shown in Figure 3 (red font). Different sections along the bridge were selected (from the outer span O_b , the inner span I_b , to the console C_b). The stages/batches used in the construction process were considered as a main criterion to choose the sections for core extraction and additional samples were obtained from regions in which the instrumentation was located (e.g., deflectometers). The instrumentation layout (black font) will be discussed in section 3.2.

Figure 3. Kalix bridge instrumentation and core extraction layout.

In total, four sections per span were selected for core extraction (red zones), the number of sections chosen was constrained to 108 cores, since it allocated a significant amount of time and resources to obtain the samples. From each section, nine cores were obtained from the same element of the girder (either the wall, bottom, or top slab) as shown in the cross section drawing in Figure 3. Out of these nine cores, three are used for compression test, three to determine modulus of elasticity and three for fracture of energy. Currently, the tests are being performed at Luleå University of Technology (LTU) laboratory. A summary of the results for compressive strength obtained so far (as of January 2023) are shown in Table 1.

Table 1. Compressive strength results from core extraction MPa.

O ₁	O ₂	O ₃	O ₄	I ₁	I ₂	I ₃	I ₄	C ₁	C ₂	C ₃	C ₄
71.12	59.03	57.69	52.36	-	60.60	57.33	43.43	-	-	-	-
69.43	53.32	59.19	-	-	59.44	62.74	57.15	-	-	-	-
-	-	57.99	-	-	56.43	-	-	-	-	-	-
-	-	58.97	-	-	-	-	-	-	-	-	-
-	-	54.81	-	-	-	-	-	-	-	-	-

2.3 Boundary conditions

From the technical drawings and visits on site, initial boundary conditions were identified. It is important to stress out that the symmetry in geometry of the bridge includes the supports of each pillar as labelled in Figure 2. Continuity of the bridge is enforced by the continuous reinforcement along the bridge, no joint was constructed between the element's casting stages, except from the pendulum joint at the end of the balanced cantilever part. The support over pillars 1,2,5, and 6 were set to constraint vertical movement, meanwhile the support over pillars 3 and 4 constrained vertical a longitudinal displacement, allowing bending and torsional rotation.

The joint at the end of the cantilever segment consisted of two pendulum hinges, allowing for independent longitudinal displacement, and bending rotations of the two connected cantilever ends. However, the transversal and vertical displacements, as well as the torsional rotation, are forced to remain equal.

3 LOAD TESTS AND MONITORING

3.1 Proof-load test

The designed proof loading was performed at the beginning of January 2022, and it is extensively described elsewhere (Gonzalez-Libreros et al. 2022). It comprised three different load cases (Load case I, II and III), where the vehicles (see Figure 4(a)) were loaded with additional gravel material. Subsequently, they were placed in four different positions (position 1 to 4), giving a total combination of 36 different load patterns. For load case I, one vehicle was in the center of the cross section (see Figure 4(b)). Load case II consisted of two vehicles placed symmetrically with respect to the bridge axis. In load case III, four trucks were used and distributed in two rows with the same transversal layout as for case II.

Three different load levels were set with the aim to evaluate the serviceability state under low and high loading conditions for each load case. The levels were set at: 0%, 50% and 100% of the

Figure 4. (a) Truck and Lorry dimensions in meters. (b) Truck position on the cross section in meters.

additional weight at which the truck can be loaded. It is important to note that for load cases II and III, the total weight applied to the structures need to be multiplied by two and four, respectively, due to the double layout of trucks on the cross section specified in Figure 4(b). Table 2 shows the weight per axle of a single truck and lorry for each load level.

Table 2. Weight in ton per axle in each load level for the vehicle shown in Figure 4 (a).

Load Level/Axle	A1	A2	A3	A4	A5	A6	A7	Total
Empty (0%)	5	4.3	4.8	0	3.8	0	4.8	22.7
Half (50%)	5.9	6	7	3.8	6.3	7	7	43
Full (100%)	5.9	9.7	9.4	7.2	8.9	10.9	10.9	62.9

Table 3 shows the four different positions along the length of the bridge that were set per every load case and load level to assess the bridge structural response under the loading condition. The time allocated for data recording per every position was five (5) minutes. This time was established to guarantee the stabilization of the readings and reduced the time of testing as it was performed under extremely low temperatures (-25°C).

Table 3. Truck location and main measurements during the proof loading.

Position	Location* and main measurement result
1	5.0 m from pier 6, shear strains
2	13.8 m from pier 6, maximum bending strains
3	42.0 m from pier 6, shear strains
4	47.0 m from pier 4, maximum displacement at hinge

*Measured from the given pier in direction from Kalix to Luleå.

3.2 Instrumentation

A measurement plan was designed to assess the bridge's behavior during the proof loading test. The deployed instrumentation shown in Figure 3 (black font) aimed to target: strains (in the pre-stressing bars S_p and concrete surface: S_c and DIC), displacements (D_1 - D_3), inclination (I_1 - I_2), and acceleration (A_1 - A_4). All the instrumentation was carefully chosen to feature resistance to temperatures up to (-30°C). Most of the measurements of the bridge were acquired at a sampling frequency 50 Hz, except for Fiber Optic Sensor (FOS's) strain measurement, which varies from (8.333 to 12.5 Hz). Temperature was measured at several locations using thermocouples type T distributed as follows: Two located into induced holes in the box-girder's walls, one located on the locker where the data acquisitions wires were being stored, one inside the concrete box girder and one located outside the box girder, in the top slab.

4 EXPERIMENTAL AND NUMERICAL RESULTS

4.1 Results from in-situ instrumentation

The three deflectometers displayed in Figure 3, consisted of two (2) optoNCDT located at mid-span between pillar 5 and 6, positioned in each flange side of the box girder and one (1) Noptel placed at the pendulum joint. The displacements retrieved from the proof loading test

performed showed, in general, a tendency to be stabilized during the measurement time of the testing as shown in the highlighted gray zone in Figure 5. This means that the time allocated for each load level allowed for instant deformations and the viscoelastic effects of the boundary conditions to be steadied.

Figure 5. Deflection in time for Load case I with load level 0% measured by OptoNCDT and Noptel.

Figure 6 shows the data retrieved from the proof loading performed at position 2 from the OptoNCDT located at midspan between pillars 5 and 6, and Figure 7 represents the data read by the Noptel at the hinge (pendulum joint). Deflections recorded by the Noptel were significant lower to those read by the OptoNCDT due to the position of the loading level, therefore, for the sake of better appreciation of the data, the vertical axis of both OptoNCDT and Noptel were fitted as displayed in each load level. It is important to highlight that due to the constructions works aimed to the final stages of the new Kalix bridge and demolition of the old one from the contractor side, some load levels present disturbances on the displayed data or peaks at certain time in comparison with other load levels.

Figure 6. OptoNCDT deflections for load cases I, II and III.

Figure 7. Noptel deflections for load cases I, II and III.

4.2 Calibration of numerical models

A linear elastic model was developed using Robot structural Analysis (Autodesk 2022), as shown in Figure 8. This model represents the Kalix bridge by means of continuous frame elements joined by a hinge which allows for independent longitudinal displacement and bending rotations of the two connected cantilever ends. The sectional and material properties were initially assigned based on the original design parameters. This model will enable to achieve the structural response evaluation under serviceability loading conditions replicating the proof loading test performed (see section 3.1).

The calibration of the numerical model followed an iterative procedure, as more information of the bridge is gathered, model updating is accomplished by progressively incorporating the new estimations into the structural model to meet model predictions with the retrieved testing data. First attempts of model updating showed that the modelled system was more

flexible than the behavior obtained in the testing, which is common for structures which visually showed a good condition throughout all the serviceability years (Faber et al. 2000). Therefore, in the calibration process, stiffness was adjusted to properly capture the on-site material properties and the actual mechanical behavior of the rigid diaphragm at the supports.

Figure 8. Structural model developed in Robot Structural Analysis (Autodesk 2022).

Before initiating the proof loading, all the instrumentation was zeroed to provide every device with a baseline reading when “no loading” was on the bridge. To achieve a validated model that resembles more closely the data display in section 4.1, an initial model (A) has been progressively modified as follows:

- Model A: Parameters are set following the information obtained from technical drawings materials (i.e., geometry, material properties, boundary conditions, etc).
- Model B: From model A, compressive strength is updated, following the core extraction and testing described in section 2.2.
- Model C: From the material update incorporated in model B, length offsets are then included at the abutments and mid-supports to account for the rigid diaphragm and transversal stiffening beams, causing a reduction of the elastic length of the element.

In the evaluation of results, only those retrieved for position 2 are displayed. Position 2 is of special interest in the evaluation of the bridge bending behavior as a previous condition assessment performed determined that the prestressing tendons in the bottom slab at this point have a utilization ratio in bending beyond 100%.

The displacement shape comparisons for half of the bridge between models A, B and C are shown in Figure 9, only load case III at position 2 is evaluated, where also the data recorded from the deflectometers OptoNCDT and Noptel are displayed. It is possible to observe how all the results obtained with different models, showed a resemblance of the structure’s proof loading deformed shape when comparing them with the measured data.

Figure 9. Deformed shape of progressive calibrated models (a) LCIII 0%. (b) LCIII 50%. (c) LCIII100%.

Tables 4 and 5 show the calibration results achieved when tuning material properties and boundary conditions, where $\Delta_{L/2}$ represents the displacement results at midspan between pillars 5 and 6 (OptoNCDT) and Δ_h represents the displacement results at the hinge (Noptel). In general, a good approximation is attained, where only in LCIII 50% results overpassed 20% of error at the hinge. The main reason for this is addressed that when performing that load level during the proof loading test, it was registered disturbances due to activities done by the contractor on the bridge, aimed to its demolition, modifying the recorded data in comparison to other load levels.

A better approximation was achieved for the first midspan from Kalix side than from the hinge, this may be related to a not accurate idealization of the pendulum joint behavior and additionally, to long-term deformations at the hinge associated to creep which is a well-known problem that bridges built by the balanced cantilever method undergo (Plos & Gylltoft 2006).

Table 4. Calibration results when comparing with OptoNCDT data.

	Model A			Model B		Model C	
	Δ	$\Delta_{L/2}$	error	$\Delta_{L/2}$	error	$\Delta_{L/2}$	error
	cm	cm	%	cm	%	cm	%
LCIII 0%	0.26	0.28	9.79	0.27	5.53	0.26	1.6
LCIII 50%	0.46	0.55	15.7	0.52	11.87	0.5	7.9
LCIII 100%	0.64	0.81	20.02	0.77	16.41	0.74	12.8

Table 5. Calibration results when comparing with Noptel data.

	Model A			Model B		Model C	
	Δ	Δ_h	error	Δ_h	error	Δ_h	error
	cm	cm	%	cm	%	cm	%
LCIII 0%	0.09	0.1	12.37	0.1	8.97	0.11	14.7
LCIII 50%	0.15	0.2	25.5	0.19	22.82	0.21	21.9
LCIII 100%	0.18	0.19	1.94	0.18	1.25	0.2	6.3

The longitudinal rotation retrieved by the inclinometers for the load case III 100% is presented Figure 10 (a). It is possible to appreciate how it was not feasible to achieve a steady rotation of the recorded data during the five minutes of the proof loading, especially, at the abutment. Main assumptions regarding not reaching steady readings are ascribed to viscoelastic effects of the boundary conditions. Therefore, an improvement of the boundary conditions should be performed which considers the instant deformations and the viscoelastic effects of the pillar and abutment.

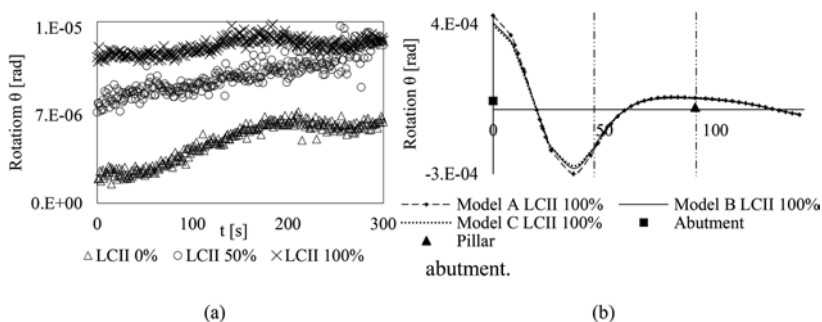

Figure 10. (a) Abutment rotation recorded in time. (b) Rotation achieved in numerical models.

All the data analysis and the results from the structural modelling showed how the actual structural response of the bridge under serviceability conditions was higher than the predicted with designed parameters by nearly 30%. This type of results is often attained and the main reasons ascribed are due to system effects, load redistribution, contribution of non-structural elements and bearings not performing in the expected way (Faber et al. 2000). It was also shown how the advantage of developing a structural model provides to decision makers a solid foundation to acknowledge the results coming from monitoring. Without an a-priori model based on designed parameters and as well as an updated model by parameter identification it would not be feasible to recommend options for corrective measures assertively (Ye et al. 2020).

5 CONCLUSIONS

This paper highlighted the importance of complementing proof-load testing and monitoring with structural models, particularly when the structure is subjected to external interference that could affect the quality of the monitored data. The presented case study investigated the structural performance of a 65-year-old prestressed concrete bridge located in Northern Sweden under serviceability loading conditions. The results and data gathered from the load testing indicated a stiffer structural response condition when compared with the numerical model built with parameters found on the technical drawings. This difference could be related to system effects, load redistribution, contribution of non-structural elements and bearings not performing in the expected way.

A better approximation was achieved for the first midspan from Kalix side than from the hinge, this may be related to the impact of long-term deformations at the pendulum joint associated to creep. Further studies should be performed to determine with a better degree of accurateness the boundary conditions that govern the structural response of the bridge. Moreover, the rotation did not reach steady readings during the five minutes of the proof loading, especially, at the abutment.

The progressive calibration process allowed to recognize how updating material properties and boundary conditions improved the structural model results when compared with monitored data at the same rate. The results obtained from the updates developed from model A to B (Young's modulus updated) improved in approximately 5%, when compared with testing data, which was nearly the same percentage when updates were introduced from model B to model C (Young modulus and boundary conditions updated). Therefore, structural monitoring and condition assessment should always account for methodologies to assess material properties and boundary conditions with the same level of importance.

ABSTRACT: A new bridge was built in Kalix, northern Sweden, to replace the existing prestressed concrete box-girder bridge that had been in service for more than 60 years. The old bridge had a total length of 283.6 m divided in five spans: 43.9 m, 47.0 m, 94.0 m, 47.0 m, and 43.9 m. It was constructed using the balanced cantilever method with segments with a length of around 3.0 m. The need for replacement arose from recommendations extracted from an assessment of the old bridge state and capacity. In addition to the construction of the new bridge, its replacement prompted the need to evaluate and define the demolition procedure of the existing structure. The demolition procedure had to be carefully studied to avoid damages to the new bridge and stability related issues but also to avoid falling debris in the Kalix River, which is part of Natura 2000 protected area. In this paper, the different aspects considered for the development of the demolition strategy are discussed. These aspects include the use of bed-rock anchored tendons, intermediate support fixing at specific locations, and proper evaluation of position of the demolition equipment supported by the bridge, among others.

1 INTRODUCTION

Demolishing an existing bridge is always a challenge, especially if the bridge is located in a protected natural site; public discussions related to it represent all the time a good opportunity to share knowledge among the bridge engineers.

The initial plans of the bridge designed in 1955-1956 were studied in detail (Figure 1), to understand the structural details and construction phases involved in the initial built of the bridge.

2 PLAN FOR DEMOLITION

The existing bridge over the Kalix River is a five-span box-girder post-tensioned concrete bridge, built with balanced cantilevers (“*freivorbau*”). It was replaced by a new bridge in 2022.

Figure 1. Kalix bridge lay-out.

The initial construction phases were studied in the old building plans and the demolishing procedure tried to follow similar de-construction steps (Daescu et al, 2022).

2.1 Spans 1 and 6

The initial building conditions involved the use of a general formwork solution, and it was estimated that the demolition procedure should have a similar approach. Of course, the input from the contractor was also considered carefully.

2.2 Spans 2-3 and 4-5

According to the original technical documentation, these spans of the bridge were constructed in $\approx 3.1\text{m}$ long sections. The evaluation of the demolition procedure considered the deconstruction of the bridge in a reversed-engineered process to the construction one.

The following are identified as critical points in the deconstruction procedure:

- Establishing the deconstruction phases, i.e., in what order and how large sections can be removed.
- Fixing the intermediate supports 3, 4 and evaluating the bending moment capacity of the intermediate support fixing system.
- De-coupling the bridge key-points., i.e., how to ensure safe transition between the two different statical systems, spans 1 and 6, and spans 2 3 and 4.
- Evaluating the footing condition during the deconstruction phases, i.e., how to prevent loss of stability at the foundation bedrock interface.

3 DEMOLITION DESIGN APPROACHES

Five demolition design approaches were studied to determine the optimum method for the demolition procedure. Modeling used the AxisVM software.

These five design approaches had to consider the following:

- Using a certain number of tendons anchored into the bedrock, to stabilize the bridge during deconstruction.
- Limiting the axial force in the bedrock anchors to avoid shear failure in the bridge.
- Fixing/blocking solutions for the existing pinned-supports.
- Checking the shear capacity of the bridge at the bedrock anchors fixing points.

The own weight of the demolition equipment (300kN) was included only in the 1st approach, but was left aside for the rest, since we needed to reduce the bending moments over the blocked supports 3 and 4 to a theoretical minimum value.

3.1 1st demolition design approach

The evaluation took into consideration removing $\approx 3.1\text{m}$ long sections, one by one, symmetrical to the supports 3 and 4, respectively; the aim was to evaluate the maximum axial force that can appear in the anchors (installed before process start, as sketched in Figure 2) due to the unbalance produced in the two cantilevers.

Figure 2. Studied anchoring system.

Figure 3 presents the variation of the axial stresses in the anchors, during the evolution of the demolition procedure (steps 1 ... 28, represented as blue segments).

From these results we can draw the conclusion that the required axial capacity of the tendon is about 17.6MN. Thus, the following issues raised:

- The tendon's capacity requirement is quite high, and a group of anchors might be necessary.
- The shear capacity of the bridge, at the position of the anchoring tendon is about 1.39MN, compared to the 17.6MN shear force applied by the anchor on each web in the bridge cross-section.

Figure 3. Variation of the axial stresses in the anchors – 1st approach.

3.2 2nd demolition design approach

The second approach involved placing anchors at about 9.3m distance (about three casting sections apart), meaning that on each side of the pier 3[4] should have three anchoring sections. Besides these tendons, in the final phase of the deconstruction, additional tendons should be installed closer to the pier 3[4], spaced at about 3m (at each casting section), as presented in Figure 4.

A maximum force of about 1.96MN resulted for anchor (+3) in the initial phase (step 00) of the demolition process, corresponding to the moment of the demolition of the decoupling sections. The rest of the steps, the maximum axial force in tendons was about 1.5MN.

This reduction in the axial force in the tendon leads to the following conclusions:

- The axial force in tendons is sufficiently small to be easily anchored.
- The utilization degree of the shear capacity of the bridge cross-section is about $1.96/1.39 \approx 141\%$ next to the tendon (+3).

Figure 4. Variation of the axial stresses in the anchors – 2nd approach.

3.3 3rd demolition design approach

This approach is similar to the 2nd one, but we tried to reduce the necessary number of tendons and the axial forces in tendons by optimizing the deconstruction phases.

The evaluation procedure is illustrated in Figure 5; similarly, the blue cells indicate the cross-section to be demolished in a specific step (1 .. 27).

A maximum force of about 1.96MN was recorded for tendon (+3) in the initial phase (step 00) of the demolition process, corresponding to the moment of the demolition of the decoupling sections. The rest of the steps, the maximum axial force in tendons was about 0.68MN.

This reduction in the axial force in the tendon leads to the following conclusions:

- The axial force in tendons is sufficiently small to be easily anchored.
- The utilization degree of the shear capacity of the bridge cross-section is about $1.96/1.39 \approx 141\%$.
- The drawback of this solution is that there are still needed 16 tendons.
- It is necessary to use an additional system for the stabilization of the reinforced concrete wall inside the bridge, above the pier, in the final deconstruction phase.

Figure 5. Variation of the axial stresses in the anchors – 3rd approach.

3.4 4th demolition design approach

This approach modifies the 3rd one by trying to reduce the necessary number of tendons and the axial forces in tendons by optimizing the deconstruction phases and by introducing a blocking system for the hinged support above the pier 3[4].

Besides these tendons, in the final phase of the deconstruction, additional laminated steel profiles should be used to block the hinged support above the pier 3[4], allowing the stabilization of the reinforced concrete wall inside the bridge, above the pier.

The evaluation is illustrated in Figure 6; similar to the previous figures, the blue cells indicate the cross-section to be demolished in a specific work step (1 .. 27).

A maximum force of about 1.96MN was recorded for tendon (+3) in the initial phase (step 00) of the demolition process, corresponding to the moment of the demolition of the decoupling sections. The rest of the steps, the maximum axial force in tendons was about 0.68MN.

This reduction in the axial force in the tendon leads to the following conclusions:

- The axial force in tendons is sufficiently small to be easily anchored.
- The utilization degree of the shear capacity of the bridge cross-section is about $1.96/1.39 \approx 141\%$.
- The additional system for the stabilization of the bridge in the final deconstruction phase consists of minimum 2 x HEB200 steel profiles located on both sides of each steel hinge (four hinges/pier). The maximum stress in the steel profiles is about 164N/mm^2 .

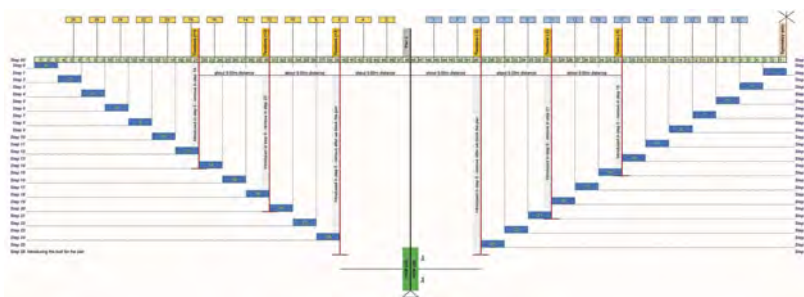

Figure 6. Variation of the axial stresses in the anchors – 4th approach.

3.5 5th demolition design approach

This last approach modifies the 4th one by trying once more to reduce the necessary number of tendons and the axial forces in tendons by optimizing the deconstruction phases and by introducing a slightly different blocking system for the hinged support above the pier [3][4]. Besides these tendons, from the initial phase of the deconstruction, on-site casted reinforced concrete should be used to block the hinged support above the pier [3][4], allowing the stabilization of the reinforced concrete wall inside the bridge, above the pier. This approach is illustrated in Figure 7; the blue cells indicate the cross-section to be demolished in a specific work step (1 . . .27).

Similar to the previous evaluations, a maximum force of about 1.15MN was recorded for tendon (+3) in the initial phase (step 00) of the demolition process, corresponding to the moment of the demolition of the decoupling sections. The rest of the steps, the maximum axial force in tendons was about 0.44MN.

This reduction in the axial force in the tendon leads to the following conclusions:

- The axial force in tendons is sufficiently small to be easily anchored.
- The utilization degree of the shear capacity of the bridge cross-section is about $1.15/1.39 \approx 83\%$.
- The additional system for the stabilization of the bridge in the final deconstruction phase consists of casted-in-place reinforced concrete walls, chemically anchored into the pillar.

3.6 Overview of the five studied approaches

These five studied cases evolved following the discussions with the general contractual for the demolishing works (NCC infrastructure). The request was to study the possibilities of using as less tendons as we could during the demolition process; for this purpose, step-by-step evaluation procedures were used. A general overview is presented in the Table 1.

Figure 7. Variation of the axial stresses in the anchors – 5th approach.

Table 1. Results overview.

Approach	No. of tendons	Support 3[4] type	Anchor max. axial force [MN]	Bridge shear capacity [MN]
1 st	2	fixed*	17.6	1.39
2 nd	16	fixed*	1.50	1.39
3 rd	16	fixed*	1.42	1.39
4 th	12	fixed**	1.42	1.39
5 th	12	fixed**	1.14	1.39

*The fixed support is a result of the anchors balancing/preventing the rotation.

**Laminated profiles or cast-in place concrete blocking are used to block the rotation of the support.

4 INTERMEDIATE SUPPORT FIXING

There were studied two distinct fixing solutions:

- By using chemically anchored rebars and additional concreting.
- Fixing the hinge with the help of additional steel profiles.

4.1 Rebars and concrete

An estimated reinforcement ratio was computed, to design the necessary anchorage system to be applied.

The evaluation took into consideration removing ≈ 3.1 m long sections, one by one, symmetrical to the supports 3 and 4, respectively; the aim was to evaluate the maximum bending moment that can appear in the blocked support above the pier (installed before process start) due to the unbalance produced in the two cantilevers. In this way, one can establish the necessary tensioned reinforcement that can prevent the overturning of the support 3(4).

The variation of the bending moment in the support, during the deconstruction process was evaluated in a step-by-step approach.

As a conclusion for this scenario, the built-in support should be able to provide a minimum bending (overturning) capacity of about 1.9MNm/m.

The obtained bending (overturning) capacity of the system is evaluated to ≈ 2.45 MNm/m, using 2x4 Φ 28 S500 steel bars.

4.2 Laminated steel profiles

Laminated steel profiles were used to block the hinged support above the pier 3[4], allowing the stabilization of the reinforced concrete wall inside the bridge, above the pier. Each of the four hinges above the pier was blocked by using a pair of HEB200 laminated profiles. The additional

system used for the stabilization of the bridge in the final deconstruction phase managed to effectively block the hinge, while the maximum stress in the steel profiles is about 164 N/mm².

5 FOOTING EVALUATION

The original documents provide the following information:

- Geometry for the foundation system and for the piers.
- Load bearing capacity of the ground, considered in the initial design.

The aim is to estimate the variation in the pressure under the existing footing, based on the de-construction phases. For this, the 3D model used in the previous evaluations was completed with the pier and the foundation system, as presented in Figure 8.

Figure 8. 3D model of the bridge, used for footing evaluation.

The start point of the analysis were the 4th and 5th approaches presented previously, but using the following hypotheses:

- there were used only two anchors on each side of the pier: Tendon (+3) and Tendon (-3).
- the surface support (between the footing and the soil) was considered with the rigidity $k_s = 100$ MN/m/m/m, to better observe the deformation of the footing, during the demolition phases.
- the connection between the bridge and the pier was considered as:
 - pinned in the 1st part of the analysis, to evaluate the pressure under the footing under the convoy loads.
 - pinned connection in the 2nd part of the analysis, to evaluate the pressure under the footing and stresses in anchors, during the de-construction phases.
 - moment connection in the 3rd part of the analysis, to evaluate the pressure under the footing and stresses in anchors, during the de-construction phases.

Table 2 presents the pressure funder the pier's footing, in all studied scenarios. Several standard convoys were used, according to Swedish TDOK code (2013).

Table 2. Footing pressure – convoy (j).

Scenario	Min pressure [kPa]	Max pressure [kPa]
no. 1	-334	-309
no. 2	-365	-309
no. 3	-375	-309

6 CONCLUSIONS

As expected, the study of the demolition procedures for the existing Kalix River bridge proved to be quite challenging. All the input data had to be chosen carefully, both in terms of

geometry materials and loads in order for the contractors to be able to have the optimal approach for the demolition (see Figure 9). For the studied case, additional considerations needed to be considered due to its location in a natural protection area. Among the parameters that were considered, it is possible to find: bridge stability, avoidance of undesirable movements during the demolition, bridge and footing capacity, and the selection of a demolition strategy that follows the construction process with the aim of counterbalancing the overturning moments during demolition.

Five different approaches were studied. These approaches provided a very carefully studied technical solution that included:

- Bed-rock anchored tendons, in a specific configuration, to keep the bridge segments in equilibrium at all stages.
- Careful evaluation of the shear capacity of the bridge webs, at the tendon's fixing points, to avoid local or global failure in bridge segments.
- Intermediate support fixing in the final stages of the de-construction.
- Precise positioning of the demolition equipment on the bridge – very important for the overall equilibrium of the structure.
- Footing evaluation to verify the changes in pressure due to the demolition process.

Figure 9. Kalix bridge during demolition, with anchors in place (courtesy of NCC Infrastructure).

Evaluation of the approaches showed that that even though only two anchors might be required to guarantee the stability of the structure (approach 1), the expected axial force is higher than the shear capacity of the bridge. Approaches 2-5 showed expected axial forces in the tendons obtained considerably lower than those of approach 1, however only for approach 5 they were lower than the bridge shear capacity.

Experimental study on constitutive law of stainless steel under multiaxial stress

E. Horisawa, K. Sugiura, Y. Kitane & Y. Goi

Graduate School of Engineering, Kyoto University, Kyoto, Japan

ABSTRACT: Stainless steel does not require painting and can contribute to the reduction of life cycle costs of structures. In general, material constitutive laws are essential to accurately evaluate the seismic behavior of structures in numerical analysis. In this study, the yield surface and flow rule of stainless steel were experimentally investigated to establish the multiaxial constitutive law. Axial forces and torques were applied to cylindrical specimens to represent various stress states. The yield surface of stainless steel in the plane of axial and shear stress were determined, and the evolution of plastic strain after yielding was observed. It was shown that austenitic grades exhibited isotropic yield surfaces, while duplex ones exhibited elliptical ones with an eccentricity of 0.7. It was also confirmed that the standard deviation of the direction of plastic strain propagation from the theoretical value is about 10 degrees, and the associated flow rule could be applied.

1 INTRODUCTION

Stainless steel is increasingly being used as the main material for civil engineering structures especially in severe corrosive environments due to its corrosion resistance. One of the reasons for adopting stainless steel is that it does not require periodic repainting which is necessary for typical steel structures. In addition, since stainless steel is theoretically 100% recyclable after use, making it an earth-friendly material from the perspective of effective utilization of global resources. Therefore, although the initial cost of stainless steel is high, it is possible to reduce the life cycle cost of structures (Gardner et al. 2007, Kere & Huang 2019).

To accurately simulate structural behaviour using analytical method such as finite element analysis, the material constitutive law that correctly expresses the relationship between stress and strain is essential. Regarding the constitutive law of stainless steel, several fundamental studies were reported so far. Under monotonic loading, classically Ramberg and Osgood proposed a stress strain equation with a round house shape, and it is now namely known as Ramberg-Osgood formulation (Ramberg & Osgood 1943, Hill 1944). The R-O curve has undergone various improvements to date, for instance, Arrayago et al. showed modified R-O curve (Arrayago et al. 2015). Apart from monotonic loading, studies in terms of the constitutive law under cyclic loading of tension-compression were also reported (Bondar et al. 2018). However, the plastic constitutive law of stainless steel under multiaxial stress such as tension in two axes and tension-torsion has rarely been studied so far due to the difficulty of testing.

Japan is one of the countries with the most frequent earthquakes in the world, and bridges built in the country must satisfy seismic design requirements. Since bridges are subject to repeated random loads during an earthquake, the stress generated in structures are not only simple tension-compression, but also complex multiaxial stress. Therefore, when investigating the seismic behavior of structures using finite element analysis, it is necessary to use material constitutive laws that are suitable for multiaxial stress states.

The plastic constitutive law under multiaxial stress is generally composed of the yield criterion, the flow rule, and the hardening rule, regardless of the material. The first item, yield criterion, represents the stress state at which virgin material yields under multiaxial stress, as typified by the Mises' yield criterion, and there are several studies on typical stainless steels (Wu & Yeh 1991). The second element, the flow rule, specifies a plastic strain path of the material after yielding, and can be classified into two cases: associated flow rule and non-associated flow rule. The last item, the hardening rule, is a rule that describes how the yield surface of a material changes once it has yielded, and is generally referred to as the isotropic, kinetic, or combined hardening rule. Research on this constitutive law of stainless steel has been conducted mainly in the field of plastic engineering, but there are almost no studies that have experimentally verified them in the study on bridges. By clarifying the exact constitutive equation of stainless steel, which has not been studied extensively, it will be possible to evaluate the seismic performance of stainless steel bridges and to rationalize them. They are expected to promote the spread of stainless steel bridges and labor-saving structures.

This study aims to establish a plastic constitutive law for stainless steel under multiaxial stress, and the experiments related to the yield criterion and the flow rule, which are two of the three components of the plastic constitutive law, were conducted. In addition, basic knowledge for establishing the constitutive law of stainless steel was obtained. This study also aimed Firstly, this proceeding introduces the experimental method for the yield criterion of stainless steel, and then presents the yield surface obtained by the experiment. Secondly, it is shown that the flow rule of stainless steel is associated with the yield condition by observing the plastic strain under multiaxial loading. Finally, a summary of these contents is presented at the end of this proceeding.

2 YIELD SURFACES

2.1 Materials and test pieces

The test to determine the yield surface was performed using two steel grades: the most common austenitic stainless steel SUS304 (EN 1.4301) and the nickel-saving duplex stainless steel SUS821L1 (JIS original). The mechanical properties and chemical compositions of these materials given by steel companies are shown in Tables 1 and 2, respectively. SUS821L1 has more than 1.6 times the yield strength and less than 1/4 of the nickel content of SUS304.

Specimens used for the test had a shape of a hollow cylinder with 20 mm in outer diameter, 18 mm in inner diameter, and 1 mm in thickness at the center part as shown in Figure 1. To apply torque to the specimen, end cross section of the specimen is D-shaped, consisting of a circular arc and a straight line. In the test, axial force was applied in the longitudinal direction of the specimen, and torque was applied around the longitudinal axis (in the direction of arrows in Figure 1). The outer diameter D and inner diameter d of the specimens were measured using a digital caliper prior to testing.

Table 1. Mechanical properties of stainless steels.

	Yield stress	Tensile stress	Elongation
	MPa	MPa	%
SUS304	277	591	60
SUS821L1	455	662	46

	C	Si	Mn	P	S	Ni	Cr	Co	Cu	N
SUS304	0.05	0.28	1.8	0.037	0.024	8.62	18.38	<1.0	-	-
SUS821L1	0.018	0.31	3.15	0.023	0.000	2.14	20.90	0.06	1.04	0.17

Figure 1. Nominal dimensions of test pieces (unit is mm).

Figure 2. Strain gauge arrangement.

2.2 Stress and strain measurement

Axial force N and torque T were measured by load cells built into the testing machine as described below. Using these values, axial stress σ and shear stress τ acting on the parallel sections of the specimen were calculated using Equations 1 and 2.

$$\sigma = \frac{4N}{\pi(D^2 - d^2)} \quad (1)$$

$$\tau = \frac{16DT}{\pi(D^4 - d^4)} \quad (2)$$

The Mises's equivalent stress is as follows.

$$\sigma_{eq} = \sqrt{\sigma^2 + 3\tau^2} \quad (3)$$

Additionally, axial strain ε and shear strain γ of the specimen were measured by rosette gauges attached to the center part of the specimen as shown in Figure 2. Two triaxial strain gauges (FRA-5-11, TML) of a 5 mm gauge length were used for one specimen, with one gauge parallel to the longitudinal axis of the specimen and the other two gauges inclined at 45 degrees from the longitudinal axis. Referring to previous studies on shear strain measurement by strain gauges (Huang et al. 1993, Khan & Liang 2000, Khan et al. 2007), axial and shear strains of the specimen were calculated from these strain gauge readings using Equations 4 and 5.

$$\varepsilon = \varepsilon_0 \quad (4)$$

$$\gamma = \varepsilon_{45} - \varepsilon_{-45} \quad (5)$$

Using the elastic modulus E and shear modulus G in addition to the stresses and strains, the respective plastic strains and equivalent plastic strain when the material is isotropic are given by following Equations 6-8. Here, the elastic modulus and shear modulus were obtained by regression analysis of data with equivalent stress between 20 and 80 MPa.

Figure 3. Schematic diagram of loading paths.

Figure 4. Specimen setup.

$$\varepsilon^p = \varepsilon - \frac{\sigma}{E} \quad (6)$$

$$\gamma^p = \gamma - \frac{\tau}{G} \quad (7)$$

$$\varepsilon_{eq}^p = \sqrt{(\varepsilon^p)^2 + \frac{(\gamma^p)^2}{3}} \quad (8)$$

2.3 Test procedure

Yield surfaces can be obtained by loading in any direction on the plane of axial and shear stresses and plotting the multiple yield stresses. Experimental methods for obtaining yield surfaces have been shown in previous studies (Štefan et al. 2021), and is also briefly explained here.

Figure 3 shows a schematic diagram of loading paths to obtain the yield surface. At the beginning of the test, only tensile stress is applied until the equivalent plastic strain reaches the offset strain ε_{off}^p which is defined as yielding (path 1 in the figure). After that, unloading is

performed to the origin of the $\sigma - \sqrt{3}\tau$ stress plane, and loading is performed again in the same way for compression indicated by path 2. Performing this procedure for the 12 paths shown in the figure, the yield surface is identified from 12 plots of yield stress.

An axial force-torsion multiaxial testing machine (EHF-10/TQ1, SHIMADZU) shown in Figure 4 was used for the above test. During the loading, axial force and torque speed were controlled so that the generated equivalent stress σ_{eq} was 2 MPa/s. In this study, the offset strain ϵ_{off} of 0.005%, which was used in some previous studies (Ishikawa & Sasaki 1988, Ishikawa 1997), was used as the definition of yielding. Preliminary experiments were conducted with a smaller ϵ_{off} of 0.0001%, confirming that the variability of the test results was much larger than the case with ϵ_{off} of 0.005%.

2.4 Results

The initial yield surface of the stainless steels obtained by the above test procedure are shown in Figures 5 and 6, and the Mises' yield criterion, which is the most common yield criterion, is indicated by a dashed line in Figure 5. In addition, Hill's equation (Hill 1948), which is an anisotropic yield function, is also shown in Figure 6. These yield criteria for the biaxial stress state of axial stress σ and shear stress τ in this study are expressed by the following equations.

$$f_{Mises} = \sqrt{\sigma^2 + 3\tau^2} - Y \quad (9)$$

$$f_{Hill} = \frac{\sigma^2}{\sigma_y^2} + \frac{\tau^2}{\tau_y^2} - 1 \quad (10)$$

where, Y is a general yield stress, σ_y and τ_y are yield stresses under pure axial or shear stress condition, respectively. Here, Y is the average of all loading paths, and the average of the two uniaxial stresses is used for each yield stress in Hill's yield function. It can be confirmed that the yield surface of SUS304 is consistent with the Mises' yield criterion, although the test data in the second quadrant is outside of the Mises' yield criterion. On the other hand, the yield surface of SUS821L1 shows an ellipse with a major diameter in the shear stress axis and an eccentricity of 0.7, which is in good agreement with Hill's anisotropic yield function. In addition, the standard deviation of the yield stress of SUS304 for the Mises' condition and that of SUS821L1 for the Hill's anisotropic condition were both 10 to 20 MPa. Duplex stainless steels exhibit anisotropy in the metallurgical structure due to the rolling process (Chalapathi et al.

Figure 5. Measured yield surface of SUS304.

Figure 6. Measured yield surface of SUS821L1.

2022), and it is known that the tensile strength of plates also varies depending on the direction from which the specimens are taken (Horisawa et al. 2021). Since the steel bars in this study were manufactured by hot rolling, anisotropy in strength was also confirmed.

3 FLOW RULES

3.1 Methodology

The flow rule is a rule that describes the evolution of the plastic strain increment in a multiaxial stress state and is generally expressed by the following Equation 11.

$$d\varepsilon_{ij} = \frac{\partial f}{\partial \sigma_{ij}} d\lambda \quad (11)$$

where f is called the plastic potential, and $d\lambda$ is a positive constant. In this study, the test results are compared with the associated flow rule where f is the Mises' yield criterion or the Hill's yield function. This equation also indicates that the direction of plastic strain increment is perpendicular to the yield surface under the associated flow rule.

The flow rule for stainless steel is verified using the plastic strains measured during the initial yield surface identification tests described in Chapter 2. In the following section, the plastic strain paths obtained when loading was applied until the plastic strain of 0.005% are considered.

3.2 Result and discussion

The plastic strain paths of stainless steel observed in the tests are shown in Figures 7 and 8. The degrees in these figures represent the clockwise loading path angles shown in Figure 3, and the dashed lines represent the direction of plastic strain increment due to the associated flow rule using Mises' or Hill's yield criterion. The plastic strain paths of SUS304 can be seen to deviate clockwise from the associated flow rule in the first and second quadrants, whereas in the third and fourth quadrants, the results are in good agreement with the theoretical directions. From Figure 8, the ones of SUS821L1 evolved in directions generally close to the associated flow rule with Hill's equation as the plastic potential. Both results show the standard

Figure 7. Plastic strain paths of SUS304.

Figure 8. Plastic strain paths of SUS821L1.

deviation of around 10 degrees from the theoretical value, and the standard deviation in the direction for SUS821L1 was reduced from 16 degrees to 4 degrees by using Hill's yield criterion. These results show that with appropriate yield criterions, the plastic strain increments of stainless steel follow the associated flow rule.

The vectors of plastic strain increments on the yield surface obtained by regression of test result with the equivalent plastic strain from 0.004% to 0.005% of Figures 7 and 8 are shown as arrows in Figures 5 and 6. It is confirmed that the incremental plastic strain vectors for stainless steel are oriented normal to the yield surface. On the other hand, in regions where the difference between the vector and theoretical values is large, such as the second quadrant of SUS304, the yield surface is seen to be highly distorted, indicating that the perpendicularity to the experimental yield surface is maintained to some extent.

4 CONCLUSIONS

Toward the future development of multiaxial plastic constitutive equations for stainless steels, material tests on yield criteria and flow rules were conducted in this study. Yield stress and direction of plastic strain propagation were experimentally observed in each proportional loading path. The austenitic SUS304 satisfied the isotropic Mises yield criterion, and the duplex stainless steel SUS821L1 satisfied Hill's anisotropic yield function with predominant shear stress and the standard deviation of less than 20 MPa, based on yield surfaces specified under biaxial stress conditions of axial and shear stresses. In addition, the direction of the plastic strain increment on the yield surface is perpendicular to the yield surface for the two steel grades examined in this study, and the associated flow rule is satisfied. In the future, verification of the anisotropy of duplex stainless steels and material tests to define a hardening rule are planned. With these experiences, the goal of this study is to establish a material constitutive law for the rational design and the evaluation of seismic performance of stainless steel bridges that reduces its life cycle costs. The results of this study contributed to the construction of the material constitutive equation, which is a fundamental element for this purpose.

ABSTRACT: The complexity of reinforcement and consequent corrosion of concrete have been technical issues of the transition segments of the hybrid wind turbine tower. A novel concrete transition segment using prestressed ultra-high performance concrete (UHPC) that does not necessitate ordinary reinforcement is applied to a 4.8MW H160 prestressed hybrid wind turbine tower. The mechanical behaviors of the transition segments only with reinforced concrete segment (T-C80RC) and the UHC140 segment without ordinary reinforcement (T-UHC140) are investigated using 3D finite element models. The comparative study shows that UHPC in T-UHC140 improves the overall mechanical performance.

1 INTRODUCTION

Offshore wind energy has attracted growing attention as a renewable wind energy source with increasing concern on global energy security (Lana 2021; McKenna 2022). A higher wind turbine tower (WTT) has the benefits of accessing sufficient and stable wind resources. Recently, the super-high WTT has been constructed using a hybrid WTT consisting of prestressed concrete section in the lower part and steel section in the upper part. The crux of the hybrid WTT for structural performance is the transition segment which connects the steel and concrete sections.

Ultra-high performance concrete (UHPC), with enhanced mechanical properties and durability, enables prestressed concrete structures that require reduced or no ordinary reinforcement (Yu 2020). It has been demonstrated that UHPC can improve flexural and shear properties, crack control capacity, and the ultimate bearing capacity of the prestressed structure even without ordinary reinforcement (Brian 2001; Ridha et al., 2018). It has also been shown that UHPC enables higher towers while reducing the cost of construction, transportation, and installation (Jammes 2009; Lewin and Sritharan 2010). Thus, it is promising to use the unreinforced prestressed UHPC segment for the transition segment of WTT to avoid the complex reinforcement and improve durability. Extensive research on the structural behavior of the prestressed UHPC transition segment without ordinary reinforcement is needed to exploit the advantages.

This paper investigates the performance of the transition segment of an offshore 4.8MW H160 wind turbine tower by comparing the behaviors between the transition segment of the

ordinary high-strength reinforced concrete segment (T-C80RC) and the transition segment of UHC140 segment without ordinary reinforcement (T-UHC140).

2 TRANSITION SEGMENT MODEL

2.1 Basic information

The structure of a 4.8 MW prestressed steel-concrete wind turbine tower with a height of 160 m is illustrated in Figure 1.

Figure 1. Transition segment (4.8MW H160).

The lower part of the structure (< 110.5 m) is a concrete section, and the upper part (≥ 110.5 m) is a steel section. The transition segment is mainly composed of a concrete segment and a steel segment. The steel segment is connected to the concrete segment by prestressed bolts and prestressed steel strands, which both pass through the concrete wall and are anchored at the bottom of the steel segment. The traditional transition segment (T-C80RC) uses a large amount of steel reinforcement, including horizontal circular reinforcement, vertical reinforcement, channel-strengthen reinforcement, and constructional reinforcement, as shown in Figure 2(a). In this study, a novel transition segment using UHPC (T-UHC140) without ordinary steel reinforcement is proposed. Figure 2(b) shows a sketch of the T-UHC140, and Table 1 summarizes the dimensions and the reinforcement ratio of the T-UHC140 segment. The material parameters used in this paper are listed in Table 2.

Figure 2. 3D view of transition segment.

Table 1. Dimensions and reinforcement ratio of transition segment.

Type*	D_{tu} (mm)	D_{tb} (mm)	t_{ru} (mm)	t_{tb} (mm)	h_{tb} (mm)	h_{tc} (mm)	h_{tu} (mm)	ρ_v (%)			
								R_{hc}	R_v	R_{cs}	R_c
T-C80RC	4180	4300	460	220	2500	1240	1500	0.84	0.60	0.55	0.85
T-UHC140								0	0	0	0

* T-C80RC is the transition segment with C80 reinforced concrete segment; T-UHC140 is the transition segment with UHC140 segment without ordinary reinforcement; D_{tu} , D_{tb} , t_{ru} , t_{tb} , h_{tb} , h_{tc} , and h_{tu} are indicated in Figure 1; R_{hc} is horizontal circular reinforcement; R_v is vertical reinforcement; R_{cs} is channel strengthen reinforcement; R_c is constructional reinforcement; and ρ_v is volume ratio of reinforcement.

Table 2. Material parameters of structural components.

Component*	Material	E (MPa)	ν	P (kg/m ³)	σ (MPa)	α (°C ⁻¹)
Concrete segment	C80	3.8×10^4	0.2	2400	-	-
	UHC140	4.6×10^4	0.2	2400	-	-
Ordinary reinforcement	HRB400	2.0×10^5	0.3	7900	360	-
Prestressed steel strand	1860 class 15.2mm	1.95×10^5	0.3	7900	1320	1.2×10^{-5}
Steel segment	Q355NE	2.0×10^5	0.3	7900	290	-
Prestressed bolt	10.9M56	2.0×10^5	0.3	7900	900	1.2×10^{-5}

* E is Young's modulus; ν is Poisson's ratio; ρ is density; σ is yield strength; and α is thermal expansion coefficient.

2.2 Constitutive model and concrete damage-plasticity model

The constitutive models of C80 high-strength concrete and UHC140 are shown in Figure 3. The constitutive model of C80 high-strength concrete is defined according to GB50010-2010. For C80 concrete, the standard value of compressive strength (f_{ck}) is 50.2 MPa, the standard value of tensile strength (f_{tk}) is 3.11 MPa, the design value of compressive strength (f_c) is 35.9 MPa, and the design value of tensile strength (f_t) is 2.22 MPa.

The constitutive models for uniaxial tensile and compression proposed by Du (Du 2014) are employed for UHC140. The test values in reference (Zhang 2020) are used for the compressive strength (f_{Uck}), the standard value of tensile strength (f_{Utk}), the design value of compressive strength (f_{Uc}), and the design value of tensile strength (f_{Ut}), which are 123.8 MPa, 7.27 MPa, 88.35 MPa, and 5.20 MPa, respectively. The maximum compressive and tensile strains are $3309\mu\epsilon$ and $1500\mu\epsilon$, respectively.

Figure 3. Concrete constitutive model.

The tensile and compressive damages of concrete are characterized by the concrete damage-plasticity model (CDPM). This model is capable of representing the crack formation and post-cracking behavior of reinforced concrete in stress-strain curves under compression and tension.

The CDPM parameters selected for C80 and UHC140 are shown in Table 3. The values of CDPM parameters for high-strength concrete have been widely used, while the values of CDPM parameters for UHPC varies depending on strength levels (Li 2009; Lee and Fenves 1998). The selected values of CDPM parameters for UHC140 are verified by comparing the numerical results from finite element models with experimental data.

Table 3. Concrete damage-plasticity model parameters.

Material	Dilation angle (°)	Eccentricity	f_{b0}/f_{c0}	K	Viscosity parameter
UHC140	28	0.1	1.16	0.667	0.005
C80	30	0.1	1.16	0.667	0.005

2.3 Load cases

Three load cases for a typical wind turbine tower are considered (Table 4). SLS-S1 is used to check the serviceability limit state in S1 level.

Table 4. Load cases for a wind turbine tower.

Case	M_x (kN·m)	M_y (kN·m)	M_z (kN·m)	F_x (kN)	F_y (kN)	F_z (kN)
SLS-S1	6583.9	41537.3	440.8	917.4	4.8	-5458.8

3 NUMERICAL RESULTS

3.1 Compressive stress level

Figure 4 shows the contours of the principal compressive stress in concrete segments of T-C80 RC and T-UHC140 for load case SLS-S. The compression zone is identified by negative sign, while the tension zone is identified by positive sign. The distribution patterns of principal stresses are similar between T-C80 RC and T-UHC140 segments. The volume ratios of elements in various stress levels are profiled in Figure 5, where the limit-state stress is defined as $\sigma_c/0.6f_{ck}$ and $\sigma_{Uc}/0.6f_{Uck}$. It is observed that all elements are positioned below 1 in the horizontal axis except only a few elements at the bolt hole due to the stress concentration, which implies that both T-C80 RC and T-UHC140 segments meet the design requirements for the serviceability limit state in SLS-S1. Further, most elements in T-UHC140 are distributed in the range of $\sigma_{Uc}/0.6f_{Uck} < 0.4$, while most elements in T-C80 RC are distributed in the range of $\sigma_c/0.6f_{ck} < 0.7$. Thus, T-UHPC140 has a lower compressive stress level and a higher stress safety margin than T-C80 RC, but concrete material in T-C80 RC more saturates the compressive performance.

Figure 4. Principal compressive stress.

Figure 5. Volume ratio of various stress levels.

3.2 Tensile stress level and class of cracking control

Figure 6 shows the contours of the principal tensile stresses in T-C80 RC and T-UHPC140 segments for load case SLS-S. The tensile stress levels of concrete segment are not defined in current design codes, and cracks are usually allowed in the concrete segment under working condition. In this study, the tensile stress level is indexed by the volume ratio of elements in various stress intervals ξ_i . Figure 7 plots ξ_i profiles in terms of σ_t/f_{tk} and σ_{Ut}/f_{Utk} . It is found that the elements exceeding the requirement value of tensile strength appear at the bolt holes, where the stress concentration occurs. However, their volume ratio is less than 1%, which is negligible. Otherwise, the stress level (σ_t/f_{tk} or σ_{Ut}/f_{Utk}) is less than 1 and the values are relatively low, which indicates a low tensile stress in concrete segments of T-C80 RC and T-UHC140. In addition, T-UHC140 is manifested by a lower tensile stress level than T-C80 RC.

The class of crack control in the concrete segment of T-C80 RC and T-UHC140 can be classified as level 2 from GB50010-2010 [8], since the concrete tensile stress is lower than the concrete tensile strength. Because of the lower tensile stress, T-UHC140 facilitates a good crack control, which is even better than that of ordinary reinforced concrete.

Figure 6. Principal tensile stress.

Figure 7. Volume ratio of various stress levels.

4 CONCLUSIONS

In this paper, a novel prestressed UHPC transition segment without ordinary reinforcement for super tall H160 wind turbine is proposed. In the transition segment of the tower, the prestressed UHC140 concrete segment without ordinary reinforcement can replace the prestressed C80 reinforced concrete segment. In load cases SLS-S1, the stress distribution of T-UHC140 and T-C80 RC is similar, while T-UHC140 possesses better mechanical properties and higher stress safety margin than T-C80 RC.

ABSTRACT: Drone inspection is becoming quite common in condition monitoring of built infrastructure such as bridges. For the repair of defects identified from such inspection use of Engineered Cementitious Composites (ECC), also known as Strain-Hardening Cementitious Composites (SHCC), a class of advanced fibre-reinforced cement-based materials with ductile tensile properties can be effectively used as indicated in many structural applications over the last twenty years. In particular, their use in link slabs of the bridge decks as well as other structural elements in reinforced concrete and composite bridges is quite noteworthy. This paper reviews several such applications in light of the emerging challenges in bridge design requiring long service life and low life cycle costs throughout operation and maintenance. It is concluded that in spite of its higher initial material cost, the use of ECC/SHCC in bridge construction and repairs would result in lower life cycle costs, carbon footprint and better sustainability.

1 INTRODUCTION

Transportation infrastructure such as roads, bridges, ports, airports etc. are an integral part of the modern landscape. They form the lifeline of cities until they fail to serve the purpose for which they have been designed leading to a significant surge of social costs or even catastrophic accidents (National Academies of Sciences et al. (2020)). As per the American Society of Civil Engineers (ASCE) Infrastructure Report Card released in 2017 (ASCE (2017)), the U.S. has 614,387 bridges, almost four in 10 of which are 50 years or older. Out of them, 56,007 or 9.1% were structurally deficient. Many of the bridges are approaching the end of their design life. The estimate of the investment required for bridge rehabilitation in the US alone is at least US \$123 billion.

An estimated 6.3% of the total bridge deck area belonged to structurally deficient bridges in 2016, a small improvement from 9.5% in 2007 (Figure 1a). The situation in Europe is not much better which was tragically illustrated by the sudden collapse of the Morandi bridge in August 2018 in Genoa, Italy. Subsequently, it was revealed that a declining investment in routine inspection, repair and maintenance was a leading cause of the failure. The fast-developing economies of countries like India and China account for the bulk of the world's construction activities are also facing the challenge of fast-track building while ensuring durability, resiliency and sustainability, as illustrated in Figure 1b (Li (2019b)).

1.1 *Current challenges in bridge engineering*

The challenges faced by the infrastructure sector as a whole be it transportation (land, water, air), water (irrigation, drinking water), or power generation (thermal, nuclear, renewable etc.) - all have many common features such as design for long service life, the minimum cost of maintenance, minimum carbon footprint in both construction and operation etc. (Lepech and Li (2009)). A specific category of transportation infrastructure such as bridges has specific challenges that must be addressed. Among these, ensuring a long service life of up to and exceeding 100 years is a major challenge faced by engineers all over the world. Keoleian et al (Keoleian et al. (2005)) discussed a life cycle modelling-based concrete bridge design approach to compare the use of an ECC link slab to replace conventional steel expansion joint which is often a source of major damage needing frequent repairs. The demolition, repair, and recycling of materials and wastes from deteriorated infrastructure remain to be studied in detail. The development of low life cycle cost, low-carbon modular design is beneficial to the reduction of infrastructure deficiency (Kaewunruen et al. (2016)). ASCE (2017) recommended the following key actions to address the challenges of bridge infrastructure, among others.

- Increase funding from all levels of government to continue reducing the number of structurally deficient bridges, decrease the maintenance backlog, and address the large number of bridges that have passed or are approaching the end of their design life.
- Bridge owners should consider the costs across a bridge's entire life cycle to make smart design decisions and prioritize maintenance and rehabilitation.

1.2 *Drone inspection of bridges*

Drone (also referred to as unmanned aerial system, or UAS) inspection of bridges is an increasingly popular method being adopted by the engineering community worldwide (Shi et al. (2021); Azari et al. (2022)). Drones are able to provide a detailed view of the bridge, allowing engineers to identify any potential issues in the structure. Drone inspections are becoming more and more common as they offer a cost-effective way to inspect bridges quickly and accurately (see Figure 3). Drones provide an efficient way to inspect the bridge structure, allowing the inspector to quickly identify any potential issues. Drone inspections can provide a detailed overview of the bridge and identify any structural problems, such as cracks, corrosion, and deterioration. Additionally, drones are able to provide high-resolution images of the bridge, allowing for detailed analysis of the structure.

The use of drones for fracture-critical inspections is more challenging at present. Cameras and today's sensors still have little capability to see through dirt, debris, and corrosion which can hide critical defects. However, using the primary payloads of high-resolution visual and thermal imaging cameras, modern drones can identify most of the defects such as cracks, delamination, spalling, corrosion etc. That needs immediate attention. One of the challenges of data generated by a drone inspection is its voluminous nature which made it impossible to analyse using conventional manual methods. Machine learning and AI have made it possible to automate the processing of such voluminous data to identify the most common defects. An advantage of drone inspection of is the possibility for comparison of the inspection data collected at different points of time to estimate the change in the condition of the structure as illustrated in Figure 1b.

2 THE USE OF ECC/SHCC

Once the defects in the bridge are identified, the repair and maintenance require the selection of the right materials and methods for the best results. Innovation in new technologies, especially the development of materials such as fibre-reinforced composites is enabling bridges to be built stronger, last longer, require less maintenance and have a lower carbon footprint. As already discussed, Sensors and robots such as drones are being used in both new and old bridges for real-time or near real-time structural health monitoring so that problems can be identified and addressed earlier to improve public safety. To reduce the time for the construction or repair of bridges, prefabricated elements are being increasingly used. Engineered Cementitious

Composites (ECC) or Strain-Hardening Cementitious Composites (SHCC) is a class of fibre-reinforced cement-based composites that can be designed for a range of compressive strength while ensuring a requisite degree of tensile ductility (Li and Mishra (1996); Li (2008)).

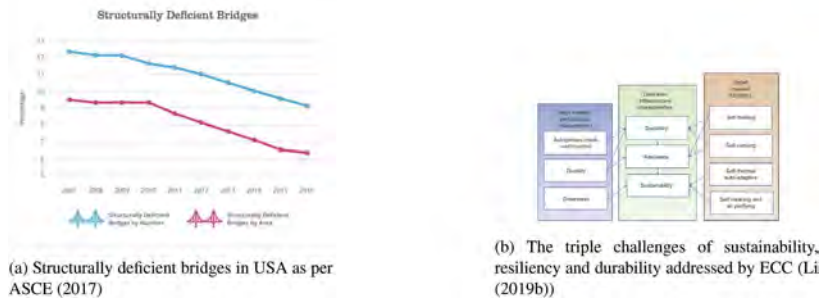

Figure 1. Structural design and sustainability.

As shown in Figure 3, the characteristic material property of ECC is reflected by its tensile stress-strain behaviour and cracking pattern. In contrast to the brittle nature of plain concrete which fails with a single crack under relatively low tensile stress, and the characteristic strain-softening behaviour of ordinary fibre-reinforced concrete, ECC continues to carry tensile stress beyond the first crack and even exhibits tensile strain-hardening accompanied by multiple micro-cracking phenomena. As a result, the average and maximum crack width of ECC is typically below 100 microns or less. These two unique properties of ECC, namely the high tensile strain capacity and inherent crack width control, can be effectively deployed in a number of structural applications to address major challenges faced by bridges, as discussed in previous sections. Figure 4 shows the graphical representation of a brief literature review undertaken to understand the state of progress in terms of the application of ECC/SHCC in real-life bridge scenarios using the connected papers' graphical representation. Table 1 gives a list of such applications taken from the textbook by Li (Li (2019a)).

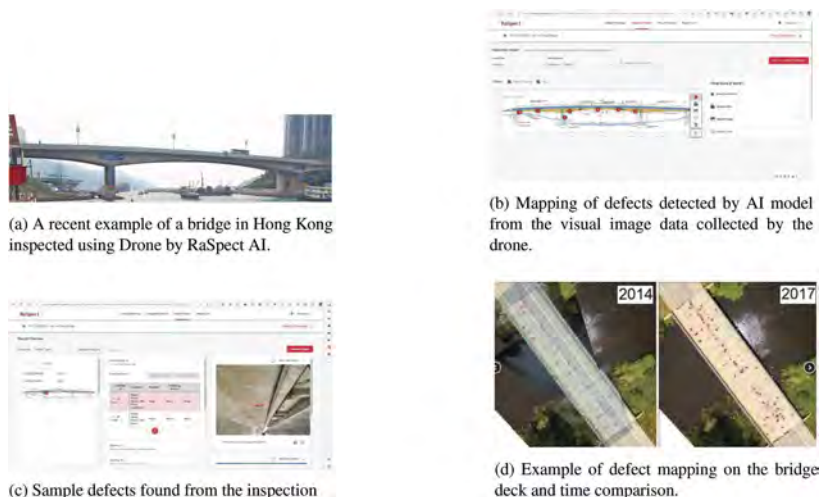

Figure 2. Moving towards drone-based monitoring.

2.1 Link slabs for bridge joints

Lack of watertight bridge joints leads to water leakage, which would cause premature deterioration and failure of the beam support zones, bearings, and underlying substructure elements. This is a major source of deterioration that requires frequent repairs. The application of ECC/

Figure 3. Typical tensile stress–strain behaviour of ECC with average crack-width data (Mishra, D K Yu, J Das, A Leung 2018).

Table 1. Application of ECC in transport infrastructure (bridge) [Li (2019a)].

Application	Problem Solved	ECC property utilized	Placement method
The bridge deck and road pavement link-slab retrofits	Reduce frequency and cost of bridge deck maintenance; Reduce traffic noise	Tensile ductility to accommodate thermal deformation; tight crack width; Fatigue resistance; wear durability	Cast-in-place or precast
Composite bridge deck	Reduce the risk of fatigue failure of steel deck; Reduce cost and weight	Tensile ductility; fatigue resistance	Cast-in-place
Patch repair of bridge deck	Reduce maintenance frequency and cost	Tensile ductility; durability against wheel loads and chloride environment	Cast-in-place
Rigid-frame railway bridge beam-column joint connection	Reduce steel reinforcement congestion	High shear capacity even without steel reinforcement	Precast in factory

Figure 4. Connected papers map showing (a) drone inspection of bridges, (b) application of ECC link slab in bridge deck joint linked to (Lepech and Li (2009)).

SHCC link slabs in place of conventional bridge joints offers an innovative solution to the problem. Lepech and Li (Keoleian et al. (2005)) developed a Life Cycle Assessment model specifically for bridge decks accounting for materials production and supply chain, construction and maintenance processes, construction-related logistics, and end-of-life management. The model indicated that the ECC/SHCC bridge deck system has significant advantages over conventional joints. It has 40% less life cycle energy consumption, 50% less solid waste generation, and 38% less raw material consumption. Based on the findings by (Keoleian et al. (2005)), construction-related traffic congestion was a dominant factor in life cycle cost assessment. The first ever real-life application of ECC link slab was launched at a bridge in Grove Street over the inter-state highway I-94 under the Michigan Department of Transportation (MDOT) (Lepech and Li (2009)). The performance of this bridge has been monitored ever since and it has been found to have performed exceedingly well throughout the reporting period up till 2015 (Li (2019a)).

Figure 5 shows a schematic of the link slab and a photograph of a similar bridge where an ECC link slab was implemented by the Virginia Department of Transport (VDOT) recently in 2018 (Walus and Engineer (2010)). According to (Thorkildsen et al. (2020)), the US Department of Transportation reports widespread practice of replacing conventional joints in bridge decks with link slabs by various state departments of transportation in New York, Maryland, Virginia and Massachusetts etc. Many of these applications including those in Virginia and Maryland reported successful use of ECC/SHCC and ultra-high-performance concrete (UHPC) in the construction of link slabs. Such applications are gaining popularity all over the world not only for joints at bridge decks (Hou et al. (2018)) but also in regular concrete road pavements (Zhang et al. (2017, 2010)). Compared to asphalt pavements, the driving comfort of concrete pavements is normally lower due to the existence of joints. The joints also reduce the durability of the reinforced concrete pavement due to susceptibility to infiltration of moisture and deicing salt etc. which in turn causes corrosion of reinforcement. Repair and maintenance cost is thus likely to increase with the presence of joints. By using low-shrinkage engineered cementitious composite (LSECC) strips in place of joints of conventional concrete pavement, it is possible to localize the fine cracks into the LSECC strip and significantly enhance long-term durability and reduce maintenance cost. This technique has been already applied to real-life projects in Japan (Rokugo (2010)) and China (Zhang et al. (2017, 2013)).

2.2 Bridge deck repair

Potholes on highway pavement surfaces, especially on concrete bridge decks have been arising concerns among transportation authorities and infrastructure/maintenance engineers. Asphalt pavements are notorious for their susceptibility to moisture ingress and the formation of potholes that require frequent repair. Concrete, on the other hand, is a longer-lasting alternative. However, it is also prone to cracking, delamination, and spalling and needs constant monitoring and repair. Bridge decks and pavements made of steel-reinforced concrete is additionally prone to corrosion-induced cracking and delamination. Dynamic loading from vehicular traffic causing fatigue is another major accelerating factor of such damage. Sahmaran and Li (Sahmaran et al. (2008)) showed that the high tensile ductility of ECC/SHCC can yield higher resistance to corrosion-induced spalling. It was also found that after 100k cycles of fatigue loading, the crack width in the reference concrete link slab specimen increased from 50 μm to greater than 0.6 mm, while the crack width in the ECC link slab remained close to 50 μm (Li (2008); Lepech and Li (2006a)) showed the superior performance of High Early Strength ECC (HES-ECC) as an overlay patch repair material under fatigue loading. Actually, one of the early applications of ECC was in patch repair of concrete pavements in which a high early strength ECC was deployed (Lepech and Li (2006b)). An ECC patch repair was carried out at the bridge deck of Curtis Road over highway M-14 in southern Michigan state in October 2002 in collaboration with the Michigan Department of Transportation (MDOT). In comparison with a side-by-side patch repaired with a conventional pre-packed commercial patching material, ECC performed far better. While in two years the conventional repair material had heavily deteriorated and had to be re-done, the ECC patch demonstrated desirable performance without much cracking and damage until the year 2007 when the entire bridge deck was re-laid. Another example of a real-life application of ECC for patch repair was carried out in November 2006. A HES-ECC patch repair was implemented at Ellsworth Road Bridge over highway US-23 (S07 of 81074) in Ann Arbor, Michigan (Lepech and Li (2006b)) with MDOT. The HES-ECC was a self-compacting mix and it was compared with the performance of a side-by-side patch done with Thoroc 10-60 (a commercial patch repair material). In the subsequent 2 to 3 years, the performance of ECC as a durable repair material was proven satisfactory in one of the harshest environments comprising effects of restrained shrinkage, freeze-thaw cycles, deicing salts, temperature fluctuations etc., in addition to heavy traffic loads. The damage in the ECC patch was minimal with maximum crack width remaining less than 100 μm in the ECC, as opposed to close to 2 mm in the control.

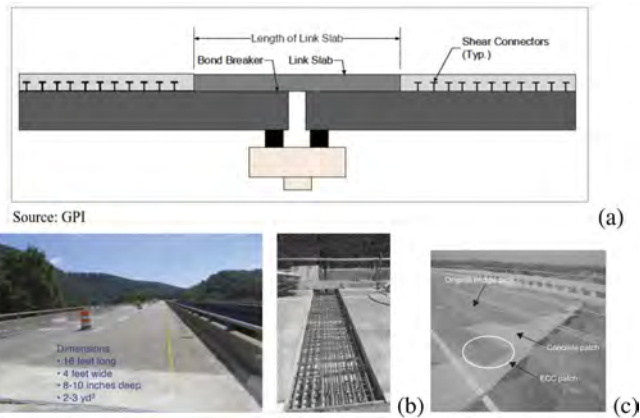

Figure 5. (a) Schematic of a typical full-depth link slab (Thorkildsen et al. (2020)) (b) Photograph of the ECC link slab on I-64 over Dunlap creek by VDOT (Walus and Engineer (2010)) (c) Photograph of the first patch repair using ECC on a bridge deck of Curtis Road in Ann Arbor, Michigan in 2002 (Li (2014)).

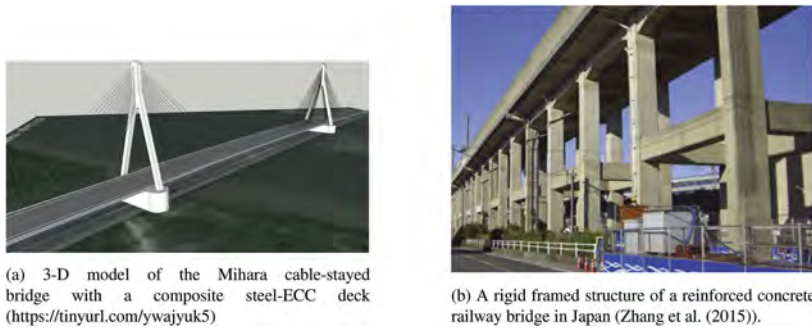

Figure 6. 3-D model and rigid structure.

2.3 Composite bridge deck

ECC/SHCC can be a suitable material for composite construction as shown by (Zhang et al. (2019)) where they have also taken into account the self-healing ability of ECC/SHCC which enhances its durability characteristics. A composite bridge deck taking advantage of the durability of ECC owing to its tight crack-control ability was designed and built in 2004 in Japan. The Mihara bridge in Hokkaido was a 962 m long cable-stayed bridge with a middle span of 340 m and a full deck area of 20,000 m^2 . It had a 38 mm thick ECC top layer to protect the steel deck underneath from corrosion. The bridge was opened to traffic in 2005 and it had a designed service life of 100 years. It is expected that the savings from reduced maintenance and repair costs would be substantial for the structure over its service life. Figure 6a shows a 3-D model of the bridge.

2.4 Strengthening bridge structure

ECC/SHCC has been proven to be a suitable material for applications where the structure is required to resist dynamic loads such as in an earthquake. Because of the high energy absorption capacity of ECC/SHCC stemming from its unique energy-dissipating failure mode, many researchers have used ECC/SHCC to form critical joints in structures subject to cyclic loading. It was concluded that ECC/SHCC outperforms conventional concrete in strengthening bridge structures (Li and Mishra (1996)). In a review paper, (Shang et al. (2019)) have cited a large number of studies that showed the advantages of ECC/SHCC as a repair material for structural strengthening over the conventional approach which uses fibre-reinforced plastics (FRP) and steel plates.

FRP is a brittle material and is prone to debonding from the substrate concrete, whereas steel plates are susceptible to corrosion. In a comprehensive experimental study, (Zhang et al. (2015)) showed the advantage of using ECC in mitigating the reinforcement congestion problem in beam-column joints designed as per the earthquake-resistant code requirements in Japan. At shear span to depth ratio $a/d = 2.8$, the shear capacity of the beams with and without stirrups increased by 20.6% and 107.6% respectively when using ECC in lieu of conventional concrete.

2.5 Other potential applications and scope for future research

Among other applications of ECC/SHCC that are in the domain of transportation in general are tunnel lining, repair of viaducts, structural strengthening of embankments and ports using FRP-reinforced or fabric-reinforced ECC/SHCC etc. Given the micromechanical design basis of ECC/SHCC, it can be tailored for individual situations by identifying the structural performance requirements and establishing a link with material properties. It is expected that in forthcoming years with the accumulation of more research data and field performance information, applications of ECC/SHCC combined with robotic inspection in real-life structures will get a big boost.

3 CONCLUSIONS

Robotic and drone inspection of bridge structures followed by the application of Engineered Cementitious Composites (ECC) or Strain-Hardening Cementitious Composites (SHCC) in repairs and other use in bridge engineering have been illustrated by citing real-life examples. This study indicates that advanced fibre-reinforced cement composites such as ECC/SHCC with their high tensile ductility and intrinsic tight crack width control can be utilized in both new and old bridges effectively. Such application can enhance structural safety and resilience while making concrete bridges more durable and thereby reducing their life cycle cost. Specifically, the following conclusions can be drawn:

- Robotic inspection of structures such as bridges using unmanned aerial vehicles commonly known as drones is becoming increasingly popular.
- identifying major and critical defects that need urgent attention is easier, less costly and safer using such methods.
- ECC/SHCC is an excellent material choice for long-lasting and durable repair of concrete pavements including bridge decks.
- Use of ECC/SHCC link slabs in place of conventional joints at bridge decks, as well as concrete pavements, can save maintenance costs, reduce traffic disruption and increase service life.
- Using ECC/SHCC in critical structural elements and joints can enhance the ductile performance of bridges under dynamic loads such as heavy traffic and earthquakes.
- Further accumulation of laboratory research and field performance data is beneficial to promote more ECC/SHCC applications in real-life structures.

Chloride-attack fragility curve: The probability of failure is estimated at a life expectancy

J.H. Kim, T.H. Han & D.J. Jeong

Korea Advanced Institute of Science and Technology, Daejeon, Republic of Korea

ABSTRACT: Chloride attack is one of the significant problems affecting the durability of concrete structures. The time for chloride ions arriving reinforcing bars is an indicator to predict service life in the view of the rebar corrosion. The diffusivity of chloride ions in concrete is a key factor for the prediction of service life, but it is inherently distributed at a large variation. Considering the diffusivity as a random variable allows us to analyze the inherent variation. A large number of mortar samples are subjected to a test measuring the diffusivity using a miniature device complying with NT BUILD 492. The statistical distribution of the diffusivity can be developed with the measurements. Applying Fick's 2nd law with the diffusivity results in calculating the probabilistic life span of a given structure. This study finally proposes chloride-attack fragility by evaluating the probability of failure at life expectancy.

1 INTRODUCTION

The durability of concrete is designed to have sufficient resistance to chloride attack. The chloride ions permeated in concrete break the passivation of reinforcing bars, which results in initiating their corrosion. Modeling the diffusion of chloride ions in concrete allows us to predict the time to the initiation of corrosion, and it is often referred to as service life (Alexander and Thomas 2015). In contrast with the deterministic prediction, a probabilistic approach on the modeling provides the range of expected time (Bentz 2003, Kwon *et al.* 2009). It is beneficial to manage the risk of corrosion.

Furthermore, for the risk quantification we need to consider aleatory and epistemic variabilities in the probabilistic approach (Electric Power Research Institute 2018). The former stems from randomness of a performance variable (Ait-Mokhtar *et al.* 2013), which cannot be removed in practice. The latter considers the uncertainty of the model or data describing the variable. Additional experiment or detailed analysis may reduce the epistemic variability on the variable. This paper proposes a chloride-attack fragility curve considering the two variabilities independently. The fragility curve provides the probability of failure (corrosion) at a specific age (time), where the confidence level considering the uncertainty variability is specified.

2 CHLORIDE-ATTACK FRAGILITY

2.1 Fragility curve

The probability of failure is evaluated by comparing the demand and capacity of concrete durability. The demand curve indicates the requirement for concrete that should be durable, while the capacity curve represents its performance. Both indexes are represented by the probabilistic density function of age (time).

The fragility accounts for the probability of which the demand exceeds the capacity of concrete durability, and it can be depicted by the overlapping area in Figure 1. The probability density of failure is given by

$$f_X(x) = P\{X < 1\} \quad (1)$$

where $X=R/L$. Here, the probabilistic variables R and L are the capacity (resistance) and demand (load) of concrete durability, respectively. We can presume that R and L are mutually independent. The fragility curve refers the cumulative distribution of the failure,

$$F_X(x) = P\{X < x\} = \int_{-\infty}^x f_X(\xi) d\xi \tag{2}$$

and it evaluates the non-exceedance probability at the specified age (x) of a concrete structure.

Figure 1. Demand and capacity represented by a probabilistic variable.

Assuming each of R and L curves follow a lognormal distribution, the probability of failure is also represented by a lognormal distribution: $X \sim \ln N(\mu_X, \sigma_X^2)$ where μ_X and σ_X are the mean and standard deviation of the natural logarithm of X , respectively. The probability is then understood by $\ln X = \ln R - \ln L$ complying with Eq. (1). The expectation and variance of X are calculated by

$$E\{X\} = \exp\left(\mu_X + \frac{\sigma_X^2}{2}\right) \tag{3}$$

and

$$\text{Var}\{X\} = (E\{X\})^2 (\exp \sigma_X^2 - 1) = (\exp \sigma_X^2 - 1) \exp(2\mu_X + \sigma_X^2) \tag{4}$$

respectively. The coefficient of variance is then

$$\text{CV}\{X\} = \sqrt{\exp \sigma_X^2 - 1} \approx \sigma_X \tag{5}$$

and sometimes it is simply estimated by σ_X . Lastly, the median is calculated by

$$\text{Med}\{X\} = x_m = \exp \mu_X \tag{6}$$

Normalizing the probability of failure allows us to easily evaluate it using the standard normal distribution,

$$Z = \frac{\ln X - \ln x_m}{\sigma_X} = \frac{\ln(X/x_m)}{\sigma_X} \tag{7}$$

for $Z \sim N(0,1)$. Its cumulative distribution $\Phi(z)$ is conveniently used with the standard normal table. The probability of failure in Eq. (1) and the fragility in Eq. (2) are then given by

$$f_X(x) = P\{\ln X < 0\} = \Phi\left(\frac{0 - \ln x_m}{\sigma_X}\right) = 1 - \Phi\left(\frac{\ln x_m}{\sigma_X}\right) \tag{8}$$

and

$$F_X(x) = P\{\ln X < \ln x\} = \Phi\left(\frac{\ln x - \ln x_m}{\sigma_X}\right) = \Phi\left(\frac{\ln(x/x_m)}{\sigma_X}\right) \quad (9)$$

respectively.

The aleatory and epistemic variabilities can be independently modelled using a double log-normal distribution (Electric Power Research Institute 2018). Taking the aleatory variability (randomness) for the non-exceedance probability allows us to have the true fragility of

$$F_X(x) = \Phi\left(\frac{\ln(x/x_m)}{\beta_R}\right) \quad (10)$$

where β_R is the coefficient for randomness. The estimator of fragility, $F(x)$, needs to be higher than the true fragility. The epistemic variability (uncertainty) addresses the confidence level of $Q = P\{F(x) > F_X(x)\}$, which is considered with an additional lognormal distribution. Assigning the true fragility to the median of the estimator finally provides it as

$$F(x) = \Phi\left(\frac{\ln(x/x_m) + \beta_U \Phi^{-1}(Q)}{\beta_R}\right) \quad (11)$$

where β_U is the coefficient for uncertainty.

Figure 2 shows the fragility curve considering the randomness and uncertainty of X . The uncertainty variability does not affect the fragility at the confidence level of $Q=50\%$, and it passes through the median of each estimator: $F(x)=F_X(x)$ since $\Phi^{-1}(0.5)=0$. For a higher confidence level, the fragility curve moves to left so that the prediction is conservative. The higher uncertainty (β_U) the fragility curves range wider. In contrast, the randomness (β_R) controls the slope of each fragility curve. The fragility curve lies down with a higher β_R .

Figure 2. Fragility curve described by a double-lognormal distribution.

3 CHLORIDE-ATTACK FRAGILITY

3.1 Chloride diffusivity and its randomness

The diffusivity of chloride ion and its variation could be measured by the conventional test method (NT Build 492 1999). An experiment using miniature samples was conducted to collect

the variation on the chloride diffusivity. The sample was reduced to a cylinder having 30 mm-diameter and 30 mm-height while its original dimension was 100 mm in diameter and 50 mm high. The reduced dimension was fit to the samples of mortar; coarse aggregates were removed for the dimension. Beyond the dimension of the miniature sample, the procedure to measure the migration depth of chloride ions was the same with that specified in (NT Build 492 1999).

The diffusivity of chloride ion, D , was measured with 16 replicated samples of each mix. Table 1 reports the mix proportion of each mortar mix, where the effect of water-to-cement ratio was examined keeping the sand volume fraction of 58% constant. Type I Portland cement and ISO standard sand were used to produce the samples. In addition to the 30 mm-diameter cylinders for the diffusivity measurement, 40 mm cubes were made to measure the compressive strength of each mix. The strength and diffusivity were measured after the samples had been cured for 28 days. In the table, the mean and standard deviation of the diffusivity were reported. The diffusivity was thought to follow a normal distribution: $D \sim N(\mu_D, \sigma_D^2)$.

Table 1. Mix proportion of mortar samples.

Mix	Water-to-cement ratio	Sand-to-cement ratio	Strength, MPa	Diffusivity (D), $\times 10^{-12}$ m ² /s	
				Mean (μ_D)	Standard deviation (σ_D)
w/b=0.35	0.35	2.4	70.5	13.1	2.42
w/b=0.40	0.40	2.6	63.7	17.8	6.01
w/b=0.50	0.50	3.0	60.2	39.4	11.7

A lower water-to-cement ratio brought the increase in compressive strength and the decrease in diffusivity, as expected. The low water-to-cement ratio enhanced the mechanical resistance and durability of the mixes. Furthermore, it is worthwhile to note that the standard deviation of diffusivity decreased with a lower water-to-cement ratio. The randomness on the diffusivity weakens with the dense microstructure of mortar.

3.2 Uncertainty on critical chloride content

Chloride attack results in the corrosion of reinforcing bars. Passivation of steel breaks down with a certain amount of chloride ion, and consequently its oxidation accelerates leaving iron oxides consisting of rust. Therefore, the service life in terms of chloride attack is usually determined by the time of the passivation breakdown. A criterion for the determination can be stated: We expect corrosion when chloride concentration around the reinforcing bar increases up to a critical content so that the passivation breaks down.

The critical chloride content also shows variation. According to the recent review (Angst 2018), experiments on the critical chloride content, C_c , provided its mean and standard deviation as reported in Table 2. Given that the critical chloride content followed a lognormal distribution, Eqs. (3) and (4) calculated the mean and standard deviation of $\ln(C_c)$ by -0.32 and 0.67, respectively. The median was also calculated by $\text{Med}(C_c)=0.58\%$ using Eq. (6).

Table 2. Critical chloride content.

Critical chloride content (C_c), % by mass	
Mean	Standard deviation
0.91	0.69

On the other hand, in practice the critical chloride content is used as a deterministic variable. For example, $C_c=0.4\%$ is specified as the limit of endurable chloride content for a concrete structure. Its value can decrease with an emphasis on the durability of the structure. The uncertainty on the value of critical chloride content is therefore considered as the epistemic variability associating with the confidence level of the fragility curve.

3.3 Dataset to develop a fragility curve

Chloride-attack fragility curve develops by evaluating the probability of failure at a specific age. The failure due to chloride attack is defined when the migrated chloride content exceeds the critical chloride content with respect to the passivation breakdown. Fick's 2nd law predicts the chloride migration considering the diffusivity:

$$\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial r^2} \quad (12)$$

where $c(r,t)$ is the concentration of chloride at location r and time t . It is expressed in a unit of kg/m³. Given that the concrete is fully saturated having no chlorides, the chloride concentration starts to increase with the migration of chlorides on the external surface. The chloride concentration on the external surface is given by c_0 , and then the chloride concentration in concrete becomes

$$c(r, t) = c_0 \left(1 - \operatorname{erf} \frac{r}{2\sqrt{D \cdot t}} \right) \quad (13)$$

which is the solution of the diffusion equation in Eq. (12). The corrosion of reinforcing bar is declared if $c(r_0,t)=C_c$, where r_0 is the cover locating the reinforcing bar in concrete. Inverting Eq. (13) with respect to t allows us to have the service life of the concrete structure. It becomes a probabilistic variable represented by

$$X = \frac{r_0^2}{4D} \left(\operatorname{erf}^{-1} \left(1 - \frac{C_c}{c_0} \right) \right)^{-2} \quad (14)$$

Here, in this study, it was assumed that the external chloride content was $c_0=3\%$ considering the salinity of seawater and the cover was $r_0=40$ mm as an example.

The service life of X showed variation caused by the uncertainty of the critical chloride content (C_c) as well as the randomness of diffusivity (D). Both variabilities were anchored at the median of X , as described in the previous paragraph, where the fragility indicates 50% probability of failure at 50% confidence level. The aleatory variability (randomness) on the service life was first evaluated keeping 50% confidence. Taking the median of the critical chloride content, $\operatorname{Med}(C_c)=0.58\%$, made Eq. (14) have a probabilistic variable of D only. We have 3 sets of D according to the water-to-cement ratio, as reported in Table 1. A total of 100,000 samples could be produced by Monte-Carlo simulation on each $D \sim N(\mu_D, \sigma_D^2)$, and Eq. (14) resulted in 100,000 samples of X at $Q=50\%$. The coefficient of variance, $\operatorname{CV}\{X\}$ at $Q=50\%$, then approximated the coefficient for randomness (β_R) by Eq. (5)

Second, the epistemic variability (uncertainty) was evaluated at 50% probability of failure. Taking the median of diffusivity, $\operatorname{Med}(D)=13.1, 17.8, \text{ or } 39.4 \times 10^{-12}$ m²/s, leaves a probabilistic variable of C_c in Eq. (14). A total of 100,000 samples were produced by Monte-Carlo simulation on $C_c \sim \ln N(\mu_C, \sigma_C^2)$, and the service life of X at $p_F=50\%$ was calculated for each of the 3 medians of D . $\operatorname{CV}\{X\}$ at $p_F=50\%$ now approximated the coefficient for uncertainty (β_U). Table 3 reports the result of the calculation.

Table 3. Life span and its variation with respect to chloride attack.

Mix	$\operatorname{Med}\{D\},$ $\times 10^{-12}$ m ² /s	$\operatorname{Med}\{C_c\},$ %	x_m or $\operatorname{Med}\{X\},$ year	β_R or $\operatorname{CV}\{X\}$ at $Q=50\%$	β_U or $\operatorname{CV}\{X\}$ for $p_F=0.5$
w/b=0.35	13.1	0.58	9.83	0.35	1.84
w/b=0.40	17.8		5.87	0.71	1.84
w/b=0.50	39.4		1.56	0.60	1.85

3.4 Development of the fragility curve

Chloride-attack fragility curve by Eq. (11) can be developed using the median and the coefficients for randomness and uncertainty. The probability of failure predicts the extent of the corrosion. For example, 50% probability of failure represents the situation that half of reinforcing

bars in a concrete structure has been corroded. On the other hand, the confidence level accounts for the reliability on the prediction. Explaining the confidence level needs to define life expectancy: It is the age for which the prediction on the extent of corrosion is guaranteed at a confidence level. If the prediction on p_F is made at 50% confidence level, as an example, half of concrete structures within the life expectancy show a lower probability of failure than p_F .

Figure 3 shows the fragility curves of the mortar mixes produced by the water-to-cement ratio of 0.35, 0.4 or 0.5. A lower water-to-cement ratio pushes the fragility curve to right; the life expectancy increases. The median ($p_F=0.5$) of X at $Q=50\%$ confidence level is the representative value, which coincides with the service life of a deterministic approach. The chloride-attack fragility curve obtained by the probabilistic approach indicates the possibility of corrosion at a variety of confidence level. When the confidence level increases, the fragility curve moves to left. The life expectancy is calculated conservatively.

Figure 3. Chloride-attack fragility curve of the mortar mixes.

4 CONCLUSIONS

The chloride attack is a significant risk causing the corrosion of reinforcing bars, which results in diminishing the service life of concrete structures. The service life related to the chloride attack is generally predicted by calculating chloride diffusion through concrete cover. However, the variation on the prediction is not small. This paper proposes a chloride-attack fragility curve considering the aleatory and epistemic variabilities. The fragility curve represented by a double lognormal distribution considers both variabilities independently. The randomness on the chloride diffusivity through concrete is experimentally evaluated dispersing the probability of failure while the uncertainty on the critical chloride content for passivation breakdown is parameterized describing the confidence level. Finally, the life expectancy is provided indicating the age for which the prediction on the extent of corrosion is guaranteed at a confidence level.

A review on electrodeposition repair of cracked reinforced concrete

Qian Zhang & Qing Chen

Key Laboratory of Advanced Civil Engineering Materials of Ministry of Education, School of Materials Science and Engineering, Tongji University, Shanghai, China

Haifeng Yang

Guangxi Key Laboratory of Disaster Prevention and Structural Safety, College of Civil Engineering and Architecture, Guangxi University, Nanning, China

ABSTRACT: Microcracks are virtually inevitable in reinforced concrete and will accelerate the deterioration of concrete structures. Repairing microcracks with traditional techniques is difficult, especially in an underwater environment. Electrodeposition repair is an effective technology for microcracks in aqueous conditions. This review summarizes the state of the art by discussing the repair electrolyte, introducing its numerical studies, and presenting the physical design of the repair device. The latest experimental details and relative patents of electrodeposition repair are collected. Electrodeposition repair technology exhibits great potential to enhance the durability and life cycle of concrete structures. Challenges and potential research directions are mentioned in the concluding remarks.

1 INTRODUCTION

Reinforced concrete is widely used in civil, tunneling, hydraulic, or marine engineering, etc. One of the factors affecting the durability of concrete materials is cracking. Due to the brittleness of the concrete composites, cracks inevitably occur when they are induced by load, temperature, erosion, or other factors (Jiang et al., 2020). Microcracks appear in the early stages of deterioration and seemingly pose a limited threat to engineering safety. However, microcracks are the primary pathways by which harmful ions enter the interior of concrete materials. Repairing microcracks with traditional techniques is difficult for those large-scale infrastructures because of many factors, like their massive amount or untouchable position. A self-healing conception of cementitious materials has been proposed owing to the reasons above. Current literature has reviewed those studies about autogenous healing or autonomous healing technology (Li et al., 2018). This study focuses on the most recent developments in electrodeposition repair.

Electrodeposition repair is an extrinsic healing technology (Sánchez et al., 2018) and is suitable for microcracks in aqueous conditions. Electrodeposition repair mainly relies on four key elements: the direct-current field, the anode (inert conductive materials), the cathode (steel bar), and the electrolyte (water environment). When direct current is applied, OH^- is produced around the cathode, and the cation (e.g. Ca^{2+} , Mg^{2+} , Zn^{2+}) gradually migrates to the cathode through microcracks. The electrodeposits (e.g. ZnO , $\text{Mg}(\text{OH})_2$) will form and fill the microcracks since the ion concentration reaches the solubility product (Zhang et al., 2021). In addition to this, the pH value in the crack will increase continuously with the time of power on, due to electrochemical reactions occurring. The harmful ions like Cl^- will be removed by the direct-current electric field. The details of electrodeposition repair were shown in Figure 1. Electrodeposition was first applied to the repair of concrete microcracks by Japanese scholars. In the late 1880s, Japan Seaport Research Institute (Port and Airport Research Institute) and Mitsui Engineering & Shipbuilding Company proposed a method of electrodeposition repair

for cracks in ocean engineering (Yokoda and Fukute, 1992). A series of studies relevant to the parameters and theory of electrodeposition were carried out subsequently.

Figure 1. The process of electrodeposition repair (Meng et al., 2021).

2 REPAIR EFFECT AND INFLUENCING FACTORS

Normally, the repair effect is influenced by four aspects, and most research is also conducted from these perspectives:

2.1 *Electrode materials and geometry*

The anode material needs to be resistant to higher voltages, graphite and titanium is usually used as anode because of the low price and inert characteristic. Graphite anode is easily damaged during the test due to the low hardness and high brightness. Apart from that, graphite easily colors the objects that contacted with it. Therefore, titanium tends to be more popular than graphite in laboratory (Ryu, 2001). Taking the lightness and portability of anodes into account, titanium mesh is the most commonly used in laboratory investigations (Ryu, 2003).

The cathode material is steel bar. The most common type of steel is Q235, which has the dual advantage of being both inexpensive and simple to process. Q235 bar is also a commonly used steel in engineering. The diameter of the rebar depends on the size of the specimen, which is generally 5 mm to 8 mm (Zhang et al., 2021). The diameter of the rebar should be increased when the specimen is large. For the larger specimens simulating concrete beams, the steel cage is used as the cathode (Jiang et al., 2008).

2.2 *Current type and intensity*

Different sample sizes need different current values during repair. The current density is generally used to describe the current value. Current density refers to the current intensity per unit area perpendicular to the current direction. The current density at the crack position may be hundreds of times greater than that of the uncracked part. As a result, the electrochemical reaction at the crack is stronger, resulting in preferential deposits enrichment in the crack. The current density of electrodeposition is usually 0.5 A/mm^2 to 3.0 A/mm^2 . The general rule is that the higher the current, the faster the repair rate. However, the faster the deposits grow, the larger the grain size and the more loose the structure (Jin et al., 2019, Shen et al., 2020).

Some researchers (Chu et al., 2017, Chu et al., 2018) found that the repair effect is better when using pulse current. It may be that the concentration polarization of the electrolyte and the hydrogen evolution of the electrode can be alleviated during the intermittent time of the pulse current. When the specimens were repaired in ZnSO_4 solution by pulsed current, the deposits were interlaced and tightly bound to each other. While the sediment crystals under direct current had large sizes, random growth, and a loose structure. Moreover, deposits composition is not affected by the current type. However, in each pulse period, the current is zero

for a certain amount of time. In consequence, the total time of electrochemical reaction is shorter when using pulse current than that of direct current within the same repair time. In general, the effect of pulse current on electrodeposition is unclear and needs further research.

2.3 *Electrolyte type and concentration*

In most studies, single strong electrolyte solutions (MgCl_2 , ZnCl_2 , MgSO_4 , ZnSO_4 , etc.) were mainly used (Chu et al., 2014). Weak acid salts, such as acetate, are gradually accepted in order to avoid ion erosion. Existing investigations show that an electrolyte containing magnesium is the most effective solution when electrodeposition repair is conducted. The growth rate of deposits increases with the increase in electrolyte concentration. The concentration of electrolyte is generally 0.05 mol/L to 0.5 mol/L. The electrolyte should be replaced regularly during the experiment to avoid chemical reactions, evaporation, or other factors affecting the concentration of the electrolyte.

In consideration of the complex ion types in natural water environments, the coupling effects of Mg^{2+} and Ca^{2+} on the deposits were recently reported. $\text{Mg}(\text{OH})_2$ deposits on the cathode can form when $c(\text{Ca}^{2+}) < 0.0167 \text{ mol}\cdot\text{L}^{-1}$. $\text{Mg}(\text{OH})_2$ forms layered structures on the microscale. The mass and thickness of deposits increase as calcium concentration increases, while the volume of nanopores between the $\text{Mg}(\text{OH})_2$ layers decreases. Some small CaCO_3 crystal grains, including aragonite and calcite, precipitate in the layers. If $c(\text{Ca}^{2+}) > 0.05 \text{ mol}\cdot\text{L}^{-1}$, there will be portlandite in the deposits. Deposits on the cathode easily spall after the formation of portlandite (Li et al., 2021).

2.4 *Parameters of cement matrix*

The repair rate increases with the water-cement ratio of concrete (Jiang and Chu, 2005). Because the porosity of concrete will increase with a high water-cement ratio. Concrete matrix with high porosity will absorb more solutions, which leads to lower concrete resistivity. Meanwhile, the diffusion resistance of OH in the concrete also reduces. The repair rate decreases with the increase of concrete cover and crack width (Jiang and Chu, 2005). In addition to this, there are a few studies on concrete parameters. Most studies have focused on electrical parameters (Nishida et al., 2014) and numerical simulations (Chen et al., 2022a, Chen et al., 2020) of electrodeposition restorations.

3 LATEST RESEARCH

New investigations have been reported continuously because electrodeposition repair has a good prospect for cracked constructions in an aqueous environment. In this section, the recent progresses in electrodeposition repair are presented.

3.1 *Anode material*

The anode material in most studies was described as inert conductive materials such as graphite or titanium (Chu et al., 2020, Zhou et al., 2020). In fact, both graphite and pure titanium electrodes dissolve slightly in the electric field. When repairing a cracked reinforced concrete specimen, high voltage is often required because of the poor conductivity of concrete. Higher voltages easily cause the graphite and titanium to dissolve. The required voltage increases with the specimen volume, which makes the dissolution of the anode more visible. After the graphite is dissolved, black impurities will pollute the electrode and the deposits and affect the appearance and detection of the specimen.

For titanium cathodes, a passive film will first appear on the surface of the titanium electrode when the voltage is high. The passive film will reduce the conductivity of the electrode and affect the stability of the current. If the voltage is too high, pitting corrosion will occur on

the surface of the titanium electrode. It was found that titanium electrodes coated with ruthenium and iridium showed excellent corrosion resistance. The ruthenium-iridium coating can make the electrode completely resistant to corrosion during the electrodeposition repair process (Li et al., 2021, Chen et al., 2022b, Li et al., 2022).

3.2 Repair solution

A novel repair solution including $\text{Ca}(\text{CH}_3\text{COOH})_2$ and $\text{Al}_2(\text{SO}_4)_3$ was reported (Chen et al., 2022b). The innovation of this study is that the deposits are ettringite with an appropriate ratio of Ca^{2+} to Al^{3+} (Ca/Al). As one of the compositions of cement hydration products, ettringite exhibits better compatibility when it fills the microcracks. When the Ca/Al ratio is 1, gypsum is the main phase in the deposits. When the Ca/Al ratio is 3 or 5, the permeability coefficient decreased by roughly 4 orders of magnitude, and the crack closure time was lowered to 1 day after 7 days of repair. The products of all groups entered the whole fracture, and when the Ca/Al ratio is 5, the coverage ratio of the crack section can reach more than 60%. The morphology of the deposits in different Ca/Al ratio solutions is shown in Figure 2. The ettringite influenced by electric field shows extremely thin, acicular and elongated characteristics. An interlaced network structure generates because of the fibrous ettringite overlapped with each other. There are calcium crystal grains among the network, which make the netted texture denser. The microstructure of the deposits is shown in Figure 3.

Figure 2. The morphology of the deposits in different Ca/Al ratio solutions.

Figure 3. The microstructure of the deposits.

3.3 Additive agent

“Additive agent” in this part refers to the chemical substances added to the electrolyte to enhance the repair performance. The additive agent could be surfactant or complexing agent. Surfactant is a sort of amphiphilic molecule with hydrophilic and hydrophobic groups and can form ordered adsorption structures at the interface (Yasin et al., 2018). Hence, the

interface characteristics of the phase are modified. Complexing agents can form chelates with some metal ions. When the complexing agents are added to the repair solution, the chelate capacity may influence the migration of metal ions (El Bahi et al., 2020, Singh and Poolla, 2018). Accordingly, the surfactant and complexing agent are believed to facilitate the improvement of the quality of electrodeposition and optimize the crystal structures of deposits. The additive agents are commonly used in the electroplating industry, but there have been few studies in the electrodeposition repair field to date.

The effects of cetyltrimethylammonium bromide (CTAB) on electrodeposition repair was performed (Zeng et al., 2022). In $MgSO_4$ or $ZnSO_4$ electrolytes, the repair effect of crack specimens tended to first increase and then go down as CTAB content increased. Meanwhile, the adhesive strength between the steel bar and cement matrix, the Cl^- resistance, and the anti-corrosion ability of the steel bar were enhanced. The proper dosage (relative to the electrolyte volume) of CTAB is 1.00 vol%. CTAB enhances the repair effect by influencing the micromorphology rather than the components of deposits.

Sodium citrate, as a complexing agent, also enhances the repair effect (Zhu, 2021). In zinc acetate solution, the molar ratio of zinc ions to sodium citrate (Zn/SC) will affect the properties of the deposits. The deposits are zinc element and show low adhesion and a loose texture in the zinc acetate electrolyte without sodium citrate. When Zn/SC is between 3/2 and 3/6, the mass of deposits obviously increases. The adhesion ability and compactness of deposits are enhanced. The macroscopic morphology of deposits will not change when $Zn/SC > 3/6$. The reduction of Zn^{2+} is influenced by the sodium citrate solution. The formation of zinc hydroxide was promoted when the concentration of sodium citrate was more than twice that of zinc acetate. Citrate has a buffering effect on the pH value of repair solutions. Citrate keeps the pH value in a relatively stable state, which is more suitable for the electrodeposition repair of concrete.

3.4 Numerical study

A continuum damage-healing framework based on the multi-field coupling development process of the deposits was described (Zhu et al., 2021). The repair progress is affected by multiple fields such as electric fields, concentration fields, and transport-velocity fields. The electric fields were described by the current conservation equation, as Equation 1 showed. The ion transport process can be described by the Nernst-Planck equation, as Equation 2 showed. The consumption rate of Mg^{2+} in electrolyte can be described as Equation 3. The repair process will cause interface changes between the deposits and the electrolyte. The level set approach is used to monitor the growth of deposits, The ϕ of the cathode and anode is 0 and 1, respectively, as shown by Equation 4.

$$-\omega \nabla^2 V = Q \quad (1)$$

where ω = local voltage influenced by the ion concentration; and Q = external voltage influenced by the electrode interface reaction speed.

$$\frac{\partial c_i}{\partial t} - \nabla \cdot \left(D_i \nabla c_i + \frac{z_i e}{k_B} D_i c_i \nabla V \right) = R_i \quad (2)$$

where c_i = concentration of the i -th ion; D_i = diffusion coefficient of the i -th ion; z_i = valence of the i -th ion; k_B = Boltzmann constant; e = amount of elementary charge; ∇ = divergence; V = potential of the electrolyte; and R_i = source or sink term.

$$R_{Mg^{2+}} = k_1 (c_{Mg^{2+}} \cdot c_{OH^-}^2 - k_{sp1}) \quad (3)$$

where $R_{Mg^{2+}}$ = consumption rate; k_1 = constant of the precipitation reaction; and k_{sp1} = apparent solubility product constant of the Mg^{2+} .

$$\frac{\partial \phi}{\partial t} + \mathbf{u} \cdot \nabla \phi = \gamma \nabla \cdot \left(\varepsilon_{ls} \nabla \phi - \phi(1 - \phi) \frac{\nabla \phi}{|\nabla \phi|} \right) \quad (4)$$

where ϕ = reinitialization parameter \mathbf{u} = growing velocity field of deposits ε_{ls} = interface thickness of deposits; and γ = amount of reinitialization.

The generation processes were simulated by COMSOL. The filling process of deposits in cracks was displayed in Figure 4. The repair effect increased with the voltage, as shown in the figure, which is consistent with the experimental results as well. The influence of time, electrolyte concentrations, and voltages on the repair effect can be quantitatively obtained by the proposed models.

The simulation method can greatly shorten the test process and study the influence of various variables in a short amount of time. At present, there are few studies on the numerical simulation of electrodeposition repair.

Figure 4. The generation of deposits at various voltages, (a) 3 V; (b) 5 V; (c) 8 V; (d) 10 V.

3.5 Repair device

An on-site repair device for underground structure leakage cracks was proposed (Chen et al., 2019), which is used to repair structural cracks of less than 2 mm. The device is shown in Figure 5 and comprises: (1) An adjustable DC power source used to generate adjustable weak current. (2) An electrolyte container sticking to the position of crack. (3) A ruthenium-iridium-titanium plate served as anode. Compared with the prior art, this device has the advantages of non-destructive repair, erosion reduction, repair adjustment, real-time monitoring, etc.

4 CHALLENGES AND POTENTIAL RESEARCH DIRECTIONS

To date, there are few engineering applications. It should be pointed out that, new challenges will appear when we conduct electrodeposition repair in engineering, such as:

- (1) Connecting steel bars and wires through a drill hole damages the structure to some extent, so more effective methods should be explored.
- (2) There is still no more accurate evaluation method of repair effect. It is only possible to visually measure whether the sediment has filled the crack and whether water is still seeping through the microcracks. Ultrasonic, acoustic emission, or other environmentally sensitive detecting technologies are not suitable for application in engineering.

Figure 5. The structure of electrodeposition repair device. (1) Direct current power. (2) Electrolyte container. (3) Wires. (4) Wall surface with microcracks. (5) Reference electrode. (6) Electrolyte. (7) Anode. (8) Steel bar in the walls.

- (3) The temperature of the surrounding environment is critical. The rate of electrochemical deposition slows down at low temperatures.

5 CONCLUSIONS

This review reported the development of electrodeposition repair in the past three years, with a concentration on anode materials, repair solutions, additive agents, numerical studies, and repair devices. Electrodeposition repair shows great potential in a special condition, and its application scenarios have been expanding. Although a large-scale experimental test has been investigated, further research on how to promote engineering applications is required.

ABSTRACT: The traditional external wall insulation system was flawed by its own material characteristics and structural design. Foamed ceramics had also been known as “solid waste gold” in the industry. Then a new kind of foamed ceramics external wall panel was proposed in this paper. The new kind of foamed ceramics external wall panel integrated the architectural function, structural function and decorative function, which could ensure the wall panel had the same duration as the building. In this paper, the economic evaluation method of the foamed ceramics external wall panel was proposed based on full life-cycle theory in order to provide a series of investment advices for the real estate developers and consumers. Through the analysis, it showed that the new kind of foamed ceramics external wall panel could be widely used in energy-saving residential areas, which was a good solution to contradiction between resource tension and consumption growth.

Keywords: Foamed ceramics, External wall panel, Low-carbon, Full life-cycle, Net present value method

1 GENERAL INSTRUCTIONS

1.1 *External wall insulation system*

Nowadays, the performance requirements of external wall become increasingly higher. The traditional external wall insulation system which was commonly known as the building’s coat was inherently flawed. First, traditional external wall insulation system was easy to fall off

Figure 1. Insulation system falls off.

which could lead to personnel safety accidents, as shown in Figure 1. Second, the construction quality of traditional external wall insulation system was hard to meet the requirement which could lead to short service life. With the progress of science and technology, people's demand for external wall was changing as well, and fire resistance and energy efficiency are gradually becoming the new demand for buildings.

Therefore, traditional external wall insulation system was forbidden in many Chinese provinces, a new kind of external wall insulation system called "Insulation-Structure Integration External Wall Insulation System" was strongly promoted due to its excellent performance. Insulation-Structure Integration External Wall Insulation System could not only utilize the new material perfectly, but also solve the problems of building energy saving and fire resistance. More importantly, it gradually realized the demand of the building market for insulation system with the same life of the building (Alfred A.Yee. 2016).

1.2 Exterior wall material

The material of insulation layer in traditional external wall insulation system could be divided into two parts, the organic combustible materials such as polystyrene and polyurethane, the inorganic non-combustible material such as rock wool. When cracks and hollow drum appeared during the usage phase of the insulation layer, the exposed organic insulation materials were highly susceptible to fire with toxic fumes which seriously affected the evacuation of personnel and fire rescue operation, as shown in Figure 2. In 2009, China's Ministry of Fire Protection proposed that only Class A fire-resistant material could be used in the insulation layer of external wall, however, no suitable material had been found which could combine the insulation function and fire-resistant function perfectly.

Figure 2. Fire incident caused by the insulation layer.

1.3 Research purpose

A new kind of foamed ceramics external wall panel which organically combined the foamed ceramics and the Insulation-Structure Integration External Wall Insulation System was proposed in this paper, as shown in Figure 3. The economic evaluation method of the foamed ceramics external wall panel was proposed based on full life-cycle theory. At last, a series of investment advices were provided for the real estate developers and consumers.

2 CONCEPT OF FOAMED CERAMICS EXTERNAL WALL PANEL

2.1 Foamed ceramics

Foamed ceramics had been called "solid waste gold" in the industry, the product had the advantages of light weight, high strength, fire resistance, water proof and moisture proof, heat insulation, sound insulation and noise reduction, green environmental protection, stable performance, good weather resistance, etc. Foamed ceramics were produced by recycling ceramic

Figure 3. A new kind of foamed ceramics external wall panel.

tailings, fly ash, slag, coal mine stone, red mud, inorganic pollution and other industrial solid waste as the main raw materials, as shown in Figure 4. Precision-controlled foaming technology was used under 1200°C high-temperature roasting to produce a high porosity low-density closed-cell porcelain material which could reduce carbon emissions during cement production, building brick firing and transportation effectively. Moreover, foamed ceramic panels could achieve the same life as the building. There was no need to increase the cost of maintenance, renovation during the whole life cycle.

Figure 4. Foamed ceramics.

2.2 Advantages of foamed ceramics external wall panel

First, traditional external wall insulation system construction process was complex, and due to difference of the construction industry workers in skill and responsibility, construction quality was difficult to achieve the standard. At the same time, most design of the traditional external wall insulation system was completed, which led to the products not matching the buildings. In order to solve this technical difficulties, a digital service platform based on BIM information technology was provided to guide the preliminary architectural and structural design by establishing a stereotyped standard product library, which realized the integrated design of architecture, structure and decoration (Pons, O. 2010).

Second, China's construction industry was the largest in the world, and at the same time, it was also the largest carbon emitter in the world. Currently, the total building stock in China's cities and towns was about 65 billion square meters, and these buildings emitted about 2.1 billion tons of carbon dioxide in the process of use, accounting for 20% of the total carbon emissions in the world (Bonamente E, Merico M.C. 2014). Excessive carbon emissions would lead to the greenhouse effect, glacier melting, global warming and other serious environmental

problems. Therefore, the work of “carbon peaking and carbon neutral” had a long-term and far-reaching significance. Foamed ceramics were produced by recycling ceramic tailings, fly ash, slag, coal mine stone, red mud, inorganic pollution and other industrial solid waste as the main raw materials, which could reduce carbon emissions during cement production, building brick firing and transportation effectively.

At last, foamed ceramics external wall panel was of strategic importance to promote the green, intelligent and efficient synergistic development of the whole industrial chain of industrialized buildings and improved the core competitiveness of enterprises. Through the integrated design of insulation, structure and decoration, it could achieve 80% energy saving, 90% pollution reduction, 80% labor reduction and 50% reduction in construction period and it could help to realize the strategic goal of “double carbon” in the construction industry.

3 THE ECONOMIC EVALUATION OF FOAMED CERAMICS EXTERNAL WALL

3.1 Concept of full life-cycle

The whole life cycle for a building meant the whole process of material acquisition, manufacturing, transportation, installation construction, operation, maintenance and demolition of building systems.

The whole life cycle assessment was the economic evaluation of the environmental impact of the material and energy flow during the cycle of production, planning and design, construction and transportation, operation and maintenance, demolition and disposal of the building components, which was a comprehensive study of the economic, social and environmental benefits of the material.

The economic evaluation of external wall insulation system was to evaluate the energy efficiency of external wall insulation system from the economic point of view. The energy efficiency analysis of the system was carried out by applying the whole life cycle cost principle to reflect the economic benefits of the inputs and outputs of the system in the whole life cycle.

3.2 Cost component

The whole life cycle cost of a project is the cost of the external wall insulation system over its entire life cycle by adding up the various costs in net present value and subtracting the cash injection of, which could be calculated as follows:

$$LCC = I + \sum_{t=0}^T E + \sum_{t=0}^T M - S \quad (1)$$

where LCC =full life cycle cost; I =initial investment; E =operating cost; S =net salvage; T =full life cycle; t =time parameter; M =maintenance cost.

The heating fee could be calculated as follows:

$$P = K(t_i - t_w)ts \quad (2)$$

$$s = ab/1000Q\eta_1\eta_2 \quad (3)$$

where P =heating fee; K =heat transfer coefficient; t_i =indoor temperature; t_w =outdoor temperature; η_1 =efficiency of outdoor pipe network transmission; η_2 =boiler thermal efficiency.

3.3 Evaluation index

For the economic evaluation of building by using energy efficiency measures, there were two kinds of evaluation method (San-José Lombera JT, Garrucho Aprea I. 2010). One is the evaluation of an independent solution, the other one is the evaluation of multiple options (Luo Y. 2007). Absolute indicators were used for the evaluation of the economic feasibility of

an independent solution. The indicators of economic evaluation of an independent solution were usually *NPV*, *IRR*, investment profitability, payback period. Relative indicators were used for the mandatory selection of multiple mutually exclusive solutions including *NPV*, *IRR*, and *NAV*. From the perspective of real estate developers and consumers, *NPV* was used as an economic evaluation indicator, which could be calculated as follows:

$$NPV = \Delta P - \Delta I \tag{4}$$

where ΔP =net value of economic benefit; ΔI =net value of investment.

4 ACYTUAL CASE ANALYSIS

4.1 Case description

The following three insulation measures were proposed for a building in a certain area: (1) Non-insulation system; (2) Traditional external wall insulation system; (3) Foamed ceramics external wall system.

The life of residential building insulation materials was generally not less than 25 years, the above program of the initial investment, land use fees, planning and design fees were assumed to be the same in the same social resource environment. Annual maintenance and management costs for building insulation materials were estimated based on experience (Diana L, Thomas M.F. 2016). building insulation materials salvage value was depreciated on a straight-line basis at 5% depreciation rate. $t=152d$, $t_1=18^\circ C$, $t_w=-5.7^\circ C$, $a=200/t$, $b=3.4779$, $\eta_1=0.92$; $\eta_2=0.73$, $Q=0.2389kJ/kG$.

4.2 Case analysis

Economic comparison of three different insulation system about external wall was shown in Table1.

Table 1. Economic comparison of three different insulation system (CNY).

Insulation measures	Initial investment		Heating fee		Maintenance cost		Net salvage	
	<i>I</i>	Net value	<i>P</i>	Net value	<i>M</i>	Net value	<i>S</i>	Net value
Non-insulation	75	75	5.73	80.91	0.2	2.82	20.80	6.24
Traditional system	95	95	2.59	36.57	0.4	5.65	26.35	7.91
Foamed ceramics system	130	130	1.95	27.53	0.3	4.24	36.06	10.82

It can be seen from Table 1 that *LCC* of traditional system and foamed ceramics system were both less than that of non-insulation system, which indicated that insulation system was necessary for the building.

The *NPV* of foamed ceramics system and traditional system can be calculated as follows:

Foamed ceramics system:

$$NPV_1 = \Delta P_1 - \Delta I_1 = 58.18 \text{¥/m}^2$$

Traditional system:

$$NPV_2 = \Delta P_2 - \Delta I_2 = 36.54 \text{¥/m}^2$$

The payback life of foamed ceramics system and traditional system can be calculated as follows:

Foamed ceramics system:

$$T_1 = \frac{95}{80.91 - 36.57} = 2.14$$

$$T_2 = \frac{130}{80.91 - 27.53} = 2.44$$

Then, the economic benefits over the life cycle of foamed ceramics system was 1203.2¥, the economic benefits over the life cycle of traditional system was 1013.6¥.

5 CONCLUSIONS

In this paper, a new kind of foamed ceramics external wall panel which organically combined the foamed ceramics and the Insulation-Structure Integration External Wall Insulation System was proposed. Then, the economic evaluation method of the foamed ceramics external wall panel was proposed based on full life-cycle theory in order to provide a series of investment advices for the real estate developers and consumers. The results of this research project were summarized as follows.

- (1) Foamed ceramics external wall panel was of strategic importance to promote the green, intelligent and efficient synergistic development of the whole industrial chain of industrialized buildings due to its significant advantage.
- (2) *LCC* of traditional system and foamed ceramics system were both less than that of non-insulation system, which indicated that insulation system was necessary for the building.
- (3) Although the payback period of foamed ceramics system was a little bit longer than that of traditional system, foamed ceramics system had the long-term economic benefits over the full life cycle, which indicated that energy savings efficiency of foamed ceramics system was much better than that of traditional system.

Mechanical performance of steel plate combination beam bridge with clustered shear studs considering slip effect

Y.L. Yi

Anhui Transportation Holding Group Co.Ltd., Hefei, China

W.Y. Meng, N.N. Huo & X. Ruan

Tongji University, Shanghai, China

ABSTRACT: The mechanical property of composite girder bridges is significantly influenced by the mechanical performance of shear connectors. The slip between the deck plate and steel girders caused by deformed shear connectors will have an impact on the mechanical property of the entire bridge. The slip impact of the clustered shear studs is taken into account in this article in order to reflect the actual structural condition. The influence of this consideration on the force performance of the steel plate composite girder bridge is then examined by creating an ANSYS finite element model. The study focused on the deformation and stress distribution of a composite girder bridge, and the calculation analysis reveals that taking shear studs slippage into account will result in lower stress results in the deck plate and steel girder and higher overall deformation of the bridge. The longitudinal stress of the bridge deck is most significantly impacted by the shear studs connection performance, with a maximum stress variation of roughly 8%. The greatest deformation difference does not exceed 5%.

1 INTRODUCTION

Steel-concrete composite bridges select the proper material composition system in conjunction with the structural stressing characteristics and combines the benefits of both steel and concrete materials. It offers a significant benefit in many areas, including ease of construction, affordability, and beauty (Nie et al., 2012). Contrarily, shear studs are frequently used to connect the steel girders and concrete deck slab of steel-hybrid composite girder bridges, putting joint stress on every component of the structure. The mechanical qualities of the shear members, a crucial connecting component of the composite girder bridge, impact the structural performance of the entire structure, so it is crucial to research the various traits of shear studs.

The current research on shear studs focuses on two aspects: shear resistance of shear studs and slip effect.

Shear studs shear bearing capacity, tensile bearing capacity, tensile shear under the joint action of the bearing capacity and shear studs shear stiffness factors have been fully analyzed by researchers through push-out Test or finite element simulation, etc. for shear studs shear bearing capacity, tensile bearing capacity, tensile shear under the joint action of the bearing capacity and shear studs shear stiffness factors. The tensile strength, length, and diameter of shear studs, as well as the tensile strength and modulus of elasticity of concrete, are thought to be factors influencing shear performance (Amadio and Fragiaco, 2002, Moghimi and Ronagh, 2008, Qureshi et al., 2011, Shim et al., 2004, Zhou et al., 2014).

The study of the slip effect is mainly based on the finite element model, in which the shear studs deformation is considered to determine the slip at the interface of the composite beam, and then the slip effect on the force of the composite beam is analyzed. The general slip effect

will bring about the problems of increasing deflection, decreasing stiffness and decreasing load capacity of the composite beam(Gara et al., 2006, Spacone and El-Tawil, 2004, Su et al., 2016).

Comprehensive research has been undertaken, The shear performance of shear studs has been thoroughly researched; scholars have carried out numerous experiments and theoretical analyses, and the research is now more mature. However, there are still some issues with the study of the slip effect, such as the need for additional research on the impact of the ultimate load during operation and the slip effect on actual projects.

The layout of shear studs has changed recently along with the growth of assembly construction. The welded studs in the conventional composite girder structure are typically evenly and closely spaced at the point where the steel girder flange and concrete deck slab meet. However, this necessitates the lateral division of the prefabricated deck slab into many parts, reducing the structural integrity and delaying the construction process. As a result, a new type of studs arrangement is suggested, including cluster shear studs, uniformly and densely spaced shear studs in sections, and a cluster of shear studs at every other section of studs-free area on the steel girder flange. Two such types of shear studs arrangements are schematically depicted in Figure 1.

Figure 1. Layout of shear studs.

Compared with the uniform shear studs, clustered shear studs have significant advantages in bridge construction, construction design and other convenience.

- (1) The bridge transverse prestressing tendons pass easily through the studs-free zone set aside for each distance of cluster shear studs, which is suitable for the bridge transverse prestressing tendons through-length setup.
- (2) As industrial building has advanced, prefabricated deck plate technology has been included into the production of several coupled girder bridges. Cluster shear studs can erect the bridge deck by reserving holes in the shape of bridge deck plates, as opposed to evenly dispersed shear studs, which must erect the bridge deck in longitudinal and transverse blocks. This assures the prefabricated bridge deck's integrity. This ensures the prefabricated bridge deck's integrity and enhances structural performance.
- (3) Pre-drilled holes are typically used in composite girder bridges with cluster shear studs construction so that the steel girders can be attached to the deck plate later and pre-stress the deck plate more effectively.
- (4) The cluster shear studs structure also significantly increases construction efficiency, reduces the amount of in-situ concrete work, and makes it easier to replace the deck slab afterward, all of which are beneficial for bridge maintenance and operation.

2 BACKGROUND PROJECT

Study rely on the approach bridge project of Jiuwan Huihe Bridge of Guzhen-Bangbu Expressway Project. The main structure is composed of 50m simply supported steel plate combination girders and 35m continuous steel plate combination girders. The main girder adopts Q345qD I-beam straight web steel plate combination girder, and the concrete lane plate is connected with the steel main girder by clustered shear studs; the transverse connection of the main girder at the non-supporting point is in the form of small crossbeam with longitudinal spacing of 6.0m, the transverse connection of the middle pier is in the form of reinforced crossbeam, and the transverse connection of the split pier is in the form of large crossbeam. Large crossbeam form is used for the transverse connection of split piers. The steel main girders are "I" girders with a height of 2.5m for 50m span and 1.8m for 35m span, and the thickness of the steel girders is different according to the segmental length according to the different stresses. The bridge cross section is shown in Figure 2.

Figure 2. Bridge section (unit: cm).

The prefabricated travel lane slab is prefabricated in full width and connected by cast-in-place wet joints in the middle. The bridge deck plate is set with transverse prestressing tendons and pre-determined weld studs holes, and clustered shear studs are set on the upper flange of the corresponding steel girders at the weld studs holes and wet joints, and after the precast travel lane plate is positioned and installed, the weld studs holes and wet joint concrete are cast to connect with the steel girders. The precast travel lane slab is made of C50 concrete, the in-situ wet joint at the top of the pier of the middle pier is made of UHPC high-strength concrete, and the rest of the in-situ wet joints are made of C55 Compensating Shrinkage Concrete.

3 FINITE ELEMENT MODEL

3.1 Overview

In this paper, finite element analysis is used to determine the effect of slip effect on the mechanical properties of the composite beam bridge. The model is established based on the drawings of the 50m simply supported girder bridge in the approach bridge project of Jiuwan Hwoe River Special Bridge of Guzhen-Bengbu Expressway Project. The steel plate girders made of steel are supported by reinforced concrete bridge deck slabs. Combined with the material characteristics, the steel plate girder part adopts the plate unit model, and the bridge deck part adopts the solid model. The specific dimensions of the main beam, crossbeam, stiffener beam, deck slab and other components are input according to the design drawings, and the reinforcement distribution in the area of the drawings is referred to, and the reinforced concrete solid unit is established and the reinforcement distribution is input.

To study the response of various types of bridges under standard combinations, add the bridge self-weight, second phase load, vehicle load, and concrete shrinkage creep on the basis of taking the construction process into account. Then, analyze the precise degree to which the performance of clustered shear studs has an impact on structural performance.

Special attention is paid to the simulation of the spring unit for the shear studs the concrete deck slab to the steel beam, in which the stiffness of the spring unit is calculated based on the distribution of shear studs in the drawing to establish a calculation model considering relative slip. On the other hand, the spring unit is coupled at both ends to establish a calculation model without considering the relative slip. The details of the calculation model are shown in Figure 3 below.

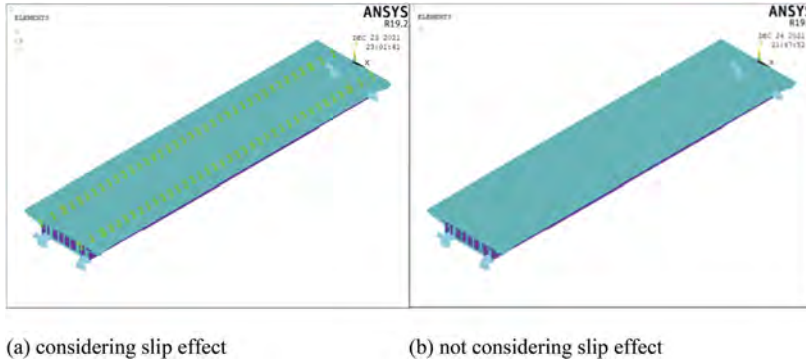

Figure 3. Finite element model.

3.2 Shear studs simulation method

The stiffness of the shear studs must be established for further study since the steel plate composite girder bridge's finite element model simulates the effect of shear studs on the connection between the concrete slab and the steel beam using spring units. Cluster shear studs employed in the background project have varying shear studs spacing from uniform shear studs, this variations will also have an impact on the group studs stiffness. A special study has been conducted to investigate the degree of stiffness reduction of the cluster studs effect.

3.2.1 Single studs shear stiffness

Regarding the shear stiffness of single shear studs, Spacone et al (Spacone and El-Tawil, 2004), combined with the launch tests of multiple groups of shear studs tests, expressed the shear stiffness of shear studs as the formula related to three parameters of shear studs shear bearing capacity (P_{max}), shear studs body diameter (d_{sh}), and concrete compressive strength (f_c).

$$K_i = \frac{P_{max}}{d_{sh}(\alpha - 0.0017f_c)} \quad (1)$$

The provisions of the European Code for Combined Structures (Eurocode 4) can be used to calculate the shear studs shear bearing capacity. Shear studs shear bearing capacity can be based on the shear studs body diameter (d_{sh}), concrete cylinder standard compressive strength (f_{ck}), shear studs material yield strength (f_y), concrete strength sub-factor (γ_{mc}), shear studs strength sub-factor (γ_{ms}) calculated from.

$$P_{max} = 0.36d_{sh}^2 \sqrt{f_{ck}E_c} / \gamma_{mc} \leq 0.7A_s f_y / r_{ms} \quad (2)$$

Combined with the specific parameters of shear studs used in the background project, 144KN can be calculated, and the shear stiffness of single studs is 374KN/mm.

3.2.2 Effect of shear studs spacing on shear stiffness

In the modeling procedure for cluster shear studs, a group of shear studs is treated as a spring unit to make the analysis simpler. Because the shear studs densities result in the discounted

stiffness, it is important to compute the mechanical properties of the cluster studs based on the mechanical properties of the single studs. The calculation technique must also take this into account. In other words, the shear stiffness of the group of studs will depend on the shear studs spacing.

Through a series of launch tests, some researchers(Huang et al., 2015) examined the force performance of various shear connector types. The results of the tests revealed that the average shear capacity per shear studs of cluster shear studs was 29% lower than that of single shear studs and the shear stiffness was 44% lower. Additionally, the force generated by a cluster of shear studs is clearly non-uniform; the stress is distributed in a “saddle-shaped” pattern from top to bottom. This reduces the bearing capacity of a single shear studs dramatically.Related numerical analysis demonstrates that: the single studs bearing capacity has a trend of first increasing and then decreasing with an increase in shear studs spacing; and the shear force direction of each row of shear studs establishes the distribution of the two large, small, and middle studs in a “saddle-shaped” pattern(Lu, 2015).

In order to quantitatively analyze the stiffness of a single shear studs group, the factors affecting the group studs stiffness can be included in two categories: the number of longitudinal rows of shear studs and the longitudinal spacing of shear studs.

Where the discount factor (ϕ) of the number of longitudinal rows of shear studs (n_p) for the group studs stiffness can be referred to the research results of Zhou Xuhong et al(Zhou et al., 2014). The following equation was used for the calculation.

$$\phi = \begin{cases} 1 & n_p \leq 3 \\ 1.0047 + 0.0071n_p - 0.0021n_p^2 & 3 < n_p \leq 7 \\ 1.0101 - 0.0117n_p - 0.0004n_p^2 & 7 < n_p \leq 15 \end{cases} \quad (3)$$

The discount factor (η) of shear studs longitudinal spacing for group studs stiffness can then be referred to the results of Okada et al.(Okada et al., 2006). The following equation was used to calculate: (where C_l is the ratio of shear studs spacing to diameter)

$$\begin{aligned} 3 \leq C_l < 13 \\ C25/30; \quad \eta &= 0.023C_l + 0.70 \\ C30/37; \quad \eta &= 0.021C_l + 0.73 \\ C40/50; \quad \eta &= 0.016C_l + 0.80 \\ C50/60; \quad \eta &= 0.013C_l + 0.84 \\ C_l \geq 13 \\ C25/30 \sim C50/60; \quad \eta &= 1.0 \end{aligned} \quad (4)$$

Therefore, taking into account the effect of the number of longitudinal rows of shear studs and shear longitudinal spacing on the stiffness of a single bundle of shear studs groups, the total stiffness (K) of a studs group consisting of n single studs (single studs stiffness of K_e):

$$K = \phi \times n \times K_e \quad (5)$$

For this project, the single bundle shear studs group consists of 30 shear studs, the longitudinal row number n_p is 5, so the longitudinal row number for the group studs stiffness discount factor ϕ is 0.98, the ratio of shear studs spacing to diameter C_l is 5.68, the corresponding stiffness discount factor η is 0.91. In summary, the single bundle shear studs group stiffness K is 10127.5 KN/mm. analyze the effect of slip effect on the structural performance of the bridge.

4 ANALYSIS OF SLIP EFFECTS

4.1 Bridge stress results

The variation of longitudinal stresses in the upper layer of the span deck slab along the bridge width with and without considering the relative slip under the standard combination of bridge self-weight, phase II load and vehicle load is shown in Figure 4.

Figure 4. Change of longitudinal stress of bridge decking of mid span bridge deck along the bridge width.

Due to the vehicle deflection and double main girders, it can be seen from the figure that the trend of longitudinal stresses along the bridge width is the same, regardless of whether the slip is considered or not: the deflection increases from one side to the other of the cross-bridge. Considering the relative slip, the longitudinal stress of the bridge deck is greater than the longitudinal stress of the bridge deck without considering the relative slip, but the maximum ratio of the difference between the two stresses does not exceed 8%. It can be seen that the relative slip has a certain influence on the maximum compressive stress of the upper layer of the bridge deck plate, the bridge deck plate and shear studs direct vector, this effect is also the most direct.

The variation of longitudinal compressive stress along the bridge length for the upper edge of the steel main girders with and without considering relative slip under the standard combination of bridge self-weight, phase II load and vehicle load is shown in Figure 5.

Figure 5. Longitudinal compressive stress of upper edge of steel main beam changes along the longitudinal direction.

When the main beam's longitudinal stress is examined, it can be seen that the change trend of compressive stress at the upper edge of the steel main beam is the same whether or not the slip action is taken into account. The stress at both ends is almost zero, and the stress near the span reaches the peak. This is because one side of the main beam is subjected to greater internal forces under the action of the vehicle deflection load. When relative slip is taken into account at the same time, the stress results are more unfavorable, and the difference between

the two is only 3%. Regarding the analysis of the steel main beam's force performance, the impact of taking shear studs slip into account is more constrained.

The variation of longitudinal tensile stresses along the length of the bridge for the lower edge of the steel main girders considering relative slip and without relative slip under the standard combination of bridge self-weight, phase II load and vehicle load is shown in Figure 6.

Figure 6. Longitudinal tensile stress of lower edge of steel main beam changes along the longitudinal direction.

One side of the main beam is subjected to greater internal forces as a result of the vehicle deflection load, so the longitudinal stress of this main beam is chosen. It can be seen that, whether or not the slip action is taken into account, the trend of the tensile stress at the lower edge of the steel main beam is the same: the stress at both ends is almost zero, and the stress near the span reaches the peak. The stress results of simultaneously taking into account relative slip are less beneficial, and the difference between the two is only 4%. The examination of the steel main beam's force performance is less affected by taking the shear studs slide effect into account.

4.2 Bridge deformation results

The variation of the bridge span displacement along the bridge width with and without considering the relative slip under the standard combination of the bridge self-weight, the second phase load and the vehicle load is shown in Figure 7.

Figure 7. Variation of bridge displacement along bridge width.

The maximum displacement occurs in the mid-span region of the simply supported beam, and the displacement in the mid-span position is selected for both types of models. It can be found that the deflection on one side is greater than the other side under the action of vehicle deflection load, but whether to consider the effect of slip, the span mid displacement change trend is the same, both sides of the bridge displacement is larger, and because of the action of vehicle deflection load, the value of deflection on both sides is not equal. Also consider the relative slip displacement results are more unfavorable, and the difference between the two is

within 3%. The effect of considering shear studs slip is more limited for the bridge stiffness performance.

5 CONCLUSIONS

- (1) The deformation of shear pins in composite girder bridges will cause interface slip. A finite element analysis method to simulate interface slip is proposed in this paper to quantitatively evaluate the influence of interface slip on the overall stiffness and internal stress distribution of the bridges.
- (2) A 50m span composite beam bridge is used as the background for finite element analysis, and the results before and after considering the interface slip are compared. The interface slip of the combined girder bridge caused by the deformation of the set shear studs will have an effect on the stress and deformation of the bridge in both longitudinal and transverse directions.
- (3) The interface slip caused by the loading of the combined girder bridge during the operation phase will have a significant effect on the longitudinal compressive stresses on the deck slab and the top edge of the steel main girders, with or without the slip effect causing a stress gap of about 8%.
- (4) The interface slip generated by the load during the operation phase of the combined girder bridge will also have a limited effect on the bridge stiffness, which will lead to changes in the overall bridge deformation. The effect of whether to consider the slip effect on the above parameters does not exceed 5%.

Risk-based prioritization of earthquake performance of RC buildings in Turkey by rapid visual scanning

M. Özdemir

Ağrı İbrahim Çeçen Universty, Ağrı, Turkey

ABSTRACT: In this paper, the rapid visual scanning method (PRDB) used in Turkey to predict the performance of RC buildings under the influence of earthquakes in a practical and fast way has been examined. In this context, 100 RC buildings that affected light, medium and heavy damage from the Afyon, Bingöl and Van earthquakes that occurred on different dates were examined and the success of the rapid visual scanning method applied was determined. At the same time, a computer program called EPA (Earthquake Performance Analysis) was developed in order to evaluate the parameters of the related data set faster, easier and without error. The results showed that rapid visual scanning method can be used for risk-based prioritization of buildings.

1 INTRODUCTION

Since the existence of the Earth, earthquakes have been occurring all over the world due to the movement of the earth's crust. In one of the countries most affected by the earthquake, Turkey. Located on the Alpine-Himalayan earthquake zone, which is one of the active earthquake zones, the country has been affected by large earthquakes in which thousands of lives and millions of dollars were lost before. According to the Earthquake Zones Map, 92% of the country is in earthquake zones and 95% of the country's population lives under earthquake hazard (KOERI, 2023). In the province of Kahramanmaraş in Turkey, earthquakes with a magnitude of $M_w=7.7$ on February 6, 2023 and with a magnitude of $M_w=7.6$ on February 7, 2023 occurred, approximately 10 thousand buildings were destroyed and more than 45 thousand lives were lost (DEMP, 2023). Between the years 1903-2014 in Turkey occurred in the range of $M = 6.0-11.0$ magnitude 119 earthquake. These earthquakes resulted in an average annual loss of 748 lives, 5291 damaged buildings and economic loss of \$ 721,610 dollars. These results clearly show the effect of earthquakes that may occur naturally and inevitably, unless the necessary measures are taken (Erdil & Ceylan, 2018).

Experience and statistics have shown the importance of determining the behavior of buildings under earthquake impact. Therefore, many studies have been carried out to determine the behavior of buildings under earthquake effects and these studies have been classified into three categories (FEMA P-154, 2015). These categories can be listed as rapid visual scanning methods (RVS), preliminary assessment methods (PAM) and detailed analyzes. Rapid visual scanning methods are quite simple and fast (Sucuoğlu & Yazgan, 2003). In this method, some parameters such as number of stories, irregularity information, structural system are obtained by making observations from outside without entering the building and then performance of the building against the earthquake effect is determined. PAM, which is another method, includes some different parameters which should be taken from the inside the building (material information, structural system element dimensions, etc.) in addition to the parameters used in RVS (Otani, 2000; Sucuoğlu et al., 2015; Kaplan et al., 2018; Boduroglu et al., 2004). Although this method (PAM) takes a little longer time-consuming than RVS, accuracy ratio is higher. The third and last method used to determine earthquake performance is detailed analysis. This method determines the performance of buildings against earthquake effects by performing linear and nonlinear analyzes (Harirchian & Lahmer, 2020a). Although this method

are highly accurate ratio, it take too time. When considering the thousands of buildings in which earthquake performance behavior should be determined, researchers have done many studies on RVS and PAM methods, which are called rapid assessment methods. The main purpose of these methods (RVS, PAM) is to risk-based prioritize buildings and to identify which buildings need detailed analysis. In this study, the rapid visual scanning method used in Turkey for risk-based prioritization of reinforced concrete buildings was examined.

1.1 Review on developed RVS methods

Rapid visual scanning methods are used to determine the risk priorities of buildings under the influence of earthquakes without the need for detailed analysis and structural analysis. All parameters used in RVS methods are collected by observing from the street without entering the buildings (Harirchian et al., 2020). The first visual scanning method was prepared in the USA in 1988 with the name “Rapid Visual Screening of Buildings for Potential Seismic Hazards: A Handbook” and was updated in 2002 and 2015 (FEMA P-154, 2015). Many countries such as Turkey (PDRB, 2019), Canada (NRC, 1993), New Zealand (NZSEE, 2017), India (IITK-GSDMA, 2005), Italy (GNDDT, 1993) have taken the FEMA P-154 method as a basis, they created RVS methods by adapting them to their seismic conditions and structural systems.

1.2 Purpose of the study

There are 2 main goals of this paper. The primary aim of the study is to obtain the seismic vulnerability scores of 100 RC buildings affected by earthquakes in different regions by using the visual scanning method used in Turkey and to prioritize the buildings according to these scores. At the same time, the percentage of success of the method will be obtained by comparing the risk-based prioritization and the real damage status of the structures. The second of these goals is to develop a computer program that can determine the earthquake performance status (damage scores) of buildings in a much shorter time and error without.

2 MATERIAL AND METHODS

2.1 Data set

The first of the datasets used was shaken by an earthquake with a depth of 5 km and a magnitude of $M_w = 7.2$ that occurred on October 23, 2011, then again on November 9, 2011, with a depth of 5 km and a magnitude of $M_w = 5.6$, and was shaken again by two major earthquakes. It was collected from the province of Van, which experienced an earthquake (DEMP, 2023). This dataset consists of 54 RC buildings. The second data set was selected from Bingöl province, which was shaken by an earthquake with a depth of 10 km and a magnitude of $M_w = 6.4$, which occurred on May 1, 2003 (KOERI, 2023). This dataset consists of 28 RC buildings and is taken from the SERU database (SERU, 2023). The third and last data set was selected from Afyon province, which was shaken by an earthquake with a depth of 7.6 km and a magnitude of $M_w = 5.8$, which occurred on February 3, 2002 (KOERI, 2023). This dataset consists of 18 RC buildings and is taken from the SERU database (SERU, 2023). The damage distribution of the collected data is shown in Table 1.

Table 1. The damage distribution of the collected data.

Damage State	Afyon	Bingöl	Van	Total
Light damage	4	15	0	19
Moderate damage	3	7	11	21
Severe damage	11	6	43	60
Total	18	28	54	100

2.2 Parameters

The number of stories, ground class, structural system type, seismic vulnerability, structure irregularity information and topographic structure parameters shown in Figure 1 from the RC buildings in the data sets were collected according to the conditions specified in Table 2 and the RC buildings were classified into damage classes (light damage, medium damage and heavily damaged).

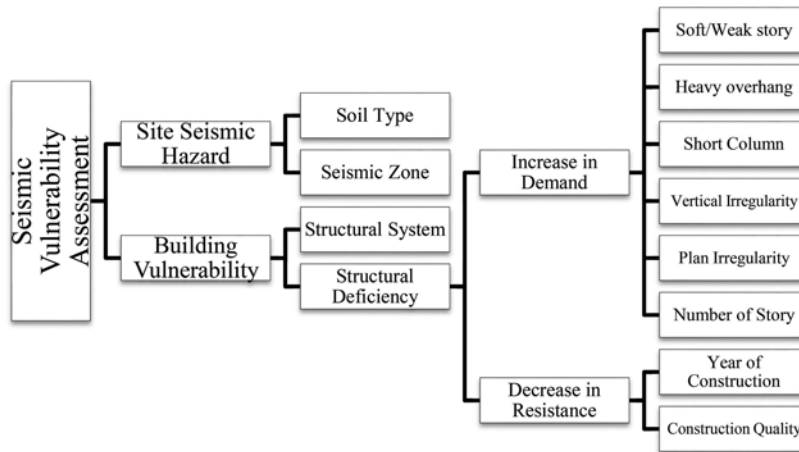

Figure 1. Parameters used in RVS methods in seismic vulnerability assessments of RC buildings.

Table 2. Parameter definitions and input features of reinforced concrete buildings collected for RVS studies.

Parameter	Description
No. of Story	Indicates the number of stories above ground
Structural System	By determining the structural system of the building, will be selected as one of the RC frame and RC frame and shear wall systems.
Soil Type	Determined according to ground survey reports
Vertical Irregularity	Columns and shear walls that do not continue along the height of the building create vertical irregularity
Plan Irregularity	It is defined as the geometrically not symmetrical plan and the irregular placement of vertical structural elements.
Short Column	Generally, ribbon window construction in industrial-type buildings or the absence of walls along the column creates the short column effect.
Heavy Overhang	The difference between the floor area on the ground and the floor area above the ground will be determined.
Construction Quality	Reflects the importance given to the quality of material and workmanship and the maintenance of the building.
Soft/Weak Story	It is expressed as the difference between story heights and the marked stiffness difference between stores.

All buildings in the data set are located in the 1st degree seismic zone according to the Turkey Earthquake Hazard Maps (TEHM, 2023), 48.96% of the buildings are Z2 ($760 < V_{S30} < 1500$), 49.48 are Z3 ($360 < V_{S30} < 760$) and 1.56 of them are on Z4 ($360 < V_{S30} < 760$) soil classes.

2.3 Methods

The method to be used within the scope of the study is to be used to determine the risky structures in Turkey, and the main purpose of the method is to determine the seismic vulnerability score of a building by giving penalty points according to the negative parameters (structure irregularity) it has, to a building that gets a starting score according to the structural system type, soil class and design spectral acceleration values. Then, these performance scores can be ranked among themselves and priority buildings with earthquake hazard can be determined. The method consists of 4 stages.

1. Determination of the building danger zone according to the design spectral acceleration coefficient (Sds) and ground class of the building whose seismic vulnerability will be determined (Table 3).

Table 3. Seismic danger zone (PDRB, 2019).

Danger Zone	Sds	Soil Class
I	$Sds \geq 1.0$	ZC/ZD/ZE
II	$Sds \geq 1.0$	ZA/ZB
	$1.0 \geq Sds \geq 0.75$	ZC/ZD/ZE
III	$1.0 \geq Sds \geq 0.75$	ZA/ZB
	$0.75 \geq Sds \geq 0.50$	ZC/ZD/ZE
IV	$0.75 \geq Sds \geq 0.50$	ZA/ZB
	$0.50 \geq Sds$	All soils

2. Determining the building base score (TP) according to the number of stories and seismic danger zone, and the structural system score (YSP) according to the number of stories and structural system type (Table 4).

Table 4. Base and structural score table (PDRB, 2019).

Total number of floors	Base score (TP)				Structural system score (YSP)	
	Danger zone				Structural system	
	I	II	III	IV	RCF	RCFW
1 and 2	90	120	160	195	0	100
3	80	100	140	170	0	85
4	70	90	130	160	0	75
5	60	80	110	135	0	65
6 and 7	50	65	90	110	0	55

3. Determining the parameters (structure irregularities, visual quality of the building) that will adversely affect the performance of the building against the earthquake effect and the scores of these negative parameters (Table 5).
4. Obtaining the seismic vulnerability score of the building according to the number 1 correlation and prioritizing the obtained scores based on risk.

$$PP = TP + \sum OPi + YSP \quad (1)$$

Table 5. Negativity parameter score (OP_i) table.

Total number of stories	Soft Storey	Apparent Quality	Heavy Overhangs	Vertical Irregularity	Irregularity/torsion effect in plan	Short Column	Topographic Effect
1 and 2	-10	-10	-10	-5	-5	-5	-3
3	-20	-10	-20	-10	-10	-5	-3
4	-30	-15	-30	-15	-10	-5	-3
5	-30	-25	-30	-15	-10	-5	-3
6 and 7	-30	-30	-30	-15	-10	-5	-3

3 RESULTS AND DISCUSSION

The seismic vulnerability scores of 100 RC buildings in the data set were determined according to the rapid visual scanning method (PDRB) used in Turkey. According to the results obtained, the rapid visual scanning method found 22% of the buildings at medium damage/risk, and 78% of them as severe damage/very risky. The method found none of the buildings to be slightly damaged/low risk (Figure 2).

Figure 2. Distribution of seismic vulnerability scores of RC buildings.

When the actual damage conditions of the RC structures in the data set were compared with the results of the rapid visual scanning method, it was seen that the rapid visual scanning method predicted the seismic sensitivity status of 66% of the buildings correctly and 34% of

Figure 3. Number of buildings where the RVS method found the correct seismic vulnerability score.

them incorrectly. In addition, the method correctly predicted 98% of heavily damaged structures, correctly predicted 57% of moderately damaged structures, and it was seen that it could not predict any of the lightly damaged structures correctly (Figure 3).

The accuracy rate of 66% obtained with 11 parameters by scanning only from the street without entering the buildings is quite successful. At the same time, it has been seen that the method has high success in detecting heavily damaged buildings. However, the method failed to detect slightly damaged reinforced concrete structures. This situation leads to the conclusion that the method needs to be updated.

4 CONCLUSIONS

RC building stock in Turkey is quite high and the majority of this building stock consists of old buildings. It is not possible to examine all these older structures with detailed analysis methods. For this reason, risk-based prioritization of buildings is required and rapid visual scanning methods are used for this.

Within the scope of the study, the current damage conditions of 100 RC structures affected by earthquakes in different regions and rapid visual scanning results were compared and the success of the visual scanning method used in Turkey in the evaluation of seismic sensitivity of RC buildings was measured.

The data set used and the results obtained show that the relevant method has an accuracy of 66% in the evaluation of the seismic sensitivity of RC buildings, but it cannot detect the structures with little damage and moderate damage. It is considered that the method should be updated by increasing the number of buildings in the data set.

At the same time, as a result of the study, rapid visual scanning methods are thought to be an effective and useful method for risk-based prioritization of buildings.

Chloride ingress of concrete structure considering the effect of early-age shrinkage

Y. Li & X. Ruan

Tongji University, Shanghai, China

T. Li & W.Y. Dou

Anhui Transportation Holding Group Co., Ltd., Anhui, China

ABSTRACT: Structural durability deterioration is a multiscale and multiphysics process and can be influenced by different factors. The influences of constructions initial status and the multiscale variation of concrete are also critical for the unexpected durability deterioration. Benefited from the development in concrete modeling, the progress in the shrinkage and durability are also prominent at meso-scale. In this paper, a comprehensive method is proposed combining the refined mesoscopic chloride ingress and the multiphysics shrinkage model. To investigate the influence of early-age shrinkage quantitatively, the numerical comparison between the 100-year chloride ingress with and without the shrinkage effect is conducted. With the modified diffusion coefficient, the ion concentration and the frontal depths of chloride ingress are all increased greatly. The extreme concentration under the 30mm concrete cover increases from 0.04kg/m^3 to 0.5kg/m^3 . The influence of different relative humidities in early-age curing is also investigated. With the drier curing environment, local tensile stress also increases greatly around the exposed surface, and the influenced area of chloride ingress is lager.

1 INTRODUCTION

The durability of reinforced concrete infrastructure is significant for structural safety and performance during long-term service. Many experiments focus on environmental exposure, substance transport, ingress resistance, and corrosion-induced crack to investigate the structural deterioration mechanisms. Various empirical functions are proposed at the beginning of this century for durability predictions. After decades of implementing the theory of durability design, the structural service performance is significantly improved with the higher strength of concrete material, the larger thickness of the concrete cover, and the introduction of specific protective measures. However, local disasters and damages can still be found in the infrastructural projects recently, which are much earlier than expected. Structural durability deterioration is a multiscale and multiphysics process and can be influenced by different factors (Li et al., 2022). Besides the factors like the coupling mechanism, the time-dependent environmental condition, or human activities, the influences of construction's initial status and the multiscale variation of concrete are also critical for unexpected durability deterioration (Hai-Long et al., 2016).

Early-age shrinkage is concrete's natural behavior after construction, leading to volume reduction and tensile strain in the cement mortar. Influenced by the water transport on the exposed surface and the mesostructure of concrete, the shrinkage behavior is non-uniform in concrete. The extreme tensile strain and the risk of local cracks can be found around the concrete surface and the narrow void between aggregates, leading to the higher diffusivity of environmental substances. So, it is necessary to investigate the influence of early-age shrinkage on the long-term durability of the reinforced concrete structure. Benefiting from the development in concrete modeling, the progress in shrinkage and durability are also prominent at the mesoscale recently (Li, Ruan, & Dou, 2023). The refined mesoscopic modeling method and the multiphysics shrinkage model can be introduced and combined herein for this comprehensive study.

DOI: 10.1201/9781003323020-501

This paper is organized as follows. Section 2 contains the comprehensive simulation for the long-term chloride ingress considering the influence of early-age shrinkage, which includes the modeling of concrete mesostructure, the multiphysics simulation of early-age shrinkage, and the solution of chloride ingress with modified diffusion coefficient. Section 3 contains the numerical comparison between the 100-year chloride ingress with and without the shrinkage effect, and the influence of different relative humidities in early-age curing is also investigated.

2 METHOD

2.1 Mesoscopic modeling

The mesostructure of concrete material is determined by the geometrical features of aggregates, the cement mortar is the continuous phase filling the void around aggregates, and the interfacial transition zone is the layer covering the particles with a thickness of around 30-80 μ m.

Mesoscopic modeling is to build the detailed sizes, shapes, positions, and orientations of aggregate particles. With the refined modeling method proposed by Ruan et al. (2019), the distribution of values of particle size, shape, and surface texture can be controlled based on the identification results based on real concrete sections in the framework as

$$S_{Agg} = \{P_{Agg}(D, \beta, T)\}. \quad (1)$$

where S_{Agg} is the set of aggregate particles and P_{Agg} is a single particle with properties such as particle size D , aspect ratio β , and surface texture T .

The three-level framework describes the parameter calculation method and the recommended distribution function. The equivalent particle size is related to the particle area, the Fuller grading solution can be controlled by the Walraven function (1980), the aspect ratio is the ratio of the particle length and width, and the value distribution can be described by the general extreme value distributions. The surface texture is controlled by different modeling algorithms to describe different aggregate types, where elliptical particles represent boulder aggregates and polygonal particles represent crushed stone aggregates.

In the detailed modeling, the sequence of particle sizes and aspect ratios are sampled following the corresponding probability distributions until the required aggregate content is reached. According to the types of aggregate material, the polygon shapes of particles are built with different numbers of vertices. Finally, the polygons are packed in a concrete model with random positions and orientations after checking the overlap between different particles.

2.2 Multiphysics shrinkage

The shrinkage of ordinary concrete includes self-shrinkage and drying shrinkage. The volume of hydration products is relatively smaller than that of the reactants, and the volume reduction caused by hydration is called self-shrinkage. Drying shrinkage is caused by changes in relative humidity (RH) and negative pressure in the capillary channels, which may be the result of the outward migration of moisture into the environment and water depletion in the hydration reaction. The shrinkage behavior occurs mainly within the cement mortar, and the aggregate effect is also important for the local mechanical response and moisture transport. As shrinkage increases, aggregate inhibits the behavior of the cement, limiting the apparent shrinkage but increasing the risk of internal microcracking.

During the multi-physical field shrinkage of concrete, self-shrinkage occurs with the hydration reaction, and drying shrinkage occurs in the unsaturated state of concrete. According to the distribution of moisture states in cement mortar, the shrinkage strain can be described as

$$\varepsilon_{cm}(x, t) = \begin{cases} \varepsilon_a, & H = 100\% \\ \varepsilon_a + \varepsilon_d, & H < 100\% \end{cases}, \quad x \in \Omega_{s,cm}, t \in \Omega_{t,sh}, \quad (2)$$

where both stages of the process can occur simultaneously in the same model, and the RH distribution is not uniform in space. ε_{cm} is the total shrinkage strain in the cement mortar; x is the spatial location $\Omega_{s,cm}$ in the cement mortar domain; t is the time point $\Omega_{T,sh}$ within the simulated shrinkage period; ε_a is the autogenous shrinkage controlled by the hydration reaction at RH, $H = 100\%$; ε_d is the drying shrinkage controlled by RH at $H < 100\%$. Based on the existing studies on the shrinkage mechanism of concrete, the self-shrinkage strain is mainly controlled by the hydration ratio, and the drying shrinkage strain is controlled by the moisture distribution in cement, which needs to consider both moisture migration and water consumption by hydration reaction.

2.3 Chloride ingress

Chloride ingress is one of the most serious mechanisms in the durability deterioration of the concrete structure. The behavior of ion transport can be described in Fick's diffusion law, and the density of ion flux is proportional to the gradient of concentration, which can be described as

$$\mathbf{J}_{cl} = -D_{Cl}\nabla c_{Cl}, \quad (3)$$

$$\frac{\partial c_{Cl}}{\partial t} = \nabla(D_{Cl}\nabla c_{Cl}), \quad (4)$$

where \mathbf{J} is the chloride ion diffusion flux ($\text{mol}/(\text{m}^2\cdot\text{d})$); D_{Cl} is the chloride ion diffusion coefficient (m^2/d); C_{Cl} is chloride ion content per unit volume of concrete (mol/m^3). To investigate the influence of mechanical status on the chloride ingress, the detailed diffusion coefficient can be modified according to the experimental regression by reference (Liu et al., 2020; Wang et al., 2018), see Figure 1. The detailed modification is presented as

$$D_{Cl,\sigma} = f(\sigma)D_{Cl,0}, \quad (5)$$

where $D_{Cl,\sigma}$ is the diffusion coefficient considering the mechanical influence; $f(\sigma)$ is the corresponding influence coefficient with the local stress σ , which can be calculated as

$$f(\sigma) = \begin{cases} 1.0 + 0.9598 \frac{\sigma}{\sigma_t} - 0.3608 \left(\frac{\sigma}{\sigma_t}\right)^2, & 0 < \sigma < 0.7\sigma_t \\ 1.0 - 1.6626 \frac{\sigma}{\sigma_c} + 2.2560 \left(\frac{\sigma}{\sigma_c}\right)^2, & 0.7\sigma_c < \sigma < 0 \end{cases}, \quad (6)$$

where σ is the local stress of cement mortar; σ_t and σ_c are the corresponding tensile and compressive strengths, respectively. So, the diffusion coefficient of cement mortar should be refined considering the detailed stress distribution.

Figure 1. Influence coefficient of local shrinkage stress on the chloride diffusivity.

According to the detailed analysis requirement, the mesoscopic stress distribution caused by the shrinkage is transferred to the distribution of diffusion coefficient, and the chloride ingress during the long-term service is solved within the domain of cement mortar. The distribution of frontal depth and the probability of ion concentration can be analyzed and discussed.

3 SIMULATION

To investigate the influence of early-age shrinkage quantitatively, two 100mm×300mm models are built for comparison with the different considerations of shrinkage behavior. The basic properties of concrete material are set based on a bridge project. In the mesoscopic model, the aggregate area ratio is controlled at 45.3%. The aggregate sizes follow the Fuller grading design within the range from 5.0mm to 25.0mm, and as the crushed stone is used as aggregate, the particles are modeled with polygons. The triangle elements are unified in the cement mortar model, and in the concrete model, the sizes are refined greatly to reflect the detailed aggregate textures. For the early-age shrinkage, the related parameters are set based on the reference (Li, Ruan, Yi, et al., 2023), which is regressed from the free shrinkage test of cement and concrete specimens. For the long-term chloride ingress, the environmental boundary is considered as the exposure to de-icing solution in the cold regions. The basic diffusion coefficient of chloride ingress in cement mortar is determined as $6.246 \times 10^{-7} \text{ m}^2/\text{d}$ from the material test, and the mechanical influence is introduced as Equation (5).

Considering the 14-day shrinkage curing in the environment with 60% relative humidity (RH), the multiphysics shrinkage of the concrete specimen can be predicted, and the quantitative validation has been published in reference (Li, Ruan, Yi, et al., 2023). Extreme tensile stress occurs around the exposed surface, which can be even larger than the tensile strength of cement mortar in the thin layer covering the aggregates. For the 100-year chloride ingress, the time-dependent distributions of ion concentration are calculated considering the influence of shrinkage stress. The differences in the concentration distributions are remarkable, and the chloride ingress results after 20-year, 60-year, and 100-year services are compared, see Figure 2. Due to the tensile stress in the upper part of concrete shrinkage, the local diffusion coefficient is relatively larger, and the frontal depths of chloride ingress are much larger compared with normal simulations.

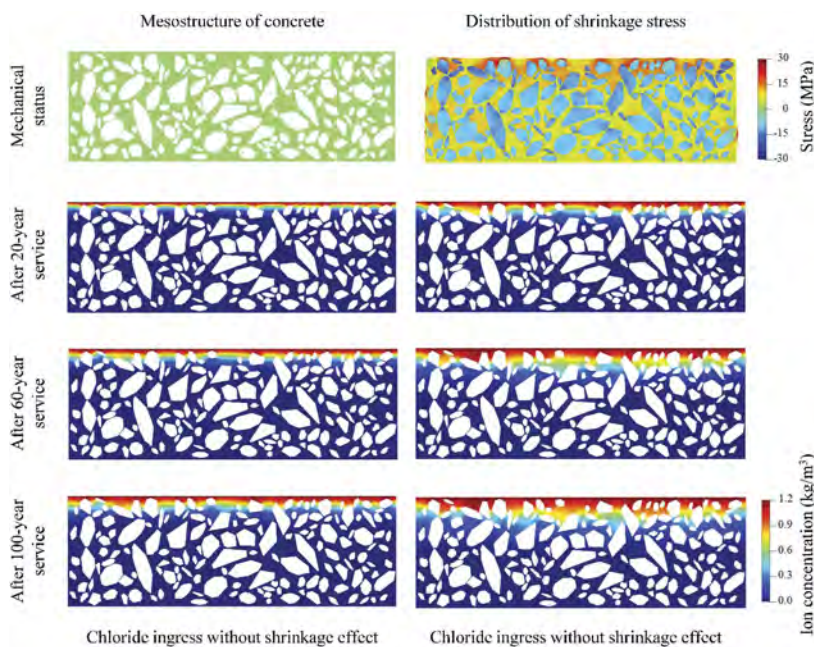

Figure 2. The distribution of ion concentration after 20-year, 60-year, and 100-year chloride ingress considering the influence of early-age shrinkage.

For the quantitative comparison between the two models, the probabilities in ion concentration at the 30mm depth under the exposed surface are analyzed, which is common to the designed thickness of the concrete cover. The local ion concentration is much higher after the consideration of stress distribution, which is reflected in the mean, 5% percentile, and 95%

percentile, see Figure 3. The extreme concentration at this depth can reach about 0.04kg/m^3 , and with the local enlarged diffusion coefficient, the extreme concentration can reach about 0.5kg/m^3 , which is larger than the critical concentration for reinforcement corrosion.

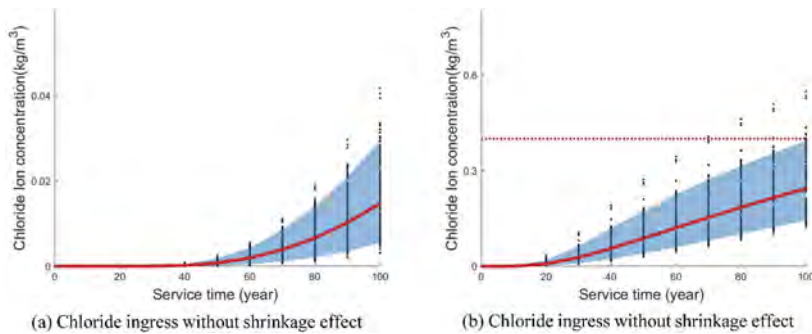

Figure 3. The time-dependent ion concentration on the reinforcement surface with the shrinkage effect.

With the proposed numerical method, the influence of different curing environments can also be discussed. The concrete shrinkage in the 40% RH, 60% RH, and 80% RH is simulated for the diffusion of influence coefficient on cement diffusivity. The eventual chloride ingress after 100-year service is analyzed and compared, see Figure 4. The influence of early-age shrinkage is important for the concrete long-term durability. With the drier curing environment, the deformation is larger around the exposed surface due to the drying shrinkage, and local tensile stress also increases greatly, which also influences long-term chloride ingress. With the RH of the curing environment decreasing from 80% to 40%, the influenced area of chloride ingress is larger, especially the part of cement mortar with large tensile stress.

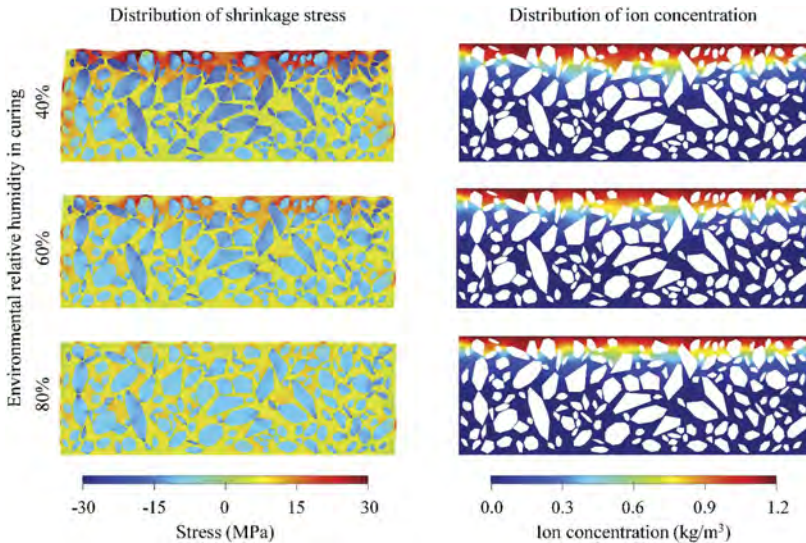

Figure 4. The distribution of ion concentration after 100-year service considering the 40%, 60%, and 80% RH in the early-age shrinkage.

For the quantitative comparison, the detailed ion concentrations under the concrete cover are extracted and compared with representative curves, see Figure 5. The extreme ion concentration increases from 0.4kg/m^3 to 0.7kg/m^3 , with the curing RH increasing from 40% to 80%. The variations of concentrations are also influenced by the early age shrinkages.

Figure 5. The time-dependent ion concentration on the reinforcement surface considering the different RHs in early-age shrinkage.

4 CONCLUSION

In this paper, a comprehensive method is proposed combining the refined mesoscopic chloride ingress and the multiphysics shrinkage model. To investigate the influence of early-age shrinkage quantitatively, the numerical comparison between the 100-year chloride ingress with and without the shrinkage effect is conducted. With the modified diffusion coefficient, the ion concentration and the frontal depths of chloride ingress are all increased greatly. The extreme concentration under the 30mm concrete cover increases from 0.04kg/m^3 to 0.5kg/m^3 .

The influence of different relative humidities in early-age curing is also investigated. With the drier curing environment, the deformation is larger around the exposed surface due to the drying shrinkage, and local tensile stress also increases greatly, which also influences long-term chloride ingress. The extreme ion concentration increases from 0.4kg/m^3 to 0.7kg/m^3 , with the curing RH increasing from 40% to 80%. The variations of concentrations are also influenced by the early age shrinkages.

Seismic performance evaluation of masonry infilled RC frame retrofitted with BRBs

R. Chelapramkandy & J. Ghosh

Indian Institute of Technology Bombay, Mumbai, Maharashtra, India

F. Freddi

University College London, London, UK

ABSTRACT: Reinforced concrete (RC) frames with unreinforced masonry infill represents a widely used construction typology across the globe, including regions characterized by moderate to high seismicity. These structures have been often designed before the introduction of modern seismic design codes, are characterized by low ductility and high seismic vulnerability and are in need for seismic retrofitting to meet the current safety standards. However, it is important to highlight that, although considered as non-structural elements, masonry infills can significantly affect the seismic response of the structure. However, their role on the seismic performance of retrofitted RC structures has been generally neglected in literature. Among the different retrofitting strategies, the use of buckling-restrained braces (BRBs) represents an effective solution to improve the seismic performance of existing RC structures. This study investigates the interaction between the BRBs and masonry infill on seismic response of a case study frame.

1 INTRODUCTION

Reinforced concrete (RC) frames with unreinforced masonry infills represent a widely used construction typology for building structures worldwide, including regions characterized by moderate to high seismicity (Dolšek & Fajfar, 2008; Akan et al. 2022). Historical and recent earthquakes have demonstrated the high vulnerability of these structures, especially when designed before the introduction of modern seismic design codes (i.e. low ductile frames) (Rossetto & Elnashai, 2003; Freddi et al. 2017; Freddi et al. 2021a). This highlights the urgent need to identify efficient and effective retrofit solutions for such structures to meet the life safety and damage limitation requirements. Among others, the use of dissipative braces represents an efficient strategy to improve the seismic performance of such low ductile buildings (Freddi et al. 2013; Gutiérrez-Urzúa & Freddi, 2022). The introduction of these braces creates a dual load path for the seismic input and increases strength, stiffness, and ductility of existing frames (Freddi et al. 2021b). Therefore, when introduced within existing frames, these braces can protect structural and non-structural building components from damage by reducing their seismic demand. Among others, buckling-restrained braces (BRBs) represent a type of dissipative devices in which a sleeve provides buckling resistance to an unbonded core that resists the axial stress, hence allowing the BRB's core to develop axial yielding in compression in addition to that in tension ensuring an almost symmetric hysteretic behavior (Freddi et al. 2021c).

Due to their brittle nature, the strength and stiffness of the masonry infills are often disregarded during the design process. However, it has been demonstrated that, from one side, they can significantly affect the seismic response of the structures; on the other side, their damage represents a significant percentage of the economic losses. For these reasons, several approaches are proposed in literature for simulating the presence of masonry infills within the

frame. Among others, a common strategy is to idealize the masonry infills as single or multiple compressive equivalent struts characterized by a highly nonlinear behavior (Crisafulli et al. 2000; Dolšek & Fajfar, 2008).

The present paper investigates the potential interactions between the retrofit system based on BRBs and the masonry infills. The numerical results provide some insights into the ability of BRBs in protecting not only the RC frame from damage but also the masonry infills. The paper is organized as follows: Section 2 describes the methodology followed for the definition of seismic fragility curves for the infilled and retrofitted infilled case study frames considering different damage states. Section 3 presents the finite element modeling strategy for the frame, the masonry infills, and the BRB devices. Section 4 presents the definition of damage states thresholds (using pushover analysis), the assessment of the seismic demand (using nonlinear time-history analysis) and the definition of seismic fragility curves for the infilled and retrofitted infilled frames. Finally, Section 5 presents the conclusions along with some future research directions.

2 METHODOLOGY

A three-story, three-bay masonry-infilled RC frame designed for gravity loads alone is selected as the case study structure and modeled in OpenSees (McKenna et al. 2000). The structure is retrofitted with BRBs following the procedure outlined in Freddi et al. (2021c). Nonlinear static analyses are performed for both infilled and retrofitted infilled RC frames to determine the damage state (DS) threshold values in terms of global engineering demand parameter (*EDP*). The maximum interstory drift ratio (IDR_{max}) is assumed as global *EDP* to synthetically describe the response of the structure, and the DS threshold values are estimated by mapping IDR_{max} to local *EDPs*, such as material strain and cross-section strength. Cloud analyses are successively performed considering a ground motion set to evaluate the seismic performance of the structure and subsequently determine the samples of structural demand by accounting for the record-to-record variability. Probabilistic seismic demand models (PSDMs) are successively derived for the IDR_{max} using the average spectral acceleration (Sa_{avg}) as the intensity measure (*IM*) (Baker & Jayaram, 2008; Eads et al. 2015). This *IM* is selected as it allows accounting for the natural period elongation that is typically observed in infilled frames as a consequence of the damage experienced by the infills during the earthquake. Moreover, it allows comparing fragility curves of structures characterized by different natural periods (i.e. the infilled and retrofitted infilled RC frames in this case). The Sa_{avg} is defined as the spectral acceleration averaged over a period band, as given in Equation (1).

$$Sa_{avg}(T_1, T_2, \dots, T_n) = \left(\prod_{i=1}^n Sa(T_i) \right)^{1/n} \quad (1)$$

where, $Sa(T_i)$ is the spectral acceleration at i^{th} period, and T_1, T_2, \dots, T_n are the ‘ n ’ periods of interest. In the present study, this period band is assumed to span from the natural period of the stiffest structure (i.e. the retrofitted infilled RC frames) to the natural period of the more flexible structure (i.e. the bare frame).

PSDMs are established by using bilinear regression models (Tubaldi et al. 2016; Freddi et al. 2017; O’Reilly & Monteiro, 2019; Aljawhari et al. 2021) based on the following expression:

$$\ln(EDP) = [a_1 + b_1 \times \ln(IM)]H_1 + [a_2 + b_2 \times \ln(IM)](1 - H_1) + \ln(\varepsilon) \quad (2)$$

where, $a_1, b_1, a_2,$ and b_2 are the regression coefficients, and H_1 is the step function with the value of $H_1 = 0$ when $IM > IM^*$ and value of $H_1 = 1$ when $IM \leq IM^*$, where IM^* is the intersection point of the two segments as shown in Figure 1. The value of the IM^* is obtained such that the fitted bilinear regressions maximize the goodness of fit coefficient (R^2) (Tubaldi et al. 2016).

Fragility curves are successively derived for the masonry-infilled RC frame with and without the BRBs. Fragility curves give the likelihood of meeting or exceeding a specific DS and

Figure 1. Bilinear probabilistic seismic demand model (PSDM) parameters.

are derived based on the PSDMs and DS threshold values according to the following expression:

$$P[DS|IM] = \Phi \left[\frac{\ln(EDP_{med}/S_C)}{\sqrt{\beta_{EDP|IM}^2 + \beta_C^2}} \right] \quad (3)$$

where, EDP_{med} and $\beta_{EDP|IM}$ are the median estimates of seismic demand and corresponding standard deviation, whereas S_C and β_C are the DS threshold value and corresponding standard deviation.

3 CASE STUDY

3.1 Case study description

A three-story, three-bay RC frame representative of non-seismically designed (low ductility) low-rise building is selected for case study purposes. Figure 2 shows the elevation view of the frame, which has a bay width of 5.49 m and an interstory height of 3.66 m. The beams have a rectangular section of 230 mm × 460 mm, while the columns have a square section of 300 mm × 300 mm. The reinforcement bars have a yield strength of 276 MPa, whereas the concrete has a compressive cube strength of 24 MPa. Experimental results for the global and local response of the case study structure are available in literature (Aycardi et al. 1994; Bracci et al. 1995) and allowed the validation of the numerical model of the frame in OpenSees. Additionally, Figure 2 shows the considered unreinforced masonry infill with openings of 18% of the infill area, and the dissipative braces (i.e. D1 to D3).

Figure 2. Case study infilled frame layout and placement of the dissipative braces.

3.2 Finite element modeling of the RC frame

The 2D model of the case study structure is developed in OpenSees. Columns and beams are modeled using the *beamWithHinges* element consisting of a central elastic part and two lateral portions with a specified length where a fiber approach is used to represent the nonlinear response of the section. The *Concrete02* and *Hysteretic* materials are used to model the concrete and longitudinal steel, respectively. The beam-to-column joints are modeled using four rigid off-sets and a two-node *zeroLength* rotational springs. Additionally, shear and axial column failure are also modeled in OpenSees within *zeroLength* nonlinear springs. More details on the numerical model of the frame can be found in Freddi et al. (2013), (2017), (2021c).

3.3 Finite element modeling of the masonry infills

Unreinforced masonry infills within the RC frame are modeled following the recommendations of Dolšek & Fajfar (2008). The equivalent single diagonal strut modeling method is used to simulate the masonry infill behavior (Crisafulli et al. 2000; Wu et al. 2022). According to Dolšek & Fajfar (2008), the initial stiffness of the masonry infill can be defined as follows:

$$K_i = \frac{G_w L_{in} t_w}{H_{in}} \quad (4)$$

where, H_{in} , L_{in} , and t_w represents the height, length, and thickness respectively of the infill, and G_w is the infill shear modulus. The maximum force F_m of the masonry infill is determined as:

$$F_m = 0.818 \frac{L_{in} t_w f_{tp}}{C_I} \left(1 + \sqrt{C_I^2 + 1} \right), \text{ where, } C_I = 1.925 \frac{L_{in}}{H_{in}} \quad (5)$$

where, f_{tp} is the cracking strength of the masonry infill, and C_I is the coefficient that takes into account the interaction between the infills and the surrounding frame.

Figure 3 shows the force-displacement back-bone curve of the masonry infill - represented by four branches. The thickness of the infill is considered as 100 mm, and the shear strength and the shear modulus of the masonry infills are adopted from Hak et al. (2012) as 0.31 MPa and 1089 MPa, respectively. According to Dolšek & Fajfar (2008), the cracking force of the masonry infill (F_c) is assumed to be 60% of the maximum force (F_m). For the infill with the window, the story drift corresponding to the maximum force is considered 0.15%, whereas the story drift corresponding to the infill collapse is considered five times the story drift at the maximum force. The present paper considers a residual force (F_r) of 5% of the maximum force. Window opening covering one-third of the horizontal length of infill is considered as shown in Figure 2. The parameter λ_0 is used to reduce the infill's strength and initial stiffness in order to account for the masonry infill's opening, defined according to Equation (6) (Dolšek & Fajfar, 2008; Troup et al. 2019)

$$\lambda_0 = 1 - \frac{1.5L_0}{L_{in}} \geq 0 \quad (6)$$

where, L_{in} and L_0 are, respectively, the total length of infill and horizontal length of openings.

Figure 3. Lateral force-displacement envelope for the diagonal struts.

3.4 Finite element modeling of the Buckling-Restrained Braces (BRBs)

The design of the BRBs are based on the capacity curve of bare frame, and the retrofit design aims to double the retrofitted frame's base shear capacity (i.e. strength proportion coefficient $\alpha = 1$) (Freddi et al. (2021c)). The first mode shape of the retrofitted frame is maintained as same as that of the bare frame by properly proportioning the stiffness of BRBs in the frame, while the simultaneous yielding of the BRB device is ensured by properly proportioning the strength of BRBs among the stories. Each BRB consists of an elastic brace and a BRB device arranged in series. This study uses the *Steel02* material in OpenSees to model the BRB device. Additional details on the BRB design can be found in Freddi et al. (2021c). Table 1 lists the BRBs design properties where, F_c^i and K_c^i are the strength and stiffness, whereas $f_{y, BRB}$, L_{BRB} , and A_{BRB} are the yield strength, length, and area of cross-section of the BRB device core.

Table 1. Design properties of the BRBs and BRBs device core.

Story	F_c^i (kN)	K_c^i (kN/mm)	$f_{y, BRB}$ (MPa)	L_{BRB} (mm)	A_{BRB} (mm ²)
1	220.3	48.4	250	2815	881
2	189.6	32.6	250	3599	758
3	109.2	29.8	250	2270	437

4 SEISMIC FRAGILITY CURVES

4.1 Threshold mapping of damage states

Figure 4a shows the base shear vs. IDR_{max} results of the nonlinear static analyses performed for both the infilled and retrofitted infilled frames. The reduction in the base shear after attaining the peak value is related to the damage in the masonry infills. The DSs for the structural components are defined as Slight (S), Moderate (M), Extensive (E), and Complete (C) based on the distinct local responses of the structure listed in Table 2, along with the corresponding IDR_{max} at the onset of each DS. It is worthwhile to note that, due to the non-symmetric placement of the BRBs, nonlinear static analyses are carried out both in the positive and negative direction, providing slightly different capacity curves and DSs threshold values (marked in Figure 4a). Subsequently, the DS threshold values are taken as the average values from the two directions. For the infill panel, IDR_{max} value corresponding to the development of first crack on majority of infill at one floor is taken as threshold value corresponding to the Slight DS (SI). In order to incorporate the uncertainty in DS threshold estimation, a dispersion of 0.3 is assumed.

Table 2. Damage states description for infill panel, infilled frame and infilled frame retrofitted with BRBs.

Damage states	Description	Maximum IDR (%)	
		Infilled	Infilled + BRBs
Slight	50% of columns at one floor have yielded	0.57	0.52
Moderate	50% of columns at one floor experienced concrete crushing	1.33	1.52
Extensive	Average of Moderate and Complete	2.16	2.32
Complete	50% of columns at one floor experienced shear failure initiation	3.00	3.12
Slight	Infill panel Majority of infills at one floor develop first crack	0.019	0.019

4.2 Probabilistic seismic demand model

A set of 240 ground motion records from Baker et al. (2011) is used to perform the nonlinear time history analysis on the infilled frame and retrofitted infilled frame. The fundamental time period of the bare frame, infilled frame, and retrofitted infilled frame are 1.2s, 0.160s, and 0.156s, respectively. The period band considered for the calculation of the Sa_{avg} spans from 0.156s to 1.2s, with intervals of 0.1s. Figure 4b shows the bilinear PSDMs for both infilled frame and retrofitted infilled frame developed by following the approach discussed in Section 2. The results show a good fitting in both cases with R^2 values of 0.90 and 0.87. The expression of the bilinear PSDM, respectively, for the infilled and retrofitted infilled frames are as follows:

$$\ln[IDR_{max}(\%)] = [-1.17 + 1.02 \times \ln(Sa_{avg})]H_1 + [1.11 + 2.37 \times \ln(Sa_{avg})](1 - H_1) \quad (7)$$

$$\ln[IDR_{max}(\%)] = [-1.18 + 1.08 \times \ln(Sa_{avg})]H_1 + [0.46 + 2.50 \times \ln(Sa_{avg})](1 - H_1) \quad (8)$$

with values of IM^* , the intersection point of two segments, being equal to 0.18g and 0.32g for infilled and retrofitted infilled frames.

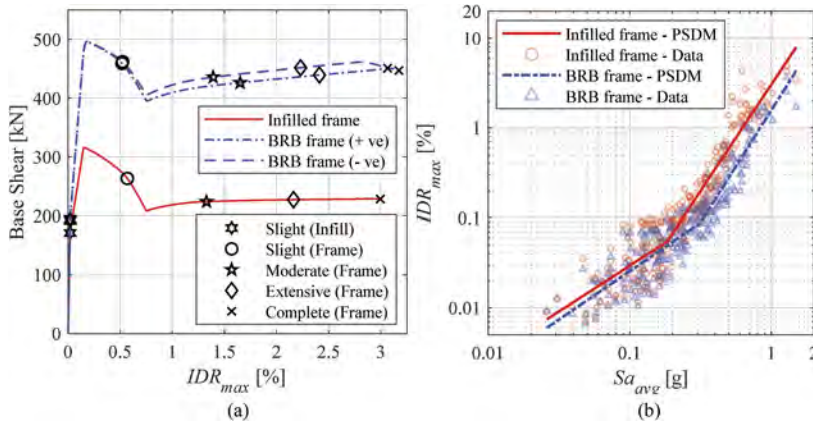

Figure 4. (a) Base shear vs. IDR_{max} curves and mapping of IDR_{max} values with different damage state thresholds; (b) Bilinear PSDMs of the infilled frame and retrofitted infilled frame.

4.3 Seismic fragility curves

Figure 5 shows the fragility curves for the infilled and retrofitted infilled frames. The median values of Sa_{avg} corresponding to different DSs are listed in Table 3. There is a significant decrease observed in the seismic fragility of the structural components after the retrofitting with BRBs, that is evident with the increases in the median values of Sa_{avg} for Slight, Moderate, Extensive, and Complete DS, respectively equal to 30%, 39%, 35%, and 32%. The advantages in protecting the infill panels from cracking is more modest. The comparison of the fragility curves shows an increase of 17% in the median values of Sa_{avg} for the Slight DS of the infill panels. This reduction in the seismic fragility shows the characteristics of the BRB device to provide a supplementary path to the lateral loads induced by the earthquake and to enhance the seismic performance by dissipating the earthquake energy. Moreover, a reduction in dispersion of 5.5% and 9.5% is observed, respectively, for the structural and non-structural components after the retrofitting with BRBs.

Table 3. Median values (in units of g) of lognormal fragility curves.

Structure type	Building frame				Infill panel
	Slight (S)	Moderate (M)	Extensive (E)	Complete (C)	Slight (SI)
Infilled frame	0.493	0.705	0.865	0.993	0.065
Infilled + BRB frame	0.641	0.984	1.166	1.312	0.076

Figure 5. Seismic fragility curves of infilled and infilled frame retrofitted with BRBs.

5 CONCLUSIONS

The present study investigates the use of buckling-restrained braces (BRBs) for the seismic retrofitting of low ductility reinforced concrete (RC) frames. In particular the study focuses on the presence of masonry infills and their interaction with the BRBs. A three-story, three-bay masonry-infilled RC frame designed for gravity loads alone is selected as the case study structure and modeled in OpenSees. Masonry infills with openings are added to the model as single compressive diagonal struts in the two directions. Nonlinear static analyses were performed for both the infilled and retrofitted infilled frames for determining the DS thresholds, followed by the derivation of the PSDMs and fragility curves. The comparison of the fragility curves shows a significant improvement in the seismic performance of the structural components after the retrofitting with increases of the median Sa_{avg} values of 30%, 39%, 35%, and 32%, respectively for the Slight, Moderate, Extensive, and Complete DSs. A more modest increase (i.e. 17%) in the median value of Sa_{avg} was observed in the Slight DS of the infill panel. Future work may consider the different uncertainties for seismic evaluation of a retrofitted infilled frame and its life-cycle cost estimation.

LCA and EPD need digitalization

U.R. Pannuti

ICMQ S.p.A., Milan, Italy

ABSTRACT: The Italian Government has issued a message on the importance of digital investment when designing infrastructures included in the PNNR (National Resilience and Recovery Plan), approved by European Commission in June 2021. It calls for the verification of significant contributions for one or more environmental objectives embedded in the sustainability report, taking into account the life cycle of the infrastructure. The EPD (Environmental Product Declaration), based on the product LCA (Life Cycle Assessment), allows for estimating those environmental objectives. To design a sustainable building/infrastructure, disposing of products' information on their environmental impacts in a format is paramount so that they can be available and automatically importable into the building/infrastructure model in the LCA calculation software. On this matter, the digitization of environmental data and their integration on the BIM (Building Information Modeling) model could hit the target. This article reviews the benefits of EPD digitization and why LCA and EPD need it.

1 INTRODUCTION

Some European Countries have introduced mandatory LCA for new buildings into their national legislation. The United States, France and other countries are investing in requiring sustainability performances from products, while in Italy the new Decree on minimum environmental criteria for the design of new buildings, assigns a reward score for the designer that performs an LCA study for the building. This kind of LCA, unlike that of a simple product, can be performed if all the environmental impacts of materials that are installed into the building are already known. The document that shows the environmental impacts on the final user is the EPD, generally published in form of a pdf file. EPDs are released on the website of the Program Operator, the body that sets the rules for the verification and publication of EPDs. Since the environmental impacts of the products are listed in a pdf file, it may be difficult to read, write, and transfer them to the software for calculating the LCA of the building. The digitization of environmental impacts is why we stress the importance of having such data in a format useful for its integration with current technologies, such as BIM (Building Information Modelling), and legislative requirements. Moreover, BIM is strongly recommended by Italian law (see paragraph 3).

2 THE SITUATION IN EUROPE

To govern the EPD development process, the International Standard ISO 14025 “Environmental labels and declarations - Type III environmental declarations - Principles and procedures” (International Organization for Standardization 2006) requires a specific entity, named the Program Operator, to define the rules, according to the International Standard for:

- PCR (Product Category Rules) developing;

- LCA developing (general requirement);
- EPD developing (format and content);
- EPD verifying rules;
- EPD publishing.

The EPD has become a fundamental tool to demonstrate manufacturers' sustainability efforts and to drive growth in the construction sector. A few years ago, many major North-American building design Companies set the EPD as the only selection factor for their suppliers. Indeed, those who presented a product with EPD had the possibility of being chosen for building designs aimed at LEED submission (Leadership in energy and environmental design) (U.S. Green Building Council 2019), a rating system for the design, construction and management of sustainable high-performance buildings. In France, starting from January 2022, the LCA study is mandatory for new buildings.

Each European Country has an established Program Operator for EPDs verification and publication, which is the reason behind establishing Eco Platform, the European Association of leading Program Operators in the construction sector. One of its main objectives is to harmonize the EPDs verification process to facilitate the mutual recognition of EPDs. It is achieved by implementing a unique format (characterized by the Eco EPD logo), based on compliance with the EN 15804 Standard "Sustainability of construction works. Environmental product declarations. Core rules for the product category of construction products" (European Committee for Standardization 2012), which is mandatory to calculate the LCA of a construction product. Eco Platform is aware of the importance of having the EPDs in a simple format to spread the interchange process, so in 2020 it launched the Eco Portal to display all the digitalized EPDs. The used format is ILCD (International Life Cycle data)+EPD one, developed by the Indata Network technical group (International Open Data Network for sustainable construction), composed of different European Association members (also Italy). The format ILCD +EPD (see paragraph 6) has been considered as the most suitable for digitization software and comprehensive with all the information that could be gathered from an EPD.

3 THE NORMATIVE IN ITALY

The first step for the digitization process occurred with the publication of the Tender Code, Legislative Decree n. 50/2016 (Italian Government 2016), which introduced the use of electronic methodologies and tools. The Baratonno Decree or BIM Decree (Ministry of infrastructure and transport 2017) mandatorily requires the use of electronic methodologies and tools in the public tender with a modular approach over the years, depending on the economic value of works. It is the official introduction of the BIM into the design stage of an infrastructure. Similarly, starting in 2017, the Ministry for the Environment requires, for the construction of new buildings with the Decree on the Minimum Environmental Criteria (Ministry for the Environment 2017), the use of construction products that have a specific value of recycled content. This value must be verified through a number of methodologies, and among those, is the environmental product declaration published on EPDIItaly, the Italian Program Operator. Finally, the Italian Government and the ecological transition Ministry (already the environmental Ministry) are investing in the sustainability of the infrastructure/construction works with the PNRR. More than 25 billion € have been allocated for infrastructure, and the Guidelines for the PFTE (Economic Technical Feasibility Project) (Higher council of the Public works and Sustainable infrastructure and mobility 2021) have been developed in order to facilitate the PNRR implementation.

The sustainability concept is prominent in the PFTE, as the Report on Infrastructure Sustainability has become one of the mandatory elements to develop along the infrastructure design process. It's really an innovative element that links sustainability to the digitization needs, in order to design construction work in a modular approach, from the first stages.

Most of the elements of the Report are connected to environmental data of the products that will be included into the infrastructure and their assessment and digitalization help the process of infrastructure LCA calculation.

In fact the Report places particular emphasis on the LCA of infrastructure with certain environmental issues, such as:

- CO₂ calculation, with reference to Carbon footprint. The Carbon footprint calculation, performed by the designer, can be assessed by an independent third party such as an accredited Certification Body in compliance to ISO 14067 (International Organization for Standardization 2018).
- Verification of the LCA infrastructure. The designer can develop a LCA for the infrastructure. The assessment can be performed by an independent third party, in compliance to ISO 14040 (International Organization for Standardization 2006) and ISO 14044 (International Organization for Standardization 2006).

The above items could be calculated if the environmental data of materials that makes up the infrastructure are available. This kind of data are a prerogative of EPD development and must be available, at the early stages of the project, so that they can be used for the LCA of the infrastructure itself. No environmental impacts of construction products mean no LCA of infrastructure. The absence of environmental impact of the construction product means a LCA of the infrastructure can't be performed. This approach can only be pursued through a digital transformation of the use of data, towards which the Report is strongly pushing. The BIM approach is a methodology that addresses the needs mentioned above.

In the following paragraphs the author is going to explain how.

4 LCA AND BIM: A MARRIAGE MADE IN HEAVEN!

The connection of design activities allows designers to choose the appropriate building products and to manage any changes in real time. This approach constitutes the present and not the future for designers working in the field of digital information modelling, BIM.

In recent years, the design and realization of buildings and infrastructures have been the subject of various sustainability rating systems e.g. LEED or Envision (Institute for sustainable infrastructure 2012), a North American protocol for the sustainability of infrastructures, which is widespread in Italy. In this sense, the information provided by the manufacturers and their construction products is necessary to score the work. Indeed, the most widespread rating systems reward the availability of environmental information, right from the first phase of the project. In this sense, the simultaneous presence of an environmental information management system (such as the BIM) and an information communication tool (such as the Environmental Product Declaration EPD) is useful for optimizing the process of environmental information sharing between the various actors. Project development is thus simplified, facilitating possible revisions. The EPD allows, through clear and transparent communication and, above all, verified by an independent third party, data such as, for example:

- Global warming;
- Abiotic resource depletion - elements;
- Depletion of abiotic resources - fossil fuels;
- Acidification of soil and water;
- Ozone layer depletion;
- Eutrophication;
- Photochemical ozone creation.

The visibility of the environmental characteristics of these products for the life cycle of each of the phases and structure through a BIM system, is an opportunity for the manufacturer to be an active participant in the sustainable design of the building and infrastructure.

5 THE DIGITIZATION PROCESS

For the above stated reasons, it is appropriate that the environmental information is in a machine-readable format to facilitate import into the calculation software for the building/infrastructure LCA.

As already mentioned, Eco Platform has implemented a method of returning digital EPD data through a special portal called Eco Portal, through which the various Program Operators share their published EPDs. Indeed, the most representative international Program Operators have outlined a scenario in which the digitization of EPDs is a fundamental practice in EPD publication activities. For this reason, the Eco Portal, which publishes in digital format all the Eco EPDs published by the various Program Operators that have joined the initiative, allows users of the service to draw on a carnet of environmental data from all over Europe.

From now on, the Eco Portal will represent a further, internationally visible enhancement of the efforts made by manufacturers to develop an EPD. Their EPDs are visible on the Eco-Portal, following the digitization carried out by the Program Operator who published the EPD. The Eco-Portal allows access to the databases of the main Program Operators and also national databases. The Eco-Portal is linked to the web page of the Program Operator that finalized the digitization. The digitization process starts with the input of the EPD environmental data by the Program Operator or automatically by the manufacturer. The digitization software populates the Eco-Portal (see Table 1).

Table 1. The number of digitalized EPD into the Eco Portal.

Program Operator	Number*
EPD Norway	1704
Institut Bauen und Umwelt e.V.	616
EPD Danmark	544
BRE	319
EPDIItaly	284
International EPD System	236
MRPI	197
EPD Ireland	99
ITB/Other	77

* data as of September 2022.

Digitization carried out through the Eco-Portal entails several benefits:

- international visibility of a product's environmental data;
- significant reduction of effort in generating and reporting data;
- sharing of data in a single format (ILCD + EPD); this format combines the information contained in the EPD documentation, available in pdf format, with that required by the European Commission;
- common rules for data use, through the exchange of files in standard format (xml and csv, at the moment);
- future interaction, through special APIs (Application Programming Interfaces), with the main software for the development of the LCA of buildings;
- possibility for the user to use a special filter to identify: the language of the EPD, the country of origin, the manufacturer, the validity of the EPD, the originating Program Operator and, most importantly, the type of data (specific or average) to be used.

With the above advantage, the digitized EPD will be a reference for designers developing the LCA of the building or infrastructure, increasing the dissemination of environmental data of construction products.

The ILCD + EPD format contains more than 100 claims, among which we list the most relevant:

- adopted life cycle (cradle to gate, cradle to grave, . . .);
- mandatory information, such as EPD impact indicators for each life cycle stage;
- additional national information, such as recycled content, required by national legislation for buildings;
- other information that can be extracted from the EPD document (company name, production site, database, reference PCR, data collection period, functional unit, . . .);
- data verification and validation information (certification body, program operator, . . .).

The Program Operator transforms all entered data into a tabular format and, after a validation process carried out at the European level, assigns a unique code to the data set, thus making it visible and downloadable in xml/csv format from the online platform. EPD data feed the European Eco-Portal database for use online in building and infrastructure design systems.

The benefits of digital design can be visible in the building and infrastructure design process because, in addition to technical characteristics, environmental characteristics derived from an EPD can be available for each component material.

6 CONCLUSIONS

Many sudden changes are taking place in the construction industry in terms of sustainability and digitization, demonstrating their close interdependence. One cannot be separated from the other. After all, how would it be possible to build a smart highway, equipped with sensors to optimize traffic management, provide information to users and perform predictive maintenance, without a digital design model? Sustainability requires digitization.

And it is encouraging that the Italian government is also persuaded of this, sending out a message on the significance of the use of digital models in the design of infrastructures included in the National Resilience and Recovery Plan. The specific reference to the opportunity for contracting authorities to provide for the awarding of a bonus score in the design when using specific electronic methods and tools will enable the use of BIM to be expanded, speeding up the process of innovation needed to achieve those effectively measurable results in terms of environmental and social sustainability that Europe is asking us for. At the same time, greater digitization will guarantee higher levels of quality, ensuring greater time certainty and more precise cost control. Key factors for ensuring the economic sustainability of infrastructure.

The PFTE requires in the sustainability report the verification of certain environmental aspects that can be fulfilled by the EPD, the environmental identity card of the construction product, which could be available in a machine-readable format, increasing its use in the LCA calculation tool of buildings or infrastructures. Indeed, it is not possible to know the environmental impacts of a construction project if one does not have any knowledge of the environmental data of the construction products.

This will be very relevant in the coming years when the Italian investment plan will be relying on the shared use of digital modelling data for infrastructure design.

Using monetization to harmonize life-cycle assessment and life-cycle cost analysis for green public procurement of pavement projects

B. Moins, D. Hernando, W. Van den bergh & A. Audenaert
University of Antwerp, Antwerp, Belgium

ABSTRACT: This research applies monetization to harmonize life cycle assessment (LCA) with life cycle cost analysis (LCCA) for implementation in the green public procurement of pavement projects. The monetized environmental impact (MEI) shows an excellent correlation with the net present value. As both indicators are expressed using the same unit, LCA and LCCA can be easily combined into a single sustainability indicator. The MEI is mainly determined by the impact of the upper asphalt layers. The structure with bitumen stabilized material (BSM) and no asphalt base has the lowest MEI, followed at a certain distance by the structure with unbound and lean asphalt bases. The cement-bound section and another BSM section show the highest MEI. Finally, a detailed hotspot analysis highlighted that climate change, particulate matter formation, and use of non-renewable energy resources contributed over 90% of the total MEI.

1 INTRODUCTION

Environmental awareness in pavement engineering and procurement is rapidly increasing. Additionally, sustainable practices that conserve nonrenewable resources and reduce waste streams are continuously supported by the pavement industry (Williams et al., 2019). This is progressively leading road agencies to the implementation of green public procurement (GPP). A way to help road agencies make informed decisions about the environmental impact of the pavement works they procure is to implement environmental indicators in GPP (Hernando et al., 2022). Furthermore, researchers clearly indicate that economic and environmental studies should focus on the long-term impact of projects as opposed to only impacts up to the construction phase (Moins et al., 2022). Two methods often used to describe the environmental and economic long-term impact are life cycle assessment (LCA) and life cycle cost analysis (LCCA), respectively.

However, most studies use LCA and LCCA separately or with little integration (França et al., 2021). Hence, it is important to harmonize LCA and LCCA to facilitate the transition from standard procurement to green procurement. Combining LCA and LCCA results can be difficult because both methods often use different methodological assumptions and indicators. For example, LCA studies often use multiple midpoint indicators for life cycle impact assessment (LCIA) whereas LCCA studies mostly use a single indicator to describe economic impact. Even though LCA studies can express the results using a single indicator when weighting is applied, it is not recommended by the ISO 14040 and 14044 standards on LCA as it increases the level of uncertainty. Nevertheless, it is commonly used in the interpretation phase as it can identify the most relevant impact categories and enables the aggregation of results (Amadei et al., 2021, Hernando et al., 2022).

One of the methods suitable for harmonizing LCA and LCCA is monetization, which expresses environmental impact using a single monetary value. As with LCCA, it is recommended

discounting future impacts in monetization using a social discount rate (Servaes et al., 2017, Zhang, 2017). In other words, using monetization to express the environmental impact is comparable to employing the net present value (NPV) for quantifying the economic impact.

There are various ways to monetize the external costs of environmental impacts. One subdivision includes the damage cost approach (DCAP), avoidance cost approach (ACAP), and replacement cost approach (RCAP) (Smith et al., 2020). DCAP values all damage caused by an externality and includes the social cost of carbon which values all damages to society because of climate. ACAP accounts for all externalities based on the total cost to reach a certain policy target. RCAP considers the cost of externalities based on the total cost to repair or replace the adverse impacts of those externalities. Another subdivision is based on the individuals' willingness to pay (WTP) or willingness to accept (WTA). WTP is the maximum amount an individual is willing to pay to avoid an undesirable change. Conversely, WTA is the minimum compensation an individual is willing to accept to consent to an undesirable change (Pizzol et al., 2015, Zhang, 2017). Literature shows that impacts according to WTA can be up to seven times higher than according to WTP because of income effect, bad-deal aversion, and study design (Arendt et al., 2020). However, note that all monetization methods have also been criticized because their link to income makes them wealth sensitive. Therefore, it is advised to discuss the geographical scope and use of equity weighing (Arendt et al., 2020).

To the authors' knowledge only a few studies combined pavement engineering with the monetization of environmental impacts. Their focus was mainly on monetizing social and safety aspects of the road user such as number of crashes, transportation related pollution, and road noise and not the impact of different pavement structures (Arter et al., 2021, Bi et al., 2019, Hofstetter and Müller-Wenk, 2005, Yang and Magalotti, 2016).

2 OBJECTIVE AND SCOPE

The first objective of this study is to examine the feasibility of expressing the environmental impact of a pavement project in monetary values to align with LCCA methodology. Another objective is to analyze the relationship between monetized environmental impact (MEI) and NPV using a test case. The third objective is to identify the individual materials/processes and impact indicators with the largest share in the overall MEI. All three objectives contribute to the ultimate goal of harmonizing LCA and LCCA so they can be combined in a single indicator.

3 MATERIALS AND METHODS

3.1 Description of the selected test case

Input from previous research was used as a test case for applying monetization. As shown in Figure 1, five alternative pavement structures with various base layers are considered, namely: unbound (UB), cement-bound (CB), lean asphalt (LA), bitumen stabilized material (BSM)

Figure 1. Overview of test track showing material suppliers, production locations, and considered pavement sections.

type A (asphalt base layer required), and BSM type B (no asphalt base layer needed). For the asphalt surface and asphalt base layer, AC10 and AC14 mixtures are used, respectively.

All structures were designed for a maximum traffic load of one million 100-kN equivalent single axle loads (ESALs) over a period of 20 years following local design guidelines (Awv, 2013, Awv, 2010). These reference structures alter layer thicknesses based on average material performance values per pavement layer. The assumption of the Flemish pavement design method is that the layer thickness of the reference structures is valid provided that each layer meets minimal material specifications. Thus, it is assumed that all alternatives will have the same service life.

Table 1 provides the material composition of the different pavement layers. Two different types of construction and demolition waste (CDW) are included: reclaimed asphalt pavement (RAP) and recycled concrete aggregate (RCA). From a recycling point of view, using RCA is preferred over RAP for UB and CB mixtures as higher recycling rates for RCA are allowed according to Flemish specifications.

Table 1. Material composition.

Base type	AC 10	AC 14	UB-base*	CB-base	LA-base	BSM-base
Crushed coarse aggregate [%]**	54.9	48.6			19.8	
Crushed fine aggregate [%]**	23.5	4.8				
Natural sand [%]**	9.4	3.8			26.1	
Added filler [%]**	6.1	1.9			0.1	
RAP [%]**		38.1			53.2	96.7
RCA [%]**			100	89.4		
Virgin bitumen [%]**	6.2	2.8			0.8	2.1
Portland cement (CEM III/A) [%]**				2.1		1.0
Water [%]**				8.5		0.2***

* This material is also used for the subbase.

** Percentage by total weight of mixture.

*** The BSM mix was designed with a water content of 5.7%; however, it was noticed the RAP was too moist during production. Therefore, the water content was reduced to 0.2%.

3.2 LCA methodology

3.2.1 Goal and scope

The functional unit of this research is: “1 m² of asphalt pavement designed according to Flemish specifications for a maximum traffic load of one million ESALs over 20 years”. The analysis period will be 40 years. This research will consider the environmental impact from raw material extraction up to and including the waste processing of RAP and RCA.

The environmental impact of RAP and RCA is modelled considering the end of waste (EOW) criteria for CDW aggregates proposed by the Joint Research Centre of the European Commission (Luis Delgado et al., 2009). These criteria allocate all impacts up to and including the crushing and sieving of the CDW to the waste product. The impact of transporting RAP and RCA after processing is allocated to the next life cycle. In Flanders most contractors process RAP and RCA at their own plant using mobile processing plants; therefore, RAP and RCA are burden free when entering a new life cycle as no further transportation to the production plant occurs.

Note that the system boundaries do not consider the impact associated with road users. Furthermore, small maintenance interventions such as crack filling are not considered as full rehabilitation (mill and replace) is more common in Flanders. Based on discussions with the Flemish pavement industry, rehabilitation intervals of 10 years, 20 years, and 40 years were considered for the asphalt surface course, asphalt base course, and base layer, respectively. Note that unless pavements are designed using a life-long approach (perpetual pavements), bases are designed to reach their distress limit at the end of the design period. This research did not consider perpetual pavements, so rehabilitation will be needed. LA and CB base types

are subjected to cracking and to a lesser extent permanent deformation. If the distress limit for cracking is reached, they must be fully replaced. BSM and UB (sub)bases are only subjected to permanent deformation, so they are not fully replaced. Therefore, only the full replacement of LA and CB bases is considered within the system boundaries.

3.2.2 Life Cycle Inventory (LCI)

The ecoinvent 3.8 database was accessed to couple primary data to the upstream supply chain data for all inputs except for bitumen, for which Eurobitume's LCI was used. Regarding transportation, primary data was used based on the locations of the suppliers, production sites and construction site, as shown in Figure 1. Unless otherwise indicated, all ecoinvent records were used in line with previous research (Moins et al., 2022).

The average energy consumption of the mobile cold recycling plant to produce the BSM was monitored during a test track: 0.26 l diesel per ton of BSM produced. To produce the CB base, the energy consumption of the ecoinvent dataset "*Lean concrete| production, with cement CEM III/A | Cut-off, U*" was copied. The required energy to produce the asphalt mixtures was determined using thermodynamics laws (Santos et al., 2018, Vandewalle et al., 2020). This resulted in the following energy consumptions:

- AC 10 surface = 298.8 MJ/ton
- AC 14 base = 298.6 MJ/ton
- LA base = 297.5 MJ/ton

Depending on the material type, a combination of equipment was modelled for the construction, deconstruction, and waste processing phases. All types of equipment were modelled using the same ecoinvent dataset, namely "*Machine operation, diesel, >= 74.57 kW*". However, their hourly fuel consumption was determined using the formula provided by the US Environmental Protection Agency for nonroad engine emissions modeling (Epa, 2002) and adjusted within the dataset. The following combinations were modelled:

- Construction:
 - Bitumen-bound and CB: Paver with two tandem rollers.
 - UB: Grader with a wheel loader and soil compactor.
 - BSM: Paver with one soil compactor and one tandem roller.
- Deconstruction:
 - LA: Milling machine and sweeper.
 - CB: Excavator with jackhammer and wheel loader.
- Waste processing:
 - All (except UB and BSM): Mobile jaw crusher with two wheel loaders.

3.2.3 Life Cycle Impact Assessment (LCIA)

A recent review on monetary valuation in LCA showed that a report written by Trinomics on behalf of the European Commission provides one of the most recent monetization methods available (Amadei et al., 2021). The approach starts with the environmental footprint (EF) LCIA method to determine the environmental impacts. With the emergence of environmental product declarations (EPDs) in mind, the EF v3.0 EN 15804 method was chosen as the LCIA method for this research as it uses the same environmental indicators and units.

Then, these environmental indicators are expressed in monetary value using the factors shown in Table 2, which also provides the corresponding cost approach. The framework in the report uses several sources to obtain the monetization factors including DG Move, the MMG method, ReCiPe, the Environmental Prices Handbook, as well as advice from the Joint Research Centre (JRC) of the European Commission. The monetization values were derived for the EU27 and adjusted to each country based on the relative 2018 gross domestic product per capita with an income elasticity assumption of 0.8 (Smith et al., 2020).

Note that the monetization values presented in the Trinomics report are provided in 2018 euros. It is recommended updating these values for inflation using the consumer price index (CPI) (Amadei et al., 2021). Therefore, the monetization values were recalculated as 2022 values. The values for the CPI indexes were obtained using the Eurostat database.

Monetizing environmental impacts requires one additional step to normal LCA studies: discounting the value of future impacts using a social discount rate, which is conform with LCCA studies. A 2017 update of the report describing monetization of the MMG method proposes a social discount rate of 3% (Servaes et al., 2017). This value is in line with the recommendations of the Flemish government. However, a literature review revealed that a value of 4% is the most used discount rate in LCCA studies focused on pavements (Moins et al., 2020). Therefore, this analysis will apply a discount rate of 4%. The monetized environmental impact (MEI) is determined using Equation 1:

$$MEI = \sum_{n=0}^{40} \sum_{i=1}^{15} \left(MF_i \times \frac{EI_{RM,i} + EI_{T,RM,i} + EI_{WP,i} + EI_{T,WP,i} + EI_{P,i} + EI_{T,site,i} + EI_{C,i} + EI_{DC,i}}{(1+r)^n} \right) \quad (1)$$

where MEI = monetized environmental impact; i = environmental indicator i; MF_i = adjusted central monetization value; n = year of impact; r = discount rate (4%); EI_{RM,i} = environmental impact from raw materials; EI_{T,RM,i} = environmental impact from raw material transportation; EI_{WP,i} = environmental impact from waste processing; EI_{T,WP,i} = environmental impact from transportation of secondary materials; EI_{P,i} = environmental impact from production; EI_{T,site,i} = environmental impact from transportation to the construction site; EI_{C,i} = environmental impact from construction; EI_{DC,i} = environmental impact from deconstruction.

Table 2. EU27 monetization values.

EF v3.0 EN 15804 indicator	Unit	Cost approach	Central monetization value [EUR ₂₀₁₈ /unit]	Adjusted central monetization value [EUR ₂₀₂₂ /unit]
1. Climate change	kg CO2-eq	ACAP	0.1025	0.1176
2. Ozone depletion	kg CFC-11 eq	DCAP	31.4	36.0
3. Ionising radiation, Human health	kBq U235 eq	DCAP	1.2E-03	1.4E-03
4. Photochemical ozone formation, Human health	kg NMVOC eq	DCAP	1.19	1.37
5. Particulate matter	Disease incidence	DCAP	784 126	899 583
6. Human toxicity, non-cancer	CTUh	DCAP	163 447	187 513
7. Human toxicity, cancer	CTUh	DCAP	902 616	1 035 520
8. Acidification	mol H+ eq	DCAP & ACAP	0.344	0.395
9. Eutrophication, freshwater	kg P eq	DCAP	1.92	2.20
10. Eutrophication, marine	kg N eq	DCAP	3.21	3.68
11. Ecotoxicity, freshwater	CTUe	DCAP	3.82E-05	4.38E-05
12. Land use (Soil quality index)	Dimensionless		1.75E-04	2.01E-04
13. Water use	m3 water eq	Resource depletion	4.99E-03	5.72E-03
14. Resource use, fossils	MJ	Resource depletion	1.30E-03	1.49E-03
15. Resource use, minerals and metals	kg Sb eq	Resource depletion	1.64	1.88

4 RESULTS AND DISCUSSION

The results of the LCA are shown in Figure 2. Part A illustrates the MEI per pavement structure and pavement layer. Even though the asphalt surface and asphalt base layer only account

for 6% to 23% of the entire pavement thickness depending on the structure, they account for 53% to 84% of the total MEI. This means that the environmental impact of pavement structures is mainly determined by the upper asphalt layers. As the BSM type B structure eliminates the asphalt base layer entirely, this structure has the lowest total MEI. The UB structure requires the thickest asphalt package; however, it does not have the highest impact because the EOW criteria result in a base layer with far lower impact than other bases. The LA structure shows a similar impact as the UB structure: the higher impact of the LA base cancels out with the lower impact of the thinner asphalt package. The CB and BSM type A structures have the highest overall impact.

The relationship between the environmental and economic impact expressed in monetary units is depicted in Figure 2b. There is an excellent linear correlation between the NPV and MEI, showing that both indicators provide the same conclusion. The ratio of the NPV to the MEI is 4.31 on average. In other words, if a single sustainability indicator were to be developed in GPP by aggregating LCA and LCCA results with a 50/50 contribution, MEI results should be multiplied by 4.31 before being added to the NPV.

Figure 2. Results of the LCA: (a) MEI per base type and pavement layer, (b) Relationship between MEI and NPV.

The results of the detailed hotspot analysis are shown in Figure 3. Overall, three environmental indicators of the EF v3.0 EN15804 method are responsible for more than 90% of the MEI: climate change (CC), particulate matter formation (PMF), and use of non-renewable energy sources (UNRE). This is in line with previous research where global warming potential, fine particulate matter formation, and fossil resource scarcity accounted for over 85% of the single score of asphalt mixtures when ReCiPe 2016 (H) was used as the LCIA method (Hernando et al., 2022).

Figure 3. Detailed hotspot analysis of the MEI per life cycle phase and per environmental indicator.

Table 3 shows an overview of the three main hotspots per material type. The top three hotspots for the upper asphalt layers are mainly linked to the production impact of the mixtures:

bitumen production (A1), energy use (A3) and transportation of raw materials (A2). For the base layers, the hotspots mostly move further along the life cycle transportation to the construction site (A4) and use of construction equipment (A5). So, the main hotspots for individual life cycle phases depend on the type of material; however, almost all life cycle phases are highlighted in Table 3, except for the transportation (C2) and processing (C3) of waste. This shows the importance of considering the full life cycle in sustainability analyses.

Table 3. Top three environmental hotspots per material type.

Material	Share, Indicator, Process or Phase		
	#1 hotspot	#2 hotspot	#3 hotspot
AC10	16.8% UNRE Bitumen (A1)	7.1 % CC Energy (A3)	6.9% CC Transport (A2)
AC14	11.2% UNRE Bitumen (A1)	10.4% CC Energy (A3)	7.2% CC Equipment (C1)
UB base	31.9% CC Transport (A4)	21.1% PMF Transport (A4)	19.2% CC Equipment (A5)
CB base	20.0% CC Cement (A1)	15.0% CC Equipment (A5)	8.7% CC Transport (A4)
LA base	14.0% CC Energy (A3)	9.4% CC Equipment (A5)	8.0% CC Transport (A2)
BSM base	18.1% UNRE Bitumen (A1)	11.6% CC Equipment (A5)	8.0% CC Cement (A1)

5 CONCLUSIONS

The ultimate goal of this study was to harmonize LCA and LCCA so they could be combined in a single indicator. The first objective was to examine the feasibility of expressing the environmental impact of pavement project in monetary value to align with LCCA. An approach described by the European Commission was applied in this study, which uses monetization values for the EU27 zone. Literature concludes that geography is an important parameter to consider as monetization methods are mainly income sensitive. So, it is advised to adjust the monetization values based on the location of the study. However, once the correct values are computed, calculating the MEI can easily be aligned with an LCCA as it follows the same steps as determining the NPV.

The second objective was to study the relationship between the MEI and NPV using a test case. A comparison of five pavement structures with various base layers was used for this. The BSM type B had the lowest MEI (9.5 €/m² over 40 years). The UB and LA structures showed a similar impact of around 12.8 €/m² during the analysis period. Finally, MEIs of 13.7 €/m² and 14.5 €/m² were obtained for the BSM type A and CB structures, respectively. An excellent linear correlation between the NPV and MEI of the pavement sections was obtained, showing that both indicators provided the same conclusion. The NPV showed economic impacts in €/m² that were on average 4.31 times higher than the environmental impact of the MEI expressed using the same unit.

The final objective was to perform a hotspot analysis. The hotspot analysis showed that three environmental indicators were responsible for over 90% of the MEI: climate change, particulate matter formation, and use of non-renewable energy sources. This was in line with the 85% for the same three indicators when the ReCiPe single score was used in a prior study. Another important conclusion was drawn when individual materials and processes were evaluated. The three main hotspots depended on material type; however, when considering all findings, almost all life cycle phases were highlighted at least once, except for the transportation and processing of waste. This showed the importance of life cycle thinking, especially when waste materials were used since the hotspots tended to be appear more towards the end of the life cycle for base layers.

Of note, this research only applied one monetization method to a test case whereas literature shows that multiple methods exist. Therefore, as part of a sensitivity analysis, it is recommended testing multiple monetization methods and comparing how the results are affected depending on the method used. Furthermore, it is recommended that additional datapoints be added so that the ratio between the MEI and NPV can be calculated in a more detailed way. Afterwards, the effect of weighing and summing both indicators should be analyzed. This will

allow expressing environmental and economic impacts using a single value, making the selection of the most sustainable pavement alternative in GPP more straightforward.

ABSTRACT: Sensors create synergies in monitoring. The use of sensors to determine the reaction of a tunnel cross-section or tunnel maintenance to certain rock formations and to monitor construction and functional components is common practice in tunnelling today. Sensors can detect physical effects such as deformation, strain, vibration or temperature under real conditions that are not always easily described by numerical models. Nevertheless, given the complexity of modern tunnels and modern rehabilitation methods, as well as the interdependencies between components, comprehensive instrumentation can provide crucial insights for digital twin considerations. The aim of this contribution is to show how digital twins of tunnel cross-sections can be created using sensor monitoring information and what added value they can provide for cross-section performance assessment.

1 INTRODUCTION

Construction models, sometimes called digital twins, die at birth. An important goal is to bring these models back to life during the operational phase and maintenance of existing tunnels, especially during retrofits or interventions. Designers and tunnel operators invest a lot of time and money in creating analytical models to document the design of tunnel structures and rock formations and to perform simulations. The continuous use of a virtual model as a digital twin during operation is an excellent means of visualising all of the important components, performing analyses and calculations and improving the understanding and control of the long-term behaviour of the structural and functional components of the tunnel and rock formations during operation. In the preliminary study for the “MONTUN” project (Neuner et al., 2022, Strauss et al., 2022), a list of modern measurement systems (Strauss et al., 2020, Strauss et al., 2018) and software products for recording deformations in tunnel structures were compiled as a collaboration between the Austrian Federal Railways, the Vienna University of Technology, and the Vienna University of Natural Resources and Life Sciences. The most common system used in geodesy was the total station or laser tracker which has been in use for many years. The reason for this is that it can match newer innovations in terms of both accuracy and manageability. The second measurement system used was laser distance sensors which work on a similar principle to the tachymeter but without mirror reflection.

The inclinometer chain or “Shape Accel Array” (SAA) system, also provided by TU Wien, was mounted along the ring in the inner wall of the tunnel. The information from the continuous measurements of the monitoring systems provided an excellent basis for setting up a digital twin by means of Non-linear Finite Element models (Canestro et al., 2021, Slowik et al., 2021, Spyridis & Strauss, 2020).

2 FIELD TESTS

2.1 *Demonstration and monitoring systems*

The preliminary studies for this project were carried out by the Austrian Federal Railways, the Vienna University of Technology, and the Vienna University of Natural Resources and Life Sciences with the aim of analysing modern measuring systems used for the assessment of the monitoring of deformations in tunnel structures, see also Neuner et al., (2022). As a demonstrator for the filed investigations, the HABA reinforced concrete mouth profile 3600/2250 was used. It was manufactured according to ÖNORM EN 1916 and ÖNORM B5074 and has comparable geometric properties to real tunnel profiles. The profile was designed with 30 cm deep and 20 cm wide slots in the crown area, in the upper and lower strut area, in order to reduce the bending stiffness and thus generate significant 3D deformations which can occur in real tunnel shells. The loading processes were applied via tie rods. The HABA-Maul profile is a reinforced concrete profile C25/30 with $a = 4$ cm concrete cover and 36 pieces of $d = 8$ mm longitudinal reinforcement on the inner and outer circumference of the profile as well as a $d = 9$ mm per 8 cm ring reinforcement on the outer side and $d = 9$ mm per 6 cm on the inner side.

2.2 *Loading procedures & processes*

The mouth profile positioned on the HABA company site made it possible to apply a controlled load regime in predefined load steps in a relatively short time. Figure 1 provides more details regarding the load application (Beigel, 2023). In order to record the system response due to the loading processes the following monitoring systems were used. A Digital Image Correlation System DIC was used for the digital image correlation strain determination and the evaluation of out-of-plane displacements - profile deformation. A SAA inclinometer consists of a chain of individual inclinometers and was used for the measurement of inclination angles in the two main planes. Using an initial zero measurement, the SAA inclinometer can be used to derive displacements and deformations along the chain and thus the deformations of the mouth profile. A HBK Fibre Optic Inclinometer uses fibre brags along a lamella to monitor and measure the strains on defined points. From these measurements not only can the strains be derived but also the inclination angles and hence the profile deformation too. The load tests were carried out on the mouth profile on 7th February 2022, 9th February 2022 and 23rd February 2022. During the entire period from 7th February 2022 to 23rd February 2022, a continuous recording of the mouth profile deformations was made by means of SAA. The load test on 7th February 2022 was performed to a maximum load of 80 kN (4 x 20 kN threaded rod load) with the main objective of capturing the elastic system response and profile stiffness information for setting up the digital twin. The digital twin was then used to obtain a numerical prediction of the maximum load which was 400kN (4 x 100kN). Visible cracking on the inner surface of the mouth profile as well as on the outside of the stringers occurred for the first time at about 120kN. The load test on 9th February 2022 was carried out to a maximum load of 200 kN (4 x 50 kN threaded rod load) with the main objective of obtaining a non-elastic system response or initiating cracks to determine the suitability of the monitoring system for crack detection and plastic deformation. Further details on the analysis of the suitability of monitoring systems for tunnels that are renovated during operation can be found in Beigel, (2023).

Figure 1. (a) Load application by means of strain-controlled threaded rods, (b) Load application by means of hydraulic presses.

3 DIGITAL TWIN ANALYSES

The digital twin of the mouth profile was constructed using a two-step approach: (a) the reproduction of the profile by means of a 2D non-linear finite element digital twin, and (b) the reproduction of the profile by means of a 3D non-linear finite element twin. The software solution used was ATENA Science from the company Červenka Consulting (Červenka et al., 2013). This two-stage procedure was chosen in order to obtain an understanding of the significant elements in the digital twin development in the first stage and to analyse the model updating procedure using the monitoring information in 2D and then transfer it to the 3D model. Figure 2(a) shows the digital twin model used in ATENA 2D and Figure 2(b) indicates the material properties. The reinforcement was characterised by a linear material model, the location of which is shown as solid black lines in the drawing. In addition to the classical Digital Twin updating of the material properties and the bearing conditions, e.g. by sequential updating procedures or sensitivity analyses, the updating of the geometrical positions of the reinforcement in the profile and of the depths of the subsequently inserted slots in the ridges and sidewall areas of the profile as well as the updating of the load application by using the monitoring information from the different loading phases were essential for this project.

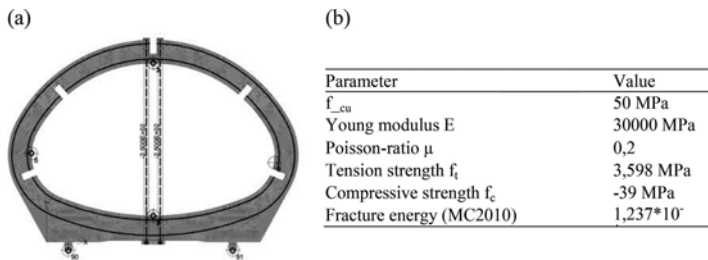

Figure 2. Nonlinear Finite Element 2D Digital Twin (a) Atena 2D Model, (b) Material parameters.

Besides other challenges, it was a crucial part of the digital twin setup process to model the load application effectively and realistically in order to allow the simulation of the load paths resulting from the test days.

The investigated applied load scenarios are shown in Figure 3, with (a) the force-controlled approach, (b) the approach with two external applied prestressed tendons, (c) the displacement-controlled approach, where only a one-sided loading in the ridge area was investigated in a first test.

A displacement-controlled variant using temperature loading and a force-controlled loading approach using a prestressing force was also investigated (Beigel, 2023). The Digital Twin simulation evaluated in the following is based on the force-controlled loading approach via two external preloads where the preload force was increased in specified steps. The fitting was performed using support points along the entire load path and for several displacement and force monitoring points within the profile. More details on the digital twin adjustment can be found in Beigel (2023).

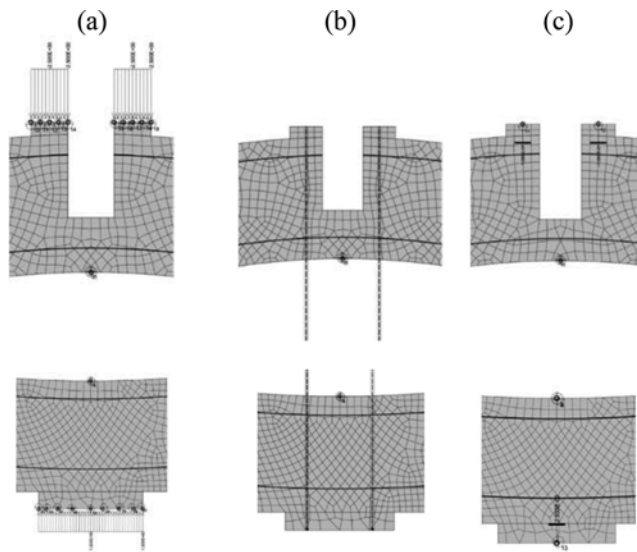

Figure 3. Digital Twin Details – Load transfer studies: (a) force-controlled, (b) coupling via external prestressing, (c) displacement-controlled.

Horizontal displacement in x-direction: With regard to the deformation of the profile, the horizontal displacements in defined points of the profile were of interest in a first approach especially since the deformation line of the mouth profile, which contained elements of yield joints and also rigid body movements, as well as the displacements in the bearing conditions could be detected. Figure 4 provides an overview of the results of the horizontal displacements in the x-direction. In particular, it shows (a) the tunnel cross-section with the measurement points and the corresponding coordinate system of the simulations, (b) the x-displacements for the 200 kN plane, (c) the force-displacement diagram for the x-displacement at point 25. In this diagram, the FE simulation is compared with the laser tracker (reference measurement) and the SAA. The diagram in Figure 4(d) shows the simulation results of the x-displacements at points 1, 17 and 25. Comparing the displacement at the load level of 80 kN before and after the maximum load of 200 kN shows plastic deformation. It can be seen that the deviations of the FE simulation from the reference measurement of the laser tracker are very small and thus very good results were achieved. The SAA measurement achieved a similar result compared to the laser tracker.

Vertical displacement in z-direction: In addition to the horizontal displacements at the defined points, the vertical displacements were also of significant importance for the comparison and updating of the model. Figure 5 provides the results of the displacements in the z-direction. Figure 5(b) shows the z-displacements occurring at Stage 80 kN. In Figure 5(c), a force-displacement diagram for the z-displacement at point 1 can be seen. The comparison of the laser tracker (reference measurement) and the SAA results show that they are in very strong agreement. It can be seen that the deviations of the NLFEA simulation from the reference measurement of the laser tracker are very small up to a load of 140 kN. From 140 kN to the load level of 200 kN, the simulation evokes a slightly stiffer system response than the reference measurement. However, the unloading load correlates very well with the reference measurement. The diagram in Figure 5(d) shows the simulation results of the z-displacements at points 1, 17 and 25. Comparing the z-displacement at the load level of 80 kN before and after the maximum load of 200 kN, a plastic deformation is evident.

Principal strains on the inner tunnel surface: The third important measurements, which were also used for the continuous updating process of the digital twin, were the main strains on the inner surface of the profile. Figure 6 shows the principal strains for the 200 kN level. In Figure 6(b), the minimal principal strains are shown while Figure 6(d) shows the maximal principal strains. It can be seen that the negative principal strains develop in the inner regions of the notches. In contrast,

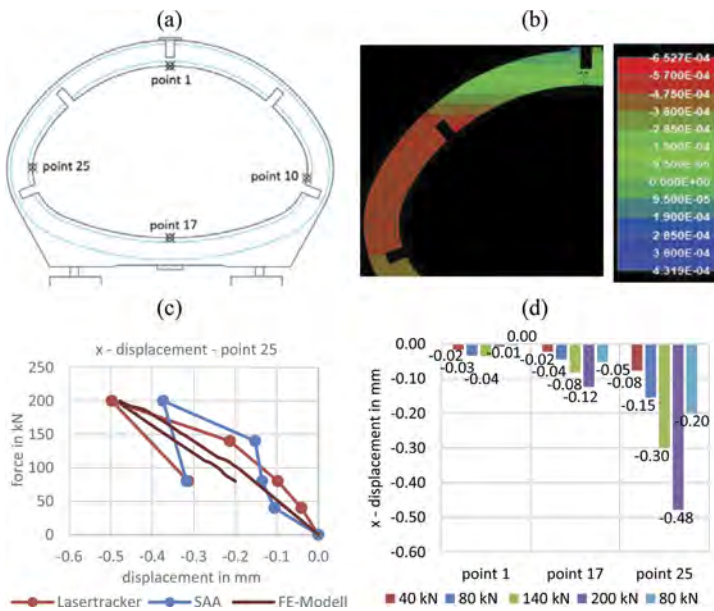

Figure 4. Digital Twin analyses of displacements in the x-direction (displacement controlled).

the positive principal strains occur at the interfaces opposite the notches, as expected. Figure 6(c) shows the simulation crack pattern at the 200 kN level with crack widths of up to 0.13 mm in the inner region of the flange notch. In addition, Figure 6(a) shows the crack in the ridge notch area caused by the test load.

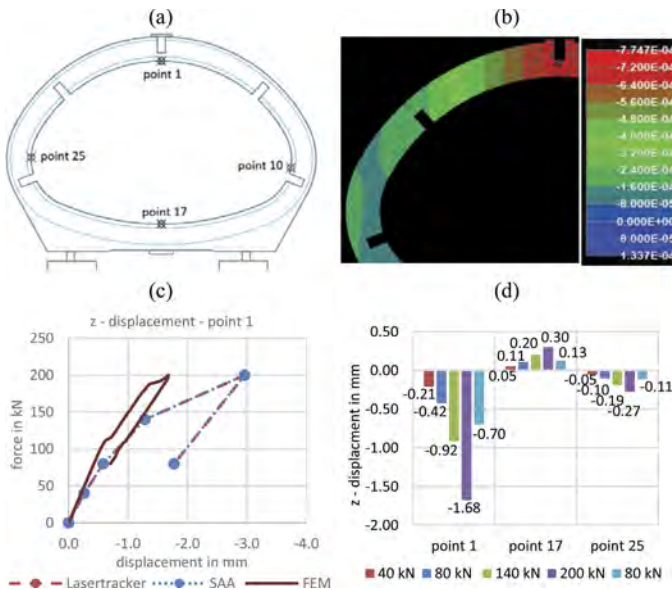

Figure 5. Digital Twin analyses of displacements in the x-direction (displacement controlled).

As Figure 6(a) clearly shows, massive cracks (“yield joint” formation) occurred next to the tie rods in the ridge area due to the reduction in cross-section and due to the deformation-controlled load application at a load level of 200kN. This could also be reproduced exactly with the ideally adjusted digital twin, as indicated in Figure 6(c) in the spatial crack pattern and in

Figure 6. Principal strains and crack pattern at 200kN loading (displacement controlled).

Figure 6(b) and (d) in the compressive and tensile principal normal stress distributions. The modelled yield joint formation with the compression (red) and tension (blue) zones, which are also massive criss-crossed by cracks (black), showed a very good agreement with the monitored ones and could be analysed via digital twin in their spatial distribution and complexity in the further course of the load increase. The in-depth 2D and 3D analyses with the crack pattern analyses up to the ultimate load of 400 kN can be found in Beigel (2023).

4 DIGITAL TWIN ANALYSES AND MONITORING SYSTEMS

It became apparent from the analyses that the establishment of a digital twin for this tunnel profile required a multi-step process and several sensitivity analyses and adjustments of stiffness ratios and support conditions along the load path. The digital twin was ultimately able to contribute greatly to a detailed understanding of the behaviour of the imperfectly symmetrical tunnel cross-section as well as to the understanding of the level of approximations against the level of detailing and value of information as outlined in the new fib Model Code 2020. In particular, it was possible to set up the digital twin in relation to several monitoring systems and also to show the limits of the updating procedure against the monitoring ring uncertainties.

5 CONCLUSIONS

Several innovative monitoring systems and the Digital Twin Tuning process were investigated in controlled field trials for their suitability for use in tunnel retrofit processes. The studies have shown that accurate Digital Twin systems require a multi-stage updating process using information from advanced monitoring systems.

Life-cycle and sustainability impact of composite and combined concrete tunnel linings

P. Spyridis

TU Dortmund University, Dortmund, Germany

K. Bergmeister

University of Natural Resources and Life Sciences (BOKU), Vienna, Austria

ABSTRACT: Tunnels typically comprise large scale infrastructure projects, where a demand for an increased service life is present. On the other hand, temporary structures often do not need to be designed for a service life longer than a few years only or they can form part of the permanent structure. In addition to this, the use of composite or combined primary and secondary concrete tunnel linings (considering the conventional tunnelling approach) can significantly influence the CO₂ equivalent emissions footprint of tunnel projects – particularly during construction. The present paper discusses a reliability life-cycle based methodology to adjust safety factors used in the design of tunnel linings in order to reach a specified service life, i.e. a variation of the safety factors used leading to an analogous reliability level at the start of the structures' lifetime, which in turn provides a modification of the expected service life duration. Furthermore, the outcome of this approach is assessed in terms of sustainability under the spectrum of the recently introduced climate-change limit state. The results indicate the possibility to deploy a novel design concept which allows to improve a tunnel structure's profile holistically, i.e. with consideration of traditional design criteria such as construction costs and structural safety, but also acute future oriented needs such as the service life and the climate impacts of tunnel infrastructure.

1 INTRODUCTION

1.1 *Background situation*

Measurements and analyses in the last decades have confirmed the critical increase of greenhouse emissions and global average temperature, and consequently the possibility of an irreversible climate disruption in the immediate future. At the moment, intense efforts are devoted toward stabilising climate change, moreover within very narrow time margins, by posing accelerated reduction measures for CO₂ and other greenhouse emissions as well as similar environmental impacts in every human activity. This directs acute demands in the construction industry, which – accounting only for construction related emissions A1-A5 per EN 15978 (CEN 2012) – carries approximately 13% of annual global environmental impacts in terms of energy consumption and more than 20% in terms of construction material (mainly concrete and steel) production (GlobalABC 2021). Tunnelling is a rapidly increasing sector, with intensive energy and construction materials consumption, and – although it leads to overall environmentally beneficial solutions for many types of infrastructure – it is a major producer of climate change agents. Optimised tunnel and structural design concepts are therefore highly necessary, since they can vastly influence material consumption and facilitating resource-efficient construction layouts.

1.2 *Fundamentals of environmental impacts and sustainability in construction*

The environmental sustainability in construction can be assessed on the basis of the European standard EN 15978 (CEN 2012), and it is determined separately for operation and construction

stages and at different asset life cycle stages (modules). The scope of the modules is summarised in Table 1. Although various measures can be implemented for the environmental/climate impacts of construction, greenhouse gas emissions are represented herein as based on their equivalence of with CO₂ in terms of climate impact. This is a measurement scale developed and implemented by the United Nations' Intergovernmental Panel on Climate Change (IPCC 2021) to represent the influence of various gases on global warming. CO₂ equivalents are also referred to as "Global Warming Potential" (GWP) and abbreviated as CO₂-eq in mass units (kg). For a product (including construction products such as structural concrete constituents) these values can be found in its respective Environmental Product Declaration (EPD), which is defined by ISO 14025 (ISO 2020). Common Product Category Rules (PCR), i.e. guidance for EPD development, are outlined for the construction sector in Europe by EN 15804 (CEN 2019).

Table 1. Scope and classification to life cycle stages according to DIN EN 15978 (CEN 2012).

Life cycle stages:	Product stage	Construction process stage	Use stage	End of life stage	Benefits and loads beyond the system boundary
Modules	A1 – A3	A4 – A5	B1 – B7	C1 – C4	D
Construction phase	A1 Raw material supply A2 Transport A3 Manufacturing	A4 Transport A5 Construction and installation processes	B1 Use B2 Maintenance B3 Repair B4 Replacement B5 Refurbishment	C1 De-construction/ Demolition C2 Transport C3 Waste processing C4 Disposal	D Reuse, recovery and recycling potential
Operation Phase			B6 Operational energy B7 Operational water		

1.3 Climate Limit State – a novel design concept for sustainable structural design

Although significant progress has been made in measuring and reducing the emissions of construction products and materials by implementing alternative constituents as well as alternative energy sources for production, the application of overall climate efficient design concepts is still sporadic and inefficient with respect to the societal demands as these are expressed in governance targets for emission limits. In order to deliver transparent and measurable rating of ecological requirements in design, a new limit state termed "Climate Limit State (CLS)" has been proposed by Haist et al. (2022a, 2022b) for inclusion to structural design codes and standards. This is intended to complement the already established Ultimate Limit State (ULS), Serviceability Limit State (SLS) and Durability/Service Life thresholds. Moreover, this is placing the authority and responsibility of the climate impact reduction on the hands of the design engineers, who are also in turn driving forces for the specification of materials and the selection of construction techniques and technologies. The proposed CLS considers the CO₂-eq emissions resulting from construction but also the service life of the structure in an amortisation timeframe for emissions. The limit state is expressed as a proportion of whole-life emissions to a reference structure without emission mitigation measures and factors-in the allowable emission thresholds as required to decelerate or reverse global warming (Haist et al. 2022b). Account can then be made for low-emission materials, techniques and technologies, as well as optimised component detailing and dimensioning, but also on degradation processes, and it can apply at detail/component or structural system level (Haist et al. 2022a). The overall formulation of the CLS is provided on the example of a concrete member in Equation 1 and further explanatory details and examples can be retrieved from Haist et al. (2022a, 2022b). As seen, a vital and integrated element leading to increased sustainability rating is the length of the element's service life and the asset's life-cycle management programme.

$$CLS_{bm} = \frac{GWP_{eco,bm} \cdot \gamma_{GWP,eco} / t_{sl,eco,bm}}{GWP_{ref,bm} / t_{sl,design,bm}} \leq \alpha_{GWP} \quad (1)$$

where:

- CLS_{bm} : Climate Limit State Index for building members (bm)
- $GWP_{i,bm}$: Global Warming Potential of the building member (bm), in kg of CO₂-eq considering the considering the life cycle stages A1-A5, B1-B5 and C according to EN 15804 (CEN 2012), with i = eco or ref for ecologically optimised or reference member respectively
- $t_{sl,i,bm}$: Service life (sl) of the building member (bm), in years, respectively with i = eco and design, for optimised and reference member with typical/nominal service life.
- $\gamma_{GWP,eco}$: Partial safety factor for the building member's GWP considering uncertainties of the environmental impact
- α_{GWP} : target value of the year-specific GWP reduction to achieve climate protection goals in the concerned sector and geographical area

1.4 Proposed novelty and scope of the paper

The situation described above strongly advocates the need to reduce the GWP of materials related to the permanent and temporary support at the A1-A3 stages. But apart from this, it is possible to optimise the design life-cycle of the linings. In conventionally constructed tunnels, the standard method of a sprayed concrete lined tunnel (SCL) includes a temporary primary lining of sprayed concrete, a permanent cast-in-situ or sprayed secondary and a waterproofing membrane between them. The temporary lining is assumed to be used for the stabilisation of the underground excavation in the short-term in order to allow safe conditions for casting the long-term lining support. Over the last two decades, an innovative tunnel design philosophy has been established considering the traditionally primary lining as part of the long-term structure. According to (Spyridis 2014), a long service life for primary lining sharing the loading with the secondary lining can lead to a material reduction of 40-45% for tunnel construction, while the savings in concrete consequently result in additional savings in excavation volumes. Such design approaches have been successfully performed in the past, with examples including the recently completed London's Crossrail (Elisabeth line) (Spyridis et al. 2013), and the Brenner Base Tunnel (Bergmeister & Murr 2019). In the present study, plane-strain analyses with soil-structure interaction, including both the primary and secondary lining are carried out for a realistic SCL tunnel cross section. The design outcome is compared based on the GWP (CO₂-eq emissions), and the numerator of the Climate Limit State of Equation (1) in particular. The results enhance the argument that advanced analysis methods with consideration of the structure's life-cycle characteristics, can dramatically influence the linings' climate impact, and hence the overall impact of tunnel projects.

The tunnel structure selected for the comparative analyses is a conventionally excavated, non-circular, closed shell in soft ground. The dimensions of the excavation are approx. 13.5 by 10.0 m (width/height). The crown and water table depths are assumed at 25 m and 4 m from the surface respectively and the soil layers are: Made ground (0 - 7 m); Clay type 1 (7 - 38 m); Clay type 2 (38 - 46 m) – see also Figure 1. The primary and secondary linings are assumed to be sprayed and cast concrete respectively. Two design approaches are accounted for, namely with and without load sharing. In the first case, the primary lining remains as a load bearing element in composite action and load sharing with the secondary lining for the entire service life of the tunnel, and in the latter case the primary lining's service life is ended once the secondary lining is in place. The total GWP for each solution is calculated based on the required material quantities per the design. The service life spans are accordingly assumed at $t_{sl,prim} = 1$ year and $t_{sl,secd} = 120$ years.

2 PARTIAL SAFETY FACTORS ADJUSTMENT TO DESIGN SERVICE LIFE

The service life of a structure may be expressed in conjunction to its time-dependent performance level and be processed in the reliability discipline, as discussed by Frangopol et al. (2004) and as integrated in codified performance-based assessments (fib 2012) and tunnel project specifications (Bergmeister, 2012), considering the reliability level inherited to the structure at the very

beginning of its service life. A structure's service life can be defined as the "assumed period for which a structure or part of it is to be used for its intended purpose with anticipated maintenance but without major repair being necessary" (CEN 2002). Reliability can be inversely expressed by the failure probability per Equation 2 – with Φ , the cumulative function of the standard Normal distribution, and p_f the failure probability per annum. Based on Equation 5, and assuming statistical independence of annual failure events, the values of β_n for different reference periods (n in years) can be calculated solving Equation 3, and the structure's service life ends when the minimum acceptable (terminal) target reliability β_{TARGET} is reached.

$$\Phi(-\beta) = p_f \quad (2)$$

$$\Phi(\beta_n) = [\Phi(\beta_1)]^n \quad (3)$$

A simplified methodology to evaluate the design service life of a tunnel lining through an engineered scaling of the involved ULS partial safety factors is presented in detail by Spyridis (2014). This method uses a transformation of Cornell's expression of the reliability index β , i.e. based on mean values and standard deviations of the resistance and action stochastic variables, and the fractile-based expression of their characteristic values per Eurocode 0 (CEN 2002), and it yields the (combined) nominal safety factor γ_{nom} of a load-bearing structure per Equation 4 – with v_i the coefficient of variation ($v_i = \sigma_i / \mu_i$) for the load (S) and the resistance (R), and k the characteristic fractile value factor for the required statistical confidence and the test sample size.

$$\gamma_{nom} = \frac{1 - k \cdot v_R}{1 + k \cdot v_S} \cdot \frac{1 + \beta \cdot \sqrt{v_R^2 + v_S^2 - \beta^2 \cdot v_R^2 \cdot v_S^2}}{1 - \beta^2 \cdot v_R^2} \quad (4)$$

In the presented case study, the partial safety factors for steel and concrete material are set to $\gamma_s = 1.15$ and $\gamma_c = 1.50$ respectively. Adjusted load partial safety factors are used, namely $\gamma_{shor-term} = 1.10$ and $\gamma_{long-term} = 1.50$ following Spyridis (2013).

3 DETAILS OF SOIL-STRUCTURE INTERACTION MODELLING AND ANALYSIS

The numerical models implemented non-linear Mohr-Coulomb plasticity with a mesh of 5430 3-noded triangular solid material elements and 650 Timoshenko-beam elements to model the ground and the liners respectively. The analysis is performed in a plane-strain model by use of Rocscience FEM software. The used geotechnical parameters are presented in Table 2 below. These properties are chosen in coherence with previous project case studies, described in (Spyridis et al. 2016). The analysis procedure delivers the loads in the linings due to soil-structure equilibrium and it includes a total stress, undrained state in the temporary condition (i.e. soil is considered to be watertight due to the unloading compaction of clays) and then a switch to effective stress drained/ pore water pressure state for the long-term. To simulate the face advance stress relief and 3D arching effects during excavation, a 50 % relaxation employing the stiffness reduction method is implemented (Pöttler 1990). The analysis steps are summarised below:

- 1) In situ stress – nullified deformation equilibrium
- 2) Softening at the excavation area/simulated relaxation
- 3) Excavation (removal of cross-section soil elements) and installation of primary lining.
- 4) Installation of secondary lining
- 5) Application of porewater pressure
- 6) Switching to long-term drained parameters
- 7) Degradation (removal) of primary lining, i.e. long-term situation of secondary lining

For both the primary and secondary linings, the assumed thickness in the model is 300 mm each; although the design results in some adjustment for the lining thicknesses, these are not reiterated in the FEM analysis. The primary lining stiffness is assumed at 15 GPa to simulate the gradual simultaneous soil convergence and lining stiffness development (Pöttler, 1990), but the secondary lining it is set to 30 GPa. The linings are analysed as fully linear elastic materials and they are designed as plain unreinforced concrete or as concrete with a B500 rebar mesh of $\text{Ø}10/100$ and $\text{Ø}16/100$ mm for the primary and the secondary lining respectively.

4 LIFE-CYCLE BASED SUSTAINABILITY ANALYSIS

The GWP of the materials is calculated based on the weights of the constituents and published data (retrieved from Haist et al. (2022a) and online environmental declarations). For both sprayed and cast concrete the assumed cement type is Portland CEM I 42.5 R. For sprayed concrete, the proposed mix is derived from recipes in Ikumi et al. (2022), but both sprayed and cast mixes are deliberately selected with similar mixes of equivalent strength. The details are listed in Table 3 below. Based on these data, the following aggregate GWP values for the A1-A3 modules are calculated (note that the rebar quota is independent of the lining thickness):

Primary lining (Total perimeter: 37.5 m):	Concrete (sprayed)	391	kg CO ₂ -eq/m ³
	Bar reinforcement	10	kg CO ₂ -eq/m ²
Secondary lining (Total perimeter: 35.5 m):	Concrete (cast in situ)	405	kg CO ₂ -eq/m ³
	Bar reinforcement	25	kg CO ₂ -eq/m ²

5 RESULTS

The FEM calculation results are expressed as the combination of normal forces and bending moments along the lining. A typical design practice for tunnel linings observes the applicable structural design codes and assumes that the linings behave as unit-width shell elements with axial/flexural load interaction. Given the fact that tunnel linings have a uniform thickness and reinforcement quantities, the design loads resulting from the analyses are compared against the structural capacity envelope of the lining which is represented in the form of interaction diagrams (hoop thrust against bending moment), also termed Capacity Limit Curves (CLC) (Spyridis et al. 2016). CLCs for structural concrete members are here produced in accordance to Eurocode 2 (CEN 2021). The CLCs of Figure 2 present all design combinations of axial forces and bending moments juxtaposed to the envelope of the cross-section's design capacity distinguishing the design assumption and dimensioned lining in a comprehensive graphical verification. Also, the lining thickness $d_{\text{prim}}/d_{\text{secd}}$ is noted. The design point (most onerous load pair coinciding with the CLC envelope) is defined by adjusting the concrete lining thickness, where two detailing concepts are implemented: (i) relying solely on plain unreinforced concrete, and (ii) relying on rebar mesh reinforced concrete. The data set name coding indicates the combination of the characteristics [Lining]-[Design concept]-[Detailing approach], with:

- Lining: Primary (Prim) /Secondary (Secd)
- Design concept: Individual life cycles (Ind)/Combined/Composite function (Com)
- Detailing: Concrete (Con)/Concrete and rebar (ConReb)

The lining dimensioning for each dataset are summarised in Table 4, along with the respective numerators of Equation (1), considering the GWP of the materials at A1-A3 life cycle stage per running meter, the service life of each solution being equal to the nominal service life $t_{\text{sl,prim}}$ or $t_{\text{sl,secd}}$, and assuming an overall safety factor of $\gamma_{\text{GWP}} = 1.0$. Table 4 is used as a basis for comparison between the different solutions on the basis of the assumptions clarified above.

Table 4. Concrete lining details and respective A1-A3 GWP assessments.

Dataset and analysis	Lining thickness (mm)	GWP in kg CO ₂ -eq per tunnel running meter			SUM
		Concrete	Rebar	Time adjustment (Eq. 1)	
Prim-Ind-Con	220	3226		3226	3277
Secd-Ind-Con	430	6182		52	
Prim-Ind-ConReb	210	3079	375	3454	3503
Secd-Ind-ConReb	340	5032	888	49

Secd-Com-ConReb	330	4745	888	47	

6 DISCUSSION: CLIMATE AND SUTAINABILITY OPTIMISATION IN TUNNELLING

The analysis above demonstrates a rational engineering and quantifiable procedure to assess the environmental impacts in tunnelling based on the A1-A3 (material) life cycle stages whilst predefining the expected service life of a structure also at the design stage and only accounting the reliability at delivery. The sustainability analysis is based on the widely accepted GWP metrics, and the newly introduced Climate Limit State. This is complemented by predefining appropriately selected safety factors in coherence with the initial structural design reliability threshold. This connotation is already made evident in the summary of results in Table 4: A governing effect in the analysis is the yearly apportionment of emissions and hence an amortisation of the environmental impacts over the service life of the tunnel. This life cycle effect has to be understood as a critical planning, design but also maintenance decision for any future tunnel project. At the same time, the Climate Limit State can be directly integrated into current structural design codes.

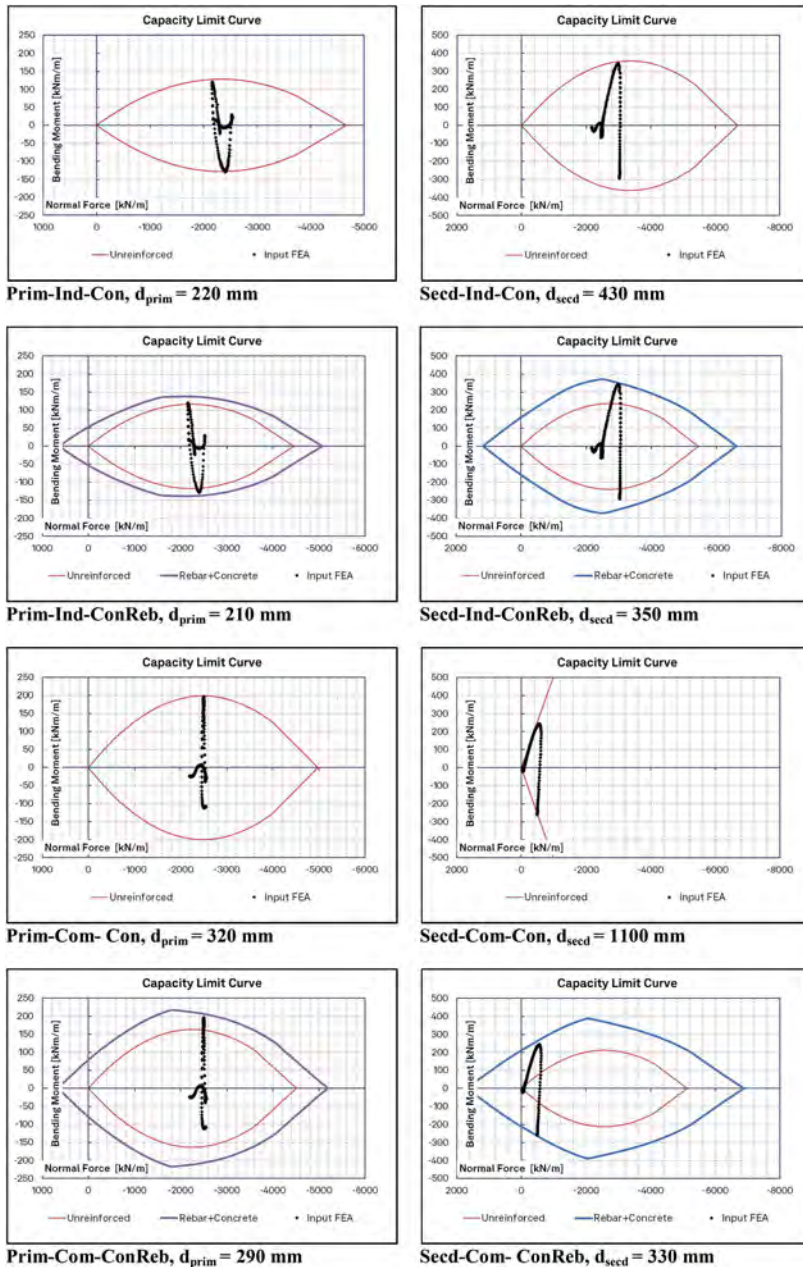

Figure 2. Capacity Limit Curves (CLC) for all analysed cases; see also the correspondence of the resulting lining thickness with the numerator in numerator of Equation (1).

As main takeaways of this study, it is briefly summarised that integrating the primary lining to the permanent, long-term support may require slightly higher dimensioning and possibly slightly higher quality control requirements in the initial phases of the project. However, this leads in this case to a reduction in life-cycle CO₂-eq. emissions by a tremendous 95 % or even more, compared to the standard approach of sacrificial primary lining. Moreover, the investigation demonstrates that enhancement of a lining's bending resistance by the use of rebar reinforcement allows a reduction of its thickness, which in turn can lead to a lower GWP as compared to completely unreinforced concrete.

This article explains a uniformly applicable methodology for a combined structural and sustainability assessments of tunnel structures which can immediately account for the above aspects. However, further insights should be gained on the aspects of structural, life cycle and sustainability engineering in tunnelling and infrastructure construction in the wider sense, with account on all asset phases (A1-D), reliability, quality, as well as material and construction technologies.

Assessing highway bridge scour reliability and risk under changing floods

N. Devineni & M. Ghosn

The City University of New York, New York, USA

ABSTRACT: Hydraulic events threaten highway bridge safety as more than 55% of bridge failures in the United States (U.S.) are attributed to floods. It is now well-documented that climate change could cause an increase in extreme precipitation leading to larger and more frequent floods in many U.S. regions. This study presents a systematic framework for the reliability analysis of bridges under future changing flood conditions. The bridge scour safety assessment process is demonstrated using a case study representing bridges over Schoharie Creek in Upstate New York, with more than 100 years of peak flow data and evidence of an increasing trend. Our results show that this trend could cause about an 18% increase in the probability of scour failure over the 75-year service life of bridges designed using current procedures. The reliability index for foundation scour should ideally surpass $\beta = 2.5$ to effectively lower the risk to acceptable levels.

1 INTRODUCTION

Wardhana and Hadipriono (2003) showed that flooding and scour contributed to almost 53% of all bridge failures in the U.S. between 1989 and 2000. Additionally, a study on the status of bridge failures in the U.S. from 1800 to 2009 conducted by Sharma and Mohan (2011) showed that floods caused the maximum number of bridge failures – accounting for 38% of the 1,814 failures that occurred in those years. In recent decades, floods have increased in intensity and frequency in the U.S., especially across the Northeast, Pacific Northwest, Midwest, and Great Plains (Slater and Villarini, 2016; Milly et al. 2005; Collins, 2009, Ahn and Palmer, 2015). Long-term analysis, based on over 100 years of peak flow records, also shows an increase in flooding in the northern half of the eastern prairies and parts of the midwest (Peterson et al. 2013). Particularly vulnerable to increased flooding are highway bridges that often form critical, if not unique, access links to many riverine communities. For example, Hurricane Irene in 2011 had cut off for several days a dozen towns in Upstate New York and Vermont from the outside world because of extensive flooding. The hurricane-induced floods led to entire collapses or caused damages to more than 300 bridges in Vermont alone, many of which were by flood-related foundation scour (Eckholm, 2011).

The American Association of State Highway and Transportation Officials (AASHTO) Load Resistance Factor Design (LRFD) specifications require that scour at bridge foundations be designed for 100-year peak floods. The corresponding 100-year design scour depth at bridge foundations is estimated based on the Federal Highway Administration's (FHWA) Hydraulic Engineering Circular No.18 (HEC-18) specifications (Richardson & Davis, 2012). An approximate 40% of U.S. bridges are over the age of 50 years (FHWA, 2015), implying that their scour design is based on the 100-year flood estimated from data before the 1970s. With recent increases in flooding across the U.S., there is a need to reassess and, if needed, update the 100-year design floods and the corresponding design scour depths to reflect new extreme conditions.

We introduce a framework to assess for the effect of long-term changes in flood intensities and update highway bridge scour depth estimation. Long-term changes in floods are detected and used in future flood modeling. Highway bridge scour depths are estimated using a reliability-based approach (Johnson and Dock, 1998; Johnson et al. 2015; NCHRP, 2007; Lagasse et al. 2013; NCHRP, 2013) that considers all the uncertainties associated with establishing bridge structure, foundation, loading characteristics, and scour modeling. This end-to-end bridge scour safety assessment process is

demonstrated using a case study representing a hypothetical bridge over the Schoharie Creek in Upstate New York for which more than 100 years of peak flow data is available.

2 DATA AND METHODS

2.1 Streamflow data

Peak streamflow data (the maximum instantaneous discharge) from the Schoharie Creek at Prattsville, NY (USGS gauge 1350000), was used in this study (NWIS, 2020). This gauging station is part of the Hydro-Climatic Data Network (HCDN) of the United States Geological Survey (USGS). Data from the HCDN stations are reportedly free of upstream regulation and diversion. The contributing drainage area of this station is 237 mi². Annual peak streamflow data (in cubic feet per second, cfs) is available for the 1908 to 2019 water years (Oct. 1 - Sept. 30).

2.2 Hypothetical bridge characteristics

AASHTO LRFD specifications are primarily designed for medium to short-span bridges. The hypothetical bridge, therefore, took a total span of 220 feet, assuming the channel below to have a width of roughly 200 feet. The three span (60'-100'-60') bridge is illustrated in Figure 1 and for the purpose of this study, each support column has an estimated diameter of 6 feet. The depth of foundation below the streambed which is susceptible to potential scouring is represented by, y_s .

Figure 1. Profile of hypothetical bridge.

2.3 Methodology

2.3.1 Probability model and return levels

Lognormal, Log-Pearson Type III, and Generalized Extreme Value Distributions are commonly used and are reasonable, for modeling peak streamflow data (Stedinger et al. 1993). LPIII has been in use by Federal agencies since 1967 (USWRC, 1967). In this study, we used the Gumbel distribution (Type I Extreme Value Distribution) to have a minimum number of parameters that need to be estimated. The T-year design flood is estimated as follows:

$$Q_T = F^{-1}\left(1 - \frac{1}{T}\right) \quad (1)$$

where $F^{-1}(\cdot)$ is the inverse of the cumulative function of the selected probability distribution, and T is the return period for the flood event. In our case study, we are interested in the 100-year design flood. Hence, $Q_{100} = F^{-1}(0.99)$. Uncertainty in estimating the 100-year design flood is represented using a bootstrap sampling approach (Efron and Tibishirani, 1993).

2.3.2 Estimating bridge scour

The AASHTO LRFD specifications require that scour at bridge foundations be designed for the 100-year flood storm surge tide. The corresponding 100-year design scour depth at the bridge foundation is estimated following the procedure recommended by FHWA using HEC-18 (Richardson & Davis, 2012). The foundation should then be designed taking into consideration the design scour depth. This is achieved by placing the footings below the scour depth. This ensures that the lengths of piles, and their pile shafts, extend beyond the scour depth, where the remaining soil depth provides sufficient resistance against sliding failures and overturning, even after severe scour effects. The focus of this study is on local live-bed scour around bridge piers that, because of its cyclical nature, is the most unpredictable type of

scour. The HEC-18 design equation for local scour around bridge piers is a function of the flow depth, the pier nose shape, the angle of attack of the flow, the streambed conditions, the soil material size, the diameter of the pier, and the Froude number. The equation that is intended to predict the depth of maximum scour for design purposes is of the form:

$$y_{max} = 2y_0 K_1 K_2 K_3 K_4 \left(\frac{D}{y_0} \right)^{0.65} F_0^{0.43} \quad (2)$$

where y_{max} is the maximum depth of scour, y_0 is the depth of flow just upstream of the bridge pier excluding local scour, K_1 , K_2 , K_3 , and K_4 are coefficients that account for the nose shape of the pier, the angle between the direction of the flow and the direction of the pier, the streambed conditions, and the bed material size respectively, D is the pier diameter (Lagasse, 2013). F_0 is Froude's number and is defined by:

$$F_0 = \frac{V}{\sqrt{gy_0}} \quad (3)$$

where V is the mean flow velocity at the pier and g is the acceleration due to gravity. The flow depth, y_0 , and flow velocity, V , are related to the flow discharge rate, Q , and the shape of the channel represented by the cross-sectional area of the stream, A_0 . This relationship is given by:

$$Q = A_0 V \quad (4)$$

For a rectangular cross-section with a constant width, b , and flow depth y_0 , the relationship becomes:

$$Q = by_0 V \quad (5)$$

In this study, without a loss of generality, we assume that the channel cross-section is approximately rectangular. The relationship between the streamflow velocity, V , and the hydraulic radius that is related to the flow depth, y_0 , can be expressed using Manning's equation:

$$V = \frac{\Phi}{n} R^{(\frac{2}{3})} S^{(\frac{1}{2})} \quad (6)$$

where n is Manning's roughness coefficient, R is the hydraulic radius, and S is the slope of the streambed. Φ is a unit adjustment parameter equal to 1.486 when using U.S. units (feet and seconds). For SI units $\Phi = 1$. For a rectangular channel of width b , the hydraulic radius, R , can be calculated by:

$$R = \frac{by_0}{b + 2y_0} \quad (7)$$

Thus, the relationship between the flow rate, Q , and the flow depth, y_0 , is given from the equation:

$$Q = by_0 \frac{\Phi}{n} \left(\frac{by_0}{b + 2y_0} \right)^{(\frac{2}{3})} S^{(\frac{1}{2})} \quad (8)$$

Typical values for Manning's roughness coefficient, n , vary between 0.025 to 0.035 for earth (respectively for "good" condition and for a "weeds and stones" condition). It is noted that estimating the appropriate Manning roughness coefficient is associated with a high level of uncertainty. Researchers at Hydraulic Engineering Center (1986) determined that the roughness coefficient, n , follows a lognormal distribution with a CoV ranging from 20% to 35% (with an average value of 28%). Therefore, in this study, n is taken as a lognormal random variable with a mean equal to 0.025 and a coefficient of variation equal to 28%. It is also assumed that the slope, S , is known and thus the uncertainties in V are primarily due to the uncertainties in estimating n . As mentioned previously, we used Gumbel distribution to model the discharge rate, Q . Table 1 presents the values assumed for b , K_1 , K_2 , K_3 , K_4 , D , and S , for analyzing the hypothetical bridge.

Reliability analysis of a bridge pier under the effect of scour is proposed based on the work of Johnson (1995). This model is based on the observation that Equation 2 gives a conservative

estimate for the depth of the scour. The average ratio of the observed scour depth compared to the HEC-18 predicted depth was found by Johnson (1995) to be about 0.55. Also, the ratio of the true scour value over the predicted value has a CoV of 52%. This ratio is represented by a scour modeling variable, λ_{sc} , that is assumed to follow a normal distribution. Thus, according to Johnson (1995), the true scour value can be represented by an equation of the form:

$$y_{max} = 2\lambda_{sc}y_0K_1K_2K_3K_4\left(\frac{D}{y_0}\right)^{0.65}F_0^{0.43} \quad (9)$$

Table 1. Variables used in equation calculation.

Variable	Definition	Assumed Value
b	River/creek width	220 ft.
K ₁	Nose-shape of pier coefficient	1
K ₂	Angle of flow and pier coefficient	1
K ₃	Streambed condition coefficient	1.1
K ₄	Bed material size coefficient	1
D	Pier diameter	6 ft.
S	Slope of streambed	0.2%

Equation 9 assumes that the modeling variable, λ_{sc} is representative of the differences between the HEC-18 scour design equation and the true scour for all floods and rivers. It should be noted that Johnson (1995) also recommends that the factor K_3 , representing the effect of streambed conditions, should be treated as a random variable with a mean equal to 1.0 and a CoV equal to 5% to account for the possible variability of the streambed between floods. Table 2 summarizes the input data for the random variables appropriate for use with Equation 9. In this study, we assume that the scour depth is due to the single flood being analyzed and that the flooding period is always long enough for the maximum scour depth to be reached.

In summary, two equations are used to estimate bridge scour. Equation 2, as recommended by HEC-18, that estimates the maximum scour design depth given known deterministic values from Table 1. Equation 9, as proposed by Johnson (1995), that estimates the true scour depth under possible uncertainties that can arise from estimating peak streamflow, Q , Manning's roughness, n , and the bed condition factor, K_3 . In addition, Equation 9 includes a correction for the bias, λ_{sc} , between the predicted HC-18 scour when compared to the true scour. It is important to note that, while Equation 2 provides a deterministic estimate of the design scour depth, y_{design} , Equation 9 provides a range of values of the possible scour, $f(y_{max})$, when uncertainties are considered. Conjunctive use of the estimates computed from Equation 2 and Equation 9 enables us to develop the reliability analysis and extrapolate reliability indices (beta values).

Table 2. Input data for scour reliability analysis equations. Coefficient of Variation (CoV).

Variable	Definition	Mean Value	CoV	Distribution Type	Reference
Q	Peakflow	18790 cfs	80%	Gumbel	USGS NWIS (2020)
λ_{sc}	Observational bias	0.55	52%	Normal	Johnson (1995)
η	Manning's roughness coefficient	0.025	28%	Lognormal	HEC-18 (1986)
K ₃	Streambed condition coefficient	1.1	5%	Normal	Johnson (1995)

2.3.3 Reliability analysis

The purpose of reliability analysis is to study the level of bridge structural safety provided by the current AASHTO LRFD for flood-induced scour. The reliability analysis also examines how changes in the design criteria would affect the safety of bridge systems. We will use this information to calibrate appropriate load factors that adjust the design scour equation to meet different target reliability indices. We developed the reliability analysis by conjunctively

using Equation 2 and Equation 9. The bias-adjusted scour model described in Equation 9 is used in a Monte-Carlo simulation method along with bootstrapped simulations of the 100-year design flood, Q , to generate the probability distribution, $f(y_{max})$, of the true scour. From there, 10,000 realizations of maximum scour depths, y_{max} , were generated. The resulting 10,000 Monte-Carlo simulation-based y_{max} values constitute the probability distribution, $f(y_{max})$. We estimate the reliability curve, $P(Y_{max} > y_{max})$, from this distribution of y_{max} , where Y_{max} is the random variable that represents maximum scour under uncertainty. Such Monte-Carlo simulations are suitable for any random variable distribution type and failure equation. The HEC-18 scour equation, Equation 2, is used to compute the design depth, y_{design} . Note that y_{design} is based on the biased HEC-18 equation and will overestimate the depth. We compute the probability of exceeding this design depth from our reliability curve.

$$p_f = P(y_{max} > y_{design}) \quad (10)$$

In structural reliability, the probability of failure, p_f , is the probability that the resistance R (or the design scour depth) is less than, or equal to, the total applied load effect S (or the true scour depth due to possible uncertainties). Finally, the reliability index, or the beta factor, β , is computed as:

$$\beta = \phi^{-1}(-p_f) \quad (11)$$

where ϕ^{-1} , is the inverse of the standard normal distribution.

The reliability index, β , is often used as a measure of structural safety or risk. Assuming normal probability distributions, it gives the number of standard deviations that the mean margin of safety falls on the safe side. β in the range of 2 to 4 is usually specified for different structural applications (e.g., $\beta = 3.5$ was used to calibrate the Strength I limit state in AASHTO LRFD Specifications). These values usually correspond to the failure of a single component. If there is adequate redundancy, overall system reliability indices will be higher. Readers can find more detailed explanations of the reliability principles in published texts on structural reliability (e.g., Thoft-Christensen and Baker, 1982).

2.3.4 Modeling changing floods

We modeled the long-term trend in the peakflow dataset and assume that this long-term linear trend will continue into the future. By considering the 112 years of data as one dataset with some linear increase in peak streamflow across the decades, this trend can be extrapolated into the future using a modeling approach that estimates the parameters of Gumbel distribution which are allowed to change/increase with time.

The model is described as follows:

$$Q_t \sim \text{Gumbel}(a_t, b_t); t = 2021 : 2121 \quad (12)$$

$$a_t = 10370.83 + 51.71 * t \quad (13)$$

$$b_t = 5868.74 + 43.30 * t \quad (14)$$

Peak yearly flows (Q_t) are assumed to follow a Gumbel distribution with a location parameter (a_t) and scale parameter (b_t), which are both varying over time. The location parameter corresponds to the mean of the distribution and the scale parameter corresponds to the variance of the distribution. The model assumes that the location and the scale parameters are linearly changing over time. We used time (t) as an indicator for this change, but it can be substituted with Global Temperature or Global CO2 emissions data. If this trend in either the location or scale is significant based on the historical observed peak flow data, we assume that in the future, both mean (location) and variance (scale) will change over time and the model will simulate peak flow values from a Gumbel distribution with time-varying parameters. Given this model result, we can simulate future peak flows for a design life of 100 years from a Gumbel distribution whose location and scale parameters vary over time. An example of such realization for the next 100 years starting year 2021 is shown Figure 2. Also shown by a red circle in the realization is the maximum peak flow that may occur in the next 100-year time frame – a 1 in 100-year event, which related to the design flood for the future time frame. Notice that the worst event can occur anywhere in the

100-year time frame, and not always at the end of the design life. Such 100-year realizations can be simulated multiple times in a simulation mode and each time we can record the 1 in 100-year event (future design flood) as the worst event in the realized time frame. Multiple such simulated worst events (in the 100-year time frame) will form the probability distribution of the future design flood, which can then be used with the HEC-18 scour equations to assess the reliability and risk of the design scour depth.

Figure 2. A 100-year realization of the future floods. Red circle shows the maximum flood in the period.

3 RESULTS AND ANALYSIS

3.1 Changes in design flood due to climate change

The results of the model fit to the observed peak flow data from 1908-2019 for the Schoharie Creek are given in Table 3.

Table 3. Climate model parameters.

Parameter	Estimate	Standard error	p-value
Location (intercept)	10371 cfs	1295 cfs	< 0.001
Location (time)	52 cfs/year	24 cfs/year	0.03
Scale (intercept)	5869 cfs	1211 cfs	< 0.001
Scale (time)	43 cfs/year	23 cfs/year	0.05

As we can see both the location and scale have their coefficients (β_a, β_b) to be statistically significant at the 90% and the 95% confidence level. The trend in the location parameter can be seen in the trend line in the plot in Figure 3a. Figure 3b is the density plot showing an initial look at the distribution of the historical and future design floods. The median of the distributions falls at about 48,000 cfs for the historic data, and about 85,000 cfs for the future simulated data. In essence suggesting a nearly 77% increase in expected extreme-event median in the coming 100 years. This increase will lead to a shift in the reliability and risk of bridge design which needs to be reassessed. Figure 3c shows the reliability-curves. They show a change between current anticipated risk based on historical data and future expected risk based on future simulation.

We then used Equation 11 to transform these exceedance probabilities into reliability indices or beta factors. Figure 3d shows these corresponding reliability indices computed from an inverse standard normal distribution for normalized critical depths (y/y_{design}). The normalization is done using HEC-18 design depths as the basis to get the load factors for critical scour depths. A load factor of 1 indicates that the foundation is designed to satisfy the foundation depth requirement of HEC-18. In essence, Figure 3d shows the safety (in terms of a reliability index) for a specific load factor applied on an initial HEC-18 required design scour. We can also use it to choose the load factors for a specified safety or reliability index.

Table 4 shows the Beta table derived from Figure 3d. It shows the calculated design depths with variance for the historical data as its entire 100 years, as well as for the future 100 years if an imposed linear trend is assumed. The base reliability index is approximately 1.4. In Table 4, the difference between HEC-18 and Beta=2.0 scour depths is about a 3 feet increase, whereas an increase from Beta=2.0 to Beta=2.5 is about an additional 3 feet, in both instances of observed

and predicted data. This indicates that given current reliability equations for scour design, a beta of 2.5 would require nearly five feet difference in height from initial designs. Ghosn and Lagasse (2013) have previously argued that a reliability index of 3 is justifiable based on their analysis of base reliability indices for wind loads and ship collision loads. They further recommend a load factor of 2 that would provide reliability in the range of 3. Our results corroborate their recommendations. We also highlight that the load factors are close to 2 for the future data at a reliability index of 3. This increase translates into an increase in the construction costs due to the additional anticipated depth. One can develop a long-term risk and economic assessment to investigate further the implications of the failure due to scour under climate change. This trade-off is important to consider when assessing the proper standard for scour design under climate change.

Table 4. Reliability index comparison between historical and future events.

	HEC-18	$\beta = 2$	$\beta = 2.5$	$\beta = 3$
	Design Depth (ft)	Base Reliability Index (β)	Depth (ft)	Load Factor
Historical Data	15.58	1.49	18.22	1.17
Future Data		1.12	20.40	1.31

4 CONCLUSIONS

High-velocity flooding is known to be a major threat to highway bridge safety in the United States. Bridge reliability analysis is an important aspect of risk assessment because bridges can serve as critical access points to otherwise hard-to-reach cities and locations. Using data from Schoharie Creek at Prattsville, NY (USGS gauge 1350000) as a case study with over 100-years of peak streamflow data, we looked into various uncertainty models to better analyze the reliability of bridge foundation scour affected by climate change. Through HEC-18 standards on calculating scour depth based on anticipated peak streamflow, reliability curves were developed. Gumbel distribution were the basis for Monte-Carlo simulations along with uncertainties in bridge parameters for computing the probabilities of exceeding any designed scour depth. The reliability curves were then used to determine which design depths would lead to meeting specific values of target reliabilities.

Future research would include a deeper analysis of financial impacts, including better estimations of cost. The repair costs briefly emulated in this work hinge on the assumption of no total-bridge failure from any extreme event, but that is not always the case. By considering total failures as a possibility and developing bridge construction costs, one could develop Pareto trade-off curves to show the trade-off between repair costs, construction costs, and the implication of various reliability levels. This would entail further research into the history of bridges in the U.S. and their performance-based impact because the larger majority of bridges in the U.S. are nearing their design life expectancies.

Positive effects of aligned steel fiber using the electro-magnetic field on flexural behavior of reinforced UHPC beams

Y.M. Xiong, M. Yang, H. Shi & J. Zhao

School of Transportation, Southeast University, Nanjing, China

ABSTRACT: Ultra-High Performance Concrete (UHPC) has ultra-high tensile strength and toughness compared to normal concrete (NC), this advantage often benefits from the higher volume content of steel fibers. Some studies reported that the fibers are randomly distributed in the UHPC matrix, and the effectiveness of fibers is less than 40%. Increasing the fiber content has been proven to be an effective means to enhance the properties of materials, but the problems such as fiber agglomeration and local defects of materials will increase significantly. To solve the above problems, the aligned steel fiber UHPC (ASF-UHPC) was successfully developed by the theory of electromagnetism. The steel fibers aligned in UHPC matrix can optimize the fiber utilization efficiency, improve the material performance and reduce the unit cost. Meanwhile, a series of reinforced ASF-UHPC beams were cast by this method, and the bending test was conducted to study its flexural behavior, failure patterns, and load-deflection relationship. The relative fiber orientation in the reinforced beams was studied by CT 3D image technology, and the difference in flexural properties between ASF-UHPC beam and normal UHPC (N-UHPC) beam was analyzed from the point of view of the orientation of fibers. The research results show that the homogeneous magnetic field can optimize the fiber orientation in reinforced UHPC beams, and the fibers are parallel to the beam, which can improve the flexural load capacity. For instance, when the volumetric ratio of steel fibers is 2%, the flexural capacity of ASF-UHPC beam can be improved by about 24% at a low rebar ratio (0.016). Through the parametric analysis of different fiber volumetric ratios and fiber orientation, the enhancement efficiency of flexural capacity was studied, which provides reference value for improving the mechanical properties of UHPC material, reducing the cost of using UHPC and promoting carbon neutrality.

1 INTRODUCTION

Ultra-high Performance concrete (UHPC) is regarded as the best cementitious composite with superior characteristics such as high strength in compression and tension, ductility, and durability^[1]. However, the unit cost of raw materials always hindered its promotion, it is significant to develop the performance of materials and reduce the unit price. As fiber-reinforced cementitious composites, the mechanical characteristics of traditional concrete are greatly improved by mixing the fiber. The fiber reinforcing effect sourced from the relatively high volume content of steel fibers is the important reason of the superior performance of UHPC, but the enhancement in fiber volume can significantly increase the cost of raw materials^[2].

Therefore, optimizing the spatial state including direction and dosage of fibers is considered as an important means to improve the properties of UHPC materials. The research shows that the orientation and position of steel fibers in conventional steel fiber-reinforced cementing composites (SFRC) are randomly distributed, and the orientation efficiency coefficient in a certain direction is about 40%^[3]. The main way to improve the tensile properties and crack resistance of the cementitious matrix is to align the fibers.

In the present communication, the fiber alignment methods mainly include flow guidance and applied electromagnetic field^[4]. *Stähli P et al.* used the flow-properties of the fresh

(self-compacting) concrete to change the fiber distribution and orientation, which was regarded as the first time in aligning the fibers [5]. Subsequently, many scholars have studied the mechanical properties of UHPC by flow and casting methods, and these methods have drawn some interesting conclusions. *Zhang et al.* improved the device for UHPC casting to align steel fibers, the fibers aligned by self-flowing pouring, and most properties such as initial cracking strength, ultimate flexural strength and corresponding deflection of UHPC are increased significantly [6]. Subsequently, the influence of various flow fields on fiber orientation was analyzed by *Kang et al.*, and the mechanism of orientation through casting was explained [7]. However, it has been found that the UHPC flow will inevitably decay naturally during the flow process due to the conservation of energy, so, the efficiency of orientation will inevitably be unstable [8]. But more importantly, this method cannot be developed in the reinforcement structure with large numbers of densely laid-out steel rebar.

The method of external electromagnetic field to align the steel fibers was proposed by *Mu et. al.*, the paper points out that the orientation efficiency factor of steel fibers in cement mortar is about 0.90 [4]. However, there is still a key problem in the construction of engineering structures with this method, that is, the interference of the steel (such as steel rebar, profile steel, etc.) to the spatial magnetic field distribution. The typical manufacturing program of concrete structures is to first develop the template required for forming, then place the reinforced skeleton, and finally carry out the concrete pouring. Since the rebar is implanted inside the UHPC, the magnetic field must be applied after the UHPC is poured [9]. At this time, the magnetic field in the space region of the structure is bound to be affected by the steel skeleton. Therefore, it is very important to study the internal steel bar for the magnetized directional steel fiber UHPC beam.

The present study focuses on the orientation of steel fibers in freshly cast reinforced UHPC beams, and the possibility of making ASF-UHPC beams by electro-magnetic field. Firstly, the electromagnetic coils used for this study were designed. Then, the orientation of the fibers in the reinforced UHPC beam was scanned using X-ray images. Finally, the 4-point bending test was used to study the flexure mechanical properties of UHPC beams. Four UHPC beams with different fiber volume fractions and magnetic flux density (0mT and 40mT) were tested, and the flexural behaviors were discussed in terms of crack pattern, flexural moment, moment–deflection relationship, and failure mode.

2 DESIGN OF ELECTROMAGNETIC COIL

2.1 *Assembly of electro-magnetic coil*

Electromagnetic coil is a classical equipment used to produce a homogeneous electromagnetic field. A device capable of generating a unidirectional uniform magnetic field was developed, as shown in Figure 1. The test equipment includes a high conductivity copper conductor and a power supply, the wire is coated with a 0.2 mm thick polyether paint, which can effectively avoid short circuit problems and can withstand the high temperature of 120 °C, besides, and the power supply can convert 120V alternating current into 70V direct current. The skeleton of the coil is made of polymethyl methacrylate (PMMA). The PMMA frame has a circular inner space with a diameter of 200mm, which is sufficient to hold the UHPC specimens and ensure the test section is in a uniform magnetic field. During the operation of the electromagnetic coil, the internal magnetic field was measured by a Gauss meter at about 40mT.

3 UHPC BEAM MECHANICAL EXPERIMENT

3.1 *Materials and mixture proportions*

The P II 52.5 Portland cement produced by Nanjing Onoda company in accordance with the Chinese standard GB 175-2007 was used [10]. The mineral admixtures, including silica fume (SF), and fly ash (FA) were used to partially replace cement. The mix proportion of the UHPC dry mixture is summarized in Table 1. The aggregates consist of 80% coarse sand and 20% fine

Figure 1. Details of the electromagnetic equipment.

sand with the particle size range of 380-830 μm and 180-380 μm , respectively. The polycarboxylic acid superplasticizer used in this study was provided by Jiangsu Sobute New Materials Co., Ltd. with a water reduction range of greater than 30% and a solid content of about 40%.

Table 1. Mix proportion of UHPC dry mixture (by weight ratio to cement).

Cementitious material					
Cement	Silica fume	Fly ash	Sand	Water	Superplasticizer
1	0.34	0.28	1.1	0.32	0.018

3.2 UHPC material properties

In order to study the mechanical properties of UHPC materials with different fiber volume fractions of 1.0%, 2.0%. Test up of UHPC material properties tests is shown in Figure 2. Three prismatic specimens (100 mm \times 100mm \times 300 mm) were poured to determine the basic compressive behavior of the materials, and three flexural specimens (100 mm \times 100 mm \times 400mm) were prepared to determine the flexural behavior. All test results are listed in Table 2.

Figure 2. Test up of UHPC material properties tests.

Table 2. Material properties of the UHPC.

Material properties	Batch 1	Batch 2
Volume fraction of fiber (%)	1.0	2.0
Compressive strength (MPa)	105.75	119.56
Flexural strength (MPa)	11.80	18.83

3.3 Details of structural test specimen

In this test, the experimental program included tests on a total of 4 beam specimens are shown in Table 3, the all beams have rectangular cross sections of 100 mm × 100mm and length of 515 mm. The volume capacity of the electromagnetic coil is fixed, and the size of the beams is selected according to these conditions. It must be noted that the beam width was designed to satisfy the requirement that the adjacent longitudinal rebar spacing was greater than 1.5 times the steel fiber length, and the thickness of structural protective layer fulfills the code [11]. The beams were reinforced by Hot rolled ribbed steel reinforcements graded as HRB400, The mechanical properties of the steel reinforcement are shown in Table 4. Because the steel fibers can greatly improve the tensile strength of the cement matrix composites, all test beams were designed to have lower reinforcement ratios (less than or equal to 2%), the longitudinal reinforcement ratio ρ_s calculated by the equation of A_s/bd were set as 1.6 %. Since the oriented fiber technology increases fiber utilization efficiency, it is more meaningful to seek for mechanical properties with lower fiber content, the Volume fractions of fiber were set as 1.0 % and 2.0 %, respectively.

Beam specimens are divided into ASF-UHPC beam and N-UHPC studies. ASF-UHPC beam needs to be placed in the electromagnetic coil when the magnetic flux density is 40mT, the specimen number named M40. N-UHPC beam placed away from the electromagnetic coil, the ambient magnetic flux density is about 0mT, so specimen number named M0.

Table 3. Parameters used in the experimental program.

Specimen	F10M0	F10M40	F20M0	F20M40
Volume fraction of fiber (%)		1.0		2.0
Magnetic field intensity (mT)	0	40	0	40

Table 4. Properties of steel reinforcement bars.

Diameter d_s (mm)	Area A_{s1} (mm ²)	Elastic modulus E_s (GPa)	Yield strain ϵ_s (mm)	Yield strength f_y (MPa)	Ultimate strength σ_{ul} (MPa)
10	78.5	206.4	2348.7	483.6	640.2

3.4 The fabrication of the experimental beam

The production process of the UHPC experimental beams is as follows. Firstly, the assembly of the UHPC beam assembly is shown in Figure 3(a). A square groove made of ABS plastic was used as a mold for test beam casting. A pair of 1mm thick PVC plates fitted precisely to the dead end, and the spatial position of the steel bars are precisely controlled by means of preset scale lines.

Next, a forced mixer is used to mix the UHPC (Figure 3(b)). In order to avoid this unstable effect, the casting process adopts uniform casting along the long direction of the UHPC beam. The steel fibers in the UHPC matrix are closer to random distribution.

After finishing the UHPC casting process, a test beam was placed in the electromagnetic coil (Figure 1) to be magnetized while the same beam was placed in an ordinary environment, the time was controlled to 120s in this process. Then, all specimens were covered with preservative film and cured at curing chamber (20°C±2°C, HR≥95%) for 48 h. Finally, the specimens were cured in steam curing equipment (90°C±2°C, HR≥95%). After steam curing for 48 h, the specimens were gently cooled to ambient temperature for testing.

3.5 Loading procedures of beams

A four-point bending test with a pure bending length of 150 mm was performed on the UHPC beams, as shown in Figure 4. To obtain the deformation of the UHPC beams, three linear variable displacement transducers were arranged at the mid-span and supporting positions.

Figure 3. Details of test program (unit: mm).

In the initial loading stage, 5 kN was used as the first loading interval until the cracking load was reached. Then, 10kN was used as the second loading interval (adjusted according to the predicted bearing capacity). When the applied load reached 90% of the predicted ultimate load, the displacement in the mid-span was used to control the loading rate. The test ended once the load value was lower than 85% of the ultimate load. During the loading process, every loading stage was held for 5 min and the crack distribution, load, deflections, and strains were recorded simultaneously. The testing machine in laboratory controlled by an electrohydraulic servo loading system has sufficient accuracy to complete the test.

Figure 4. Details of test program (unit: mm).

4 RESULTS AND DISCUSSIONS

4.1 Magnetic orientation of fibers in UHPC

Use The distribution of fibers in UHPC detected by CT-ray is called the gold standard in this field ^[12]. In order to ensure the characterization accuracy of fiber distribution in UHPC, the measurement method should not be affected by the wall. In this study, the sample (100 mm × 100 mm × 50 mm) was cut to test the fiber distribution, as shown in Figure 5. The position of the rebar and the distribution of steel fibers can be seen in the section diagram. The cross-section of the steel bar looks regular, and the cross-section of the steel fiber is like a small dot, indicating that these components are vertically distributed with the cross-section of the sample.

The Micro-focused Computed Tomography (Y.CT Precision S) produced by YXLON was used to obtain the microstructure information of the sample. The identification of different materials from CT images is based on the density of the materials. The higher the density of the material, the higher the grayscale of the CT image. Because the density of steel fiber is much higher than other materials, so the image of steel fiber is easy to be extracted. The distribution features of steel fibers as shown in Figure 6.

The fiber distribution in the UHPC sample obtained by the classical concrete pouring method is shown in Figure 6(a), the reconstruction and qualitative visualization of 3D images

Figure 5. Sampling location of test sample (unit: mm).

Figure 6. Fiber orientation in UHPC.

from micro-CT were reported by *Liu et al* [12]. As can be seen from the Figure 6(b), the fibers are uniformly distributed in the cement matrix, and the vector direction of the fibers is not clear. In bridge engineering, the direction of principal stress is often regular, and the random distribution of fibers has lower utilization efficiency.

In this study, the fiber distribution in the parts of the sampling location is shown in Figure 6 (b). It can be seen that the distribution characteristics of fibers in UHPC matrix. The two thicker parts represent the rebar bars in the picture, while the remaining small lines are the steel fibers. Obviously, the fibers in the UHPC matrix are distributed uniformly. It indicates that the orientation of the steel fiber in UHPC matrix is the same as that of the steel rebar, so it can coordinate with the steel bar to resist the tensile stress.

4.2 Load–deflection relationship and crack pattern

Figure 7 shows the four-point flexural test results of the reinforced UHPC beams. The left side of the figure shows the load mid-span deflection curve with different fiber volume fractions, and the deflection measurement has corrected the deformation of the test system. The corresponding mid-span cracking failure mode of the test beam is displayed on the right side of the figure. The direction of fracture development and the area of the largest cracks are in the pure bending location of the beam, which indicate that the test results are relatively reliable. With the increase of fiber content, the expression of the strain-hardening behavior of the material was higher. Although the bottom of the beam has narrow cracks at many positions during the loading, a large single crack is basically formed in the weak area.

The mechanical properties of UHPC beams structure are qualitatively analyzed by the load-deflection curve of the whole process, some key data are listed in Table 5. At the beginning of loading, the UHPC beam is in the elastic stage. The young's modulus of each beam can be

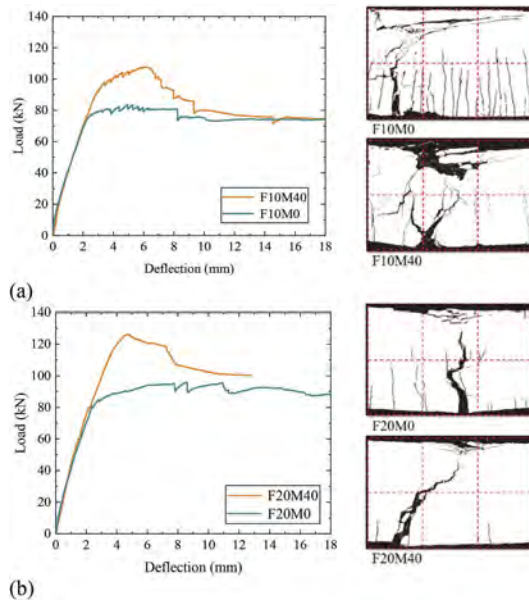

Figure 7. Load–deflection relationships and crack patterns.

deduced by applying the Euler-Bernoulli beam theory, Comparing classical UHPC beam with aligned steel fiber UHPC beam, the initial Young's modulus of these specimens is not much different. As can be seen from Table 5, aligning steel fibers provide approximately 20% (average) strength improvement over classical UHPC reinforced beams. Comparing the test results of 1% and 2% fiber volume content, it is not difficult to see that the strength index of the 1% directional steel fiber test beam (F10M40) is higher than the of 2% classical test beam (F20M0). That means that the method could halve the amount of steel fiber needed for the same mechanical performance material. So, the fiber alignment process significantly increased the yield load and peak load of each specimen, this could reduce the cost of UHPC and help spread green prefabricated UHPC structures.

Table 5. Summary of flexural test results for beams.

Name	Fiber volume fraction (%)	Yielding state		Peak state			
		P_y (kN)	Increase ratio (%)	D_y (mm)	P_p (kN)	Increase ratio (%)	D_p (mm)
F10M0	1.0	76.21		2.44	83.52		4.94
F10M40	1.0	94.53	19.4	3.15	107.77	22.5	6.10

F20M40	2.0	113.40		3.62	126.24		4.74

* P_y = load at steel rebar yield, D_y = deflection at steel rebar yield, P_p = peak load, D_p = deflection at the peak.

5 CONCLUSIONS

This study starts from the aligning steel fibers using the electromagnetic field, the distribution characteristics of steel fibers in reinforced beams were studied, and the conclusions follow:

1. It is an effective and feasible method to align the steel fibers of UHPC reinforced beam with the magnetic field, the steel fibers can still keep parallel to the magnetic lines in the mid-span of the beam. This method can effectively drive the steel fibers in the UHPC reinforced beam parallel to the long direction of the beam, and improve the utilization efficiency of steel fibers in the UHPC matrix.
2. In reinforced beams, the steel fibers parallel to the stress direction in the mid-span of the beam, which can enhance the resistance to bending and tensile properties. Compared with the traditional UHPC reinforced beams, the oriented steel fibers can well strengthen the yield load and peak load of the beams.
3. Aligning the steel fibers by magnetic field has a large application space in UHPC structure and structure manufacturing under factory conditions. It can greatly reduce the unit cost and improve the structural carrying capacity without increasing the fiber content. This green manufacturing method using electro-magnetic field devices can be recycled and provide objective value for global carbon neutrality.

ABSTRACT: Transportation Infrastructure systems are recognized as essential for economic development, territorial cohesion, and social transformation. Unfortunately, some of the key structural components of this massive system, such as bridges, are rapidly ageing, while load conditions are exceeding those for which these systems initially envisaged as they are subjected to different hazards, such as natural events or new man-made phenomena. Given that a substantial portion of the current bridge stock was constructed many decades ago, degradation phenomena and a rise in service conditions greater than those employed in the original design may have contributed to reducing the reliability level, if countermeasures are not adopted. Therefore, the assessment of the current state and the prediction of the future condition of Transportation Infrastructure, and their protection against external hazards, turn out to be essential. This contribution firstly focused on an in-depth study of the role of structural health monitoring in improving the structural resilience of transportation infrastructure and consequently its life-cycle. Subsequently, a practical example is provided to highlight the role of SHM toward structural resilience improvement for an Italian common transport infrastructure.

1 INTRODUCTION

With respect to a variety of causes, including corrosion brought on by severe weather conditions and fatigue damage, steel structures are vulnerable to time-dependent degradation and aging effects. Due to the extensive usage of steel bridges in many nations across the globe, the economic implications of these consequences are especially pertinent. Steel girders that are exposed to sea water and atmospheric corrosion deteriorate over time. In addition to other things, corrosion reduces the original thickness of connections and profiles, such as the web and flanges of steel I-girders. The damage affects the element's and section's structural characteristics owing to thickness decreases brought on by corrosion penetration (e.g. strength and stiffness) (Biondini & Frangopol 2016).

The issue of life-cycle of bridges with respect to degradation phenomena, such as corrosion and fatigue, has been investigated in the literature. The cumulative seismic damage and corrosion effects on bridges' life-cycle is deepened by Kumar et al. (2009) highlighting how the the cumulative seismic damage affects the structural reliability over time more than corrosion. The issue of corrosion deterioration effects on the seismic response of RC bridge piers has been also studied by Bartolozzi et al. (2022). The role played by bonding in the degradation of the seismic capacity has been highlighted.

With specific respect to transport infrastructure management, Kim et al. (2013) proposes a framework for structural inspection and maintenance planning, highlighting how the dependence between the appropriate maintenance and the damage degree. Aspects related to analysis and decision-making for assessing bridge life-cycle performance and cost have been deepened in Frangopol et al. (2017), considering also climate change and structural health monitoring. Life-cycle reliability, risk and resilience-based design of transportation infrastructures have been studied by Akiyama et al. (2020), highlighting the importance of studying both independent and interacting hazards to assess the bridge reliability (e.g. earthquake and tsunami, or landslide).

The relationship between structural health monitoring (SHM) and the life-cycle of bridges has been discussed in the literature, e.g. in the review work by Biondini & Frangopol (2016). Focusing on railway bridges, their reliability assessment and the role played by SHM has been studied by Vagnoli et al. (2018), comparing different types of structural health monitoring methods (e.g. model, non-model).

Despite the improvements in the knowledge provided by the existing literature, the impact of SHM in the life-cycle of transport infrastructures would need a further in-depth study. To this end, this contribution is offered; specifically to investigate how SHM can positively influence the resilience and, consequently, the life-cycle of bridge structures.

The next section brings together some aspects related to SHM toward structural resilience improvement. The following one provides an application example to highlight the relationship between structural health monitoring, resilience, and life-cycle.

2 SHM CONTRIBUTION TO STRUCTURAL RESILIENCE AND LIFE-CYCLE

2.1 *Diagnosis and prognosis*

Damage diagnosis enables decision-makers to be informed about the various forms of deterioration in civil engineering structures and the proper course of action to take in response to dangerous structural circumstances. Damage detection, localisation, quantification, and prognosis are the core stages of structural health monitoring (SHM) for damage diagnosis. The four stages may be described in more depth as follows:

- Phase 1: Determining if the building has been damaged.
- Phase 2: Phase 1 plus determining the geometric location of the damage.
- Phase 3 comprises Phase 2 and a calculation of the damage intensity.
- Phase 3 plus the assessment of the structure's remaining service life is Phase 4.

The first two steps serve as the primary pillars of the most used vibration-based damage diagnosis approaches (without the use of structural models). Phase 3 damage diagnosis may sometimes be accomplished by integrating vibration-based methods with a structural model. Phase 4 is still a difficult engineering challenge that needs interdisciplinary and predictive modelling skills, but it might provide enormous safety and financial advantages to the management of structures and infrastructure (Faravelli & Casciati 2004; Cheung et al. 2008; Domaneschi et al. 2017; Morgese et al. 2021).

A review of the literature on the many methods for spotting damage and keeping track of a structure's health based on changes in its observed dynamic characteristics is given by Doebling et al. in 1996. They are based on

- modifying modal features,
- altering dynamic flexibility,
- updating structural matrices while undergoing restricted optimization,
- nonlinear approaches,
- and neural network-based techniques.

Many of the techniques rely on a dataset of the undamaged structure as a baseline, while others need access to a comprehensive FEM of the structure to get more understanding and access to higher levels of data (e.g. quantification). The number of sensors in an SHM system has expanded over the last ten years due to significant advancements in growing processing

power and sensing technology, which in turn has led to an increase in the amount of data gathered. Advanced processing techniques are required to be used to handle this massive volume of data to transform the heterogeneous, multi-source data into various sorts of particular indications and enable efficient inspection, maintenance, and management choices. As a result, the scientific community has seen an increase in the usage of automated algorithms for data management, calculation, and structural (such as damage) detection.

Machine learning techniques, particularly deep learning algorithms, have been more useful and extensively used in vibration-based structural damage diagnostics because of their elegant performance and frequent, exacting correctness. The first involves data preparation (human involvement) to extract certain features or qualities, in contrast to the second, which may find a straight mapping from the initial inputs to the final outputs without the need for feature extraction. Deep learning is thus effectively used to handle massive volumes of data (big data) for many purposes (Avci et al. 2021).

In addition to Deep Learning, a combination of Wavelet and other time-frequency analysis and feature extraction techniques have been recently developed and applied for the processing of big data from sensor networks for the health assessment of bridge structures (Silik et al. 2022; Ghiasi et al. 2020).

2.2 *Structural resilience and dimensions*

Robustness, resourcefulness, redundancy, and rapidity are the four main components, or dimensions, of resilience, according to MCEER researchers (Bruneau & Reinhorn 2007). In detail: (1) Robustness refers to a structure's or an element's capacity to tolerate a certain amount of demand (such as damage) while retaining its usual degree of usefulness. Alternatively, one may refer to it as the idea of damage tolerance. (2) Redundancy, for instance, of load-bearing components: the capacity to create alternate load-supporting paths after the deterioration of the primary parts has a place (i.e., original elements that are replaceable); (3) Resourcefulness: The capacity to recognize problems, establish priorities, and gather materials when conditions pose a risk to the stability of the structure or one of its components; (4) Rapidity: The capacity to prioritize interventions and complete them as soon as possible to minimize losses, restore functioning, and stop additional interruptions.

There have been several studies published to help us understand structural resilience in buildings. The Resilience approach proposed by Cimellaro et al. (2010) for a condensed recovery plan is one example. The notion of immediate resilience is proposed in Domaneschi & Martinelli (2016) as being related to the automated function of certain components to make up for local out-of-services. Structural resilience has also been explored in many areas.

2.3 *SHM toward structural resilience*

The relationship between resilience and emerging digital technologies including the structure and infrastructure monitoring is a topic that has attracted the interest of the scientific community worldwide in recent years (Domaneschi et al. 2021; Wu et al. 2020).

Structural resilience is herein assumed as a Performance Indicator for life-cycle considerations of transport infrastructures accordingly with Biondini & Frangopol (2016). Following the identification of the four distinct SHM levels and the Resilience dimensions, a relationship between them can be drawn to show how the four SHM phases may be used as effective tools and methods for the assessment and enhancement of the Resilience dimensions (Domaneschi & Cucuzza 2023). Figure 1 reports the scheme with the conceptual connection between SHM phases and resilience dimensions.

If Damage Detection is taken into account as the initial level of the SHM, the information presented is the existence or absence of structural damage. It is impossible to provide any information about the location or severity of the damage. In this condition, the redundancy dimension of the same structure is directly related to the damaged state of the structure.

A redundant structure proves to be safer than a statically determined one, regardless of the sort of damage. Due to the structure's inherent lack of redundancy, the experience of the

Polcevera's Viaduct in Italy demonstrates that the issue of corrosion of the steel strands inside the concrete stays reasonably reflected the primary cause of the disaster (Domaneschi et al. 2021). For this reason, to implement the appropriate countermeasures, such as emergency measures (e.g. evacuation, traffic reduction, shutting of critical facilities), the simplest information on the presence of diseases in the structures through SHM techniques must be associated with the grade of redundancy of the structure.

Damage Localization, the second level of SHM, is related to the Rapidity dimension of resilience. The speed of the intervention and recovery stages is critical after the pathology has been identified and any localized or diffuse damage has been localized. In this situation, the SHM system may aid in decision-making to manage the emergency effectively while accelerating interventions that follow a prioritized plan.

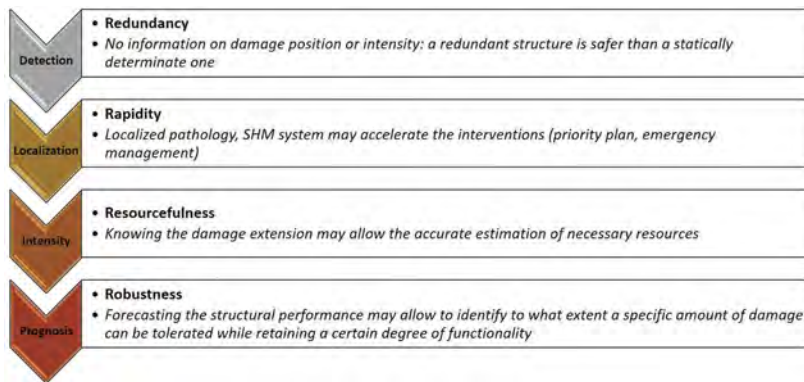

Figure 1. SHM toward structural resilience.

It is also possible to identify a connection between the Resourcefulness dimension and the third degree of Damage Intensity. The organizing and recovery phases are successfully supported by knowledge of the extent of the damage after disruptions, enabling the precise assessment of the resources that will be required.

The Prognosis level of SHM, the fourth level, is connected to the Robustness attribute of resilience. Given an evaluation of the structure's present state, the estimation of the structure's remaining life is the key subject. This SHM level attempts to predict the structural performance to withstand a given level of damage while maintaining its normal level of functionality, offering an indirect measure of structural robustness.

Thus, in light of this description and the relationships highlighted, the significance of implementing monitoring systems on structures and infrastructure to improve their resilience and safety, thereby extending their life cycle, becomes evident.

2.4 SHM toward resilience, quantitative aspects: Functionality and indices

The effect of degradation on the infrastructure is to affect and reduce its functionality. This is in association with loading conditions acting on the infrastructure, be they service actions or shocks such as severe weather conditions or medium to high intensity earthquakes. The reduction in functionality is the benchmark for calculating the infrastructure resilience (Vishwanath & Banerjee 2019).

Being able to take timely countermeasures to maintain the infrastructure before degradation significantly reduces functionality and thus becomes a critically important issue. SHM actions are intended in this direction, as they enable the restoration of functionality and thus improve infrastructure resilience. Depending on the level of SHM that can be developed on the infrastructure (from damage detection to prognosis), it will be possible to affect and improve resilience at different levels.

The detection of damage (SHM Phase 1) has a different weight on the further location information about the maintenance and functionality restoration of the infrastructure (Figure 2). And therefore, resilience R will also be positively affected by a more comprehensive SHM process that includes not only simple information about the presence of damage but also its location and quantification, to improve the speed of intervention and prepare resources for restoration as quickly as possible. A linear restoration curve has been shown in the figure for simplicity.

Moreover, Figure 2 highlights also the information related to the residual service life of the infrastructure, provided by the last and more complex SHM Phase related to predictive scenarios.

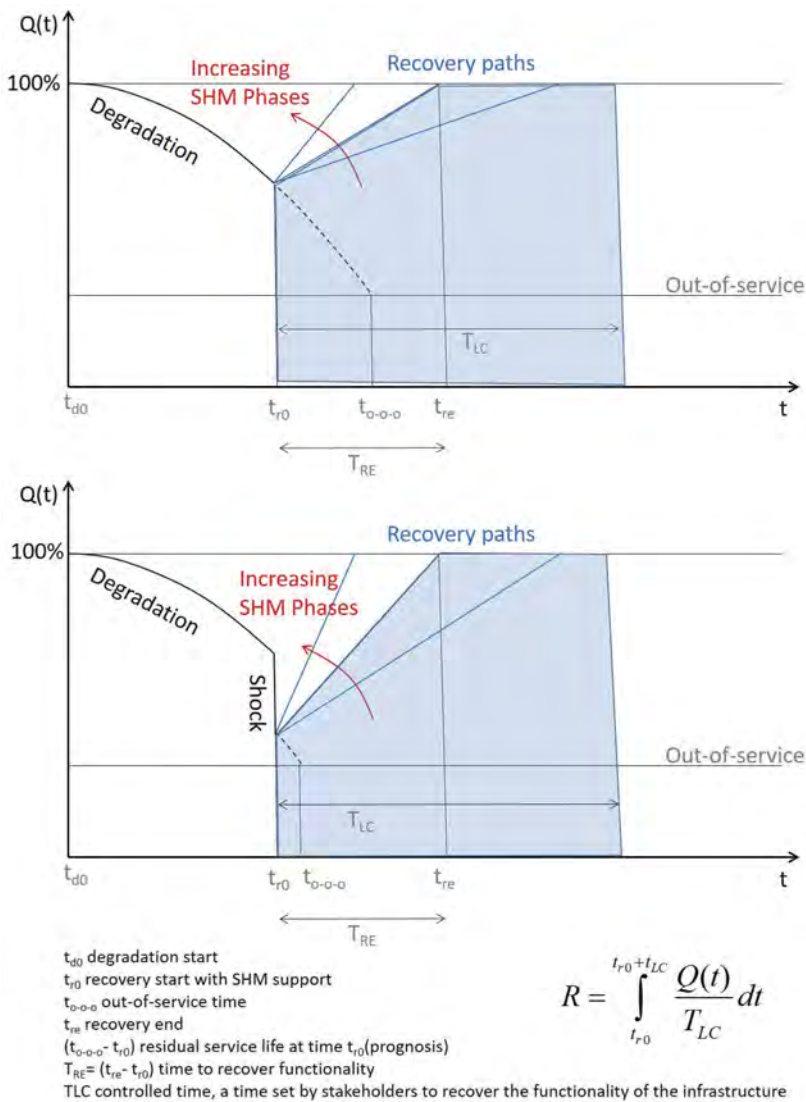

Figure 2. Resilience function: degradation only (top), and degradation with shock (bottom).

3 APPLICATION

This section provides an application example on resilience assessment of comparison between one condition without and another with a monitoring system for a reinforced concrete (RC) and prestressed concrete (PC) girder viaduct in Italy that is made up of 10 spans that are each 40 meters long. On Italian territory, this is a very frequent case study. It is a highway viaduct with three transit lanes that has been deteriorating for 20 years, starting from the time it was put into service, due to phenomena like, for instance, corrosion. A shock has been also considered, such as a significant earthquake that happened in the 20th year of the bridge's operation life.

Specialists and administrators with decades of experience in Italy's road infrastructure were consulted to quantify some useful parameters for the resilience evaluations presented in this section.

It is worth underlining that the present study is not focused on assessing the origin or the evolution of degradation; moreover, it is assumed that the monitoring system is able to detect, locate, and reasonably quantify the intensity of the damage. Figure 3 presents the functionality curves, representative of the two case studies under investigation, adopted for the present case study.

During the first 20 years after the viaduct is put into service, a reasonable reduction (roughly from 100% to 92%) in functionality due to various degradation phenomena in the structural components or, for example, even in the asphalt surface of the road, can be observed. In the 20th year an additional localized disturbance is superimposed, represented for example by an earthquake event that punctually and drastically reduces the functionality to 30% (i.e., a smaller transit lane in order to control and limit loads on the damaged infrastructure - one reduced transit lane open over three in total).

From this point, two different paths are highlighted: one represented by the infrastructure without a monitoring and damage detection system and the other where there is a monitoring system that can also locate and assess the intensity of damage with reasonable accuracy.

Both paths highlight common functionality recovery steps that can be represented by the following restoration actions: (i) opening of an alternative route outside the highway on district roads (37% functionality), (ii) widening of the already active highway lane to all vehicles (50% functionality), (iii) opening of a second highway lane (70% functionality), (iv) full opening of the infrastructure's lanes to the vehicle (95% functionality).

However, the presence of the monitoring system makes it possible to reduce the development time for some of the characteristic steps in the process of restoring functionality. In particular, it is reasonably possible to reduce the time for inspection and damage assessment from 2 months to 1 month.

The designer's choice (1 month) doesn't change, while the technical and economic feasibility design benefits from the more detailed and timely information provided by the implemented SHM system (estimated from 2 months to 1 month).

The administrative phase of publication of the call for bids did not change (1 month), while the final and executive design reasonably reduces the timelines from 2 to 1 month, again based on the quality of the information provided by the SHM system.

Finally, the intervention phase on the supports and structural components has also been speeded up from an estimated 10 months with the intervention of two teams working independently and simultaneously on the infrastructure to 6 months total.

The last phase of testing, estimated at 2 months, is assumed unchanged.

As a result of the considerations above, the resilience of the infrastructure for the case under consideration increases from the value of 0.57, without a monitoring system, to 0.71.

4 CONCLUSIONS

The research conducted in this paper delved into the relationship between structural health monitoring (SHM) and resilience, with a focus on how an efficient monitoring system can contribute to the improvement of structural resilience. Through the present exploration, it has

become apparent that monitoring activities have the potential to enhance the safety and resilience of structures and infrastructure, thereby prolonging their life cycle.

The development of a viaduct application has allowed to showcase the practical demonstration of the concepts discussed in this paper. By showing how monitoring activities can provide early warning signs of potential damage and enable rapid response to mitigate risks, it has been highlighted how an efficient monitoring system can be an essential tool in promoting the resilience of structures and infrastructure.

The analysis has also revealed that the effectiveness of a monitoring system in improving the resilience of structures and infrastructure is directly related to its ability to analyze damage-related factors and their evolution with increasing complexity. This requires not only the acquisition of data but also the capacity to interpret it and to identify the potential causes of damage, enabling preventative measures to be implemented before severe damage occurs.

Figure 3. Viaduct application, resilience assessment: w/o and with SHM.

In conclusion, this research has highlighted the crucial role that monitoring activities can play in improving the resilience and safety of structures and infrastructure. By enhancing the capacity of monitoring systems to analyze damage-related factors with increasing depth and complexity, a more comprehensive understanding of structural health and enable the development of targeted interventions to mitigate risks and promote resilience can be provided.

ABSTRACT: Transportation Infrastructure Systems are recognized as essential for economic development, territorial cohesion, and social transformation. Due to the increasing age of bridges, and given that a large part of the existing stock was built several decades ago, some of their key structural components, such as bridges, are getting older while loading conditions are often exceeding those initially envisaged as they are subjected to harsher natural events and growing levels of traffic. The increasing age of bridges, the deterioration phenomena and the increase in service conditions, exceeding those used in the initial design, contribute to reduce their reliability level. This contribution firstly explores the role that structural control can play, then it proposes a suitable measure for the formalization of this role within the life-cycle assessment of bridges and overcrossing structures. The effects of structural control are evaluated for the case study of a cable-supported bridge subjected to fatigue deterioration due to wind actions.

1 INTRODUCTION

Management of the life-cycle of products and components has received a great deal of attention starting from the first works that appeared at the half of the last century (SAIC 2006), evolving into a probabilistic approach (see the recent review in Biondini & Frangopol 2016 for applications to structures and infrastructures). In the field of structural engineering, a proper life-cycle assessment of a structure involves taking into account several time-variant aspects, ranging from the aging of the structure itself, to the evolution of the loading and the effects of maintenance and repair interventions. From the economic point of view, besides the cost of construction and maintenance of the structure, other aspects, often of greater importance, are also of interest, such as the social costs associated with the presence of an infrastructure and those related to its loss of functionality.

Transportation infrastructure systems are recognized as essential for an area's economic development, territorial cohesion, and social transformation. This opens up the issue of their aging. In many cases, some of their key structural components, such as bridges, are getting closer to their intended life while climate changes and society evolution are driving the loading conditions to exceed those initially envisaged at the design stage. In such scenario they can be indeed subjected to increasing hazards, such as natural events or manmade phenomena, and larger levels of traffic loads. Due to the increasing age of bridges, and given that a large part of the existing stock was built several decades ago (ASCE 2013), the deterioration phenomena and the increase in service condition loading, larger than those used in the initial design, might contribute to reducing the reliability level if countermeasures are not promptly taken. Therefore, the assessment of the current

state and the prediction of the future condition of bridges, as well as their protection against external hazards, has become an essential management challenge that needs to be addressed.

This work aims at contributing toward this practical goal by firstly exploring a suitable measure for the formalization of the role of structural control systems useful for the life-cycle assessment of bridges, and of overcrossing structures; subsequently, by evaluating the effects of structural control with reference to the case study of a cable-supported bridge subjected to fatigue deterioration due to wind action. The concepts explored are not restricted only to bridge structure, and can be applied, in principle, also to other structurally controlled structures.

Figure 1. Graphical representation of the possible effects of Structural Control on the Functionality function: (a) in case no extreme events will happen; (b) in case of a single extreme event at time t_{r0} .

2 FORMALIZATION OF STRUCTURAL CONTROL EFFECTS ON THE LIFE CYCLE OF OF STRUCTURES

Structural Control refers to the application of techniques, such as active and passive control systems, to manage the structural behavior of a structure. The use of such techniques can have a significant impact on the life cycle analysis of a structure.

An important aspect of a Life-Cycle Assessment (LCA) is the ability to assess the system performance considering the aging and the deterioration of a system. This capability is a key constituent of LCA since the very purpose of an LCA exercise is usually to project into the future the life of a structure and assess the related costs.

Since Structural Control is able both to reduce the extreme values of the loading effects, as well as their variances (e.g. Casciati et al 2012), it will reduce damage, and hence it will extend the service life of the structure: time t_{o-o-o} (out-of-service time) in Figure 1a. Time t_{d0} , which is the time at which damage will start, can be, for practical purposes, assumed as the time at which the structure has been completed. The other marked time instants in Figure 1 make reference at the case in which a damaging extreme event will happen. They are: t_{re} = the time at end of recovery phase, $(t_{o-o-o} - t_{r0})$ = the residual service life after a shock at time t_{r0} , $T_{RE} = (t_{re} - t_{r0})$ = the time interval to recover full functionality, T_{LC} = a time interval limit set by the stakeholders to recover the functionality of the infrastructure.

In case of the occurrence of an extreme event at time t_{r0} Structural Control will have several positive effects since it will: a) reduce the structural deterioration up to time t_{r0} ; b) reduce the final deteriorated state of the structure after the extreme event occurs, since the structure will be found in a better shape in the controlled configuration with respect to the uncontrolled one; c) speed up the recovery rate, and shorten the recovery time T_{RE} of the structure, since being the structure in a better shape before the damaging event it will be less damaged after the occurrence of the extreme event and easier to repair. All these aspects will impact the Life-Cycle Assessment of the structure.

An indicator aimed to provide a comprehensive description of the time evolution of available structural resources, which includes besides deterioration also the possible occurrence of local and global failures, is the Functionality function $Q(t)$, which is at the base of the measure R of Resilience (see, e.g. Cimellaro et al. 2010). According to well known the definition in Manyena (2006), Resilience is the “intrinsic capacity of a system, community or society predisposed to a shock or stress to adapt and survive by changing its non-essential attributes and rebuilding itself”.

In essence, Resilience is related to the capability of a system to withstand the effects of extreme events and to recover efficiently the original performance and functionality (Bruneau et al. 2003). A well know measure R of Resilience is to defined R as the normalized area underneath the functionality function $Q(t)$ of a system (Figure 1):

$$R = \left(\frac{1}{T_{LC}} \right) \cdot \int_{t_{r0}}^{t_{r0}+T_{LC}} Q(t) dt \quad (1)$$

In Equation 1 the functionality function $Q(t)$ is a dimensionless function of time t that describes the level of functionality possessed by the structure, to a value of $Q(t) = 1$ it corresponds no loss-of-function for the system, while to a suitable small value of $Q(t)$, not necessarily zero if only a Serviceability Limit State has been exceeded, it corresponds the out-of-service of the system or of the structure; t_{r0} is the time at which recovery starts after a damaging event; T_{LC} is a time set by the stakeholders to recover the functionality of the infrastructure.

Aiming at applications within a Life Cycle Assessment procedure, in this work an extended version of the Resilience measure R is proposed which includes in Equation 1 the effects of Structural Control.

In the proposed definition the normalized area subtended by the functionality function $Q(t)$ is that from the time t_{d0} at which structural deterioration starts (see Figure 1b) to include all the life of the structure:

$$R = \left(\frac{1}{(t_{r0} - t_{d0} + T_{LC})} \right) \cdot \int_{t_{d0}}^{t_{r0} + T_{LC}} Q(t) dt \quad (2)$$

Since it is very difficult to precisely define the part of curve $Q(t)$ when a damaging process is in action, the curves in Figure 1 are only indicative. Note, however, that previous experience (Martinelli & Domaneschi 2017) pointed out that the specific shape of deterioration part of the functionality function $Q(t)$ is not changed by Structural Control, but the curve is made less steep as structural control will reduce damages and structural degrade.

3 APPLICATION OF STRUCTURAL CONTROL TO WIND-INDUCED FATIGUE LIFE

Long-span suspension bridges must satisfy reliability and safety requirements. Amongst these, Eurocode 3 (C.E.N. 2004) lists fatigue during the intended life of the structure.

Indeed, wind-induced motion has been recognized (Chen & Cai 2007, Seo & Caracoglia 2013, Seo & Caracoglia 2015, Sacconi et al. 2021, Zheng & Li 2022) as an important problem for long-span bridges, and cyclic loading stemming from wind fluid-structure interaction is regarded as an important issue.

The effects of Structural Control on the fatigue life of a suspension bridge under wind loading have been studied in Martinelli & Domaneschi (2017) with reference to a numerical model of a suspension bridge inspired by the Shimotsui-Seto Bridge, in Japan. The bridge model (Figure 2) has a total length of 1400 m, a span between the towers of 940 m, a towers height of 149 m, and a vertical distance of 31 m from the main girder to the foundations. The bridge has a steel truss main girder of rectangular transversal section of 30x13 m, width and thickness respectively. A complete description and validation of the model can be found in Domaneschi & Martinelli (2013a).

In the work by Martinelli & Domaneschi (2017), the standard deviation of the internal forces is assumed as a valuable parameter for evaluating fatigue effects in the main girder following general approaches of the existent literature, and typical structural details of the deck, having opposite characteristics in relation to fatigue life, are analyzed for fatigue failure using the stresses derived from the value of the wind induced bending moment in the main girder of the bridge. Prevention of fatigue damage is a complex problem that requires the identification and characterization of the structural element most prone to fatigue effects. Typical components suffering from fatigue are the connections between members of the structure, as the stresses are typically higher at these locations. The stress components in the connections depend, besides on the time history of the loading, also on the specific geometry, technology and typology of the connection itself.

Figure 2. General view of the bridge model.

In the work by Martinelli & Domaneschi (2017) the representation of wind forces is based on the modeling of the drag force in time domain, as a completely non-linear force within the quasi-steady theory. For the lift force and the aerodynamic moment, instead, it is adopted a linearized form of the aerodynamic force and moment, with corrections for frequency-dependent loading using indicial functions. Details on the modelling of the wind loading, accounting for turbulence, can be found in Domaneschi & Martinelli (2013b).

All the wind interaction forces obviously depend on the wind velocity. The intensity of the wind loading is characterized through a representative statistical description of the average wind velocity as set forth in the IEC 61400-1 (2005) international standard, as this norm focuses specifically on applications that require a reliable statistics of the wind velocity.

The wind velocity mean value V over a time period of 10 min is assumed to follow the Rayleigh distribution, given as:

$$P_V(V_0) = 1 - \exp\left[-\pi\left(1 - \frac{V_0}{2V_a}\right)^2\right] \quad (3)$$

In Equation 3 $P_V(V_0)$ denotes the cumulative probability function for V (the probability that $V < V_0$) while V_a is the yearly average value of V .

This yearly average wind velocity value is derived from the value, V_{50} , relative to the extreme value, that has a recurrence period of 50 years, of the 10 min average wind speed. The relation between V_a and V_{50} adopted is the one proposed in IEC 61400-1: $V_a = 0.2 V_{50}$. With $V_{50} = 39.09$ m/s.

The value of V_{50} has been derived from the one, V_{150} , relative to the extreme 10 minutes mean velocity having a recurrence period of 150 years that was taken from the design specification for the bridge under study: $V_{150} = 43$ m/s.

The probability density function of the average 10 min wind velocity will be used in the following to describe the statistics of the wind loading for evaluating the occurrence of fatigue damage in selected structural details of the bridge deck.

In Martinelli & Domaneschi (2017) two hypothetical different details, having opposite characteristics in relation to fatigue life, were considered. A nominal stress component S was derived at a critical position in a deck connection from the lateral bending moment, M_y , in the girder on the base of the following linear law:

$$S = b_1 b_2 M_y \quad (4)$$

In Equation 4 the proportionality factor b_1 summarizes the effects of the deck connection details and of the girder section properties, while the factor b_2 scales the intensity of the input. Dependence on the other components of the main girder's internal forces is neglected.

A simple damage accumulation strategy, of the Miner's type (Committee on Fatigue and Fracture Reliability of the Committee on Structural Safety and Reliability of the Structural Division, American Society of Civil Engineers 1992) is then used to find the resulting effects of the constant amplitude cycles:

$$D = \sum_{i=1}^d D_{i,S_i} = \sum_{i=1}^d \frac{n_{i,S_i}}{N_{i,S_i}} \quad (5)$$

In Equation 5 D is the cumulated damage over the life of the structure, D_{i,S_i} is the fraction of damage suffered by the material due to a number n_{i,S_i} of cycles at stress level S_i while N_{i,S_i} is the fatigue strength (i.e. the number of cycles to failure at stress level S_i given by a so-called S-N curves). The S-N curves herein adopted are those reported in Eurocode 3 (fatigue) (C.E.N. 2004), and failure is assumed to occur when $D = 1$.

To better frame the impact of fatigue effects, the structural details studied were at the extremes of the sensitivity to fatigue effects among the details for which Eurocode 3 (fatigue) (C.E.N. 2004) gives direct guidance. The more sensitive detail is characterized by a constant stress amplitude $\Delta\sigma_C = 36$ MPa at $N = 2$ million cycles, with a yield strength of the steel $f_y = 430$ MPa. The less sensitive detail is characterized by $\Delta\sigma_C = 90$ MPa at $N = 2$ million cycles, with a yield strength of the steel $f_y = 430$ MPa.

3.1 Considered structural control settings

Different control settings are considered to assess the effects of Structural Control. These correspond to the ones already considered also in Martinelli & Domaneschi (2010). The control devices considered belong to the quite general fluid dynamic dampers family, able to perform either in a passive configuration or in a semi-active one. These control devices are positioned so that they connect the deck to the towers (Figure 3). Two orientations of the dampers are defined: transversal to the deck, denoted as TD, and longitudinal to the deck, indicated as LD. Transversal devices TD give a large contribution to the reduction of the deck transversal oscillations, while the LD devices help create a dissipative torque.

The three control settings considered are: passive-optimal (PO), passive-semi-active (SA), and uncontrolled (UNC). All controlled configurations comprise both TD and LD devices. The passive-semi-active configuration SA is obtained assuming that the transversal device TD can act as semi-active ones. The longitudinal devices LD are always of the passive type.

Figure 4 and 5 depict the degrading part of the functionality function $Q(t)$ due to wind-induced fatigue for the most sensitive structural detail ($\Delta\sigma_C = 36$ MPa at $N = 2$ million cycles) and for the least sensitive one ($\Delta\sigma_C = 90$ MPa at $N = 2$ million cycles). The degrading part corresponds to the time interval $t_{d0}=0 < t < t_{r0}=150$ years, and no extreme events have been assumed to happen. The curves in Figures 4 and 5 have been obtained by recalculating the data presented in Martinelli & Domaneschi (2017).

The effects of structural control are massively beneficial (Figure 4) for the most sensitive detail, showing a huge reduction in the predicted value of the damage. The curves in the figure are linear since the same distribution of average hourly wind velocity has been assumed for each year. Note that very little is gained in terms of fatigue life going from the passive optimal PO scheme to the semi-active SA one. With the hypotheses on the distribution of the wind velocity made, the uncontrolled structure life exceeds the 100 years mark.

The less sensitive detail, instead, has no problems (Figure 5) in reaching the intended design life of the structure, even in the uncontrolled case.

Application of Equation 2 to the curves in Figure 4 leads, for $t_{r0}+T_{LC} = 100$ years to a value of the extended Resilience $R = 0.5, 0.9, 0.9$ for the UNC, PO, SA cases, respectively, highlight as the proposed index can be useful in assessing the structure's resources within a Life Cycle Analysis.

Figure 3. Top view of the deck at the towers, with the position of longitudinal LD and transversal TD devices.

Figure 4. Deteriorating part of the functionality function $Q(t)$ due to wind-induced fatigue for the most sensitive structural detail.

Figure 5. Deteriorating part of the functionality function $Q(t)$ due to wind-induced fatigue for the least sensitive structural detail.

4 CONCLUSIONS

Life cycle analysis involves assessing the environmental and economic impact of a structure over its entire life cycle, from construction to demolition. This analysis takes into account factors such as the use of materials, energy consumption, maintenance, and disposal. In this respect, structural control can be of help under several points of view.

Improved durability: Structural control techniques can help to minimize the impact of environmental factors such as wind, on the bridge structure. By reducing the damage caused by these factors, the bridge can last longer and require less frequent repairs and maintenance.

Increased safety: By monitoring and controlling the behavior of the bridge, structural control systems can help to detect and respond to any anomalies or potential failures before they

become serious safety concerns. This can help to minimize the risk of accidents and ensure the safety of users.

Reduced environmental impact: Structural control systems can help to minimize the use of materials and energy during construction and operation of the bridge. By reducing the amount of resources required, the environmental impact of the bridge can be minimized.

Improved cost-effectiveness: By reducing the need for maintenance and repairs, structural control can help to reduce the lifetime cost of the bridge. This can make the bridge more cost-effective and help to ensure that it provides value for money over its entire life cycle.

Digital Twin - solution in the digital age for improving critical infrastructure resilience to extreme events

M.Q. Tran, H.S. Sousa, E. Teixeira & J.C. Matos

Civil Engineering Department, ISISE, University of Minho, Guimarães, Portugal

H.T. Dang

University of Transport and Communications, Hanoi, Vietnam

ABSTRACT: Risk management is one of the approaches to improve the efficiency and safety of critical infrastructure against extreme events. This approach focuses on the design of robust CI and strong protection systems. In this way, the probability and consequences are minimized. However, extreme events are increasing in both number and severity. CIs (especially those built in the past) find it difficult to withstand and adapt to these extreme events. As a result, a recent dramatic shift has shifted from robust design to focus on preparedness, response, and resilience. Accordingly, CI can withstand the majority of adverse effects at higher-than-normal thresholds. In the event of destruction or damage, the CI can bounce back to normal operation more quickly with minimal resources. Increasing understanding and improving the resilience of CI to extreme events contribute to sustainable cities. Although considerable research has been conducted on the resilience of Critical Infrastructures systems over the years, it still has gaps. This paper applies the Digital Twin concept to the infrastructure domain to improve CI system resiliency. A comprehensive analysis of the critical infrastructure characteristics and resilience is implemented. The results show that the Digital Twin has the ability to fill research gaps, enhancing the resilience of critical infrastructure.

1 INTRODUCTION

A structure, system, or component that is crucial to the maintenance of a society's essential functions and whose disruption or destruction will have a negative impact on the society's ability to function sustainably is referred to as critical infrastructure. Critical infrastructures, as opposed to regular infrastructure, play a significant role in a nation's society. If there is a problem, a CI can cause disruption, affecting society and human activities.

The damage caused by extreme events can have enormous consequences. Disruptions in the operation of critical infrastructure can cause cascading failures, overloading the system. At the same time, it can lead to the collapse of all other infrastructures in a domino effect. To protect these lifelines during and after disruptive events, it is critical to strengthen the resilience of critical infrastructures to any type of disruption or disaster.

Critical infrastructure resilience is the ability to continue to deliver essential services reliably and with minimal disruption in the face of any extreme event (Royce Francis et al., 2014; AM Bento, Minh TQ, 2022). A system's resilience is determined by various factors, the most important of which are dynamic skills and rapid response strategies. Infrastructure resilience is increasingly valued and considered in design goals to enhance usability and sustainability for the entire system's development.

When a hazardous event occurs, risk management measures cannot be enough. With critical infrastructure at risk, reacting, responding, and accelerating recovery solutions is imperative. Critical social functions, critical infrastructure, must be restored or adjusted as quickly as

possible. The inability to completely eliminate disasters and the need to be prepared for major crises have led to views of having to “live with” extreme events (Minh TQ et al., 2022a). Resilience studies have gained global attention. Conventional infrastructure management mainly focuses on visual inspection, physical measurement, and expert evaluation of an infrastructure domain in isolation. Different approaches have been considered by many scientists (Ayyub, M. B et al., 2013; Bialas, A., 2016). However, these studies are limited by their consideration of different hazards, cascade effects and uncertain conditions, dealing with technical, organizational, economic and human domains as well as integration of time and space aspects.

M. Grieves first proposed the idea of digital twins as a concept for product lifecycle management in 2003 (Michael W. Grieves, 2003). Both academia and business are increasingly acknowledging the value of DT. Since the day it was first conceived and created until the present, DT has been used and put into practice, demonstrating its viability in a variety of industries, particularly product design, automatic production, manufacturing, automotive, and aviation (R.K Phanden et al., 2021; Minh TQ et al., 2022b).

Digital Twins are used as a comprehensive tool for monitoring, analyzing, controlling, and optimizing a system throughout its entire lifecycle. Because of ongoing digitization efforts, it is becoming increasingly possible to implement Digital Twins of large-scale systems. With its outstanding advantages, Digital Twins ensures a virtual copy in an up-to-date state. The Digital Twin concept, with its updated, integrated intelligent and adaptive functions and digital approaches, represents a potential approach to the field of infrastructure services. Virtual objects, when combined with the right tools, can improve the operational resiliency of infrastructure services.

Based on these initial assumptions, in this paper, the applicability of the Digital Twins concept is considered to improve the resiliency of critical infrastructure protection and operation against catastrophic events extreme. The Digital Twin paradigm is well suited for a framework that promotes increased resilience throughout the crisis life cycle.

2 RESILIENCE IN CRITICAL INFRASTRUCTURES

2.1 *Critical infrastructures*

Critical infrastructure is “the organizational structure and the physical and vital importance to the society and economy of a country”(Federal Republic of Germany, 2009). Their collapse or deterioration could result in protracted supply shortages, major disruptions to public safety and security, or other severe repercussions.” Specifically, the areas of energy, information and communication technology, water supply, and technical transport, as well as those of health, media and culture, food, finance, insurance, government, and administration, are seen as significant. In addition, some infrastructure networks, such as electricity or communication networks, cover entire continents and are interdependent across borders. Social engineering is deeply integrated and interacting with critical infrastructure. Increasingly complex and integrated infrastructures, networked societies, climate change, and worldwide political instability enhance the probability of dangerous situations in the medium and long term with critical infrastructure.

2.2 *Critical infrastructure resilience*

The concept of resilience is applied in many domains of research including ecology, psychology, eco-economics, and national security. . .(M. Wied et al., 2019). In the context of critical infrastructures, resilience refers to the capacity to continue delivering important services reliably and with few interruptions in the face of unspecified disturbances, as well as the capacity to regain full functioning after an impact. Accepting that not all future events are foreseeable and that unexpected occurrences will occur is essential to resilience (E. Hollnagel, 2010). In contrast to conventional risk management, which seeks to detect and restrict the effect of particular hazards, resilience management seeks to increase the system’s attributes so that it can better withstand threats future occurrences of any kind.

Resilience: subject resilience is closely related to vulnerability, the ability of the system to withstand disturbances caused by extreme events and to maintain the performance of the socio-economic, environmental, and physical components of the system. Resilience to extreme

events damages can be considered only in places with past events, since the main focus is on the experiences encountered during and after the extreme events. The resilience of the critical infrastructure layer depends on the characteristics of the system, as well as a set of dynamic skills and coping strategies, and recover. Overall, this highlights that resilience is not a given, purely static property, but can be actively enhanced and achieved.

Figure 1. Infrastructure performance in the case of a disruption (P. Klimek et al., 2019).

As disruptions unfold, system performance fluctuates: first, system performance decreases as the impact of the shock is absorbed, then performance increases during the recovery phase, and finally, depending on system behavior, performance levels off at a lower, equal, or higher level than before the shock (Figure 1). In each of these stages, a distinct set of skills is needed and must be triggered in accordance with the circumstances. The theoretical framework of the resilience cycle describes this.

This cycle typically consists of a planning phase, an absorption phase, a recovery phase, and an adaptation phase. During the cycle, the system engages its resilience capabilities, some of them momentarily (e.g., robustness) and some continually (e.g., monitoring). A highly resilient system will learn from prior disruptions and system behavior, as well as repercussions, and incorporate adjustments to present processes or technology, leaving it better equipped to confront future disturbances when the cycle starts again (D. Rehak et al., 2019).

3 DIGITAL TWINS

3.1 *Digital twins*

Digital twin technology is a virtual digital model of an object, but unlike conventional digital simulations, this digital object is very intelligent and has the ability to acquire and analyze large data sources, and a variety of actual objects. There is a data flow between the virtual and the actual object, and through the sensors on the actual system, the virtual part is updated so that the state of the system can be monitored in real-time. In other words, Digital twin technology integrates Artificial Intelligence, Machine Learning and analyzes software with data to create a living digital simulation model that updates and changes as physical objects change. A digital twin continuously learns and updates from multiple sources to describe its near-real-time status, working conditions or location, thereby helping to make accurate diagnoses about the status of the device, and object when any abnormal changes occur. Digital twin greatly improves real-world objects (such as optimizing the design of airplanes, and cars, or automating and increasing the productivity of a production line), but at the same time improving itself based on newly updated data from real models.

3.2 *Properties of the digital twins*

There are many views on the components of the digital twin expressed under various definitions. However, essentially digital twin must consist of five parts: (i) the physical part, (ii) the virtual part, (iii) the connections, (iv) the data and (v) the services (Figure 2).

Figure 2. Components of digital twins (P. Klimek et al., 2019).

a. The physical part

One of the main parts of a digital twin is the real part of the object (the physical part). The physical objects in the digital twin are capable of perceiving the outside world. In other words, like the human senses, the real part of the digital twin is equipped with sensor systems to get real data. The object of study - for example, a bridge - is equipped with various sensors related to important functional areas. These sensors generate data about various aspects of a physical object's activity, such as energy output, temperature, weather conditions, and more. This data is then forwarded to a processing system and applied to the digital twins.

b. The virtual part

The virtual part of the digital twin are virtual models created by digital transformation that are reflected by the real object. Different from conventional simulation models, this model contains all the information about reality. The virtual part is always updated and changed according to the physical part. The virtual part is not simply an object that is established through conventional design models with the characteristics of shape and size. Traditional computer-aided engineering and design (CAD/CAE) modeling is often just the starting point of a DT.

c. The connections and data flow between physical part and virtual part

Actual objects constantly change in all aspects: quality, nature, characteristics, among others. Creating a digital model corresponding to a moment in time of a real object has been done many times before, but it is not considered a digital twin because there is no connection and data flow between physical part and virtual part.

The digital twin model is clearly distinguished from the digital model, and the digital shadow model interconnection and interactive flow of data between the parts. If the data flow between an existing physical object and a digital object is fully integrated in both directions, this constitutes the reference "Digital Twin" (A. Fuller et al., 2020)

Figure 3. Digital model, shadow and twin (A. Fuller et al., 2020).

The connection and data flow between the real part and the virtual part form a closed loop. In there, the real data is transmitted from the sensor to the virtual part to help the model continuously update attributes. The virtual model also provides predictive cases, and possible scenarios, affecting human decisions to the real part. Two parallel data flow coexist, interact, and complement each other.

In the past years, technologies for cloud storage or internet of things or technologies for data transmission have not achieved the current achievements. It is very difficult to make the

connection between parts. However, now that these technologies have developed quite strongly, some technological barriers have been removed. The connection and data flow between real entities and virtual models is possible.

d. The services

Reviews show that digital twins can have applications in many areas. Main serviceability to the ability to integrate the real world into the virtual world. In the virtual world, people can perform tasks that are not possible in the real world. Destructive experiments, texture response perceptions, or full lifecycle reviews of an object can be visualized in the virtual world. Not only that, supporting important decisions greatly affects the real audience.

3.3 *Digital twins enabling technologies*

a. Technologies for physical objects

As discussed above, physical objects are an integral part of DT because they are data sources from the real world. Technologies implemented in the physical object make the DT aware of data such as geometrical shape, physical properties, and mechanical precision. Currently, sensor and measurement technologies deployed for DT include IoT sensing technology, reverse engineering, image recognition metrology, and particle sensing technology (Qi, Q et al., 2019).

b. Data construction and management technologies

The high-fidelity digital twin model contains a lot of complex information, including some data that needs to be stored intact, some data only a small part in the implementation process. Therefore, data construction and management technology is quite important in DT.

As we know, the data obtained is often multi-source and contains many noisy signals and messy arrangements. The purpose of data construction and management technology is to separate data that is valuable and meaningful to specific audiences from big data. The raw data will not be effective without cleaning, converting or reducing the size. Data construction and management can be divided into the following aspects: analytical visualization, data mining algorithms, and predictive analytics capabilities. Data mining and analysis algorithms will rely on AI to develop.

c. Virtual modeling technologies

Virtual modeling technologies allow users to visualize specific objects in the DT, while helping to manage information about geometry and texture response. Currently, there are many Computer-Aided Design (CAD) software that can display the geometric information of a physical object, such as UG, AutoCAD, SolidWorks, and Creo.

For the structure response side, many physics-based theories/models have been established to reveal the mapping relationship between input and behavior, such as computational fluid dynamics models (CFD), finite element modeling (FEM). Tao and Zhang suggest that behavioral models describe the mechanical correspondence of production equipment can be implemented specifically using finite element models and neural networks (Tao, F. and Zhang, M., 2017)

d. Connection and data transmission technologies

One of the most difficult issues to implement DT is the technology to connect and transfer data between the real and virtual parts. To realize real-time control and virtual-real state mapping, high-fidelity connection methods are needed for DT. Connection protocols for exchanging data between physical space and cyberspace are now strongly developed through different software and platforms.

Currently, wireless transmission methods including Zig-Bee, Bluetooth, Wi-fi, ultra-wideband are gradually replacing and becoming more modern. A series of application program interfaces (APIs) are commonly used to exchange data between different software to perform data transfer at the software level. Recently, 5G technology can be applied to meet the demand for high data rate, high reliability, high coverage and low latency.

4 DIGITAL TWINS FOR IMPROVING CRITICAL INFRASTRUCTURE RESILIENCE TO EXTREME EVENTS

A Digital Twin idea and framework applied to resilient critical infrastructures can help to synchronize existing research efforts and expedite the implementation of theoretical discoveries in a cost-effective way creative. This notion encompasses both Data Science and the digitally-created opportunities. A proposed model of Digital twins includes the main components and their interactions. This proposed model will be used to meet key requirements of the Digital Twin Conceptual Framework needed to increase resilience in critical infrastructures (Figure 4).

Figure 4. Proposal model structure of the digital twin concept with the real-world section to improving critical infrastructure resilience to extreme events.

The real-world segment may include any group of systems of interest, ranging from individual machine components to factories, buildings to cities, processes to complex interconnected systems-of-systems, and communities to networked socio-technical systems such as critical infrastructures. It is frequently referred to as an analog system, real system, or physical system, even if it may have software-implemented intelligent control systems. Depending on the use case, the system boundaries define the portion of the real world captured by the Digital Twin.

Initializing the virtual replica is the initial stage in establishing a Digital Twin, followed by modeling and data collection. Structural models, such as CAD models or component lists, describe the composition and features of the modeled section of the real world. They are accompanied by dynamic and functional behavioral models, such as simulation models or models built using machine learning or artificial intelligence. The structural model frequently serves as a semantic container for current and historical state data and behavioral models. The type and sophistication of the semantic container are determined by the intended use case and the nature of the data, which can range from raw sensor data and unstructured information such as natural language text or speech, non-normalized photographs, etc. to curated instances of data types, schema-bound data, and ontology-compliant data.

When designing the components of the DT system, the system boundaries of the real infrastructure under consideration must be established. Outside of the system’s limits, the external environment creates changes and disruptive occurrences that have an effect on the system. In addition, the purpose of the DT must be specified in order to extract the stakeholders, users, use cases, data sources, and design objectives for the replica and tools. In the first stage, relevant situations for each infrastructure type can be identified. For example, for urban facilities near rivers, extreme weather or floods situations are addressed. In subsequent iterations, the Digital Twin may be expanded to encompass other sorts of disruptions and services.

The federation of various Digital Twins allows regulatory requirements to be mapped to infrastructures. Along the import/export interfaces, regulatory processes and needs for data governance, privacy, and protection can be addressed. With the proper interfaces, system-of-systems can be linked to create similar virtual system-of-systems with a higher level of complexity and sector couplings. It is essential that the networked Digital Twins and their corresponding models accurately depict the emergent or self-organizing behavior of the actual system.

A Digital twins model is applied to the proposed critical infrastructure (Figure 5). This model consists of real part, imaginary part and full components as defined by Digital twins. Together they form a unified, functioning system. In accordance with this conceptual paradigm, a Digital

Twin that functions continuously and encompasses all stages of infrastructure operation, including regular operation and extreme occurrences, is continually operational.

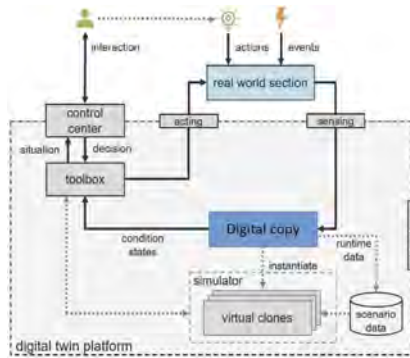

Figure 5. Digital twin conceptual model for infrastructure operation supporting improved resilience for extreme events.

The Digital Twins platform proposes for CI deployed in the cloud, using data collected from the real to update and connect to the virtual. At the heart of the architecture, virtual replicas receive and deliver data through streaming services and store that data in a database.

If necessary, Toolbox provides the ability to clone a virtual duplicate of critical infrastructure and initialize it to the present condition of the physical world. The digital twins are then utilized for forecasting and simulating alternative system configurations or interventions. In addition to new out-of-the-box actions advised by system specialists, optimization techniques may be employed to uncover system improvement opportunities. In addition, the replica is used to recreate the predicted sequence of events based on updated runtime and initialization data retrieved from historical records or the engineered scenario database.

The Control Center resembles an interface for stakeholders, directing each scenario and providing access to the toolset. It includes a situation room that has been augmented with the findings of Digital Twin monitoring and analysis. The control center can be accessed remotely, allowing stakeholders from diverse companies to take consistent action.

5 CONCLUSIONS

In this paper, the requirements for the operation and crisis management of critical infrastructures are presented, in order to improve their resilience to unforeseen events. The Digital Twin Model is a new, comprehensive, and effective approach to improving the resilience of critical infrastructure to extreme events.

Overall, applying the Digital Twin concept to critical infrastructure permits the development of new strategies and the study of past errors. This solution offers to play a significant role in tackling the issues faced by infrastructures and societies that are becoming increasingly complex and linked. The Digital Twin is the principal instrument for methodically driving resilience, as intelligent tools promote resilience.

Integrating many uncertain data sources and system model types into a Digital Twin architecture, evaluating smart technologies to help the recovery cycle, and ensuring the scalability and dependability of the IT platform are significant obstacles.

Flood Vulnerability Index (FVI) of infrastructures for reducing adverse flood events

M.Q. Tran, H.S. Sousa, E. Teixeira & J.C. Matos

Civil Engineering Department, ISISE, University of Minho, Guimarães, Portugal

ABSTRACT: Floods disrupt peoples' lives and livelihoods worldwide and are one of the most common and severe natural hazards. The effects of flooding are devastating, especially in lower-income countries where the infrastructure, such as drainage and flood control systems, tends to be less developed or even un-existing. Flood vulnerability has the potential to support decision-makers in planning better measures to adapt to and mitigate the negative impacts of flooding. Assessing vulnerability to floods is often complicated because it involves many factors, sectors, and aspects. As a result, methods that simplify and improve flood vulnerability assessment are essential. Various approaches such as vulnerability curves, disaster loss data, computer modeling, and indicator-based methods have been investigated and well-accepted for assessing flood vulnerability. Reviewing these methods and contrasting their advantages and disadvantages is the goal of this study. After considering the methods comprehensively, the indicator-based approach provides a clearer picture of the overall flood vulnerability in each area. This study also provides a general and simple introduction to the indicator-based method to promote a better understanding of this method.

1 INTRODUCTION

1.1 *Floods and their effects*

Every time an extreme flood occurs, property, infrastructure, people, and animals are severely affected. Critical infrastructures such as bridges were swept away, and houses were submerged by flood water. In addition, the prolonged flood situation also affects agricultural activities. Floods, for example, can damage crops and reduce food supplies. Flash floods (a flood in which the water level rises very quickly when a large volume of water moves quickly from high to low terrain) are the number one weather-related cause of loss of human and animal lives. An indirect consequence of floods is the contamination of other resources. As an example, floods can disturb the public water supply by bringing waste from sewers, ponds, and landfills into the environment. Water pollution affects human health and spreads harmful viruses.

Floods may not be the most catastrophic event (unlike tsunamis or earthquakes), however they cause the most damage and affect most people. At the same time, Flood is also the most common of the disaster events. The number of floods between 2000 and 2019 accounted for 44% of all disasters. Meanwhile, all other negative events remained below 30% (Figure 1).

Along with global climate change, the number of flood events in the past two decades has increased markedly. During the period 1980-1999, the total number of flood events was 1389. Between 2000-2019, the number of flood occurrences increased to 3254 (Figure 2). It has been observed that flood events are increasing in frequency and intensity, with a 57% increase from the previous time period, constituting the largest increase in disaster events. Not only stopping there, the number of people affected by floods also accounts for the highest percentage. In the decade 2000-2019, floods affected up to 1.65 billion people, representing 41% of all disasters.

Figure 1. Percentage of occurrences of disasters from 2000-2019 (United Nations Office for Disaster Risk Reduction, 2019).

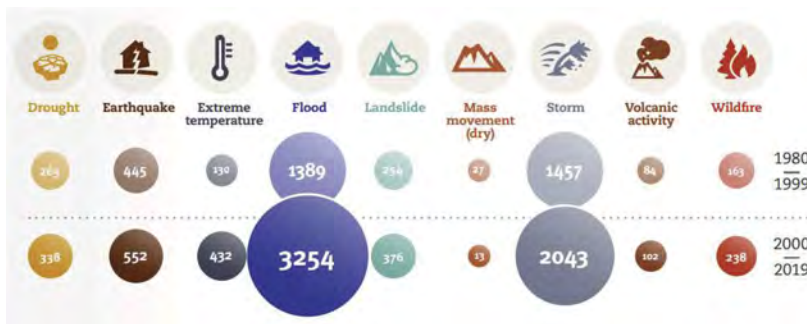

Figure 2. Total disaster events by type: 1980-1999 vs. 2000-2019 (United Nations Office for Disaster Risk Reduction, 2019).

1.2 Food risk and vulnerability

Flood events are becoming more frequent and severe in both intensity and frequency. Despite assessment, risk management and mitigation measures in recent years, flood impacts remain a serious problem. Floods are negatively impacting the economy and society worldwide at an alarming rate. Floods normally occur after prolonged signs from nature, such as heavy rain and high winds, or can arise suddenly and abnormally due to causes, such as hydroelectric dam failure, sudden flood discharge, among others. In previous studies, flood risk was considered as a problem to be assessed and remedied when the incident happened, not proactively (Z. Vojinovic, M.B. Abbott, 2012). With a new and more developed approach along with the advance of science and technology, nowadays, flood risk is deemed for management to propose solutions for prevention.

Currently, a clear definition of flood risk management does not exist. However, there is one most accepted and used definition: the potential for a community to be affected by a flood hazard depending on severity, vulnerability, and exposure (S.F. Balica, N.G. Wright, 2010; A. Bento, M.Q. Tran, H.S. Sousa, E. Teixeira, 2022; G. Cremen, C. Galasso, J. McCloskey, 2022; J.F.S. Barrionuevo, H.C. Noblejas and FF.J.C. Prados, 2022). In other words, flood risk is determined by three factors: (1) Hazards (H), (2) Exposure (E), and (3) Vulnerability (V). Figure 3 shows the relationship between the components and flood risk management.

The total elimination of a hazard (H) is impossible; thus flooding may occur in a specific region in the study and there might be no way to avoid it. Only forecasts based on hydrometeorological analysis can be used to minimize its effects. At the same time, exposure (E) to floods of human activities is natural, and people must appear in economic zones to participate in production activities, build new infrastructure, among others. Therefore, an important factor to tackle for flood risk management is related to vulnerability. Vulnerability (V) corresponds thus to the expected degree of harm under certain exposure conditions, susceptibility, and resilience.

Figure 3. Relationship between flood risk management and its components.

Flood vulnerability is hence a key factor in flood risk assessment and damage assessment. This can be easily seen through the “butterfly effect” or the “domino effect”, where just a small fraction of the damage in a flood can lead to enormous consequences for a risk management concept.

2 APPROACHES AND METHODS FOR ASSESING VULNERABILITY TO FLOODS

There are many definitions of vulnerability, mentioned in many fields with many factors (Timmerman, 1981; Canon, 1994; Susan L. Cutter, 1996; Caroline, 1998; Alexander, 2012; W.E.Morrison, M.W. Nelson, J. F. Howard, E.J. Teeters, J.A. Hare, R.B. Griffis, J.D. Scott, and M.A. Alexander, 2015; Kumar, Bhattacharjya, 2020). Being vulnerability treated as an abstract concept, there is no consensus across industries, thereby the need to quantify it to better describe it. However, there are some similarities between the published studies. Therefore, vulnerability can be defined as the degree of loss or degradation of the deemed object (the system under consideration) before a harmful agent. For different fields of study, vulnerability can depend on several aspects, concerning the subject being considered. In the present study, flood vulnerability is mentioned and analyzed.

A number of flood vulnerability assessment methods have been developed by previous studies (J.F.S. Barrionuevo, H.C. Noblejas and FF.J.C.Prados, 2022), but the effectiveness of these methods is not high due to many factors. Vulnerability assessment methods are usually divided into the following basic groups: (i) vulnerability indicator method; (ii) vulnerability curve method; (iii) disaster loss data method; and (iv) modeling method.

The vulnerability indicator method is based on specifying vulnerability with a certain value through variables affecting vulnerability. Until now, this method has been widely used and preferred by policymakers. For flood vulnerability, indicators affecting the impact of floods on social, environmental, physical and economic aspects are considered. Usually, indicators are chosen by experts. However, for each region and each expert’s point of view, the indicators are often not the same or have little in common. This method is only useful for specific flood areas.

The vulnerability curve method is an approach based on the relationship between risk and related factors that depends on fully documented and published case study data. This group of methods uses variables in a specific area to evaluate, and build the damage curve step-by-step. Despite its accuracy, this method is rarely used due to space limitations (applicable only to a particular group with documented data) and consumes a lot of resources and efforts for conducting investigation, assessment and surveys. This approach is essentially founded on data from well-documented case studies so typically restricted to dwellings in a specific area.

Disaster loss data is a method for predicting future events and vulnerabilities by evaluating past data regarding losses. This method is not as accurate as desired, although quite easy to implement, due to the published loss data in a number of reliable sources (the national

information system, and the damage reports of the agencies). Damage and losses from flood events are recorded, from which damage predictions are performed. However, the data are not continuous and are often only comprehensive for severe floods, so predictions are often less accurate.

Modeling method considers the use of models, simulation evaluation, prediction of depth, height and flood pattern. Vulnerability assessment is carried out through model analysis results: predict flood prone locations, damage levels in each model area, forecast vulnerability according to a specified scale. This modeling approach can better assess vulnerability at a smaller scale than other methods, since it focuses on specific areas. In contrast, it is unable to describe a clear relationship between flood damage and forecast maps. The different vulnerability assessment methods each have their own advantages and disadvantages (Table 1).

Table 1. Advantages and disadvantages of vulnerability assessment methods.

Methods	Vulnerability indicator methods	Vulnerability curve methods	Disaster loss data methods	Modeling methods
Advantages	<ul style="list-style-type: none"> - Has specific, intuitive categorical value; - Widely researched and used; - Can evaluate in general or specific to each area. 	<ul style="list-style-type: none"> - Precise on the area under consideration since it was established on the basis of actual investigation. 	<ul style="list-style-type: none"> - Simple, easy to do thanks to finding open sources. 	<ul style="list-style-type: none"> - Very well applied to a specific area with full parameters.
Disadvantages	<ul style="list-style-type: none"> - Depends on several variables of many fields; - The choice of weights for the factors is controversial. 	<ul style="list-style-type: none"> - Takes a lot of time and effort; - Not applicable to different areas. 	<ul style="list-style-type: none"> - No significant accuracy. 	<ul style="list-style-type: none"> - Low accuracy in the absence of survey data; - Difficult to implement in a large area.

Flood vulnerability index methods (FVI) have proved to be more effective in recent studies (S.F. Balica, N.G. Wright, 2010; Nasiri et al., 2016; C.T. Van, D.Q. Tri, N.T. Son, T.T.T. Thao, D.T.H. Hoa, 2019). FVI assesses vulnerability not directly, but rather through various aspects of the main system. In this sense, it can be comprehensively reviewed and assessed in a large area, raising public awareness, and supporting the government in flood risk management. However, this method is less rigorous in the use of parameters. Parameters are selected based on the experts' opinions, often without regard to the importance of the parameters. In other words, the relevant parameters are all considered, and then calculated equally. At the same time, the flow and hydraulic conditions of the area are not analyzed in detail.

3 FLOOD VULNERABILITY INDEX (FVI)

As mentioned above, FVI provides a quick, reliable and relatively comprehensive flood vulnerability assessment method. Figure 4 schematizes its simple structure. This method uses sets of indicators covering all aspects of the area to assess flood vulnerability. The indicators used allow comparison of flood vulnerability in different areas. FVI can measure trends in changes in components, helping to identify and monitor the action priorities needed in flood response. These features provide strategically important information for flood risk planning and management.

a. FVI factors

Each component of vulnerability is assessed through three factors: exposure (E), susceptibility (S) and resilience (R). The interaction between vulnerability factors and components forms thus the foundation of the FVI method, illustrated in Figure 5.

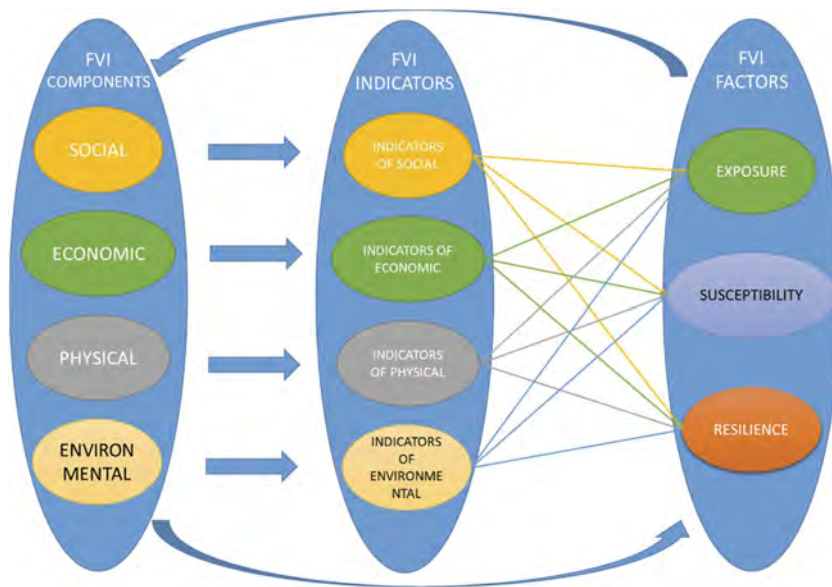

Figure 4. Flood vulnerability index (FVI) structure.

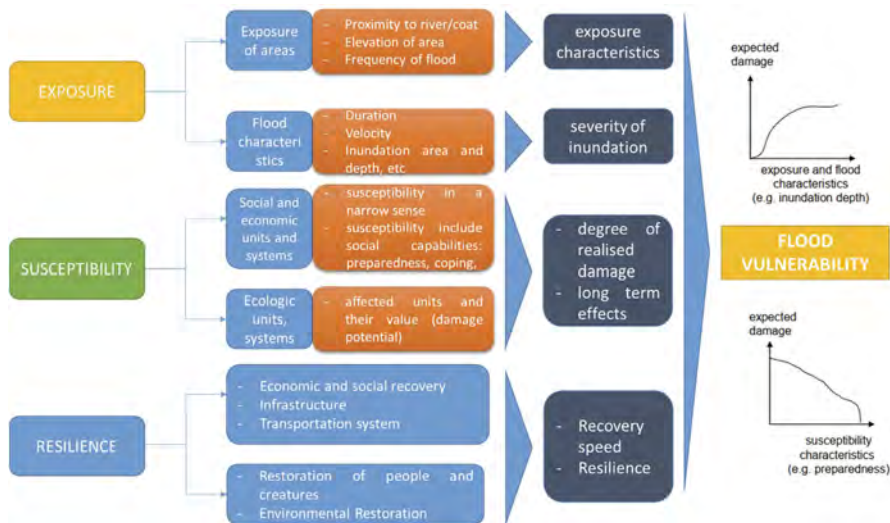

Figure 5. Factors to be used in flood vulnerability assessment.

The factors in a vulnerability assessment have a close relationship with each other and directly affect the total vulnerability index of the system. Two views, based on two mathematical relationships, have been studied and herein presented in Equations 1 and 2 (R F Connor, K Hiroki, 2005):

$$Vulnerability = \frac{Exposure \times Susceptibility}{Resilience} \quad (1)$$

$$Vulnerability = Exposure + Susceptibility - Resilience \quad (2)$$

In the proposed method, in order to directly identify the vulnerability values, Equation 3 was selected for implementation. Accordingly, Equation 2 becomes:

$$FVI_{total} = \frac{\left(\frac{E \times S}{R}\right)_{social} + \left(\frac{E \times S}{R}\right)_{economic} + \left(\frac{E \times S}{R}\right)_{environment} + \left(\frac{E \times S}{R}\right)_{physical}}{4} \quad (3)$$

b. FVI indicators

In a component, there are different aspects expressed through the parameters of the system. These parameters are characteristics of a certain region (i.e. the area under consideration). These parameters are commonly referred to as flood vulnerability indicators. In other words, flood vulnerability indicators are detailed components of the system that are considered in terms of social, economic, environmental, and physical components. However, within a system, there are many indicators, which may or may not be related to flooding vulnerability. Understanding and reviewing the indicators is thus essential to being able to make an accurate forecast.

Numerous studies have been conducted on selecting indicators to calculate flood vulnerability. The indicators depend quite heavily on the study area. By indepth analysis, the sets of indicators are increasingly reduced and optimized. These sets of indicators are quite concise and still provide the required accuracy (S.F. Balica, N.G. Wright, 2010). From 1993 to 1997, according to the detailed database of the World Bank, up to 1200 indicators were used to calculate and assess vulnerability (Albert Adriaanse, 1993). By 2007, (S.F. Balica; N. Douben; N. G. Wright, 2009) studied and improved the accuracy of the flood vulnerability index. From 80 considered indicators, 40 were analyzed and selected. Afterwards, (S.F. Balica, N.G. Wright, 2010) continued to study and subdivide the indexes for specific regions in the world, including: 20 for river basin scale, 22 for sub-catchment and 27 for urban area. In 2014, (N.T. Cam, 2014) proposed a weight-based flood vulnerability assessment method using 44 indices of components including 3 exposure indices, 28 susceptibility indices, and 13 resilience indices.

c. FVI components

In a system, the components social, economic, environmental and physical exist simultaneously. The social component provides indicators describing the social context, adaptive capacity, skills, knowledge, awareness and behavior of the constituents of the community at the considered geographical scales. The economic component represents the economic development level of the area under consideration. Economic indicators provide assessments of the capacity to produce and distribute goods and services affected by floods. The economic component is herein considered based on two points, When the economy develops and grows, the level of recovery and flood resistance increases, and also the potential damage increases. The environmental component provides criteria for damage to the environment caused by floods. Environmental activities, such as urbanization, industrialization, deforestation, and reforestation, among others, have been directly linked with flood vulnerability. The physical component refers to how physical conditions, either natural or human-made, can affect the vulnerability to flood of a given area. After obtaining the vulnerability indices of each of these components, the vulnerability can be assessed through the final index indicated in Equation 4:

$$FVI_{total} = \frac{FVI_{social} + FVI_{economic} + FVI_{environment} + FVI_{physical}}{4} \quad (4)$$

Through the FVI_{total} , information on the vulnerability of a certain geographical area is provided quickly, straightforwardly and reliably, since this index has given relatively complete consideration to the components of the system. Using the FVI_{total} , vulnerability levels can be compared across regions. By mapping vulnerability, flood risk reduction approaches can be designed and optimized. Along with that, identifying root causes of vulnerability provides essential information

for planning risk management and limiting flood damage. The extent of vulnerability to flood is determined by various sources. The most commonly used flood vulnerability scale is specified in Table 2.

Table 2. Flood Vulnerability Index (FVI_{total}) scale.

Level	FVI _{total}	Designation	Description
1	< 0.01	Little or no vulnerability to floods	Very small flood vulnerability, fast recovery area, high resilience, flood adaptive area, small exposure, an area that does not usually flood.
2	0.01 – 0.25	Low vulnerability to floods	This is an area where occasional floods occur. Components can be damaged but recover quickly, highly resistant.
3	0.25 – 0.5	Vulnerable to floods	The area is relatively prone to flooding. When having a flood, the vulnerable components are able to recover slowly, but gradually over the months, receiving the right amount of investment.
4	0.5 – 0.75	High vulnerability to floods	Flood frequency is relatively large, and flood level is high. This area is vulnerable to flooding, the resilience and adaptability is poor, and the restoration investment is very small.
5	0.75 - 1	Very high vulnerability to floods	High frequency of floods, high degree of flooding. This area is vulnerable to flooding, recovery is very slow, resilience and adaptation are poor, investment in restoration is very small, Budget is scarce

4 CONCLUSIONS

Vulnerability is an important aspect of assessing and mitigating the negative impacts of flooding events. The paper clarified the relationship between factors in flood vulnerability, from there, got an overview of the vulnerability. To minimize damage from floods or other negative events, it is necessary to reduce the vulnerability of communities and critical infrastructure by providing early warning, strengthening infrastructure, and taking countermeasures in the worst-case scenario.

There are many methods of assessing flood vulnerability, but each method has its own advantages and disadvantages. By analyzing the components and indicators of flood vulnerability, the paper proposes using FVI to flood vulnerability assessment, at the same time, providing a set of indicators to assess vulnerability.

The vulnerability method only contributes to mitigating the negative impacts of floods, however, it also has uncertainties due to the influence of many factors. These factors vary over both space and time, making it difficult to predict with complete accuracy.

ABSTRACT: This paper presents the validation of finite element models for modal analysis of prestressed concrete high-speed railway bridge decks. Structural modeling is developed with different levels of complexity using beam finite elements and three-dimensional solid finite elements. Geometrical and mechanical properties of the bridge decks are calibrated based on data gathered from both design technical documentation and outcomes of an experimental campaign, including non-destructive tests and laboratory tests. The results of finite element analyses are compared with the experimental outcomes based on dynamic modal tests to validate the structural models, collect information about the structural behavior and dynamic response of the bridge decks, and support the condition assessment of the railway bridges.

1 INTRODUCTION

Bridges are essential to transportation infrastructure systems and represent key components for economic and sustainable development of countries. It is therefore a priority to protect, maintain, and manage aging bridges over the entire life-cycle (ASCE 2021). An urgent need in many countries worldwide, including Italy, is related to knowledge about condition state and residual performance for huge stocks of aging bridges. This information is critical for public authorities and bridge owners to ensure effective bridge management based on a rational allocation of the available resources (Biondini and Frangopol 2016, 2019). Visual inspections, diagnostic activities, repair and maintenance interventions, and structural health monitoring may be adopted to gather information and data about the actual structural response and detect damage (Andrade and Alonso 2001, Frangopol et al. 2008, Malerba 2014). The results of these activities are crucial for a successful implementation in practice of life-cycle criteria and methods with the purpose of addressing future maintenance and management needs. They can also provide early warning of structural damage before significant repair or maintenance actions are planned (Frangopol and Soliman 2016). The importance of an integrated approach to gather data from inspections and diagnostic activities is also emphasized by recent codes of practice and guidelines (CSLLPP 2020).

This paper presents the validation of finite element models for modal analysis of concrete bridge decks as part of a more extensive activity for condition assessment and experimental testing of a group of viaducts along a high-speed railway line in Italy (Figure 1). The investigated bridges have been built between 1985 and 1989 and are characterized by prestressed concrete (PC) simply supported grillage decks and reinforced concrete (RC) bridge piers. The deck is composed by six longitudinal precast PC beams, five transversal RC beams (i.e., two outer and three inner beams), and a top RC slab. The viaducts along the railway line have a total length ranging from 67.20 m for a two-span viaduct to 1036.50 m for a 29-span viaduct. The span length is varying between 23.60 m and 36.50 m. The number of investigated grillage bridge decks is 126. The experimental campaign included a 12-span PC box-girder viaduct, for a total amount of 11 high-speed railway viaducts and 138 bridge decks investigated. The grillage bridge decks are investigated in this paper based on structural analysis and experimental dynamic modal tests.

Figure 1. High-speed railway bridges with PC grillage decks and RC piers.

2 INSPECTION-BASED CONDITION ASSESSMENT

Visual inspections represent fast activities and early assessment procedures to gather information about bridge condition state compared to diagnostic activities and structural health monitoring. However, results of visual inspections are generally affected by inspector subjectivity and may be limited by the accessibility to structural and non-structural components. On the other hand, the use of high-resolution cameras and drones can support inspection activities and judgments. Moreover, standardization of inspection activities by means of guidelines can significantly reduce uncertainties and subjectivity associated to inspectors and the results of visual inspections can also be efficiently used to update the reliability assessment of the system (Estes and Frangopol 2003). In this way, periodic visual inspections of infrastructural facilities may provide a preliminary indication of the actual structural deterioration state and its evolution in time. Nevertheless, this information is generally not sufficient to eventually plan maintenance and repair interventions.

For the bridge viaducts investigated in this paper, diagnostic activities have been combined with inspection activities to assess material characteristics, deterioration state, and residual structural performance. More specifically, non-destructive tests, such as rebound hammers and ultrasonic tests, have been used to estimate the mechanical characteristics of materials. Furthermore, laboratory tests on concrete cores and samples of reinforcing steel bars have been conducted to gather additional information about material characteristics and damage state. The condition state of the bridges is then quantified by performance indicators associated with the detected defects at various scales, from the elementary components of each grillage deck (i.e., longitudinal beams, transversal beams, and slab) up to the constitutive components of each bridge span module (i.e., deck, piers, and abutments). Statistical analysis has been carried out on the dataset of performance indicators with the aim of prioritizing further investigations and suggesting possible corrective interventions to better assess and ultimately improve the condition state of the most critical elements within the investigated bridge stock. The results of the extensive campaign of diagnostic activities have been also used to inform the development and calibration of the structural models presented in this paper.

3 DYNAMIC MODAL TESTS

The high-speed viaducts under investigation have been dynamically analyzed with the purpose to extract modal parameters and use them to further calibrate the finite element models. Due to the large number of bridges to be instrumented, a wireless sensor network has been adopted to enhance and speed up the entire experimental campaign. In fact, eleven different viaducts have been investigated, with a total amount of 138 spans dynamically assessed. Each studied span has been instrumented through a couple of sensors placed at midspan (Figure 2a). Furthermore, for each viaduct one span was instrumented also through a denser sensors setup (Figure 2b) in order to detect higher order modes. The sensing devices adopted consist of wireless accelerometers with MEMS technology (by LORD microstrain), with a full scale of 10g or 40g. Sensing devices with lower full scale have been positioned on the deck substructure, while the 40g accelerometers have been placed on railway track sleepers and used to identify the properties of the travelling railway vehicles (i.e., train type and speed). The sensors synchronization has been performed and controlled by their base station.

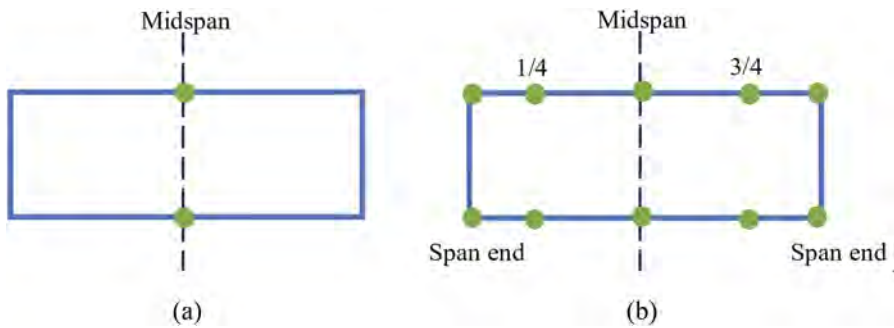

Figure 2. Sensors setup adopted during the dynamic experimental campaign: (a) basic setup; (b) denser setup. Accelerometers positions on the span are highlighted by green circles.

For each span, the accelerometers have been placed, together with the base station, on the bridge for a total amount of time ranging from 10 to 15 hours. In this way it has been possible to acquire an adequate number of train passages. The acquisition setup is collected in Table 1. Additional details regarding the experimental campaign can be found in Bernardini et al. (2021).

Table 1. Acquisition setup adopted during the experimental campaign.

Sampling frequency 10g accelerometers [Hz]	256
Sampling frequency 40g accelerometers [Hz]	1024
Trigger threshold for deck accelerometers (10g) [m/s^2]	0.05
Trigger threshold for track accelerometers (40g) [m/s^2]	0.5
Pre-trigger [s]	5
Minimum observation length [s]	40

The acquired signals contain both forced and free motions, as shown in Figure 3. The viaducts free decays, after train transit, have been used for modal analysis. Therefore, before being processed, the measured accelerations have been treated with the purpose to remove the forced motion (boxed in red in Figure 3) and retain only the free decay (boxed in green in Figure 3). Once the accelerations have been purged from the forced motion and the isolated free responses, collected during the testing interval, have been put in series one with each other, it has been possible to use the time series corresponding to each sensor composing the mesh as input for the commercial software ARTEMIS, used for modal identification. Therefore, modal parameters, namely eigenfrequencies, and the associated mode shapes and damping ratios, have been estimated.

Figure 3. Example of recorded midspan deck acceleration. Forced motion boxed in red, free decay boxed in green.

4 FINITE ELEMENT MODELING AND VALIDATION

Structural modeling is developed with different levels of complexity adopting beam finite elements and three-dimensional (3D) solid finite elements. Geometrical and mechanical properties of the bridge decks are calibrated based on data gathered from design technical documentation and results from experimental activities which include non-destructive tests and laboratory tests. Moreover, the results of dynamic modal tests are used to validate the numerical models and investigate the dynamic response of the bridge decks.

Beam finite element models allow for an adequate balance between representativeness of the structural response and computational cost. This kind of modeling is particularly effective at representing the overall response of the structure and capture the role of the main structural elements (i.e., longitudinal and transversal beams).

3D solid finite element models are more effective to represent the actual bridge geometry, capture the local structural response at the stress-diffusion zones and incorporate local contributions to the stiffness properties of the structural system. These models are also a further support to validate the beam finite element models. On the other hand, they have a larger computational cost compared to beam models.

The definition of geometry, topology, boundary conditions, restraints, and mechanical properties of the finite element models based on the available technical documentation and data gathered from diagnostic activities is described in the following, along with the results of modal analyses with emphasis on the validation process based on the results of dynamic testing. Individual bridge deck spans are firstly considered for a preliminary calibration of the structural model with the experimental results. A joint model with two spans is hence considered to investigate the role of the railway track superstructure (e.g., ballast).

4.1 *Mechanical characteristics of concrete*

The mechanical characteristics of concrete have been assessed based on the results of the non-destructive sclerometric and ultrasonic experimental tests and laboratory compression tests on concrete samples. Table 2 reports the mean value of compressive cube strength and elastic modulus, along with the coefficient of variation (CoV) of the compressive cube strength, resulting from a statistical analysis combining the outcomes of non-destructive and destructive tests for one of the inspected bridge deck. Mean values have been assumed as nominal values and adopted in the validation process of the structural models.

Table 2. Statistical results from diagnostic activities.

Element	Mean compressive cube strength R_{cm} [MPa]	CoV(R_c)	Mean elastic modulus E_{cm} [MPa]
Longitudinal beams	61.18	3.12 %	35821
Transversal beams	42.77	6.29 %	32174

4.2 *Beam finite element modeling*

The cross-sectional geometry of the structural elements has been defined for the different bridge components based on design technical documentation and results of survey and inspection activities. Figure 4 shows an isometric view of the structural model with solid section of the longitudinal beams (Figure 4a) and transversal beams with collaborating top slab (Figure 4b).

The bearing support devices are modeled by rigid constraints. At the location of the unidirectional roller supports, the displacement components are constrained along vertical and transversal direction. At the location of the hinge supports, also longitudinal displacement component has been constrained.

For the structural (deck) and non-structural (ballast) masses density values of 2.5 t/m^3 and 9 t/m^3 , respectively, are assumed. The masses have been considered concentrated at the nodes and the portion of the mass at each node has been calculated in proportion to the corresponding influence area in the plan view.

Figure 4. Isometric view of a beam model of the bridge deck: (a) longitudinal beams and (b) transversal beams with collaborating top slab.

Figure 5 shows the mode shapes of a bridge deck associated to first and second bending and torsional eigenfrequencies. Table 3 compares the first three natural frequencies obtained from both numerical analysis and experimental dynamic tests for one of the inspected bridges. The numerical vs experimental comparison allows to validate the numerical model of the bridge deck in terms of geometry, stiffness, and mass properties associated to the bridge members.

Figure 5. Natural vibration modes of the deck based on the beam modeling: (a) First torsional; (b) First flexural; (c) Second torsional; (d) Second flexural.

Table 3. Numerical vs experimental natural frequencies for a bridge deck.

Mode	Natural frequency [Hz]	
	Numerical	Experimental
First torsional	5.61	6.33
First flexural	5.63	5.92
Second torsional	19.94	19.88

4.3 Three-dimensional solid modeling

The 3D solid finite element modeling has been developed based on the volumetric sectional area reported in the design technical documentation of the different bridge deck members. Figure 6 shows a transversal section of the bridge deck with longitudinal beams (Figure 6a),

end ribs (Figure 6b), and stiffening transversal beams (Figure 6c) with collaborating top slab. The implementation of the structural model is based on the reference transversal sections that have been extruded along the longitudinal direction.

Figure 7 shows the 3D solid model, with a finite element discretization selected to guarantee adequate shape factor and aspect ratio (Figure 7a) and to accurately reproduce the tapered portions of the longitudinal beams adjacent to the transversal elements (Figure 7b). The model is mostly composed by hexahedral finite elements except for the elements that form the tapering portions of the longitudinal beams, which are based on tetrahedral elements with triangular or rectangular base. At location of the roller supports, the vertical and transversal displacement components have been constrained on the footprint of the support devices. At location of the hinge supports, also the longitudinal displacement components have been constrained.

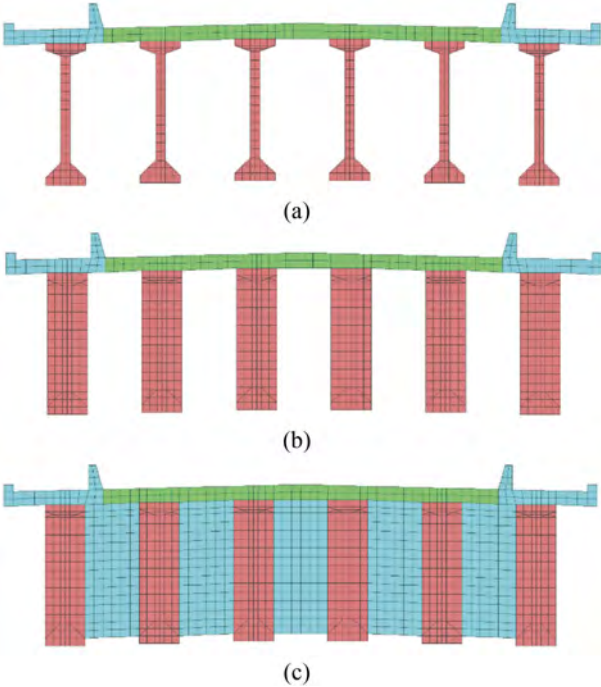

Figure 6. Transversal cross-sectional modeling and finite element discretization of the deck with (a) longitudinal beams, (b) end ribs, and (c) stiffening transversal beams with collaborating top slab.

Figure 7. Three-dimensional solid model of the deck: (a) isometric view and (b) detail of the end region.

Figure 8 shows the natural vibration modes of a bridge deck associated to first and second bending and torsional modes. Table 4 compares the first three natural frequencies obtained from the two numerical models (i.e., beam and solid models) versus the experimental results.

Figure 8. Natural vibration modes of the bridge deck based on the solid modeling: (a) First torsional; (b) First flexural; (c) Second torsional; (d) Second flexural.

Table 4. Numerical (beam and solid models) vs experimental natural frequencies of a bridge deck.

Mode	Natural frequency [Hz]		
	Numerical (Beam Modeling)	Numerical (Solid Modeling)	Experimental
First torsional	5.61	6.38	6.33
First flexural	5.63	5.28	5.92
Second torsional	19.94	20.50	19.88

This comparison indicates a good agreement between the two models, as well as between numerical and experimental results. These successful comparisons validate the numerical models and confirm the accuracy and effectiveness of the beam modeling of the grillage bridge deck, characterized by lower computational cost and easier management and interpretation of the overall structural response compared to a 3D solid modeling.

4.4 Modeling of railway tracks and interaction of bridge decks

The multi-span railway bridge superstructure participates in the structural response for both the contribution of non-structural elements (i.e., ballast and railway tracks) and for the interaction between adjacent bridge decks. The role of the railway tracks has been investigated with the 3D finite element model through the joint modeling of two adjacent spans of a viaduct. The railway tracks have been modeled with beam finite elements attached to the bridge deck by means of elastic links, that simulate the role of the ballast, with estimated stiffness of 190 MN/m^2 . Outside the bridge deck, for a length of 40 m beyond the deck ends, the elastic connection of the tracks has been attached to the ground. Figure 9 shows an overall isometric view of the model of two adjacent decks (Figure 9a) and a detail of the railway track-bridge deck connections

Figure 9. Modeling of railway tracks and interaction of adjacent bridge decks: (a) isometric view of two adjacent spans with railway tracks; (b) detail of the railway track-bridge deck connections.

(Figure 9b). As expected, it has been found that the role of the railway tracks in the structural response is quite limited and modal analysis conducted on this assembled structural model leads to negligible variations of natural frequencies due to this interaction.

5 CONCLUSIONS

This paper presented the validation of finite element models for modal analysis of concrete grillage bridge decks as part of a more extensive activity for condition assessment and experimental testing of a group of viaducts along a high-speed railway line in Italy. Structural modeling has been developed with different levels of complexity adopting beam finite elements and 3D solid finite elements. Geometry, topology, boundary conditions, restraints, and mechanical properties of the structural models have been based on the available technical documentation and data gathered from diagnostic activities, which include non-destructive tests and laboratory tests. Along with models of individual bridge decks, a joint model with two adjacent decks has been also considered to investigate the role of the railway track superstructure. The outcomes of dynamic modal tests have been hence used to validate the numerical models.

The results indicated good agreement between the two types of modeling, as well as between numerical and experimental results. These successful comparisons allowed to validate the numerical models and confirmed the accuracy and effectiveness of the beam modeling of the grillage bridge deck, characterized by lower computational cost and easier management and interpretation of the overall structural response compared to a 3D solid modeling. Finally, it has been found the role of the railway tracks in the structural response is quite limited, with negligible variations of the natural frequencies due to the railway track-bridge deck connections.

BOLINA Ingegneria, Venice, Italy

ABSTRACT: Historic masonry buildings are often heavily damaged by earthquakes, resulting in huge loss of cultural heritage. Several studies have shown the effectiveness of seismic vulnerability mitigation via base isolation systems (BISs). This paper presents a major BIS project for seismic retrofitting of an existing strategic masonry building, which was built in the early 1950s in Perugia (Italy) and hosts the Umbria Region headquarters and other major public offices. The BIS design started from a historical investigation on the original design, fabrication and modifications of the masonry building. On-site experimental tests on both subsoil and masonry structure, as well as geometric surveys, were carried out, allowing a good knowledge of the building and calibration of three-dimensional structural models. The structural characteristics, historical value and public function of the building delineate a case study with considerable importance in the field of seismic isolation of existing masonry buildings.

Keywords: Seismic base isolation, Historic masonry buildings, Structural analysis, Construction

1 INTRODUCTION

Construction industry is among the largest global economy sectors, particularly if the most industrialized countries are considered. The uncertain nature of potentially harmful events (be they natural, anthropic or a combination of them), structural response of engineering facilities to such events, and consequences on property and people call for performance-based engineering methods and implementation of risk-based concepts in structural engineering (Dickson et al. 2012). In addition, a rational approach to disaster risk mitigation of civil infrastructure relies upon consideration of life-cycle performance of structures, accounting for aging and deterioration of materials, components and connections (Frangopol et al. 2004) as well as interaction with climate-change-related phenomena (Olsen 2015). Civil infrastructure is indeed meant to ease and protect human life, represent the welfare and heritage of people, and host a great part of the investments of both individuals and communities (DMRH 2017).

In the context of earthquake engineering, seismic design and retrofitting of structures is usually based on damage tolerance and control, taking advantage of the dissipation of inelastic materials and redistribution phenomena under strong ground motion. Nonetheless, seismic protection of strategic facilities must rely upon their ability to be operational under ground motion, allowing disaster emergency management and hence resilience of communities. None to slight damage is thus required to strategic structures, even if a strong earthquake occurs. This is in favor of a quick recovery process at both urban and regional scales, mitigating socioeconomic issues related to people dislocation away from their houses at least to allow safety checks on damaged structures.

Seismic base isolation, namely the idea of de-coupling the sub-structure from the super-structure through cutting and installation of specific devices able to lower the seismic demand on the superstructure (shifting the fundamental vibration period of the structure in the response spectrum towards longer periods associated with lower levels of acceleration) is an ancient technique based on self-construction (Figure 1) and empirical trial-and-error practice. Examples are known since the past in many earthquake-prone regions. In more recent times, starting from the early 1970s, base isolation has started becoming a standard for new construction in areas with medium-to-high seismicity. Accordingly, specific industrial products are constantly provided, certified and installed according to the rules of specifically oriented product standards (CEN 2009, Medeot & Zordan 2017, Zordan & Medeot 2020).

Figure 1. Seismic base isolation techniques: (a) general layout and (b, c) historic evidence based on self-construction.

Base isolation is known to be an effective tool in ensuring operation of structures and infrastructures hit by a severe earthquake, preventing damage to the super-structure and fully protecting non-structural components and content. In recent years, the possibility to provide also existing structures and infrastructures (and specifically buildings originally built with a fixed base) with base isolation has become a reality. After the earthquake that hit the city of L’Aquila (central Italy) in 2009, several applications of base isolation have taken place in Italy, mainly boosted by economic incentives introduced by the Italian government for reconstruction, in order to promote an increased and diffuse seismic resilience of the national built environment. Besides, innovation in seismic isolators is even more allowing effective disaster risk mitigation in masonry buildings located in developing countries (Losanno et al. 2021, 2022, 2023).

In this study, a major base isolation project for seismic retrofitting of an existing strategic masonry building with historical-architectural value is presented. After that key data on the original design, fabrication and modifications of the masonry building are collected, the paper illustrates the other phase of the knowledge process, which was based on-site experimental tests and geometric surveys. Then, three-dimensional (3D) modelling and response analysis of the masonry building are described, highlighting the significant benefits due to seismic base isolation. The paper ends with a short description of construction phases related to the creation of the base isolation system (BIS).

2 MAIN CHARACTERISTICS AND ON-SITE ASSESSMENT OF THE BUILDING

2.1 Short description of the building

The case-study building which was equipped with a BIS is Palazzo Partigiani in Perugia, Italy. That facility is a strategic building built in the early 1950s, mostly using unreinforced masonry as construction material but also other technologies. The building hosts the headquarters of Umbria Region, Perugia public prosecutor’s office and some offices of the Italian Ministry of

Infrastructure and Transportation. The building consists of five floor levels with L-shaped plan, which is approximately 1600 m² in size (Figure 2).

The structural design for the base isolation of the building began with a comprehensive historical investigation based on archival data and literature, which allowed the authors to assess how the building was conceptually designed and fabricated.

Figure 2. External views of Palazzo Partigiani in Perugia, Italy: (a) building at the end of construction in 1950; (b) building at present.

2.2 On-site assessment

A systematic survey of construction materials, together with an extensive campaign of investigations on geometry of foundations and on the superstructure, allowed the authors to achieve an exhaustive level of knowledge on the typological and mechanical characteristics of materials and construction details. First of all, the field activity showed how the building, in its seventy years of life, has undergone two main interventions; the former consisted of a superelevation of the building with the creation of a further storey; the latter was aimed at energy retrofitting.

An extensive campaign of non-destructive tests was carried out, particularly to identify the building portion made of masonry and the other fabricated with reinforced concrete (RC). Tomography, georadar and pacometer surveys were extensively used for this purpose (Figure 3).

Specimens were extracted and tested to determine the mechanical properties of concrete. Leeb rebound hardness tests were performed to identify the type of reinforcing steel (Figure 4).

Both single- and double-flat jack testing methods were implemented to measure compressive stresses and to evaluate the mechanical parameters of the masonry, respectively (Figure 5).

Figure 3. Termography, georadar and pacometer tests for identification of materials and structural components.

Figure 4. Leeb rebound hardness test and concrete samples.

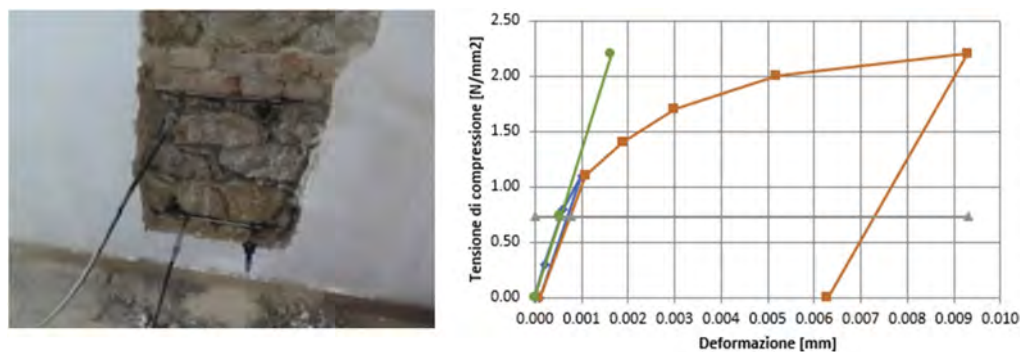

Figure 5. Double-flat jack testing and estimation of secant modulus of masonry.

Furthermore, pull-out tests on concrete were correlated to sample tests in order to obtain a general mapping of the actual properties of structural concrete (Figure 6).

Extensive endoscopy testing offered the chance to assess directly both the shape and appearance of elements, which otherwise would have been inaccessible to direct observation. This allowed the authors to carry out useful evaluations and to determine the exact sequence of layers in different parts of the structure (Figure 7).

The endoscopes gave also evidence of the state of conservation of materials and structural elements. Finally subsoil cores were extracted from boreholes, while deriving the geometry and consistence of the foundation system (Figure 8).

Figure 6. Pull-out tests.

Figure 7. Endoscopy with direct assessment of different layers and degree of conservation of materials.

Figure 8. Subsoil cores obtained from boreholes and foundation assessment.

3 STRUCTURAL MODELLING AND ANALYSIS

Structural modelling and response analysis of Palazzo Partigiani were performed according to two alternative methods, namely, the equivalent frame (EF) modelling approach and the continuum-based finite element (FE) modelling approach based on the macro-modelling of masonry (Augenti & Parisi 2019). Two software packages were used for the above-mentioned modelling approaches, i.e. 3Muri and MasterSap. Specifically, the EF modelling approach was implemented for design and safety checking of the fixed-base structure (Figure 9a). Experimental data were effectively used to model mechanical properties of materials. Afterwards, the FE model was created and calibrated against the EF model in 3Muri, reproducing approximately the same natural periods, modal shapes, and participating masses.

Nonlinear static analysis with displacement control of the original fixed-base structure showed remarkable flaws in terms of seismic capacity, evidencing huge damage to the super-structure (Figure 10a) and insufficient displacement capacity at the ultimate limit state. Therefore, a target isolation period $T_{1,ISO} = 2.1$ s was defined, starting from a fixed-base fundamental period $T_{1,FB} = 0.5$ s, in order to design the base isolation system (Figure 10b). This latter consisted of a combination of different devices, namely 63 elastomeric bearings and 43 multidirectional rollers. Simple calculations allowed minimization of the eccentricity between the centers of mass and stiffness of the structure, as shown in Figure 11.

Figure 9. Structural models of the masonry building: (a) equivalent frame model for safety checks of the fixed-base structure and calibration of the continuum finite element model; (b) FE model for design of the base isolation system.

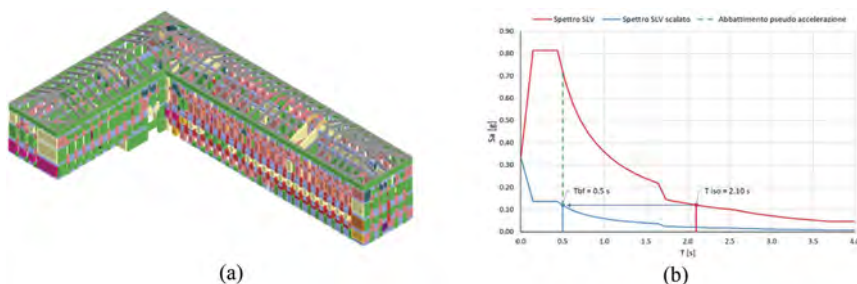

Figure 10. (a) Distribution of damage to the super-structure in fixed-base configuration and (b) identification of the base isolation target period.

Figure 11. Layout of the elastomeric isolators and multidirectional rollers.

Despite the L-shaped plan of the building, the BIS produced an almost perfect decoupling of vibration modes in the two principal directions, as shown in Figure 12. The maximum displacement at the isolation level was found to be 162 mm, whereas the top roof displacement was estimated in 185mm. This produced a maximum relative displacement at the roof level equal to 230 mm, namely, a very small roof drift ratio. Consequently, no damage to the super-structure was found in the base isolated configuration, as outlined by safety checks in the base-isolated building (Figure 13). Thus, the BIS designed for Palazzo Partigiani allows a significant reduction in seismic demand on the super-structure, hence ensuring operation during strong earthquakes.

Figure 12. Maximum displacements predicted for the limit state of collapse.

Figure 13. Outcomes of safety checks in structural elements of the base-isolated building.

4 FABRICATION OF THE BASE ISOLATION SYSTEM

The sequence of phases aiming to implement seismic base isolation at the level of the building foundation system is depicted in Figure 14. Specifically, the base isolation system was created through the following phases:

- Phase 1: Original site condition.
- Phase 2: Realization of a diaphragm wall.
- Phase 3: Cutting of masonry wall segments to create the isolation level.
- Phase 4: Fabrication of RC ring beams at the base of existing masonry walls, with removal of existing masonry (to get decoupling between sub-structure and super-structure) and final positioning of seismic isolators.
- Phase 5: Activation of the base isolation system and realization of finishes.

Figure 14. Construction phases for base isolation of the building.

5 CONCLUSIONS

In this paper, the base isolation of a strategic masonry building located in Perugia, Italy, has been presented. The building has architectural-historical value and hosts major public offices that are expected to be used to manage emergency operations after an earthquake. Therefore, the building was retrofitted with the aim of significantly reducing seismic demand on the super-structure, and hence damage. Key information on the building design, fabrication and modifications over time was collected, supporting the design of the base isolation system. On-site experimental tests and surveys were also conducted to assess materials, construction technologies, and detailing. Analysis results show that the isolation system allows the structure to significantly reduce lateral deformation under strong earthquakes, as well as to avoid damage to the super-structure. Ultimately, construction phases for creation of the base isolation system allows building operation during seismic retrofitting. The structural attributes, historical value and strategic role of the building outline a case study with significant importance in the field of seismic isolation of existing masonry buildings.
