

Life-Cycle of Structures and Infrastructure Systems

Editors

Fabio Biondini and Dan M. Frangopol

LIFE-CYCLE OF STRUCTURES AND INFRASTRUCTURE SYSTEMS

Life-Cycle of Structures and Infrastructure Systems collects the lectures and papers presented at IALCCE 2023 - The Eighth International Symposium on Life-Cycle Civil Engineering held at Politecnico di Milano, Milan, Italy, 2-6 July, 2023. This Open Access Book contains the full papers of 514 contributions, including the Fazlur R. Khan Plenary Lecture, nine Keynote Lectures, and 504 technical papers from 45 countries.

The papers cover recent advances and cutting-edge research in the field of life-cycle civil engineering, including emerging concepts and innovative applications related to life-cycle design, assessment, inspection, monitoring, repair, maintenance, rehabilitation, and management of structures and infrastructure systems under uncertainty. Major topics covered include life-cycle safety, reliability, risk, resilience and sustainability, life-cycle damaging processes, life-cycle design and assessment, life-cycle inspection and monitoring, life-cycle maintenance and management, life-cycle performance of special structures, life-cycle cost of structures and infrastructure systems, and life-cycle-oriented computational tools, among others.

This Open Access Book provides both an up-to-date overview of the field of life-cycle civil engineering and significant contributions to the process of making more rational decisions to mitigate the life-cycle risk and improve the life-cycle reliability, resilience, and sustainability of structures and infrastructure systems exposed to multiple natural and human-made hazards in a changing climate. It will serve as a valuable reference to all concerned with life-cycle of civil engineering systems, including students, researchers, practitioners, consultants, contractors, decision makers, and representatives of managing bodies and public authorities from all branches of civil engineering.

Table of contents

Preface	xli
Acknowledgments	xliii
Symposium Organization	xliv
Organizing Association	xlix
 <i>FAZLUR R. KHAN PLENARY LECTURE</i>	
Making bridges sustainable <i>E. Brühwiler</i>	3
 <i>KEYNOTE LECTURES</i>	
Probabilistic life-cycle performance assessment of corroded concrete structures: Core technologies to predict the remaining service life <i>M. Akiyama & D.M. Frangopol</i>	21
The structural life of a Cathedral and the worksites of the Duomo di Milano <i>F. Canali & D. Coronelli</i>	33
Field and laboratory tests for corrosion assessment of existing concrete bridges <i>M. Carsana, E. Redaelli & F. Biondini</i>	45
Bayesian assessment of existing concrete structures: Exploiting the full power of combined information <i>R. Caspele & W. Botte</i>	57
Safety assessment of civil infrastructure assets subjected to extreme events <i>M. Ghosn</i>	69
Digital transition in asset management of bridges – Advantages and challenges <i>J.S. Jensen</i>	81
Life-cycle sea-crossing bridge operation under strong winds in severe weather <i>H.-K. Kim, H.-Y. Cheon & S. Kim</i>	90
Resilient structures: Materials Components Systems <i>M.P. Sarkisian</i>	98
Risk and decision-making for extreme events: What terrorism and climate change have in common <i>M.G. Stewart</i>	109

MINI-SYMPOSIA

MS1: Component reuse in structures and infrastructures

Organizers: *O. Iuorio & C. Fivet*

The design and development of a demountable and reconfigurable segmented fan concrete shell flooring system	119
<i>M. Nuh, J. Orr & R. Oval</i>	
Can we reuse plasterboards?	127
<i>S. Kitayama & O. Iuorio</i>	
Re-use of existing load-bearing structural components in new design	135
<i>R.P.H. Vergoossen, G.J. van Eck & D.H.J.M. Jilissen</i>	
Quality assurance process for reuse of building components	142
<i>A. Räsänen & J. Lahdensivu</i>	
Calculating embodied carbon for reused structural components with laser scanning	149
<i>B.S. Byers, M. Gordon, C. De Wolf & O. Iuorio</i>	
Reuse of existing reinforced concrete beams: Exploration of residual mechanical characteristics and measure of environmental impact	157
<i>A. Lachat, A. Feraille, T. Desbois & A.S. Colas</i>	
Designing with recovered precast concrete elements	165
<i>T.S.K. Lambrechts, F.J. Mudge, S.N.M. Wijte & P.M. Teuffel</i>	
Building structures made of reused cut reinforced concrete slabs and walls: A case study	172
<i>N. Widmer, M. Bastien-Masse & C. Fivet</i>	
Reuse of fibrous tectonics as the secondary structure of the facade system	180
<i>A. Ahmadnia, C. Monticelli, S. Viscuso & A. Zanelli</i>	
Properties and durability of recycled concrete with mixed granulates: Application for infrastructures	188
<i>C. Paglia, C. Mosca & E.G. Cordero</i>	
Behavior of bolted shear connectors for demountable and reusable UHPC-formed composite beams	195
<i>H. Fang</i>	

MS2: Smart condition assessment of railway bridges

Organizers: *T. Bittencourt, R. Calçada, D. Ribeiro, H. Carvalho, M. Massao & P. Montenegro*

A monitoring based digital twin for the Filstal bridges	205
<i>A. Lazoglu, H. Naraniecki, I. Zaidman & S. Marx</i>	
An application of drive-by approach on a railway Warren bridge	213
<i>L. Bernardini, A. Collina, C. Somaschini, K. Matsuoka & M. Carnevale</i>	
Optimal design and application of 3D printed energy harvesting devices for railway bridges	221
<i>J.C. Cámara-Molina, A. Romero, P. Galvín, E. Moliner & M.D. Martínez-Rodrigo</i>	
Smart condition monitoring of a steel bascule railway bridge	229
<i>J. Nyman, P. Rosengren, P. Kool, R. Karoumi, J. Leander & H. Petursson</i>	

A Bayesian bridge model update with complex uncertainty under high-speed train passages <i>K. Matsuoka, D. Mizutani, C. Somaschini, L. Bernardini & A. Collina</i>	237
Computational analysis of a reinforced concrete railway bridge considering the soil-structure interaction <i>A.L. Gamino, R.R. Santos, T.N. Bittencourt, M.M. Futai & H. Carvalho</i>	244
Drive-by damage detection methodology for high-speed railway bridges applying Mel-frequency cepstral coefficients <i>E.F. Souza, T.N. Bittencourt, I. Ames, D. Ribeiro & H. Carvalho</i>	252
Evaluation of corroded reinforced concrete railway bridge subjected to concrete cracking under uncertainty <i>L.S. Moreira, T.N. Bittencourt, M.M. Futai & H. Carvalho</i>	260
Structural reliability analysis of vehicle-bridge interaction based dynamic response for a high-speed railway bridge <i>I. Ames, T.N. Bittencourt, M.M. Futai, A.T. Beck & E.F. Souza</i>	268
 MS3: Integrating life-cycle engineering concepts into community resilience and decision-support	
<i>Organizers: J. van de Lindt, J. Padgett, A.R. Barbosa & N. Makhoul</i>	
Resilience and the use of life-cycle cost analysis in civil engineering in the US <i>T. Neimeyer, B. Parsons, L. Champion, A. Kane & L. Orsenigo</i>	279
The value of multi-criteria decision analysis for asset management <i>J. Bödefeld & F. Marsili</i>	287
Toward enhancing community resilience: Life-cycle resilience of structural health monitoring systems <i>N. Makhoul & R. Kromanis</i>	295
The life-cycle of a community for physical-social interdependent resilience impacted by policy decisions following tornado hazards <i>W. Wang, J.W. van de Lindt, S. Hamideh & E. Sutley</i>	303
Impact of modeling uncertainty on seismic life-cycle cost analysis of RC building under mainshock-aftershock sequences <i>S.P. Rayjada, J. Ghosh & M. Raghunandan</i>	311
Sensitivity analysis on resilience components throughout the lifecycle of an asset <i>N.K. Stamataki & D.V. Achillopoulou</i>	319
A Markovian framework to model life-cycle consequences of infrastructure systems in a multi-hazard environment <i>K. Otárola, L. Iannacone, R. Gentile & C. Galasso</i>	325
Integrating life-cycle analysis into civil infrastructure resilience decision making: Illustrative application to seismic resilience modeling of US communities <i>M. Roohi, J. Li & J.W. Van de Lindt</i>	333
Smart resilience: Capturing dynamic, uncertain and evolving lifecycle conditions <i>R. Rincon & J.E. Padgett</i>	341

MS4: Vibration-based structural health monitoring, damage identification and residual lifetime estimation

Organizers: E. Reynders, G. Lombaert, E. Chatzi & C. Papadimitriou

Structural damage estimation using short-time Fourier transform and improved convolution neural networks 351

C. Shi, Y. Aoues, R. Troian, D. Lemosse & H. Bai

Dynamic characteristic study of a heritage structure in Tiruchirappalli city using operational modal analysis 359

S. Anjuna, N. Radhakrishnan & G. George

Optimal design of a vibration-based sensor network for bridge monitoring 367

M.F. Yilmaz, K. Ozakgul & B.O. Caglayan

Indirect bridge damage detection using frequencies identified from vibrations of a single two-axle vehicle 374

Z. Li, W. Lin & Y. Zhang

Small-scale damage detection of bridges using machine learning techniques and drive-by inspection methods 383

Y. Lan, Z. Li, Y. Zhang & W. Lin

Structural health monitoring of the KW51 bridge based on detailed strain mode shapes: Environmental influences versus simulated damage 391

D. Anastasopoulos, K. Maes, G. De Roeck, G. Lombaert & E.P.B. Reynders

Dissipated hysteretic energy reconstruction for high-resolution seismic monitoring of instrumented buildings 399

M. Roohi, E.M. Hernandez & D.V. Rosowsky

Follow-up assessment of a prestressed concrete road bridge based on dynamic bridge behaviour – analysis of structural integrity and evaluation of maintenance condition 407

T. Reimoser, R. Veit-Egerer, A. Schmitt & Y. Benitz

Laboratory validation of an arduino based accelerometer designed for SHM applications 415

S. Komarizadehasl, E. Delgado, G. Ramos, J. Turmo & J.A. Lozano-Galant

Pre-posterior effectiveness of modal extraction techniques for vibrational tests design 422

A. Lotti, D. Tonelli, S. Zorzi, D. Zonta & E. Tubaldi

MS5: Life-cycle performance assessment of civil engineering systems

Organizers: M. Akiyama, D.M. Frangopol & H. Matsuzaki

Structural reliability assessment of RC shield tunnels with nonuniform steel corrosion 433

Z. He & C. He

Life-cycle analysis of aging structures based on reliability approach 439

S. Joshi, A. Thorat, H. Dehadray & M. Tundalwar

Baseline digital twin models for key performance management of prefabricated bridges 447

C.S. Shim, G.T. Roh, M.U. Kang & Y.H. Lee

Analysing the impact of local factors on the life-cycle of metallic bridge girders 453

G. Calvert, M. Hamer, L. Neves & J. Andrews

Quantifying the effects of long duration ground motions on the lifetime seismic losses of aging highway bridges	461
<i>S. Shekhar, B. Panchireddi & J. Ghosh</i>	
Seismic demand hazard assessment for RC bridges considering cumulative damage over time	469
<i>D. Herrera & D. Tolentino</i>	
Development of maintenance systems for bridge members	477
<i>K. Kwon, Y. Choi & J.S. Kong</i>	
Durability analysis and optimization of a prestressed concrete bridge strengthened by a fiber reinforced concrete layer	485
<i>S. Schoen, P. Edler, G. Meschke & S. Freitag</i>	
Multivariate inspection of German steel civil infrastructure using autonomous UAS	493
<i>D. Thomas, M. Gündel, A. Wickers, M. Alpen & J. Horn</i>	
A lifecycle analysis approach to the impact of green roofs on the structural and thermal performances of buildings	501
<i>S. Kalantari, M.R. Rashedi, R. Ehsani & F.M. Tehrani</i>	
Deep learning-based life-cycle system reliability assessment of asphalt pavement	509
<i>J. Xin, D.M. Frangopol & M. Akiyama</i>	
Climate change impact on the integrity of structures and infrastructure in mountainous or hilly areas	515
<i>Y. Tsompanakis, N. Makrakis, P.N. Psarropoulos & D.M. Frangopol</i>	
Assessing life-cycle seismic fragility of corroding reinforced concrete bridges through dynamic Bayesian networks	523
<i>F. Molaioni, Z. Rinaldi & C.P. Andriotis</i>	
 MS6: Smart maintenance and AI applications	
<i>Organizers: H. Furuta, N. Catbas & Y. Nomura</i>	
Bolt axial force detection using deep learning based on vision methods	533
<i>Y. Chen, J. Lai, G. Hayashi & T. Yamaguchi</i>	
Proposal of deep learning ensemble method for phased array ultrasonic testing for tube-to-tubesheet weld of heat exchange	541
<i>H. Hattori, J. Murakami, N. Shinmura, K. Shinoda, M. Abe, T. Katayama, R. Ioka & T. Wada</i>	
Innovative methods for the inspection of hydraulic structures	548
<i>A. Seiffert & J. Bödefeld</i>	
Behaviour of corroded bridge bearing and full-bridge modeling	555
<i>A. Hiraoka, G. Hayashi & T. Yamaguchi</i>	
Damage identification of corroded arch bridge using vibration characteristics and rotational angle	562
<i>K. Akahoshi, G. Hayashi, Y. Chen & T. Yamaguchi</i>	
Identification of spalling in concrete structures by a hammering test using autoencoder	570
<i>H. Emoto, N. Fukui, Y. Iitaka & S. Kanazawa</i>	

Corrosion progress detection in steel bridge from vehicle-mounted camera images based on deep learning	578
<i>S. Ozaki, Y. Nomura, H. Furuta, H. Yamazaki & Y. Yamato</i>	
Development of a cable inspection robot for cable-stayed bridges	584
<i>K. Kawamura, W. Zheng & M. Shiozaki</i>	
Application of cluster analysis and Markov chain model for network-level highway infrastructure management	592
<i>A. Amir & M. Henry</i>	
Digital twin-oriented maintenance: A hybrid finite element and surrogate model approach for predicting the excavation-induced tunnel displacement	600
<i>Y. Gu, L. Zhang, Q. Ai, X. Jiang & Y. Yuan</i>	
Development of simple fatigue crack propagation monitoring using IoT	608
<i>T. Ishikawa, N. Matsumoto & K. Komon</i>	
Detection of debonding of CFRP bonded steel members using the AE method	615
<i>M. Mizutani, T. Ishikawa & Y. Fujii</i>	
Condition-based maintenance of fatigue-sensitive structures using model predictive control	623
<i>S. Kong, R. Cao, J. Cheng & Y. Liu</i>	
A deep learning-based corrosion prediction model for paint-coated steel with defects	631
<i>F. Jiang & M. Hirohata</i>	

MS7: Non-deterministic model updating for structural health monitoring of existing structures

Organizers: M. Kitahara, M. Broggi, M. Beer & T. Kitahara

System identification and damage assessment of benchmark model H	641
<i>G.S. Wang, C.W. Lo & F.K. Huang</i>	
Updating simplified jack-up model using basin test data	649
<i>J.X. Cao, S.T. Quek, S.L. Zhang, C. Zhang, M.B. Cai & M. Si</i>	
Application of unscented transformation for Bayesian updating	657
<i>T. Shuku & T. Kitahara</i>	
Environmental influence on structural health monitoring systems	662
<i>J.-H. Bartels, M. Kitahara, S. Marx & M. Beer</i>	
Distribution-free stochastic model updating with staircase density functions	670
<i>M. Kitahara, T. Kitahara, S. Bi, M. Broggi & M. Beer</i>	
Efficient posterior estimation for stochastic SHM using transport maps	678
<i>J. Grashorn, M. Broggi, L. Chamoin & M. Beer</i>	
Evaluating the minimum cross-section thickness of a conveyor support structure member	686
<i>Y. Yang, D. Ogawa, T. Nagayama, S. Kato, K. Hisazumi & T. Tominaga</i>	
Scenario-oriented analysis of bridges subjected to non-deterministic combined seismic actions based on finite element modeling	694
<i>S. Yamamoto, G. Shoji & M. Ohsumi</i>	
Probabilistic-based model updating on a prestressed concrete box girder	701
<i>X. Zhou, D. Chen & C.-W. Kim</i>	

Applicable schemes for the Vehicle-Bridge Interaction System Identification method <i>K. Yamamoto & R. Shin</i>	709
Risk-based resilience assessment framework for thermal power plants after a catastrophic seismic event <i>A. Yuyama, G. Shoji & Y. Kajitani</i>	717
Non-deterministic seismic damage detection of road infrastructure analysing image training database <i>R. Kondo & G. Shoji</i>	725
MS8: Resilience and sustainability of steel based hybrid building structures in the life-cycle environment	
<i>Organizers: D. Dubina, F. Dinu & V. Ungureanu</i>	
Life-cycle assessment of cold formed steel buildings: Main influential materials and parameters <i>O. Iuorio & A. Gigante</i>	735
The new construction products regulation: Opportunity or barrier for reused constructional steel? <i>P. Hradil, L. Fülöp, M. Wahlström & C. del Castillo</i>	743
A comparative life-cycle assessment of structural composite steel-concrete floor systems – A case study <i>I. Lukačević, A. Rajić, V. Ungureanu & R. Buzatu</i>	751
Sustainability and seismic resilience of hybrid lightweight residential buildings <i>D. Dubina, V. Ungureanu & M. Mutiu</i>	759
Influence of fastening systems on the ultimate capacity of steel- faced sandwich wall panels under transverse loads <i>F. Dinu, C. Neagu, S. Lindiri & M. Senila</i>	767
Simplified assessment of the cyclic performance of steel constructions in aggressive environments <i>A. Milone & R. Landolfo</i>	775
Multi-hazard robustness assessment of seismic resistant multi-story steel frame buildings <i>D. Dubina, F. Dinu & J. Dominiq</i>	783
Laser scanning technology for the evaluation of damage in complex building envelopes after extreme load events <i>P.C. Zdrengha, F. Dinu, S. Herban & C. Neagu</i>	791
Design strategies for reusable structural components in the built environment <i>F. Kavoura & M. Veljkovic</i>	799
MS9: Recent development IoT- and ICT-based infrastructure inspection and management	
<i>Organizers: C. Kim, V. Sarhosis, M. Noori & Y. Zhang</i>	
A computer vision-based identification of natural frequency of a pole structure and damage detection <i>D. Kawabe & C.-W. Kim</i>	809

A framework for digital twinning of masonry arch bridges <i>I.B. Muhit, D. Kawabe, D. Loverdos, B. Liu, Y. Yukihiro, C.-W. Kim & V. Sarhosis</i>	817
Quality analyses of crowdsourced smartphone trips for bridge dynamic monitoring <i>T.J. Matarazzo, I. Dabbaghchian, L. Cronin, S.N. Pakzad, S.S. Eshkevari, H. Yin, R. Lassman, P. Santi & C. Ratti</i>	825
Remote ambient vibration-based scour monitoring system <i>S. Kitagawa, H. Yano, C.-W. Kim & D. Kawabe</i>	833
The ratio of stress amplitudes between two directions around welded part of trough rib in orthotropic decks with fatigue cracks <i>R. Saita, M. Ueno, Y. Sugimoto & H. Onishi</i>	841
Ambient-vibration-based operational modal analysis and cable tension estimation in the long-term SHM of a cable-stayed bridge <i>W.J. Jiang, C.-W. Kim & K. Ono</i>	849
Uncertainty quantification of modal properties using half year monitoring data of a plate girder bridge <i>Y. Goi & C.-W. Kim</i>	857
Study on estimation of reaction force based on vibration measurement of girders <i>I. Kim, S. Watanabe, Y. Goi, Y. Kitane, K. Sugiura & N. Okubo</i>	865
Change in vibration characteristics of steel poled structure with damage <i>M. Kato, Y. Goi, Y. Kitane, K. Sugiura & Y. Adachi</i>	872
 MS10: Advances in life-cycle earthquake engineering	
<i>Organizers: L. Capacci, M. Akiyama, F. Biondini & D.M. Frangopol</i>	
Review of advances in life-cycle seismic risk and resilience of bridges and bridge networks <i>L. Capacci, F. Biondini & D.M. Frangopol</i>	883
Agile analysis of life-cycle damage cost of concrete frame structures under earthquake <i>J.M. Bairán & M. García</i>	892
Methodology for determining optimal countermeasure for bridges under seismic and tsunami hazards <i>H. Ishibashi, M. Akiyama & S. Koshimura</i>	899
Seismic damage control of bridges with deteriorated seismic isolation bearings by rupture of anchor bolts <i>H. Matsuzaki</i>	906
Probabilistic resilience assessment of aging bridge networks based on damage disaggregation and stationary proposal importance sampling <i>L. Capacci, F. Biondini & A.S. Kiremidjian</i>	914
Dynamic characteristic of geodesic domes with different location of mass <i>D. Bysiec, T. Maleska & A. Janda</i>	923
Life-cycle benefits of seismic protection using a novel active mass damper <i>C. Fontana, M. Caruso, R. Pinho, F. Menardo, G. Rebecchi & A. Bussini</i>	931
Decision-making procedures for optimal seismic-energy integrated retrofitting of buildings <i>M. Caruso, R. Pinho, R. Monteiro & R. Couto</i>	939

MS11: Life-cycle asset management and the complexity of socio-environmental-technical transitions

Organizers: A. Hartmann, M. Hertogh, J. Bakker & H. Roebers

Multi-stakeholder service life design for rail level crossings <i>Y. Shang, R. Binnekamp & A.R.M. Wolfert</i>	949
Preference-based service life design of floating wind structures <i>H.J. van Heukeelum, A.C. Steenbrink, O. Colomé, R. Binnekamp & A.R.M. Wolfert</i>	957
A life-cycle assessment framework for pavement management considering uncertainties <i>A. Vargas-Farias, J. Santos, A. Hartmann & F. Van der Pijl</i>	965
To replace or not to replace: A model for future functional performance of bridges <i>S.C.A. Mooren, A. Hartmann & S. Asgarpour</i>	973
The end-of-life of bridges: Integrating functional, technical and economic perspective <i>A. Hartmann & J.D. Bakker</i>	981
How to estimate costs of replacement for an aging infrastructure, a Dutch case study <i>G.A. De Raat</i>	989
Plannability of maintenance in life-cycle decision making for infrastructure <i>J.D. Bakker & R. Treiture</i>	995
Predictive twin for steel bridge in The Netherlands <i>G.A. de Raat, J.D. Bakker, G.T. Luiten, J.H. Paulissen, B.Q. de Vogel, H. Scholten & S. de Graaf</i>	1003

MS12: Advanced strengthening and retrofitting solutions for existing concrete structures

Organizers: N. Randl & E. Rossi

Numerical investigation of the effects of graphene on the mechanical properties of fibre reinforced cementitious matrix composite <i>X.M. Zhu, M.N. Su & Y.C. Wang</i>	1013
Experimental behavior of FRCM-confined concrete under high temperature <i>F. Faleschini, C. Pellegrino & K. Toska</i>	1021
Retrofit of RC bridge half-joints: Applications and remarks with emphasis on post-tension techniques <i>G. Santarsiero, V. Picciano, A. Masi & G. Ventura</i>	1029
Enhancing Textile Reinforced Concrete materials by admixing short dispersed fibres <i>E. Rossi & N. Randl</i>	1037
Shear strengthening with F/TRC: Experimental investigation on real scale RC beams <i>E. Rossi & N. Randl</i>	1044
State of the art in flexural prestressing of RC members with SMA materials <i>J. Rogowski & R. Kotynia</i>	1050
FRP shear dowels - Experimental investigation <i>Đ. Čairović, M. Zlámal, J. Venclovský & P. Štěpánek</i>	1058
Bond behavior of CFRP-concrete systems using toughened epoxies <i>D.V. Achillopoulou, A. Kosta, A. Montalbano & F. Choffat</i>	1065

The effect of fatigue loading on the behavior of externally bonded CFRP-to-concrete joints using the grooving method	1073
<i>M. Khorasani, G. Muciaccia & D. Mostofinejad</i>	
Externally applied textile reinforced systems on RC members: Innovative and sustainable materials and techniques	1081
<i>F. Bencardino & R. Curto</i>	
Experimental investigation on strengthening of RC members with HSC overlays	1089
<i>N. Randl & M. Steiner</i>	
Innovative shear strengthening with post-installed undercut anchors	1097
<i>N. Randl, P. Harsányi & J. Kunz</i>	

MS13: Safety and durability of high-performance structures

Organizers: X. Gu & Q. Yu

Evolution of seismic fragility of reinforced concrete columns subjected to corrosion	1107
<i>Y. Liu, W.P. Zhang, X.L. Gu & Y. An</i>	
Experimental study on water absorption in unsaturated concrete	1115
<i>J. Fang, C. Jiang & X.L. Gu</i>	
Monitoring electrochemical chloride extraction process by testing chloride ion contents in electrolyte	1122
<i>C. Song, C. Jiang & X.L. Gu</i>	
Experimental study on stress recovery behavior of Fe-SMA subjected to multi-activation	1127
<i>Q.Q. Yu, Z. Y. Chen, X.L. Gu, X.W. Xiao, W.P. Zhang & Y.H. An</i>	
SMFL-based probability distribution of minimum cross-sectional areas of corroded steel bars	1134
<i>J.L. Qiu, W.P. Zhang, Q.Q. Yu & Z.P. Chen</i>	
Reliability analysis considering epistemic uncertainties with small initial sample and successive updating data	1141
<i>Y. Fei, Y. Jiang, Y. Leng, L. Wang, Z. Chen</i>	
Numerical simulation of freeze-thaw damage deterioration of concrete in cold region	1149
<i>J. Jiang, Y. Wang, Z. Liu & Z. Chen</i>	
Smart aggregate-based automated concrete stress monitoring via deep learning of impedance signals	1158
<i>J.T. Kim, Q.B. Ta, Q.Q. Pham, N.L. Pham & T.C. Huynh</i>	

MS14: Coupled chemical, physical, and mechanical processes in cementitious materials for short- and long-term behavior of R.C. and P.C. structures

Organizers: G. Di Luzio, R. Wan-Wendner, M. Alnaggar & J. Vorel

LCA assessment related to the evolution of the earthquake performance of a strategic structure	1169
<i>D. di Summa, A. Marcucci, M. Nicolò, F. Martignoni, A. Carrassi, L. Ferrara & N. De Belie</i>	
The influence of the expansive site of delayed ettringite formation on the anisotropy of expansion evaluated by mesoscale discrete model	1177
<i>M. Fujishima, T. Miura & H. Nakamura</i>	

Chemo-physics and mechanics of RC for behavioral simulation in micro-seconds to years <i>K. Maekawa, K. Iwama & Y. Takahashi</i>	1185
Temperature dependent modelling approach for early age behavior of printable mortars <i>A. Robens-Radermacher, J.F. Unger, A. Mezhev & W. Schmidt</i>	1193
Experimental study on effect of winter curing conditions on mechanical properties of concrete <i>F.L. Li, W.L. Lu, W.Q. Peng, Y.D. Tang & L.F. Xu</i>	1201
Hygro-thermo-chemo-mechanical coupled discrete model for the self-healing in Ultra High Performance Concrete <i>A. Cibelli, L. Ferrara & G. Di Luzio</i>	1209
Crack healing under sustained load in concrete: An experimental/numerical study <i>G. Di Luzio, A. Cibelli, S.M.J. Al-Obaidi, S.M.I. Radwan, M. Davolio, L. Ferrara, R. Wan-Wendner & Y. Wang</i>	1217
Homogenized mesoscale discrete model for coupled multi-physical analysis of concrete <i>J. Eliáš & G. Cusatis</i>	1225
Early-age cracking in concrete slabs with FRP reinforcement <i>J.E. Bolander, H. Roghani & A. Nanni</i>	1233
Toward distinguishing the chemical, physical, and wetting-drying sulfate attack on concrete <i>I.A.N. Omrani, M. Koniorczyk & D. Bednarska</i>	1241

MS15: Deconstruction and reuse of steel and lightweight metal structures

Organizers: M. Kuhnhenne & P. Kamrath

Requirements for gutting and demolition cost index <i>H. Kesting & M. Helmus</i>	1249
Numerical determination of the wrinkling stress of steel polyurethane sandwich panels for reuse scenarios <i>K. Janczyk & M. Kuhnhenne</i>	1257
Allowable strength estimation of vertical members used for system scaffolds considering reusability <i>N.G. Jang, J.H. Won, S.S. Ko, J.K. Bong & D.H. Chung</i>	1265
Limits of reuse of steel <i>P. Kamrath</i>	1270
The deconstruction of a steel based single story hall <i>P. Kamrath</i>	1278
On the development of regulations for the increased reuse of steel structures <i>H. Bartsch, F. Eyben, J. Voelkel & M. Feldmann</i>	1287
RFID-based traceability system for constructional steel reuse <i>P. Hradil, K. Jaakkola & K. Tuominen</i>	1295
Environmental and economic impact of steel industrial buildings made of reclaimed elements <i>R. Buzatu, V. Ungureanu & P. Hradil</i>	1303

MS16: Assessment of existing masonry arch bridge infrastructure

Organizers: M. Gilbert, G. Cardani, T. Boothby & D. Coronelli

- Optimal strengthening of masonry arch bridges with externally bonded reinforcing layers 1315
M. Bruggi & A. Taliervo
- Static and seismic assessment of Ponte delle Capre, a masonry arch bridge 1323
F. Casarin, S. Bellin, M. Mocellini & R. Fabris
- Damage accumulation in the structural life and assessment of masonry bridges 1331
T.E. Boothby & D. Coronelli
- Three-dimensional limit analysis of barrel arch bridges 1338
D. Coronelli & M.C. Giangregorio
- The reinforced arch method for the life of the ancient bridge of Omegna 1344
L. Jurina, E.O. Radaelli & D. Coronelli
- Numerical investigation of 3D response characteristics of masonry bridges by detailed mesoscale masonry models 1352
M.S. El Ashri, S. Grosman, L. Macorini & B.A. Izzuddin
- Experimental investigation of the effect of masonry infill on the performance of masonry arch bridges 1360
S. Amodio, M. Gilbert & C.C. Smith
- Multi-fidelity modelling of masonry arch bridges under traffic loading 1368
S. Grosman, Q. Fang, L. Macorini & B.A. Izzuddin
- Analysis of masonry arch bridges using multi-scale discontinuity layout optimization 1376
L. He, N. Grillanda, J. Valentino, M. Gilbert & C.C. Smith
- The role of history in the structural assessment of a multi-span masonry arch bridge 1384
G. Zani, P. Martinelli, G. Cardani & M. di Prisco
- Stochastic load-carrying capacity assessment of brick masonry arch bridges 1392
B. Liu, I.B. Muhit & V. Sarhosis
- New UK guidance for the assessment of masonry arch bridges 1400
M. Gilbert, C.C. Smith & S. Amodio

MS17: Recent advance in seismic protection systems: Design, modeling and testing strategies of traditional and innovative solutions

Organizers: A. Pavese & M. Furinghetti

- Prestressed lead damper for seismic protection of structures 1411
V. Quaglino, C. Pettoroso, E. Bruschi & M. Sartori
- Nonlinear analysis of base isolated buildings with curved surface sliders including over-stroke displacements 1419
F.C. Ponzo, A.D. Cesare & N. Lamarucciola
- Effects of wear on the friction coefficient of a curved surface slider 1427
V. Quaglino, E. Bruschi, E. Çavdar, G. Özdemir, V. Karuk & U. Özcamur
- Effects of rubber shear modulus variability on the seismic response of isolated bridges 1435
M. Marra & S. Silvestri

Prediction of the response of a lead-core rubber bearing using machine learning <i>T. Zhelyazov, S. Ólafsson & R. Rupakhety</i>	1443
Experimental assessment of anti-seismic devices performance <i>A. Pavese, S. Reale & M.J. Fox</i>	1450
Vulnerability assessment of bridges within the Italian highway network <i>S. Reale, A. Pavese & M. Furinghetti</i>	1458
Life-Cycle Assessment (LCA) of fiber-reinforced reclaimed-rubber seismic isolators <i>F. Cilento, D. Losanno, C. Menna, C. Ciriello & F. Parisi</i>	1466
Definition of a design procedure of seismic isolation systems based on rubber bearings <i>M. Furinghetti</i>	1474
Inverse design of isolated structures using predicted FEMA P-58 decision variables <i>H.G. Pham & T.C. Becker</i>	1481
Seismic behaviour of building using damage-avoidance shearwall hold-downs <i>L. Budi</i>	1489
MS18: Safety and maintenance of masonry arch bridges: diagnostic, monitoring, modelling, risk analysis and retrofit interventions	
<i>Organizers: F. Cannizzaro, N. Cavalagli, C. Chisari, B. Pantò, F. Scozzese, P. Zampieri & M. Zizi</i>	
Preliminary investigation on the response sensitivity of masonry arch bridges subjected to scour <i>F. Scozzese, A. Dall'Asta & E. Tubaldi</i>	1499
A methodology to derive scour fragility functions for masonry arch bridges <i>G.D. Di Dieco, M. Pregolato & A.R. Barbosa</i>	1507
Experimental modal analysis and finite element model updating of a historical masonry arch bridge <i>M. Morici, V. Nicoletti, G. Leoni & F. Gara</i>	1515
Influence of site effects on the seismic vulnerability of masonry arch bridges <i>Ö. Saygılı & J.V. Lemos</i>	1523
Computational strategy for the design of monitoring for masonry arch bridges using DIC procedures <i>S. Grosman, Q. Fang, L. Macorini & B.A. Izzuddin</i>	1530
Influence of uncertain mechanical parameters on the load-bearing capacity of multi-span masonry arch bridges <i>M. Zizi, C. Chisari & G. De Matteis</i>	1538
Simplified analysis on multiring masonry arch bridges <i>R. Piazzon, P. Zampieri & C. Pellegrino</i>	1546
Effects of changing temperature in the vibration-based model updating of a masonry bridge <i>P. Borlenghi, A. Saisi & C. Gentile</i>	1552
Numerical approaches to assess the load capacity of FRCM strengthened masonry bridges <i>D. Santinon, P. Zampieri, C. Pellegrino, D. Ricci, F. Iodice, A. Vecchi & F. Iacobini</i>	1560
3D collapse mechanisms of masonry bridges subjected to horizontal actions <i>L. Niero, P. Zampieri & C. Pellegrino</i>	1567

Near-collapse deformed configuration of masonry arch bridges <i>G. Stagnitto & P. Zampieri</i>	1574
Safety checking at point and section level of masonry arch bridges <i>G. Stagnitto, R. Siccardi, M. Ghioni & P. Zampieri</i>	1582
Discrete Macro-Element structural assessment of a railway masonry arch bridge subjected to pier settlements <i>D. Rapicavoli, F. Cannizzaro, S. Caddemi & I. Calì</i>	1590

SPECIAL SESSIONS

SS1: Climate change effects on life-cycle safety, reliability, and risk of structures and infrastructure systems

Organizers: F. Biondini, Z. Lounis & M. Ghosn

Framework for life-cycle tsunami risk assessment considering sea-level rise effects due to climate change <i>A.K. Alhamid, M. Akiyama, K. Aoki, S. Koshimura & D.M. Frangopol</i>	1601
Life-cycle design of concrete highway bridge decks under climate change <i>H. Shirkhani, Z. Lounis & J. Zhang</i>	1609
Climatic design data for buildings and infrastructure under changing climate in Canada <i>H. Shirkhani & Z. Lounis</i>	1617
Life-cycle structural reliability of RC bridge piers under corrosion in a changing climate <i>G.V. Nava, L. Capacci, F. Biondini & L. Casti</i>	1625
Risk based life-cycle planning for flood-resilient critical infrastructure <i>S.S. Palic, I. Stipanovic, E. Ganic, M. Kosic, A. Anzlin, M. Bacic, M.S. Kovacevic & K. Gavin</i>	1634
Equitable climate adaptation framework for levees <i>A. Mohammed & F. Vahedifard</i>	1642

SS2: SHM for life-cycle informed management of degrading structures

Organizers: M.P. Limongelli, P. Gardoni, S. Thöns & D. Lu

Integration of information quality assessment in bridge resilience management <i>N. Makhoul & M.P. Limongelli</i>	1653
Optimum inspection scheduling of steel storage tanks based on past ultrasonic thickness measurements <i>S.A. Faroz, M.S. Khan & S. Ghosh</i>	1661
The role of life-cycle civil engineering practices in smart and sustainable cities <i>M.D. Lepech, A.S. Kiremidjian & K.H. Law</i>	1669
Value of information under random decision, model, and measurement errors <i>Z.Y. Mir Rangrez, J. Ghosh, S. Ghosh & C. Caprani</i>	1677
A review on low-cost sensors compatible with open-source platforms used for life-cycle monitoring of civil structures <i>M. Komary, S. Komarizadehasl, J. Turmo, F. Lozano, J.A. Lozano-Galant & X. Ye</i>	1685

On the utilization of multiple information for the integrity management of deteriorating systems 1693
G. Costa, M.P. Limongelli & S. Thöns

SS3: Monitoring of structures for informed decision making

Organizers: A. Strauss & D.M. Frangopol

Recent progress developing a rating framework for evaluating SHM for bridge scour 1705
P.J. Vardanega, G. Gavriel & M. Pregnolato

Predicting the usefulness of monitoring information for structural evaluations of bridges 1713
N. Bertola & E. Brühwiler

Monitoring and data informed approaches for the condition assessment of existing structures 1721
E. Apostolidi, M.F. Granzner, A. Strauss & R. Geier

A novel low-cost inclinometer sensor based on fusion technology for structural health monitoring applications 1729
M. Komary, A. Alahmad, S. Komarizadehasl, J. Turmo, J.A. Lozano-Galant & Y. Sun

Sensor monitoring for engineering structures: Applications to tunnels 1737
A. Strauss, F. Sattler, B. Täubling-Frueux, C. Seywald, H. Neuner, V. Kostjak & D.M. Frangopol

Digital twins for bridges – concept of a modular digital twin based on the linked data approach 1745
T. Zinke, S. Reymer, S. Kosse, P. Hagedorn, M. König, F. Wedel, S. Schneider, S. Marx, S. Nieborowski & S. Windmann

SS4: Artificial intelligence-based life-cycle management of infrastructure systems

Organizers: Y. Dong, D.M. Frangopol & X. Lei

Sustainability-informed intelligent management of aging civil infrastructure systems with emphasis on bridge networks 1755
X. Lei, Y. Dong & D.M. Frangopol

Meta-learning method for efficient time-variant reliability analysis of deteriorating structures 1763
T. Gao, J. Cheng, Y. Liu, M. Cheng & D.M. Frangopol

Optimization of sewer flushing programs: A deep reinforcement learning approach 1770
A. Keshvari Fard & X.-X. Yuan

Carbon emission reduction in railway maintenance using reinforcement learning 1778
J. Sresakoolchai & S. Kaewunruen

Intelligent monitoring and control method of the life-cycle cable-stayed bridge with steel-concrete composite beam 1786
G.W. Yao, G.F. Zhang, S.Y. Li, Y.F. Wu, E.G. Jiang & Y.D. Zhu

Integrating unstructured data analytics and BIM to support predictive maintenance 1794
S. Sobhkhiz & T. El-Diraby

SS5: Concrete damage assessment using coda waves

Organizers: C. Gehlen, E. Niederleithinger, J. Timothy & T. Kränkel

- Ultrasonic monitoring of large-scale structures - input to engineering assessment 1805
N. Eppe, C.A. Sanchez-Trujillo & E. Niederleithinger
- A new technique to detect altered stresses in tendons early 1813
N. Sträter, F. Clauß, M.A. Ahrens & P. Mark
- Comparison of structural analysis results with coda wave interferometry measurements 1821
S. Grabke & K.-U. Bletzinger
- About the separation of impacts on coda waves in concrete 1827
F. Diewald
- A virtual lab for damage identification in concrete using coda waves 1834
G. Vu, G. Meschke, J.J. Timothy & E.H. Saenger
- The hydration of cement paste: Thermodynamics driven multi-scale modeling of elastic properties and coda wave interferometry based monitoring 1842
E. Jäggle, J.J. Timothy, F. Diewald, T. Kränkel, C. Gehlen & A. Machner

SS6: Life-cycle redundancy, robustness, and resilience indicators for aging structures and infrastructure systems under multiple hazards

Organizers: F. Biondini & D.M. Frangopol

- Financial risk assessment of flexible infrastructure systems 1853
N. Acuña-Coll & M. Sánchez-Silva
- Time-dependent assessment of corrosion impact on R/C members 1861
M. Calò & G. Gabbianelli
- Resilience-based optimal management of aging bridge networks under mainshock-aftershock sequences 1869
L. Jafari, L. Capacci, F. Biondini & M. Khanmohammadi
- Risk-based optimal life-cycle maintenance of post-tensioned concrete bridges considering accuracy of inspection methods in structural model updating 1877
M. Taeb, A.B. Mehrabi & K. Lau
- Seismic safety assessment of “Palácio do Itamaraty” at Brasília reliability-based 1885
P.Q. Rodrigues, J.C. Pantoja & P.S.T. Miranda

SS7: Bridge weigh-in-motion systems and applications to structural health monitoring

Organizers: S. Mustafa & D. Cantero

- Bridge weigh-in-motion to support SHM 1895
D. Cantero
- Bayesian-based bridge influence line identification and uncertainty estimation 1903
S. Mustafa, I. Yoshida & H. Sekiya
- Bridge weigh-in-motion: Feedback on various types of bridges 1911
F.B. Cartiaux, V. Le Corvec, J. Semiao & A. Brouste

Estimation of remaining fatigue life of railway bridges using measurements from the WIM system	1919
<i>M. Zakharenko, G.T. Frøseth & A. Rönquist</i>	
Bridge-weigh-in-motion by strain of transverse stiffener and heavy-truck traffic characteristics in Fukuoka area, Japan	1927
<i>E. Yamaguchi, Y. Furusato, R. Nakamura & K. Horiuchi</i>	
Deep sensor-fusion approach to vehicle detection on bridges using multiple strain sensors	1935
<i>H.T. Vuong, A. Takasu & T.P. Doan</i>	
SS8: Performance, safety, and cost of civil infrastructure in a life-cycle context	
<i>Organizers: Y. Li, P. Yuan, Y. Dong & D.M. Frangopol</i>	
Masonry design for extended life-time usage by implementing joint behaviour	1945
<i>T. Molkens, J. Smits, S.V. Hout & R. Meuleman</i>	
Data-driven life-cycle risk assessment of bridge networks using Bayesian network	1953
<i>M. Cheng & H.O. Gao</i>	
Risk-based life-cycle loss assessment using statistical moments	1961
<i>Y. Zhang & Y. Li</i>	
Effects of high temperature on web crippling strength of lean duplex stainless steel tubular sections	1967
<i>Y. Cai, C.-C. Lee, S.-L. Mak, L. Wang & F. Zhou</i>	
Risk-based fatigue assessment of orthotropic steel decks	1975
<i>J. Heng, Y. Dong, C. Baniotopoulos & S. Kaewunruen</i>	
Life-cycle management of offshore wind deteriorating structures under ship collision accidental events	1983
<i>P. Salazar L., J. Morán A., P. Rigo & P.G. Morato</i>	
SS9: Risk-based prioritization and monitoring of bridges for road infrastructure management in Lombardy region, Italy	
<i>Organizers: F. Biondini, M.P. Limongelli, C. Gentile & M. Belloli</i>	
Static monitoring of a masonry arch bridge: Evaluating the effects of changing environment	1993
<i>P. Borlenghi, C. Gentile, M. D'Angelo & F. Ballio</i>	
Structural health monitoring of bridges based on GNSS	2001
<i>S. Bianchi, L. Capacci, M. Anghileri, F. Biondini, G. Rosati, G. Cazzulani, S. Barindelli & S. Caldera</i>	
Remote monitoring of a concrete bridge through InSAR and GNSS measurements	2009
<i>O. Lasri, P.F. Giordano, M. Previtali & M.P. Limongelli</i>	
How to prioritize bridge maintenance using a functional priority index	2017
<i>M. Arena, G. Azzone, V.M. Urbano, P. Secchi, A. Torti & S. Vantini</i>	

SS10: Deterioration modeling of concrete, rebar, steel and bond performance

Organizers: X. Gao, X. Ren & J. Li

Analysis of mechanical behavior of bond between plain rebar and concrete 2027

X. Gao, Y. Yu, C. Su & J. Li

Residual bearing capacity of corrosion-damaged reinforced concrete columns with annular cross sections 2035

Y. Jiang, H.-P. Chen & W.B. Li

Steel liner corrosion and its effects on the leak-tightness of the nuclear containment structure 2043

X.B. Li, X.Y. Wu & J.X. Gong

Influence of combined corrosion of carbonation and cyclic loading on reinforced concrete beams 2051

L.X. Zhu, Z.J. Zhou, Y.Q. Tian & C.R. Chen

SS11: BRIDGE|50: Experimental testing and model validation for life-cycle design and assessment of RC/PC bridges

Organizers: F. Biondini, F. Tondolo, S. Manto & C. Beltrami

Large-scale experimental testing of 50-year-old prestressed concrete bridge girder 2061

P. Savino, A. Quattrone, D. Sabia, B. Chiaia, F. Tondolo, M. Anghileri, F. Biondini & G. Rosati

Experimental tests for mechanical characterization of prestressed concrete bridge deck beams 2069

M. Anghileri, G. Rosati, F. Biondini, P. Savino & F. Tondolo

Experimental campaign for corrosion assessment of 50-year-old PC deck beams 2077

M. Carsana, E. Redaelli, D.O. Valoti & F. Biondini

Experimental validation of nonlinear finite element analysis of PC bridge deck beams based on the results of full-scale load tests 2085

M. Anghileri & F. Biondini

Dynamic response of PC bridge beams under different damages 2093

D. Sabia, A. Quattrone, P. Savino & F. Tondolo

SS12: Exploiting digitalization in the intervention planning for transportation infrastructure

Organizers: B.T. Adey, S. Moghtadernejad, S. Chuo & H. Mehranfar

Decentralized control-based intervention policies for road networks 2103

Y. Nakazato, D. Mizutani & T. Nagae

Efficient early estimates of bridge interventions: Costs, required possession times and associated failure risks 2112

H. Mehranfar, B.T. Adey, S. Chuo & S. Moghtadernejad

Estimation of bridge component condition states with varying data availability 2120

S. Chuo, B.T. Adey, H. Mehranfar & S. Moghtadernejad

State-of-the-art in the use of responsive systems for the built environment 2128

J. Suo, C. Martani, A.G. Faddoul, S. Suvarna & V.K.T. Gunturu

Digital twins in construction practice – A use case driven implementation based on existing theory 2136
T. Zinke, C.P. Schimanski, D. Schäfer, M. Rowsell & R. Schumann

SS13: Strengthening and rehabilitation of steel bridges

Organizers: X. Jiang, X. Qiang & Z. Lv

Numerical analysis of weld throat crack of rib-to-deck reinforced by bonding angle steel 2147

Z.L. Lv, X. Jiang, X.H. Qiang, H.L. Wu & J.M. Ding

Flexural behavior of prestressed concrete beams strengthened with external CFRP tendons 2154

L.L. Chen, X.H. Qiang, X. Jiang & P. Liu

Rehabilitation of cracked diaphragm cutouts in steel bridge using Fe-SMA 2162

Y.P. Wu, X.H. Qiang, X. Jiang, H.L. Wu & J.M. Ding

Numerical study on the mechanical behavior of Fe-SMA/steel hybrid joints based on cohesive zone modeling 2170

Y. Shu, X.H. Qiang, X. Jiang, Q.L. Zhang & H.L. Wu

Full-scale experimental study on strengthened riveted gusset joints 2178

S. Wang, Q. Su, B. Liu, X. Jiang, L. Chen & C. Zhang

SS14: Data management and analysis for predictive maintenance of aging infrastructure

Organizers: F. Schmidt, M. Rasol & L.F.M. Sanchez

Weather condition effect on the road surface friction: A preliminary assessment based on sensor data 2187

M. Rasol, F. Schmidt & S. Ientile

Prediction of recovery time of infrastructure functionalities after an earthquake using machine learning 2195

B. Derras & N. Makhoul

Condition assessment and management protocols for concrete infrastructure affected by internal swelling reactions: Challenge and research needs 2203

R. Medeiros, A. Bergmann & L.F.M. Sanchez

The efficiency of laboratory test procedures for assessing field performance of concrete against Alkali-Aggregate Reaction (AAR) 2211

A. Bergmann, R. Medeiros & L.F.M. Sanchez

Digital twins for civil infrastructure: A case study on the Clifton suspension bridge (Bristol, UK) 2219

M. Pregnolato, S. Gunner, E. Voyagaki, R. de Risi, G. Gavriel, P. Tully, N. Carhart, T. Tryfonas & C. Taylor

SHM analysis for damage detection using time series analysis methods 2227

F. Schmidt, F. Chabi & J.-F. Bercher

SS15: Reinforced concrete-to-concrete interfaces: experiments and modelling

Organizers: V. Palieraki & S. Cattaneo

- Effect of size on the shear strength between old to new concrete interface 2237
S. Cattaneo & M. Scamardo
- Experimental behavior of interfaces with anchors to thin overlays 2245
E. Oikonomopoulou, V. Palieraki, E. Vintzileou & G. Genesio
- Calculation of the interface resistance in RC construction using different codes 2253
V. Palieraki, E. Vintzileou & S. Cattaneo
- Performance-based design of new concrete walls for building seismic rehabilitation 2261
S.M. Alcocer & B. Moctezuma
- Composite action in tunnel linings by use of shear connectors in concrete interfaces 2269
K. Mitroulis, N. Mellios, P. Spyridis & K. Bergmeister

SS16: Risk-informed life-cycle management of bridges

Organizers: I. Venanzi, M.P. Limongelli & U. Alibrandi

- SHM-informed management of bridges in a life-cycle perspective 2279
L. Ierimonti, F. Mariani, I. Venanzi & F. Ubertini
- Integration of MCDM-based regional flood hazard indexing with the Cerema guidelines for risk assessment of riverine bridges 2287
M. Loli, G. Kefalas, S. Dafis, S.A. Mitoulis & F. Schmidt
- Assessment as to the best strategies for the maintenance of existing bridges 2295
A. Contardi & G. Pasqualato
- The possibility of data integration of drive-by monitoring and direct bridge monitoring 2303
M. Miyagi, R. Shin, E. Mudahemuka & K. Yamamoto

SS17: BIM-based sustainability considerations in infrastructure construction

Organizer: M. König

- Potential of holistic asset information management 2313
A. Buttgereit, M. Block, D. Gogolin & S. Gomolluch
- Towards environmental design decision-making for infrastructure planning using parametric BIM 2321
J. Hofmeyer, K. Forth, S. Esser & A. Borrmann
- BIM-based EPD adaption in the context of ecological sustainability and municipal infrastructures 2329
J. Maibaum, M. Block, M. König & A. Wachsmann
- Element approach for BIM-based life-cycle modeling of bridges 2337
M. Müller, T. Zinke & T. Ummenhofer

SS18: Optimization of inspection, monitoring and maintenance strategies for existing concrete structures

Organizers: R. Caspeele, W. Botte, G. Lombaert & A. Strauss

- Inspection and assessment of PT structures: Results from application to an existing bridge 2347
I. Mazzatura, S. Caprili, W. Salvatore, J.R. Casas, M. Gammino, F. Ferrari & A. Piscini
- Non-destructive and partially destructive test locations in RC structures: A combined spatial optimisation and Bayesian updating approach 2355
S. Karmakar, S. Ghosh, D. Saha & S.A. Faroz
- FL decision system to choose the best maintenance strategy depending on condition 2363
F. Binder, N. Hlebec, U. Schneck & A. Strauss
- Probability-based service life design of repair mortar overlay in case of chloride-induced depassivation risk 2371
K. Van Den Hende, S. Helderweirt, W. Botte, S. Matthys, R. Caspeele & G. Lombaert
- Early detection of corrosion in reinforced concrete using ultrasonic-guided waves 2379
N. Habbaba, S. Mustapha & Y. Lu
- The use of corrosion rates for the identification of damaged zones in a football stadium and efficacy of surface inhibitors as repair method 2387
C. Andrade, J.J. Muñoz & J.R. Rosell

SS19: Sustainability of steel production chain

Organizers: H. Gervasio & M.M. Sesana

- Net-zero and lightweight steel technologies for the construction sector: Overview and case studies in Italy 2397
M.M. Sesana
- Life-cycle assessment of light steel frame buildings: A systematic literature review 2405
G. Marrone, M. Imperadori & M.M. Sesana
- Building life-cycle assessment considering different structural materials 2413
J.H. de Paula Filho, M. Charlier & M. D'Antimo
- Optimised steel structures for a low carbon future 2421
M. D'Antimo
- The contribution of low carbon steel to the decarbonization of the building sector 2429
H. Gervasio, L. Simões da Silva & M. D'Antimo

SS20: Advances in performance and life-cycle design of green structural materials for a more sustainable environment

Organizers: B. Belletti, P. Bernardi & A. Sirico

- Use of coarse recycled concrete aggregates and vitrified MSW ash in eco-concrete design 2439
P. Plaza, C. Medina, A. Sirico, B. Belletti, P. Bernardi & J. Sánchez
- Vitrified beads as aggregate replacement for sustainable cementitious materials 2447
B. Belletti, P. Bernardi, S. Ravasini, A. Sirico, D. Milanese, C. Sciancalepore, M. Malavasi & A. Cortese

Mechanical strength and environmental sustainability of EAF concrete <i>F. Faleschini, D. Trento, M.A. Zanini, C. Pellegrino, V. Ortega-López & A. Santamaria</i>	2455
Sustainable design of lightened reinforced concrete flat slabs in coastal environment <i>A.J. Sánchez-Garrido, I.J. Navarro & V. Yepes</i>	2463

SS21: Durability of reinforced concrete structures and infrastructures under changing climate conditions

Organizers: S. Kessler, F. Marsili, P. Croce & F. Landi

Exploratory analysis of the impact of natural hazards on road infrastructure in the Philippines <i>M. Adarne, A. Amir & M. Henry</i>	2473
Prediction of R.C. bridge deterioration under changing environmental conditions <i>F. Landi, P. Croce, F. Marsili & S. Kessler</i>	2481
Life-cycle assessment of R.C. bridge components based on cluster analysis and stochastic process <i>F. Marsili, S. Keßler & F. Landi</i>	2489
Corrosion effects of RC bridges considering the climate change impact <i>M. Zucca, M.L. Puppio, F. Mistretta, F. Landi, P. Formichi & P. Croce</i>	2497

SS22: Life-cycle and sustainability of precast concrete structures

Organizers: B. Dal Lago, H. Rodrigues & P. Negro

Seismic response analysis of precast structures retrofitted with dissipation devices, including qualitative assessment of environmental impact <i>F. Cavalieri, D. Bellotti, M. Caruso & R. Nascimbene</i>	2507
Aggregates for innovative use in precast concrete panels: State of the Art and perspectives <i>M.L. Puppio, F. Coccu, A. Usman, M. Valdés, A. Frattolillo, M. Sassu & L. Casali</i>	2515
Environmental impact reduction of precast multi-storey buildings by crescent-moon seismic dampers hidden in beam-column joints <i>L. Casali, B. Dal Lago, A. Fulco & M. Mezzi</i>	2523
Life-cycle assessment of coal mining wastes upcycling <i>S. Muller, F. Lai, M. Nucci, E. Segù, R. Crane, W. Nash, A. Wrana, B. Bezak & L. Ferrara</i>	2531

SS23: Shaping development planning processes for infrastructure systems under future uncertainty

Organizers: B.T. Adey, A. Elvarsson & O. Román

The value of accelerating the infrastructure planning process <i>A.B. Elvarsson, B.T. Adey & O. Roman</i>	2541
Stakeholder inclusive port development planning for an uncertain future <i>M. Eskafi & G.F. Ulfarsson</i>	2549
Probabilistic circular economy assessment for infrastructures considering time-variant influencing factors <i>H. Lei, W. Wang, C.Q. Li & W. Yang</i>	2557

Data-driven infrastructure systems design for uncertainty, sustainability, and resilience <i>M.-A. Cardin, A. Mijic & J. Whyte</i>	2565
Evaluating design modifications on a building portfolio considering future uncertainty and multiple stakeholders <i>C. Martani, N. Calen & B.T. Adey</i>	2573
Exploratory modelling for transport infrastructure planning under future uncertainty <i>O. Roman, A.B. Elvarsson & B.T. Adey</i>	2580
SS24: Functional end-of-life framework applied to hydraulic structures	
<i>Organizers: E.J. Hamerslag, E. van Baaren & A. Bakker</i>	
Embedding functional performance in asset management of hydraulic structures <i>E.J.F. Hamerslag & A.M.R. Bakker</i>	2591
Assessing the functional end of life of critical hydraulic structures in The Netherlands <i>A.M.R. Bakker, E.S. van Baaren, E.J.F. Hamerslag & C.J.J. Bodelier</i>	2598
Framework functional performance hydraulic structures <i>E.S. van Baaren, J. Bredeveld, N.J.M. ten Harmsen van der Beek, T. O'Mahoney, N. Kramer, H. Berger & A. Barneveld</i>	2605
Determining the future functional requirements of a pumping-weir station with the help of data-analysis <i>L. van Gijzen & A.M.R. Bakker</i>	2612
SS25: The process of decarbonization: from ideation to specification	
<i>Organizers: D. Shook & M. Sarkisian</i>	
Resilience through superelasticity <i>D. Shook, M.P. Sarkisian & C. Horiuchi</i>	2623
Design of the urban sequoia tower <i>M.P. Sarkisian, E. Long, A. Beghini, K. Micallef & S. Jaberansari</i>	2631
Achieving net zero embodied carbon: The SE2050 program and its impact on structural design <i>C. Horiuchi, M. Stringer & N. Wang</i>	2639
Quantifying and specifying decarbonization in buildings <i>N. Wang, D. Shook, K. Chang & E. Leung</i>	2646
Carbon optimization of hybrid material structures <i>M.P. Sarkisian, D. Shook, A. Zha & C. Horiuchi</i>	2653
SS26: Structural resilience in bridge engineering: Method, theory, and practice	
<i>Organizers: A. Chen, X. He & X. Ruan</i>	
A study on the mutual effect on fatigue damage of orthotropic steel decks and pavements <i>B. Wang, D.L. Wang, R. Ma & A.R. Chen</i>	2663
Modeling of coarse aggregate based on 3D point cloud and spherical harmonics <i>J.J. Zhang & Z.C. Pan</i>	2670

Bridge tower aesthetic assessment using convolutional neural network 2678
D.L. Wang, Y. Ning, C. Xiang & A.R. Chen

Influence of different curing condition on seismic performance of reinforced concrete bridge piers 2686
Q.P. Wen, L.L. Wen, L.L. Feng, D.T. Ya & F.X. Lin

SS27: Practical applications and value of advanced computational and probabilistic modelling in life-cycle engineering

Organizers: P. Bocchini, A. Strauss & H. Sousa

Semi-probabilistic assessment of concrete bridge exploiting additional data from experiments and numerical analysis 2697
L. Novák, D. Novák, M. Cao & R. Pukl

Probabilistic structural assessment of RC bridges under corrosion based on efficient simulation methods 2705
F. Padovani, L. Capacci & F. Biondini

Life-cycle assessment of Tunnel Boring Machine (TBM) segments of a new tunnel: Carbonation attack and sulfate attack 2714
F.T. Torabian, I. Vangelisti & C. Beltrami

Holistic assessment-framework for railway noise barrier constructions 2722
M.F. Granzner, A. Strauss & M. Reiterer

SS28: Use of SHM and NDE for decision making

Organizers: N.M. Apaydin, F.N. Catbas & B. Briseghella

The state-of-the-art in health monitoring of long-span cable supported bridges in Turkey 2731
O. Çetindemir, A.C. Zülfikar & N.M. Apaydin

Informed assessment of structural health conditions of bridges based on free-vibration tests 2739
M. Mazzeo, D. De Domenico, R. Santoro & G. Quaranta

The effect of road roughness on vehicle-bridge interaction modeling 2746
A. Aloisio, R. Alaggio, A. Contento & B. Briseghella

Influence of different debonding gap types on mechanical performance of axially compressed CFST stub columns with same debonding arc-length ratio 2754
J.Q. Xue, J.P. Huang, L.Q. He, B. Briseghella & A. Contento

Dynamic assessment of a stress-ribbon CFST arch bridge with SHM and NDE 2762
J.P. Huang, L.Q. He, J.Q. Xue, S.N. Zhou, B. Briseghella, C. Castoro, A. Aloisio & G.C. Marano

Bridge maintenance prioritization by using multi-criteria decision analysis 2770
H. Silimanotham & M. Henry

SS29: Durability and structural assessment of fiber reinforced strengthening materials and strengthened structures

Organizers: F. Micelli, C. Papanicolaou, B. Ghiassi & M. Leone

- Freeze/thaw effects on the performances of FRCM strengthened reinforced concrete beams 2781
S. Verre & M. Guglielmi
- Interface experimental behavior between basalt-FRCMs and natural stones 2789
G. Bramato, M. Leone & M.A. Aiello
- Tensile behavior of a glass FRCM composite with textile lap splice exposed to freeze-thaw cycles 2796
A.S. Calabrese, V. Bertolli, P. Colombi, T. D'Antino & C. Poggi
- Effect of salt crystallization on the bond behavior of glass FRCM-masonry joints 2804
V. Bertolli, A. Cagnoni, A.S. Calabrese, P. Colombi & T. D'Antino
- On the behaviour of FRCM fibres in saturated alkaline solution 2812
M. Canestri, F. Ferretti, E. Sassoni & C. Mazzotti
- Durability of CRM reinforcements 2820
F. Micelli, A. Franco, R. Greppi & M.A. Aiello

SS30: Durability of sustainable reinforced concrete for civil engineering structures

Organizers: M. Carsana & E. Redaelli

- Performance and environmental analysis of Reclaimed Asphalt Pavement (RAP) concrete produced in industrial environment 2831
G. Masi, A. Michelacci, S. Manzi, A. degli Esposti, B. De Pascale, A. Bonoli & M.C. Bignozzi
- Life extension of existing steel reinforced structures by simple cathodic protection techniques for sustainable durability 2839
G. Sergi
- Corrosion of rebars in concrete: Comparison of preventative measures 2847
F. Bolzoni, A. Brenna, S. Beretta, M. Ormellese, M.V. Diamanti & M.P. Pedeferra
- Role of concrete and reinforcement characteristics to increase the service life of structures 2855
M.C. Alonso
- Durability performance indicators for service life analysis and quality control 2863
F. Moro & R.J. Torrent

SS31: Structural health monitoring and asset management of infrastructures

Organizers: S. AlSanad & J. Parol

- Measuring heavy traffic using alternative systems in an urban environment 2873
M.L. Soudijn, S. van Rossum & A. de Boer
- Improving the resolution and accuracy of low-cost Arduino-based accelerometers 2881
S. Komarizadehasl, G. Ramos, J. Turmo, J.A. Lozano-Galant, V. Torralba & M. Haiying
- Preventive SHM for asset management: A case study on the Mont-Blanc tunnel 2888
F.B. Cartiaux & B. Prudhomme
- Characteristics of ultrasonics guided waves in timbers under moisture and temperature 2896
R. Yassine & S. Mustapha

Asset management – Towards adaptive resilient infrastructures 2904
S. AlSanad & J. Parol

SS32: Corrosion-induced structural damage and prevention measures for reinforced concrete infrastructure

Organizers: S. Yang, F. Tang & W. Zhang

Corrosion and bond behavior of silicate dioxide particle modified enamel coated steel bar 2911
F. Tang, Y. Kuang, H. Cui & Z. Lin

Non-destructive investigation of corrosion in reinforced concrete structures and modelling the structural degradation 2918
S.T. Yang, F. Zhang, Z. Yin & X. Xi

Chloride transport properties of Portland cement and limestone systems 2925
Z.L. Jiang, Z. Dong, C.Q. Fu, Y.J. Pan & Y.C. Wang

Simplified analytical method for moment-curvature response of corroded prestressed concrete beams 2933
S. Ravasini, L. Franceschini & B. Belletti

Structural behavior of PC beams under simultaneous corrosion and sustained loads 2941
F.F. Bico, M. Bartoli, F. Di Carlo, A. Meda, F. Molaioni & Z. Rinaldi

Random field analysis of corrosion of steel in the artificial marine atmosphere 2949
W.P. Zhang, X.L. Gu, Q.Q. Yu & J. Chen

SS33: Life-cycle and sustainability performance of fastenings

Organizers: P. Spyridis, G. Muciaccia, K. Bergmeister, T. Pregartner, R. Piccinin & T. Sippel

Installation, structural, and sustainability characteristics of direct fastening in textile reinforced concrete plates 2959
P. Spyridis, J. Orlowsky & K. Bergmeister

Redundancy of concrete fastenings under combined fatigue and corrosion – A probabilistic study on catenary system installations 2967
S. Kessler, N. Mellios, A. Takriti & P. Spyridis

Long term assessment of bonded anchors with two different methods, Findley extrapolation vs. time-to-failure approach 2975
I. Boumakis, K. Nincevic, R. Piccinin, R. Wan-Wendner, T. Pregartner & K. Bergmeister

Impact of concrete age and aggregate type on anchor load performance 2983
K. Nincevic, R. Piccinin, I. Boumakis, T. Pregartner & R. Wan-Wendner

Impact of end-of-life stage in cradle-to-cradle LCA analysis of timber and timber-hybrid buildings 2991
L. Corti & G. Muciaccia

GENERAL SESSIONS

Organizers: F. Biondini & D.M. Frangopol

Shear strength assessment of FRP pre-tensioned concrete beams 3001
A. Mari, E. Oller, J. Murcia-Delso, J.M. Bairán & N. Duarte

Life-cycle cost of CFRP and steel prestressed concrete elements <i>J.M. Bairán, J. Murcia-Delso, N. Duarte, E. Oller & A. Mari</i>	3009
Numerical analysis of short-term performance of CFRP new composite anchorage <i>S. Y. Sun</i>	3017
Preliminary assessment on the effects of longitudinal cracks on carbonation-induced corrosion <i>N. Russo, M. Gastaldi, F. Lollini, L. Schiavi & A. Strini</i>	3025
Numerical evaluation on electrical resistivity of hardened cement paste using 3D pore model based on X-ray micro-CT images <i>K. Kawaai & T. Nishida</i>	3033
Coupled deterioration by freeze-thaw and chloride salt on mill-cut steel fiber reinforced concrete <i>S. Liu, Y. Liu, Y. Li, L. Fan & Z. Yang</i>	3041
Construction of hydrogen pipeline utilizing communication pipeline and experimental study on its utilization <i>T. Ishikawa & K. Itasaka</i>	3049
Modelling the thermal response of firestop sealant exposed to standard fire <i>Z. Ye, A.K. Abu, C.M. Fleischmann & R.P. Dhakal</i>	3054
Dynamic chain reaction analysis of a cable-stayed bridge by sudden loss of stays considering cable corrosion <i>Y. Aoki, H. Tsunoda, T. Akiyama, H. Gotou & S. Nakamura</i>	3062
Revisiting shape/size effect formulation of EUROCODE 2 for structural concrete members <i>S. Abdo, R. Wan-Wendner, R. Caspeele, S.C. Seetharam & Q.T. Phung</i>	3070
Guided tour of the pathological manifestations found at Rossio's historical train station <i>C. Carvalho, N. Bento & A. Silva</i>	3078
Non-destructive evaluation for voids under airport pavement concrete in-situ <i>T. Nishida, F. Izu, Y. Kobayashi, M. Aizawa & K. Kawaai</i>	3086
How to better exploit the use of LCA analysis for Ultra High Performance Concrete (UHPC) through a constitutive law which integrates chloride and sulfate attack <i>D. di Summa, F. Soave, M. Davolio, S.M.J. Al-Obaidi, L. Ferrara & N. De Belie</i>	3094
Durability of residential construction in a marine environment <i>I.N. Robertson</i>	3102
Predicting the military load class from bridge data with a multilayer perceptron <i>M. Haslbeck, J. Flotzinger & Th. Braml</i>	3110
Elaboration of a truncated probability function for the Young's modulus of concrete <i>M. Haslbeck & Th. Braml</i>	3118
The impact of surface aspect ratio on the embodied energy, embodied carbon, and embodied water of a building structure <i>M.K. Dixit & P. Pradeep Kumar</i>	3126
Performance assessment of existing prestressed concrete bridges utilizing distributed optical fiber sensors <i>H. Burger, T. Tepho, O. Fischer & N. Schramm</i>	3134

Life-cycle assessment of crack repair systems for fire-damaged concrete <i>R.M. Galano, R.S. Chan & J.M. Ongpeng</i>	3142
Rehabilitation of underground garages – defining a cost function for use in the decision-making process <i>J.M. Lozano Valcarcel, C. Gehlen, T. Kränkel, A. Schiessl-Pecka, J.D. Cassiani & S. Kessler</i>	3150
The potential for direct reuse of precast concrete slabs in buildings with “wet” joints <i>P.S. Halding & K. Negendahl</i>	3158
Life-cycle assessment of concrete hollow blocks and autoclaved aerated concrete blocks <i>J.M. Ongpeng & M.V. Umali</i>	3166
Temperature effect on static and quasi-static bridge measurements <i>K. Dakhili, T. Kebig, M. Schäfer, M. Maas, M. Bender & A. Zürbes</i>	3174
Robot-BIM integration for underground canals life-cycle management <i>H. Pourhosseini, F. Zahedi & J.M. Sardroud</i>	3182
Life-cycle cost analysis of possible solutions for converting existing single-family house into nZEB <i>C. Marincu & D. Dan</i>	3190
End-of-life rule checking for transport infrastructure: The case of navigation locks <i>K.E. Bektas & I.E. Ozer</i>	3198
Environmental and economic assessment of service life extending repairs for a concrete silo <i>N. Renne, A. Audenaert, M. Buyle & B. Craeye</i>	3206
Foundation for risk-based asset management for storm surge barriers <i>Y. Kharoubi, M. van den Boomen, M.J.C.M. Hertogh & J. van den Bogaard</i>	3214
Lessons learned from past earthquakes for horizontally curved bridges <i>E. Namlı & T. Öztürk</i>	3222
Using the USGS database to study parameter uncertainty when assessing pier scour using the HEC-18 framework <i>G. Gavriel, M. Pregolato & P.J. Vardanega</i>	3230
Time-variant reliability analysis of corroded steel girder <i>Y. Wang, W. Wang, C.Q. Li & W. Yang</i>	3238
Quantification of the effect of corrosion on the compressive membrane action in restrained hollow core slabs <i>T. Thienpont, W. De Corte, R. Van Coile & R. Caspeele</i>	3244
Bayesian pre-estimation of bridge life-cycle costs <i>T. Vagdatli, K. Petrousatou, P. Panetsos, Z. Barmpa & N. Fragkakis</i>	3252
A service value predictive system of componentized infrastructure assets <i>K. Petrousatou, T. Vagdatli, M. Voutsis, P. Panetsos & Z. Barmpa</i>	3260
Powder wastes from concrete recycling as a sustainable source of calcium carbonate mineral admixture <i>K.M. Masunaga & T. Iyoda</i>	3268
Travel time gains VS time constancy - An irresolvable contradiction? <i>M. Hoffmann</i>	3276

Reliable estimation of investment and life-cycle costs from road projects to single road assets <i>M. Hoffmann & V. Donev</i>	3284
Legal governance for BIM – rights management and lawful data use <i>B. Weber & M. Achenbach</i>	3292
Advanced life-cycle assessment of reinforced concrete bridges using digital twin concept <i>J. Rymeš, J. Červenka, M. Herzfeldt & R. Pukl</i>	3300
Sustainable reuse of public real estate assets meeting structural, conservation and territorial needs <i>G. Concu, D.R. Fiorino & E. Pilia</i>	3308
Evaluation of low-velocity impact damage in metal/composite layered structure <i>S. TerMaath, B. Ingling, J. Noland & D. Hart</i>	3316
Development of high durable precast PC deck with ultra-high-strength fiber-reinforced concrete layer <i>H. Hayashi, Y. Yasukawa, N. Oba & K. Sasaki</i>	3324
Development of digital rules for optimal auto-routing design of pipe <i>S.-E. Park, S.-W. Choi & E.-B. Lee</i>	3332
Structural response of corroded concrete columns with different rebar confinements under cyclic compressive loading <i>H.O. Aminulai, N.S. Ferguson & M.M. Kashani</i>	3340
Structural behaviour of axially loaded corroded low-strength RC columns with different confinement ratios <i>H.O. Aminulai, N.S. Ferguson & M.M. Kashani</i>	3348
Impact of as-recorded mainshock-aftershock excitations on seismic fragility of corrosion-damaged RC frames <i>E.A. Dizaj, M.R. Salami & M.M. Kashani</i>	3356
Seismic fragility analysis of nonuniformly corroded irregular RC bridges <i>E.A. Dizaj, M.R. Salami & M.M. Kashani</i>	3364
Study on the applicability of repairing rubber bearing covers by resurface vulcanization in the field <i>A. Matsumoto, R. Takahara, T. Imai & W. Abe</i>	3372
Application of BIM in design review processes for buildings <i>M. Achenbach, P. Rivas & B. Weber</i>	3380
A basic study on the evaluation of the protective effect of silane-based impregnation on mortar using electrochemical impedance spectroscopy <i>S. Nagaoka, K. Nakayama & M. Iwanami</i>	3388
Life-cycle of existing asphalt to build new highway foundation pavements: Environmental procedures according to new Italian standards, geotechnical and durability performance assessments, construction methods <i>M. Biasioli, F.T. Isfahani, D. Giometti, C. Beltrami, G. Piovano, F. Vergano & M. Marino</i>	3396
Infrastructure asset management and the role of structural health monitoring <i>A. AlBanwan, A. AlFoudari & R. AlBehbehani</i>	3404

Inclusion of Stochastic Petri-net models on a risk-based tool for the maintenance of road drainage systems	3412
<i>L.G. Rodrigues, L.C. Neves, J. Wallis, R. Brook & K. Morosiuk</i>	
Rehabilitation, strengthening and life-cycle assessment of an historical water channel Cavour masonry bridge crossing Cervo River after an extreme flood erosion at foundation pier causing massive settlement and large structural damages	3420
<i>C. Beltrami, M. Capalbo, G. Giacalone, M. Vittone, G. Comaita, I. Vangelisti, F.T. Isfahani, F. Damiani, R. Salomone, L. Casti, J. Salvioni, D. Cagliani, F. Burlone, M. Fossati & M.F. Carera</i>	
High performance computing methods for concrete surface damage identification and prevision in service highways tunnel concrete linings	3428
<i>I. Vangelisti, C. Beltrami & G. Rozza</i>	
Experimental study on quantification of carbon dioxide adsorption by different cement types and mix proportions	3436
<i>T. Iyoda, E. Ishikawa & Y. Ikeo</i>	
Value of information for a rational experimental and testing budget applied to a regional old Italian bridges database	3444
<i>I. Vangelisti & C. Beltrami</i>	
Multi-risk analysis methodology for evaluating climate change impacts at different scales	3452
<i>F.V. De Maio, R. Valsecchi, S. Osmani, C. Solari & P. Basso</i>	
Evaluation of the safety factor in masonry buildings as acceleration varies: A quick approach	3460
<i>E. Garavaglia</i>	
Attack of aggressive carbon dioxide on hardened Portland and blast furnace slag cement paste	3468
<i>F. Wagemann, F. Schmidt-Döhl & A. Rahimi</i>	
Big data in construction project management: The Colombian northeast case	3476
<i>S. Zabala-Vargas, M. Jiménez-Barrera, L. Vargas-Sánchez & M. Jaimes-Quintanilla</i>	
Numerical analysis of prestressed sleepers affected by expansive mechanisms	3484
<i>R.P. Randi, L.M. Trautwein, D.J.M. Mariata, L.F.M. Sanchez & A.C. Santos</i>	
The probabilistic fatigue life of plain concrete under low-frequency stress reversal loading	3492
<i>E.C. Ferreira, P. Sotoudeh, G. Fiorillo & D. Svecova</i>	
Influence of different coarse aggregate types on porosity and various properties in concrete	3500
<i>N. Matsuda & T. Iyoda</i>	
Visual inspection of bridges and tunnels in Italy: By experience made with different owners and methods to a new proposal for a better and more efficient inspection procedures	3508
<i>R. Salomone, F. Damiani, M. Vittone, M. Scarsi Napolitano, I. Vangelisti, G. Giacalone, A. Bombace, M. Brescia, M. Rabbia & C. Beltrami</i>	
Inspection of highway retaining walls and geotechnical sites, state of the art in Italy and possible proposals for improving procedures and effectiveness	3516
<i>M.S. Napolitano, D. Bonassi, R. Morè & C. Beltrami</i>	
Using shape optimization and principal stress line based stiffness improvement of thin-shell structure and reduce construction costs	3523
<i>Y.X. Sun, Y.Y. Yang, L.J. Leu & K. Yamamoto</i>	

Numerical verification of vehicle-bridge interaction system identification using a 3D models <i>E. Mudahemuka, S. Ryota & K. Yamamoto</i>	3531
Parametric study of the vehicle-bridge interaction system identification method <i>R. Shin, Y. Okada & K. Yamamoto</i>	3539
Influence of various admixture materials on pore structure and mass transfer characteristics <i>R. Yahiro & T. Iyoda</i>	3547
Research on the anti-sliding performance of cable clamps in an irregular elliptical suspen- dome structure <i>H.J. Wang, X.D. Ren, S.W. Xiao, L. Li & B. Luo</i>	3554
Lessons learned from highway tunnels inspection, analysis, assessment and refurbishment works <i>A. Damiani, E. Crippa & M. Rabbia</i>	3562
Deterministic and probabilistic damage calculation of offshore wind turbines considering the low-frequency fatigue dynamics <i>N. Sadeghi, P. D'Antuono, K. Robbelein, N. Noppe, W. Weijtjens & C. Devriendt</i>	3570
Developing a cost-control and project-planning based implementation of circular construction in temporary works: A framework of core supportive technologies <i>F. Tizzani, P. Herthogs & R. Stouffs</i>	3578
Life-cycle assessment of buried water-transmission concrete mains <i>H. Yáñez-Godoy & S.M. Elachachi</i>	3586
Shear strength investigation of carbon fiber reinforced polymer strips-wrapped concrete beams with regression analysis and experiments <i>P. Fan, H.F. He, S.S. Cheng, S.S. Guo & C. Liu</i>	3594
Multi-criteria assessment of reinforced limestone powder concrete slabs and columns <i>A. Radović, H. Hafez, N. Tošić, S. Marinković & A. De la Fuente</i>	3602
Development of life-cycle inventory for timber products to support the circular economy in construction <i>S. Ge, P.J. McGetrick, C. O'Ceallaigh & A.M. Harte</i>	3610
Life-cycle assessment and sensitivity analysis of a clayey sediment-based geopolymer concrete <i>L. Monteiro, H. Yáñez-Godoy, J. Saliba & N. Saiyouri</i>	3618
Research on calculation method of creep and shrinkage effects of steel-concrete-Ultra-High- Performance Concrete (UHPC) composite bridge considering construction process <i>X.G. Ma, D.W. Zhang, H.W. Ling, H.J. Shen, S.S. Guo & C. Liu</i>	3626
Interactive visualization of uncertain embodied GHG emissions for design decision support in early stages using open BIM <i>K. Forth, A. Borrmann & A. Hollberg</i>	3634
Port facilities asset management: Coping with aging infrastructure and constrained budgets on the long term <i>H. Voogt</i>	3642
Modeling and characterization strategy as a basis for improved prediction of concrete fatigue degradation in wind power plants <i>A. Baktheer, M. Aguilar, H. Becks, M. Classen, J. Hegger & R. Chudoba</i>	3649

Sustainability concept of design of concrete bridges based on LCA <i>B. Vlasatá, J. Pešta, C. Fiala, P. Hájek & M. Novotná</i>	3656
Fundamental experiments for monitoring water leakage of underground structures using plastic optical fibers <i>H. Zhang, Z. Liu, X. Ma, J. Qian & S. Akutagawa</i>	3664
Effects of structural rehabilitation on modal parameters of the Marlo Bridge <i>B. Siedziako, T.S. Nord & A. Fenerci</i>	3672
Simulation of chloride ingress into aging surface-coated concrete <i>C. Yoshii, F. Biondini, M. Iwanami & K. Nakayama</i>	3680
Embedded fibre optical strain monitoring of a bio-composite bridge <i>M. Weil, Y. Bel-Hadj, W. Weijtjens, C. Devriendt, Y.-A. Janssens & E. Voet</i>	3688
Dissipative steel and steel-concrete composite beam-to-column joints <i>G. Skarmoutsos & U. Kuhlmann</i>	3696
Seismic and energetic renovation of existing masonry buildings by innovative FRLM composite materials <i>D. Pugliese, V. Alecci, S. Galassi, A.M. Marra & M. De Stefano</i>	3704
Development of a method for resource-efficient structural maintenance of reinforced concrete buildings based on digital BIM models <i>J.-I. Jäkel, L. Kloesgen, T. Koenig, K. Klemt-Albert, H. Morgenstern & M. Raupach</i>	3712
Cost-optimization based generalized target reliabilities for reinforced concrete slab exposed to fire <i>F. Put, R.K. Chaudhary, A. Lucherini, B. Merci & R. Van Coile</i>	3720
Sensitivity of the seismic response to the modelling variables defining constitutive models of reinforced concrete frames <i>G. Karaki</i>	3728
Effect of concrete age on the reliability of existing reinforced concrete columns <i>L.C.R. Castro & S.M.C. Diniz</i>	3736
A microservice for evaluating resilience of water distribution network <i>X.Y. Yu, Y.N. Xu, F. Liu & X. Zhou</i>	3744
Project management and life-cycle cost evaluation using infrastructure-building information modeling techniques: A railway infrastructure design case study <i>M. Pasetto & G. Giacomello</i>	3752
A non-Gaussian algorithm to simulate the earthquake motion phase difference <i>T. Sato</i>	3760
Health monitoring of long-span bridges using deep learning driven by sensor measured and numerical response data <i>Z. Xue, W. Sebastian & D. D'Ayala</i>	3769
Progressive collapse behavior of RC frames subjected to reinforcement corrosion <i>L.C. Ding, Y.B. Peng & J.B. Chen</i>	3777
Numerical simulation of non-Fick moisture diffusion of pultruded GFRP bolt connection <i>Y. Sun, Y. Liu, X. Wang & H. Xin</i>	3785

A methodology for the service life estimation of timber structures <i>D. Marranzini, G. Iovane, L. Cascini, R. Landolfo, M. Nicoletta & B. Faggiano</i>	3793
Multi-scale structural integrity assessment of a series of identical components in cultural-heritage structures: The case of the Clifton suspension bridge <i>R. De Risi, T. Moody, E. Voyagaki, S. Gunner, M. Pregolato, N. Grilli & C. Taylor</i>	3800
Assessment of energy redistribution of structural collapse under seismic loads using wavelet transforms <i>N.S.D. Farhan, J. Lu, W.A. Altabey, Z. Wu, A. Silik & M. Noori</i>	3808
Application of infrared thermography in civil engineering: Limits and drawbacks <i>D. Meloni, G. Sechi & G. Concu</i>	3816
Soundness evaluation of small-scale bridge decks with portable FWD tests <i>T. Sasaki, A. Tsuboi, Y. Sugimoto, H. Kakeda & H. Onishi</i>	3824
Rut depth estimation by distortion analysis of images taken by an in-vehicle camera <i>W. Gao, K. Xue, T. Nagayama, B. Zhao, D. Su, K. Xue & B. Zhao</i>	3832
M-integral applied to fatigue life prediction in notched elastic-plastic material <i>Z.J. Zhang & Q. Li</i>	3840
Dynamic performance of connection between frame-structure and jacked caisson <i>X.Z. Lan, W.F. Wu, C. Li & Y. Yuan</i>	3848
Robustness of RC girder bridges: The case of half-joint bridges <i>P. Martinelli, M. Colombo & M. di Prisco</i>	3856
Research on imaging technology of concrete bridge bottom apparent disease detection based on machine vision <i>S.G. Cao, X.Y. Li, Y. Pan, J.L. Fu & H. Tian</i>	3864
Semi-probabilistic methods for the assessment of existing concrete structures: An overview <i>L. Casti, F. Schmidt, F. Biondini & N. Makhoul</i>	3872
Digital fatigue test of rib-to-deck welded joint details in orthotropic steel deck <i>P.Y. Li, C.S. Wang, Y. Li & D.D. He</i>	3880
Nonstructural performance improvements for seismic resilience enhancement of modern code-compliant buildings <i>M.R. Joo & R. Sinha</i>	3888
Fatigue performance simulation of UHPFRC composited deck for steel truss girder bridge <i>C.H. Zhu, L. Duan, C.S. Wang, P.Y. Li, Z. Kang & J. Kang</i>	3896
Redundancy, importance, and robustness analyses for damage scenarios of bridges <i>S. Sarmiento, J. González-Libreros, G. Sas, I. Björnsson & S. Thöns</i>	3904
Structural behavior of composite truss girder with thicker concrete deck at side span in a cable-stayed bridge <i>M.Y. Yang, C.S. Wang, Y.Q. Li & Y.C. Feng</i>	3913
Assessment of mechanical properties for ancient timber through visual and ND methods <i>S. Verre, G.F. Cauteruccio, G. Fortunato, A.A. Zappani, L. Ombres, M. Brunetti, M. Nocetti, N. Ruggieri, M. Togni, D. Marranzini, G. Iovane & B. Faggiano</i>	3920

Failure analysis of ageing RC bridges: The cases of the Polcevera viaduct and the Capriogliola bridge	3927
<i>N. Scattarreggia, A. Orgnoni, G.M. Calvi, R. Pinho, D. Malomo & M. Moratti</i>	
Digital fatigue test of flange-web welded details in guideway girders	3935

Preface

Structures and infrastructure systems need to comply with the continuously increasing demand from societal, political, economic, and environmental needs associated with aging, deterioration processes, and other multiple natural and human-made hazards affecting civil infrastructure facilities. To respond to these needs, civil engineering is undergoing a profound change towards a life-cycle-oriented design and maintenance philosophy where the system performance is considered as time-dependent and the desired levels of target performance are addressed over the entire life-cycle taking into account the effects of aging and deterioration processes, time-variant loadings, and maintenance and repair interventions, among others. This transition is at the heart of civil engineering and is promoting and guiding a considerable amount of research and relevant advances in the fields of modeling, analysis, design, inspection, monitoring, repair, maintenance, and rehabilitation of deteriorating civil engineering systems. To support this process, after a series of International Workshops on Life-Cycle Analysis and Design of Civil Engineering Infrastructure Systems, IALCCE - The International Association for Life Cycle Civil Engineering was created in 2006 (<https://www.ialcce.org>).

IALCCE covers all aspects of life-cycle assessment, design, maintenance, rehabilitation and monitoring of civil engineering systems. The objective of the Association is to promote international cooperation in the field of life-cycle civil engineering for the purpose of enhancing the welfare of society. Currently, IALCCE includes over 800 individual members from 66 countries and over 30 collective members. Seven International Symposia have been organized since the foundation of IALCCE. The inaugural IALCCE Symposium was held in Varenna, Lake Como, Italy, in June 2008, under the auspices of Politecnico di Milano. Following IALCCE 2008, a series of Symposia have been organized in Taipei, Taiwan (IALCCE 2010), Vienna, Austria (IALCCE 2012), Tokyo, Japan (IALCCE 2014), Delft, The Netherlands (IALCCE 2016), Ghent, Belgium (IALCCE 2018), and Shanghai, China (IALCCE 2020). These events have been very successful, both technically and academically, and IALCCE Symposia have become established events in the field of life-cycle civil engineering. It was therefore considered fruitful to continue this landmark series and celebrate the 15th Anniversary of IALCCE Symposia where they were initiated by bringing together recent advances and cutting-edge research in the field of life-cycle civil engineering and related topics at the Eighth International Symposium on Life-Cycle Civil Engineering (IALCCE 2023), held at Politecnico di Milano, Milan, Italy, 2-6 July, 2023 (<https://ialcce2023.org>).

IALCCE 2023 has been organized on behalf of IALCCE under the auspices of Politecnico di Milano. The interest of the international civil engineering community in the activities covered by IALCCE has been confirmed by the significant response to the IALCCE 2023 call for papers. In fact, over 750 abstracts from more than 50 countries were received by the Symposium Secretariat, and approximately 70% of them were selected for final publication as technical papers and presentation at the Symposium within mini-symposia, special sessions, and general sessions. Contributions presented at IALCCE 2023 cover recent advances and cutting-edge research in the field of life-cycle civil engineering, including emerging concepts and innovative applications related to life-cycle design, assessment, inspection, monitoring, repair, maintenance, rehabilitation, and management of structures and infrastructure systems under

uncertainty. Major topics covered include: life-cycle safety, reliability, risk, resilience and sustainability, life-cycle damaging processes (aging of structures, deterioration modeling, durable materials, earthquake and accidental loadings, fatigue and damage, fire and high temperatures, marine and severe environments, structure-environment interaction, global warming and climate change effects), life-cycle assessment and design (design for durability, failure analysis and risk prevention, structural robustness, lifetime structural optimization, long-term performance analysis, performance based design, service life prediction, uncertainty modeling, value of information, life-cycle structural safety, time-variant reliability, functionality and resilience, risk and sustainability), life-cycle monitoring, maintenance, and management (damage identification, field testing and proof loading, health monitoring, inspection and evaluation, robotic and aviation-based techniques, BIM techniques, maintenance strategies, rehabilitation techniques, strengthening and repair, structural integrity, asset management, infrastructure resilience, risk-based prioritization), life-cycle performance of special structures (bridges and viaducts, high-rise buildings, hydraulic structures, off-shore structures, precast systems, roof systems, runway and highway pavements, tunnels and underground structures), life-cycle cost of structures and infrastructure systems (decision making processes, human factors, life-cycle cost models, project management, risk-lifetime analysis and optimization, whole life costing), and life-cycle-oriented computational tools (artificial intelligence methods, evolutionary procedures, heuristic techniques, mathematical optimization, soft-computing methods, survival models and simulation), among others.

Life-Cycle of Structures and Infrastructure Systems collects the lectures and papers presented at IALCCE 2023. This Open Access Book contains the full papers of 514 contributions, including the Fazlur R. Khan Plenary Lecture, nine Keynote Lectures, and 504 technical papers from 45 countries. It provides both an up-to-date overview of the field of life-cycle civil engineering and significant contributions to the process of making more rational decisions to mitigate the life-cycle risk and improve the life-cycle safety, reliability, redundancy, robustness, resilience, and sustainability of structures and infrastructure systems exposed to multiple natural and human-made hazards in a changing climate. The Editors hope that this volume will serve as a valuable reference to all concerned with life-cycle of civil engineering systems, including students, researchers, practitioners, consultants, contractors, decision makers, and representatives of managing bodies and public authorities from all branches of civil engineering.

Fabio Biondini and Dan M. Frangopol
Chairs, IALCCE 2023

Milan and Bethlehem, April 2023

Acknowledgments

The Editors are extremely grateful to all people who contributed to the organization of the IALCCE 2023 Symposium and to the production of this Open Access Book. Particularly, the Editors would like to express their sincere thanks to all the authors for their contributions, to the members of the Steering Committee, International Scientific Committee, and National Advisory Committee for their role in ensuring the highest scientific level of the Symposium, and to the members of the Local Organizing Committee for the time and efforts dedicated to make IALCCE 2023 a successful event.

Moreover, the Editors wish to thank all organizations, institutions, and authorities that offered their patronage. At the institutional level, a special acknowledgment has to be given to the Politecnico di Milano, for organizing and co-sponsoring this Symposium along with the International Association for Life-Cycle Civil Engineering (IALCCE), as well as to the Department of Civil and Environmental Engineering for endorsing and supporting the Symposium organization.

Finally, the Editors wish to express their warmest appreciation to Mattia Anghileri, Adriano D'Iorio, and Francesco Marino, for their effective teamwork and dedication in supporting the editorial activities. Special thanks are due to Andrea Bertoni, Stella Pennini, and Gaia Gorini, who professionally managed the Organizing Secretariat with outstanding expertise, commitment, and enthusiasm, and Marco Guerini for his valuable contribution in designing and developing the Symposium website.

Making bridges sustainable

E. Brühwiler

EPFL (Ecole Polytechnic Fédérale de Lausanne) and BridgIng Consultant, Lausanne, Switzerland

ABSTRACT: Lack of incentives mainly explains why the implementation of novel methods and technologies in bridge engineering practice is generally postponed by the engineering community despite the urgent need to advance also bridge engineering to meet the objectives of sustainability. Novel engineering methods and technologies are presented in this paper to extend the service duration of existing bridges while meeting the requirements of modern use. Accurate determination of bridge behavior using data from in-situ measurements and long-term monitoring of traffic action effects allow to verify realistically the structural and fatigue safety of bridges. If interventions are necessary, a targeted use of advanced high-performance materials such as UHPFRC allows to rehabilitate and strengthen effectively reinforced concrete bridges. This approach follows the principle of sustainability to preserve material resources and their grey energy that are already in use, thereby limiting greenhouse gas emissions to a minimum when requalifying and adapting existing bridges to future use.

1 INTRODUCTION

1.1 *Sustainability and existing bridges*

Civil engineers will be called upon to find solutions to mitigate the unpredictable effects of the climate change on people. Currently, civil engineers are still primarily trained to build new structures without learning how to consider *concretely* the principles of sustainability of constructions. A turning point in the education of engineers and practicing engineers is urgently needed. To soften the effects of the climate change on people, greenhouse gas emissions must be radically reduced. It is obvious that rehabilitation, adaptation and modification of existing structures and bridges must be given first priority. We must value the existing and avoid the still commonly practiced “demolition-replacement” approach including high material consumption and high greenhouse gas emissions, and also loss of cultural values.

Civil Engineers are trained to build new structures. These “new builders” are only partially or not at all competent to engineer existing structures. That’s why, methods of new construction are applied to existing bridges under the title “re-calculation” and interventions are designed using code provisions for new structures. But an existing bridge exists ! A stress in a rebar can be measured directly. It does not have to be “re-calculated”, which, due to significant model uncertainties, leads to unrealistic though over-conservative results.

In addition, “new builders” describe a bridge that is f.ex. 60 years in use, as an “old” bridge that - like humans - has a “lifespan” of 80 to 100 years. But bridges are not living beings and have thus no “lifespan” and no “remaining life”. Bridges are useful objects, bind enormous amounts of resources and heavily burden the environment. In outstanding cases, bridges are also built culture. For economic reasons alone and out of respect for the environment, bridges should in principle be preserved for as long as people use trains and road vehicles. Bridges (and other structures) are not consumer goods to be thrown away and, at best, recycled. The profession has yet to be “converted” to the engineering of existing structures!

1.2 *Engineering of existing structures*

“Engineering of existing structures” requires an own approach as it implies to precisely determine the capacity and structural resistance of an existing structure with respect to its intended use and exposure. This process is called “updating”. The basic methodology is to collect systematically and specifically detailed information on the existing structure, by non-destructive testing methods and measurements (monitoring). In this way, the determinant variables related to the loading action effects and the resistance of structural elements are determined as realistically as possible. This procedure is not new and in principle already permitted by standards. However, it is rarely used because practicing engineers are not trained or competent to do so.

“Engineering of existing structures” has the goal to show that existing structures can be subjected to higher loads by exploring and exploiting often available load-bearing reserves while meeting the safety requirements. Only when all possibilities for updating the bridge have been exhausted and the requirements for structural safety and usability can still not be met, interventions to strengthen structural elements are necessary. The extent of the intervention and the consumption of resources should thereby be as limited as possible. New technologies and high-performance building materials are often effective means to achieve this goal.

“Engineering of existing structures” also implies “Baukultur” (building culture) and knowledge of the history of structural engineering. But most engineers have yet to develop their sensitivity for questions of cultural values of structures and the preservation of monuments of various degrees of importance. Accordingly, the subject of building culture should be part of the basic competences of structural engineers.

“Engineering of existing structures” is needed to avoid cost-intensive or even unnecessary interventions, which are often the result of incomplete know-how of structural engineers and lack of sufficient information about the existing structure.

1.3 *Standards for engineering of existing structures*

When dealing with existing structures, the “new builders” among structural engineers apply standards valid for the design of new structures. This is a problematic approach as standards for new structures are obviously not applicable to existing structures. Only some provisions may be analogously applied to existing structures.

Over the last 30 years, a methodology inherent to existing structures has evolved, presented at numerous scientific and professional conferences, and successfully applied in many existing bridge cases. However, it has not yet been fully adopted in practice by the majority of structural engineers. This is explained by the fact that there are no standards available which practicing engineers can rely on.

For this reason, the Swiss Society of Engineers and Architects (SIA) elaborated a series of standards exclusively devoted to the engineering of existing structures, published in January 2011 as SIA269 Standards (Brühwiler et al. 2012). This pioneering initiative may still be considered as unique worldwide. Switzerland is a country with well-developed built infrastructure, and the enforcing of these standards led to a marked improvement of engineering projects related to existing structures, implying significant socio-economic benefits and reducing the environmental impact of structures.

In Europe, CEN-TC 250-SC 10 is elaborating a standard, entitled “Basis of structural and geotechnical assessment of existing structures” (CEN-TC 250-SC10, 2022), which relies on contents of the Swiss SIA269 Standard. This initiative can be interpreted as a “memorandum of understanding” that standards for existing structures are needed. However, this European standard is currently limited to basic principles and still requires time and discussions to achieve agreement among all member countries.

Worldwide, in many countries there seem to be no concerns about existing bridges being exposed f.ex. to higher traffic loading or deteriorating bridge condition. Commonly, in these countries, engineering of existing structures is limited to condition assessment, and invasive methods often implement “demolition-replacement” projects, implying high construction

costs and high environmental impacts. As a consequence, the need to introduce standards for the engineering of existing structures is not prevailing in these countries.

Overall, the situation related to the engineering of existing structures is unsatisfactory and still rather unprofessional, which is also the result of the traditional conservatism of structural engineers that, as “new builders”, underestimate the significance of engineering of existing structures.

1.4 Outline

After this review of the current situation of the engineering of existing structures based on the authors rich practical experience in Switzerland and worldwide, this paper contains two main parts:

- Chapter 2 presents recent research findings by the author and his research team in the domain of *monitoring-based verification* of existing structures. Rational ready-to-use engineering methods are deduced to investigate as precisely as possible *action effects* (f.ex. due to traffic loading) on bridge structures, while current structural engineering is more at ease in the determination of ultimate resistance of structural elements.
- Chapter 3 is a brief overview of the current state-of-knowledge of the *UHPFRC Technology* to rehabilitate and strengthen existing bridges, as mostly developed and implemented in practice by the author and his research team.

Both domains follow the goal to radically *preserve existing bridges* and to follow the principle of sustainability of continued use of material resources and their grey energy, thereby limiting greenhouse gas emissions to a minimum when adapting bridges to future use.

2 MEASUREMENT AND MONITORING BASED VERIFICATION OF FATIGUE AND STRUCTURAL SAFETY

2.1 Methodology

2.1.1 Basic approach

The modern approach to existing structures is based on “updating”, which means collecting and exploiting detailed in-situ information from the existing structure while reducing uncertainties in structural parameters (Brühwiler et al. 2012). The controlling parameters are determined as precisely as needed following a stepwise procedure with increasing focus on details.

The structural safety verification is finally performed using updated values, called examination (or assessment) values. The notion of degree of compliance n is introduced in the deterministic verification of the structural safety:

$$n = \frac{R_{d,updated}}{E_{d,updated}} \quad (1)$$

where $R_{d,updated}$ and $E_{d,updated}$ are the examination values of resistance and action effect, respectively. The degree of compliance is a numerical statement showing the extent to which an existing structure fulfils the structural safety requirements. This formulation not only gives the information whether the structural safety is fulfilled. It also indicates by how much the verification is fulfilled (or not). The latter is necessary for the evaluation of results and in view of the planning of interventions.

2.1.2 Non-destructive evaluation

In a first step, examination (often called: assessment) of existing structures is typically conducted using construction drawings (if available), information on materials and visual inspection. While a broad range of sensing and monitoring technologies have been developed over the last decades, *non-destructive evaluation (NDE)* is still rarely used for the condition survey and safety verification of existing bridges. NDE techniques include both *non-destructive testing (NDT)* and *structural performance (or: “health”) monitoring (SPM)* (Bertola et al. 2022) (Figure 1):

- In NDT, instruments and sensors are deployed temporarily to measure the response due to a known stimulus, to determine structural (e.g., location of reinforcing bars, element thickness, etc.) and material properties (e.g., modulus of elasticity and strength) as well as characteristics of structural behavior (e.g., rigidity, deformation, deflections). Techniques include ground penetrating radar (GPR), ultrasonic testing (UST), acoustic emission (AE), rebound hammer testing or load testing.

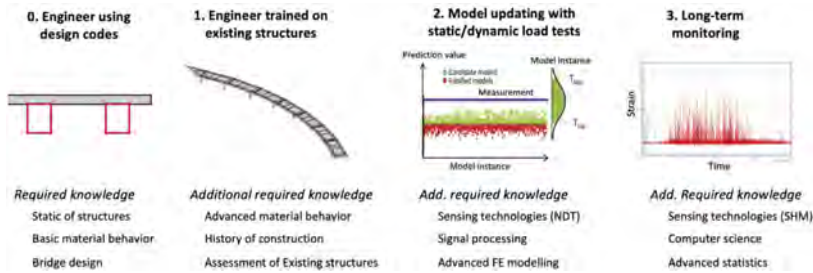

Figure 1. Stepwise procedure with increasing refinement, from Step 0 to 3, for the examination of existing structures with the associated training required, taken from (Bertola et al. 2022).

- In SPM, sensors are mounted in targeted locations of the bridge structure to collect strain and temperature data over rather long time using periodically sampled response measurements. SPM data are useful to describe condition changes and monitor degradation processes. Stress histograms due to traffic loading, temperature induced stress and changes of material and geometric properties are monitored. This data is then analyzed to support the fatigue and structural safety verifications of existing bridges.

Most sensor data such as deformations, strains and accelerations are indirect measures of material and structural properties and behavior. Therefore, data interpretation is indispensable, and in-situ measurements often must be complemented by advanced structural analysis. Calibrated finite-element (FE) models are needed to provide accurate data on structural behavior and capacity.

Although NDE information may lead to more sustainable and cost-effective management of existing infrastructure, it requires additional training for structural engineers that are usually not included in current curricula (Figure 1).

2.1.3 Practicability of NDE, in-situ measurements and monitoring

The verification of structural safety must thus be based on in-situ measurements of actual structural behavior, rather than theoretical design-based engineering values. Several ways to measure, monitor, and analyze structural behavior are possible and should be carefully selected based on the objectives of monitoring, case study, sensor availability and training of engineers.

The advent of cheap and high storage capacity hardware in recent years means that direct measurement of action effects in structural elements via structural monitoring is now a viable option. On purpose tailored compact monitoring equipment is a rational and ready-to-use tool of reasonable cost that can be used on a routinely basis by bridge engineers commissioned to perform an examination of an existing bridge. In this way, structural monitoring becomes as self-evident for engineers as f.ex. the routinely use of software tools implementing Finite Element models.

Obviously, current practitioners' perception of monitoring as being complex, costly and not always providing useful results needs to be challenged and altered. Researchers have a responsibility to support practice.

2.2 Risk-based bridge inspection

The visual inspection of existing bridges is a critical step in bridge safety verification, as the detection and quantification of damage must be accurate, reliable and useful to conduct

realistic examination of existing bridges. Often, a condition value ranging from 1 to 5 is given to each bridge. As only element-based degradations are currently considered in bridge-condition evaluations, inaccurate assessments of global structural safety are also provided by bridge inspectors.

A risk-based methodology provides a more objective and reliable examination of the bridge condition based on visual-inspection data. Degradation states of bridge elements are coupled with element-failure consequences on the global structural safety in risk analysis. Risk-based methodologies have been proposed in the past and are even in use. However, it is crucial to validate them in the field in order to have them accepted by practice.

A recent case study of a strategic road involving sixty bridges was conducted to assess bridge conditions applying a novel risk-based methodology based on visual inspections (Bertola & Brühwiler 2023). The study revealed that including element-failure consequences in bridge-condition assessments supports more accurate evaluations of the impacts of damage on the global structural safety, leading to more objective decisions on management actions and interventions. Analyses of four damaged bridges showed that traditional inspection methods often lead to over-pessimistic assessments in terms of structural damage, and this can lead to unnecessary or excessive rehabilitation interventions.

2.3 *Updating traffic action effects by structural monitoring*

In recent years, monitoring has offered a significant complement or even alternative to traditional analytical safety verification approaches. However, there still remains a lack of guidance for the use of monitored data in structural safety verification. Often, relatively short time frames of monitoring are used. Additionally, temperature effects often have a significant influence on the structural response which requires adequate consideration.

2.3.1 *Duration of monitoring*

The duration of monitoring has an important influence on predicted characteristic action effects and is thus of first importance regarding reliability of data. In order to determine if a monitoring campaign is sufficiently long to obtain a reliable extreme value estimate of the action effect, a case study of a highway bridge in Switzerland, with one year of continuous high-frequency measurements, was analyzed by means of several approaches (Treacy et al. 2014). The focus was on direct measurement of the traffic action effects in the bridge's deck slab steel reinforcement bars. A comprehensive statistical approach for determination of site- and element-specific extreme traffic action effects was conducted.

The study showed that the time required to capture stable record behavior in the deck slab rebars is highly dependent on element location and orientation, as well as the local traffic composition. The behavior of the predicted extreme values was strongly influenced by the record accumulation behavior for daily maximum measured strains. Single extreme events significantly higher than the average daily maxima had a strong effect on the extreme value predictions.

2.3.2 *Fatigue and temperature effects*

The results of 28-month-long monitoring of a slab portion of a highway viaduct using strain gauges and thermocouples were investigated (Sawicki & Brühwiler 2020). The post-tensioned reinforced concrete structure was strengthened with a layer of UHPFRC (see Chapter 3). Strain gauges were used to measure stress values in the bottom layer of reinforcement bars in the slab, while thermocouples recorded the global behavior of the structure due to ambient temperature variation (Figure 2).

The study revealed that the stress variation due to the thermal action can be as large as the response due to traffic action, even in a massive structure. Monitoring data was analyzed for fatigue and structural safety verification and compared with traditional re-calculation on Level 1, showing that assessment by re-calculation is highly conservative, leading to significant overestimation of structural action effects.

The fatigue safety of existing bridges may be assessed using data from monitoring. This data is then used to assess fatigue due to the past traffic and to extrapolate to the future service duration using traffic scenarios as given by the bridge owner. Due to the randomness of

Figure 2. Left: Scheme of monitoring with strain gauges on rebars and thermocouples (T1–T7) (dimensions in mm); right: Strain recorded during 1 day on group 1 longitudinal rebar; filtered-out “thermal wave” is shown with dotted line, taken from (Sawicki & Brühwiler 2020).

traffic loading, there exists a likelihood of over- and under-estimation of potential fatigue damage in the case of short-term monitoring campaigns. As a consequence, the influence of monitoring duration on the obtained results must be known.

To investigate this research question, datasets collected during long-term (>3 years) monitoring campaigns of two bridges were analyzed (Sawicki & Brühwiler 2022). The two road bridges had different nature of traffic: a two-lane highway viaduct with heavy traffic, and a bridge with a bi-directional regional traffic. The deck slabs of both bridges were monitored using strain gauges installed on reinforcement bars. The daily, seasonal and year-to-year measured traffic action effects were analyzed, and a theoretical equivalent fatigue damage was calculated.

The resampling method was used for the simulation of possible short-term monitoring campaigns during the period considered, with different order of heavy vehicles arriving. The Extreme Value Theory served to answer what is the required monitoring duration for reliable results. Methods to consider the monitoring duration in fatigue damage calculations were proposed and validated.

In order to verify the efficiency of the UHPFRC strengthening (see Chapter 3) and to further evaluate its long-term performance, a structural monitoring campaign was implemented, relying on low-cost, yet easily deployable, sensors, including a suite of accelerometers, strain gauges, temperature and humidity sensors (Martin-Sanz et al. 2020). The monitoring data was first processed by means of standard modal analysis methods as well as non-stationary time-series analysis tools. In a second step, a Finite Element model of the system was built and updated, and subsequently exploited to deliver a comparison between the original and strengthened structure using reliability analysis, confirming the efficiency of the UHPFRC strengthening.

2.3.3 NDT of bridge deck condition

RC bridge deck condition was monitored during one year by means of AE (acoustic emission) permanent measurements (Bayane & Brühwiler 2020). The study has shown that the structural response and characteristics of the slab under operational and environmental loading can be investigated within reasonable postprocessing work and statistical analyses. AE measurements allowed to identify the nature of cracking activity in the concrete slab as a function of traffic loading and ambient temperature variation. The method was validated on combining the AE and strain gauge measurements, performed on a bridge deck slab in service for 60 years, providing finally useful information for structural and fatigue safety evaluation.

2.3.4 Monitoring-based examination value

The examination value of the railway traffic action effect was calculated from long-term monitoring data without resorting to load models and structural analysis (Grigoriou & Brühwiler 2016). Monitoring data was obtained from measurements on a short span RC slab bridge. The action effect is represented by the distribution of its maxima per train passage. The end tail of the distribution was modelled by a shifted exponential distribution, and the examination value was calculated by extreme value theory, using additionally a confidence upper bound in order to consider the monitoring duration.

The monitoring-based safety verification procedure was developed through probabilistic modelling and reliability calculations, based on failure probabilities per freight train incident

(and not per unit of time). The duration of the monitoring period, in terms of the number of recorded freight train incidents, was considered in the examination value of the action effect by means of a confidence upper bound.

On the other hand, the annual variation of temperature had a significant indirect effect on the traffic action effect and, unless monitoring was performed over several years, the uncertainty related to this effect can only be considered by empirical factors.

The relatively simple semi-probabilistic method gave results close to the more complex FORM. For the six-month monitoring campaign, the uncertainty from the limited duration of monitoring resulted in an increase of the examination value by 18%. This increase could possibly be reduced to 10% for a one-year monitoring period and to 6% for two years.

2.3.5 *Dynamic action effects*

All previously described and other bridge measurement campaigns confirmed that there is no notable dynamic amplification of road and rail traffic effects on structural bridge elements like slabs or rail track system, if stress and strain are directly measured on relevant rebar and concrete as well as steel element locations. The plausibility of this significant finding can be explained by simple dynamic models (Ludescher & Brühwiler 2009).

Consequently, no dynamic amplification factor needs to be considered on Level 1 verifications by re-calculation using traffic load models, while on advanced level monitoring-based examinations eventual dynamic effects are implicitly included in the measurement results.

2.4 *Updating permanent actions*

In the case of massive bridge structures like the ones in reinforced concrete, often more than 60% of the total action effect on structural elements is due to permanent actions (consisting of the self-weight of the structure and equipment (f.ex. pavement)). In extreme cases, permanent actions represent 80% of the total examination value of action effect.

As a consequence, NDT is required to provide precise data of structural dimensions, in particular thickness of structural elements and pavement, and the volumetric load of materials, to update the characteristic value of permanent actions.

Updating by means of NDT reduces uncertainties which in turn provides the basis to update also the load factor for permanent action, in the framework of the basic deterministic safety verification. Application of the well-known semi-probabilistic method has shown to be an effective mean to update permanent actions effects, while adequately respecting safety requirements.

2.5 *Structural identification and value of information*

The monitoring of existing bridges has the potential to improve bridge management. Monitoring data help identify unknown model-parameter values. Then, this information is used to accurately evaluate bridge condition and behavior, such as to predict reserve capacity and fatigue resistance, avoiding invasive interventions or replacement. This model-updating method is called structural identification.

The benefits of structural identification depend on the selected monitoring system, including sensor types, number of sensors and device locations. As these choices are usually made using engineering judgment and qualitative metrics, the selected measurement systems may be sub-optimal, leading to a low cost-benefit ratio of bridge load testing and monitoring.

Methodologies now exist to design optimized measurement systems based on their cost-benefit ratio. Such a methodology has been suggested and validated by means of a composite steel-concrete bridge in Switzerland (Bertola et al. 2022, Bertola & al. 2023). It was found that a rational methodology to design measurement systems helps to reduce the number of sensors without compromising the information gain, thus significantly improving the cost-benefit of bridge load testing and monitoring.

Monitoring data from several sources can be used to develop accurate physics-based models and Error-domain model falsification (EDMF) (Goulet & Smith 2013) to analyze measurements, enabling accurate identification of structural parameters necessary f.ex. to verify fatigue safety of existing bridges (Bayane et al. 2021).

2.6 *Training in engineering of existing structures*

Structural engineers today are still educated mainly to design new structures. Engineers are thus often ill-equipped to deal with maintenance and preservation of existing structures.

Consequently, educational programs should be modernized and developed to the engineering of existing structures. Such programs would still include certain basic structural engineering courses (like structural mechanics) but also elaborate on structural behavior and material properties, and how these can be determined by means of NDT and SPM, in sum referred to as non-destructive evaluation NDE. Because these tools are traditionally not included in the structural engineering curriculum, a new set of basic interdisciplinary skills from the domains of mechanical and electrical engineering, as well as computer science (data analysis, signal processing, etc.), need to be acquired by the students.

Measurement-informed approaches for structural analysis require training beyond traditional structural engineering backgrounds. Engineers must understand the potential of sensor devices in terms of data collection and signal processing. Moreover, model updating requires building refined FE models to accurately predict structural behavior under in-situ conditions. When long-term monitoring measurements are collected, very large data sets need to be analyzed and interpreted, which requires special training. Statistical and data science tools, such as machine learning, could be appropriately used to f.ex. differentiate signal from noise.

3 REHABILITATION AND STRENGTHENING USING UHPFRC

3.1 *Introduction*

Construction of reinforced concrete bridges is very successful because it is cheap. However, the problems of insufficient durability are known for several decades. Rehabilitation of bridges in reinforced concrete using traditional methods implies high intervention and user costs which represent a heavy burden for national economies and the environment. Nevertheless, there is no end of RC bridge construction in view... ! Many bridge engineers and the profession do not seem to care about this problem and are not motivated to make progress !

UHPFRC stands for Ultra-High-Performance Fiber Reinforced Cementitious Composite materials. UHPFRC is composed of cement and other reactive powders, additions, hard fine particles, low amount of water, admixtures and very high amount of relatively short and slender steel fibers. The composition of UHPFRC is optimized with respect to compaction of particles leading to a waterproof material up to a tensile strain of about 0,1 %. The tensile strength of UHPFRC typically is about 12 MPa and the material shows significant strain-hardening behavior in tension. UHPFRC has compressive strength higher than 140 MPa. UHP(FR)C is nowadays used in many countries, mostly in the domain of new construction (Graybeal et al. 2021).

The author and his team have developed the UHPFRC rehabilitation and strengthening technology over the last 25 years by means of scientific research and applications (Bertola et al. 2021, Brühwiler 2019). In Switzerland (8,7 million inhabitants, area of 41'000 km²) there are currently more than 350 reinforced concrete structures, mainly bridges, that have been improved using the UHPFRC Technology, since 2004. This is the by far highest UHPFRC application rate in the world with respect to the size of the country.

The main reason for this successful implementation of a new technology in practice is that compared to traditional methods using concrete, mortar and epoxy coatings, the UHPFRC Technology is economic in terms of costs and material use, allows for an accelerated construction process and provides durable structures for further use reducing or eliminating maintenance costs.

By applying a UHPFRC reinforcement and waterproofing layer, the use of an existing RC bridge can continue. In this way, new requirements of use are accommodated in an economical, environmentally friendly and socially responsible manner. The UHPFRC Technology is also particularly suitable for bridges of high cultural values, since interventions are usually not visible.

3.2 Principles of UHPFRC-concrete composite elements

UHPFRC is used as a high-performance building material to improve existing bridges in traditional reinforced concrete with the aim of remedying, through a targeted supplement with UHPFRC, the known deficiencies of reinforced concrete.

3.2.1 Concept

The basic idea of reinforcing structural RC bridge elements with UHPFRC is to monolithically connect a 25 to 80 mm thick UHPFRC layer with the RC cross-section. The resulting UHPFRC-concrete composite element consists of a RC cross-section and a layer of UHPFRC or R-UHPFRC (incorporating steel reinforcement bars) according to Figure 3. The term “strengthening” used here includes the increase in resistance and rigidity of structural bridge elements. At the same time, the UHPFRC layer also provides the protection function by a watertight barrier to shield reinforced concrete from direct contact with water and chloride ions.

Figure 3. Basic configurations of the UHPFRC-concrete composite construction: a) protective function and increase in rigidity under service conditions, b) protective function and increase in element rigidity and ultimate resistance (rebars in the RC may be integrated or not in the R-UHPFRC layer).

The essentials of UHPFRC-concrete composite behavior can be summarized as follows:

3.2.2 Behaviour in bending

When in tension, the R-UHPFRC layer principally acts as an added flexural reinforcement chord for the RC member. Both the steel rebars and the UHPFRC contribute to the structural resistance. RC beams strengthened with a R-UHPFRC layer show significant increase in elastic stiffness and ultimate resistance when compared to the initial RC member.

The bond between UHPFRC and concrete is obtained by preparing the concrete substrate surface by high pressure water jetting or sand blasting. The concrete substrate has to be wetted and needs to be moist when the layer of UHPFRC is cast. This surface preparation provides a full bond between the UHPFRC and the concrete substrate with monolithic behaviour.

The plastic post-peak rotation capacity of strengthened RC beams is maintained with an appropriate design of the rebars in the UHPFRC layer. The structural behaviour in terms of moment – curvature relation and the ultimate bending resistance are calculated using the conventional sectional model, extended to account for the R-UHPFRC layer in the monolithic section (Figure 4).

Figure 4. Plane section analysis for ultimate bending resistance.

When subjected to compressive stresses, the R-UHPFRC layer acts as a compression flange but the high UHPFRC compressive strength can usually not be fully exploited. This is because the

compressive strength of the adjacent concrete below the UHPFRC layer often is three to six times lower, and thus concrete would crush prior to the UHPFRC reaching its compressive strength.

3.2.3 Behaviour in combined bending and shear

Testing of R-UHPFRC – RC composite beams revealed that the addition of a layer of R-UHPFRC delays the formation of the inclined shear crack in the concrete section. For many geometric configurations, the R-UHPFRC layer modifies the failure mode from well-known RC shear failure with little deformation to a ductile flexural failure mode.

A shear failure is observed in a composite section only for specific geometric and material configurations. Due to the experimentally observed failure mechanism, the ultimate shear resistance is composed of the contributions due to concrete web crushing, vertical steel reinforcement yielding and a two hinge-bending mechanism of the R-UHPFRC layer. Accordingly, analytical expressions have been deduced to calculate the ultimate shear strength of RC slabs and beams strengthened by a R-UHPFRC layer.

3.2.4 Fatigue behaviour

Bending fatigue tests on R-UHPFRC – RC composite elements revealed the existence of a fatigue limit at 10 million cycles at a fatigue stress level of about 50 % of the ultimate static resistance of the R-UHPFRC – RC beams. Consequently, fatigue design rules for R-UHPFRC – RC members under bending fatigue need to account for steel rebar and UHPFRC fatigue resistances. Fatigue stresses are calculated using an elastic sectional model similar to the one shown in Figure 4.

3.2.5 Design provisions

Rational design provisions for the application and implementation of R-UHPFRC in structural engineering are given in the Swiss Standard SIA 2052 (SIA2052 2016) which is still the only UHPFRC Standard explicitly treating the application of UHPFRC for the enhancement of existing concrete structures. Is the experts basic education as “new builders” the reason why other code committees don’t integrate the engineering of existing structures in their UHP(FR)C codes ?

3.3 Design concepts to improve bridges

Obviously, UHPFRC should generally be used as a material to rehabilitate and restore damaged reinforced concrete elements, thereby replacing the use of inferior materials like repair mortars or epoxy coatings. In the following, concepts are presented to increase structural resistance of R-UHPFRC improved RC bridges:

3.3.1 Project objective 1: Restoring and increasing the resistance of bridge deck slabs

Bridge deck slabs made of reinforced concrete are subject to particularly high loading due to environmental influences and traffic loads. Accordingly, there is a high demand for intervention to restore and increase the structural resistance of deck slabs.

Figure 5 shows the basic strengthening concept of bridge deck slabs by applying a R-UHPFRC layer to the existing concrete slab. Bridge deck slabs carry loads and forces mainly in the transverse direction. Correspondingly, a distinction is made between the sagging moment zone (positive bending moments) and the hogging moment zone (negative bending moments) above the webs of beams or box girders.

Figure 5. Concept of increasing the resistance of the original RC deck slab by means of the R-UHPFRC layer forming a strong R-UHPFRC tension chord in the hogging moment zone.

The concept is to significantly increase the flexural resistance in the hogging moment zone by forming a strong R-UHPFRC tension chord allowing for moment redistribution from the sagging to the hogging moment zone at ULS (ultimate limit state) according to the plasticity theory, given that the UHPFRC layer under compression in the sagging moment zone only leads to a comparatively small increase in the flexural resistance.

The R-UHPFRC tension chord must be compensated by a correspondingly strong compression zone. In order to ensure the balance of the tensile and compressive forces resulting in the bending cross-section, the effective concrete compressive strength is exploited, which has usually increased considerably (i.e. by 20 to 50 % compared to the 28-day compressive strength) during the bridge's service duration usually of several decades. This well-known time-dependent increase in strength is estimated using analytical expressions given in scientific literature and standards, and verified by means of non-destructive testing on the structure. In this way, strengthening of the compression zone can often be avoided.

By creating a R-UHPFRC tension chord, the ultimate shear resistance is also greatly increased in the hogging moment zone, such that the shear force check is usually fulfilled easily. By the R-UHPFRC reinforcement, the slab rigidity is significantly increased, which greatly reduces fatigue stresses in the steel reinforcement bars and in the concrete. The fatigue safety check is therefore usually fulfilled with margins.

3.3.2 Project objective 2: Increasing the resistance of bridge girders

The targeted use of R-UHPFRC, in particular as a R-UHPFRC tension chord, enables a significant increase in the load-bearing capacity of bridge girders in the longitudinal direction without significantly increasing permanent actions (by the additional R-UHPFRC layer) and without the intervention becoming visible. For this purpose, a modification of the static system is usually appropriate. Two basic principles are described as follows.

Principle 1: Reinforcement of continuous beams by means of a R-UHPFRC layer

In statically indeterminate systems such as continuous beams, the bending resistance in the hogging moment zone is greatly increased by the formation of a strong R-UHPFRC tension chord in order to be able to carry out a plastic moment redistribution from the sagging to the hogging moment zones at ULS, similar to the concept related to deck slabs (Figure 6). However, this moment redistribution is only possible if the bending cross-sections are sufficiently ductile, which must be verified. For this purpose, a non-linear finite element analysis is often useful if the empirical rules of standards are not satisfactory.

Figure 6. Principle of increasing the ultimate resistance of reinforced concrete bridge girders using a R-UHPFRC layer with the formation of a strong R-UHPFRC tension band in the support area.

This principle is efficient in that an increase in the load-bearing capacity (ultimate resistance) of 15 to 30% (and in extreme cases up to 50%) can be obtained. In this way, for example, severe damage such as failure of prestressing cables due to corrosion can be compensated without having to install costly additional tendons.

As in the sagging moment zone of a bridge girder, the R-UHPFRC layer only leads to a small increase of the flexural resistance, a need for additional reinforcement of the tension zone at the bottom of simple and continuous beams can be accommodated for by CFRP (carbon fiber reinforced plastics) lamellas on the underside of the bottom flange or by additional external posttensioning tendons.

Principle 2: Creation of hyperstatic systems by force-locked closure of dilation joints

For existing short and medium span RC bridges with lengths up to 80m, all dilatation joints can be eliminated using UHPFRC. Force-fit joint closure leads to hyperstatic systems. Particularly, the structural behavior of the modified abutments needs to be investigated applying recent knowledge in the area of integral RC bridge structures. In the case of existing bridges, the dilatation movement to be considered is limited to that due to changes in temperature alone, since girder deformation due to final shrinkage and creep of the existing concrete is negligible.

Bridges consisting of a series of simple beams that are force-fitted monolithically in the support zone by R-UHPFRC, are converted into a continuous beam and are thus analyzed like continuous beams according to Principle 1.

Figure 7a shows the concept of joint closure in the abutment area of a single span beam. In the case of pier-like abutments with large dimensions, a frame structure can be created. By modifying the end zones of the beam to frame corners, the bending stress is redistributed from the sagging zone to the frame corners and thus relieved. By installing the R-UHPFRC tension chord in the abutment zones and a UHPFRC layer over the entire deck, the dilatation joints are eliminated and the reinforced concrete is protected from chlorides and water.

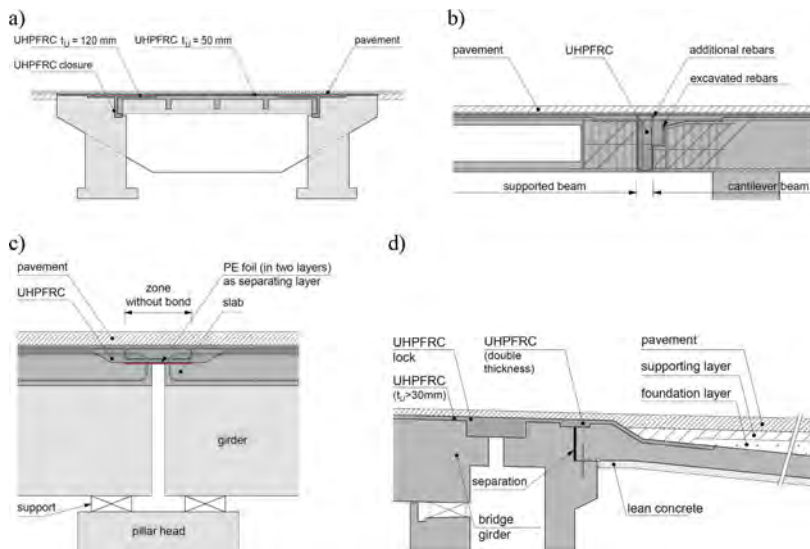

Figure 7. Principle of UHPFRC joint closure: a) in the abutment zones of a single span bridge to create a half-frame, b) force-locked Gerber joint, c) partial joint closure for beam chains, also called “link slab”, and d) creation of a semi-integral bridge end.

Figure 7b shows the constructional detail of a force-locked Gerber joint, which is bending- and shear resistant. The UHPFRC lock is anchored into the existing RC bridge structure with rebar inserts on both sides.

In the case of single span girders in series, the partial joint closure at the level of the deck slab shown in Figure 7c can be suitable. A relatively massive unbonded slab in R-UHPFRC, called “link slab”, is anchored in the adjacent RC deck slabs to connect two adjacent bridge girders by a continuous deck slab. The length of the connecting UHPFRC slab is designed such that temperature related deformations are absorbed by deformation of the “link slab”. The static functioning of the original simple beams is not modified by this intervention. This “link slab” principle can also be implemented in the transition from the bridge to the road for dilatations up to ± 10 mm.

Figure 7d shows the design of a semi-integral abutment by means of a R-UHPFRC lock connecting the bridge deck slab to the transition (or approach) slab, thereby waterproofing the bridge end zone and eliminating the dilation joint above the bridge bearing and thus a major bridge damage situation.

By forming force-locked UHPFRC connections, the structure is stiffened, which usually increases structural resistance. Obviously, the entire strengthened structure and in particular the UHPFRC-locked zone must be analyzed accordingly and the force flow in the modified structure must be carefully verified.

3.4 Three selected recent applications

Among numerous UHPFRC application projects with involvement of the author in conceptual design, dimensioning, project proof and quality control, three recent projects are selected and briefly described in the following:

3.4.1 Riddes Viaduct

The 1.2 km long road viaduct (Figure 8a) consisting of a twin continuous box girder in post-tensioned concrete built in 1976 is a major overpass over a railway line, highway and a river.

Figure 8. a) UHPFRC ready mix plant next to the Riddes Viaduct, b) UHPFRC casting on the deck slab.

RC damage including corrosion of prestressing tendons and steel rebars as well as alkali-aggregate reaction lead to a significant deficit in structural resistance. Strengthening intervention was urgently needed. The objective of the intervention was to over-strengthen the girder for flexural resistance to accommodate for (1) potential loss of 1/3 of post-tensioning, (2) 30% AAR-related forecasted concrete strength reduction and (3) local damage of the deck slab.

The R-UHPFRC intervention method was found to be most cost-effective and rapid to rescue the viaduct's post-tensioned concrete structure. The concept and design of strengthening was following the principle shown in Figure 6 and the design provisions of the Swiss UHPFRC standard (SIA 2052, 2016) including detailed non-linear FE analyses. The UHPFRC layer was cast in 2021 on the deck slab of the viaduct using a casting machine (Figure 8b).

3.4.2 Aare Bridge Schinznach

This 120 m long three span road bridge for bi-directional road traffic and with a pedestrian walkway was built in 1954. This bridge belongs to the first generation of steel-concrete composite bridges and has significant cultural values.

The cross section consists of two main steel girders and the RC deck slab. The RC slab showed ordinary steel rebar corrosion damage, and the pedestrian walkway had to be widened to accommodate for future user demand. In addition, examination of the composite structure and the deck slab revealed deficits in structural capacity and thus structural strengthening was required.

Figure 9. a) View of the steel-concrete composite bridge after R-UHPFRC strengthening, b) casting of UHPFRC with immediate application of curing compound.

The strengthening consisted in adding a 60mm thick layer of UHPFRC incorporating steel reinforcement bars in orthogonal directions to waterproof and protect the RC slab as well as to increase the resistance of the slab in the transverse direction and the hogging moment capacity over the piers in the longitudinal direction. The UHPFRC casting works were realized in two days in Summer 2022 (Figure 9b).

The R-UHPFRC strengthening was optimized such that strengthening of the two steel girders could be avoided, reducing the intervention on the main structure in steel to the renewal of the corrosion protection coating only.

3.4.3 Viaducts Pont d'Ouche

Built as part of a vast motorway program in the 1960s, the 504 m long Pont d'Ouche twin viaducts are one of the major elements of the A6 motorway in France (Figure 10a). At the time of their construction, they were unique by its geometric characteristics, since built entirely in curves and in slope, and by the structure being made up of prestressed prefabricated isotatic beams with spans of 36m with cast-in-place connecting slabs. This rational structural system for RC viaducts, which was very often realized in France and worldwide, allowed realization in a record time of 20 months and the inauguration of the viaducts in October 1970.

Figure 10. a) View of the twin viaduct structure with triple PC-girder cross section, b) casting of UHPFRC and curing with a plastic foil.

Installation of a robust water proofing layer in UHPFRC, repair of rebar corrosion damage and structural strengthening of the slab zone near the curbs to resist possible vehicle impact forces on the new vehicle retaining system, were the main reasons for realizing the UHPFRC project. The UHPFRC layer on the deck slab of the first viaduct was cast in 2022 using a casting machine (sure 10b). The same UHPFRC intervention will be realized in 2023 on the adjacent viaduct.

3.5 UHPFRC Technology and sustainability

The two most efficient materials in the building industry, steel and cement, are currently criticized as being particularly harmful to the environment. This ignores the fact that it depends on how these building materials are used. UHPFRC contains relatively high quantities of

cement and steel, so that the energy input and greenhouse gas emissions per kg of UHPFRC are high compared to most other building materials.

Nevertheless, the principles of sustainability can be well respected through the targeted use of UHPFRC. This is because UHPFRC is a high-performance building material with which the required technical performance of structures is achieved with small material quantities. In addition, “eco”-UHPFRC mixtures have already been developed (Hajiesmaeili et al. 2021), allowing for a reduction of the environmental impact of the UHPFRC material alone. Also, UHPFRC can be decomposed and recycled.

When dealing with existing structures, the use of UHPFRC leads to: “*Improve instead of replace!*” UHPFRC technology is able to rehabilitate and strengthen, actually to salvage, existing RC structures. In this way, material resources and grey energy already in use are further utilized, thanks to a relatively small amount of UHPFRC. The existing structure is valorized and upgraded in an economic manner.

4 CONCLUSION

Engineering of existing bridges comprises accurate determination of structural behavior and targeted use of advanced materials for improvement of structural performance with the ultimate goal of limiting construction intervention to a strict minimum while extending the service duration and thus limiting “life cycle costs”.

Two basic novel engineering methods and technologies were described to preserve existing bridges and to improve them to accommodate to the requirements of future utilization:

- NDE (non-destructive evaluation) is ready to be used in engineering practice to determine accurately traffic action effects with the goal to achieve realistic structural and fatigue safety verifications of existing bridges.
- If interventions are necessary, the UHPFRC Technology provides effective solutions to rehabilitate and strengthen existing bridges with little use of materials to upgrade them for future utilization.

These methods and technologies have already been successfully applied in practice, demonstrating their effectiveness. Recently, the Swiss Federal Roads Office has published a documentation to facilitate the use of the UHPFRC Technology for the preservation existing and the construction of new engineering structures of the road infrastructure (FEDRO 2023).

The presented approach follows the principle of sustainability to preserve material resources and their grey energy that are already in use, thereby limiting greenhouse gas emissions to a minimum and thus *making bridges sustainable*.

Probabilistic life-cycle performance assessment of corroded concrete structures: Core technologies to predict the remaining service life

Mitsuyoshi Akiyama

Waseda University, Tokyo, Japan

Dan M. Frangopol

Lehigh University, Bethlehem, Pennsylvania, USA

ABSTRACT: Predicting the performance and remaining service life of deteriorated reinforced concrete (RC) structures based on observational information obtained by means such as visual inspection and monitoring remains a very challenging task in the structural engineering community and the subject of this keynote paper. After experimentally studying the process of steel corrosion and the subsequential impact that corrosion has on the structural performance and integrity of deteriorated RC structures, it was determined that existing numerical simulation techniques need to be improved to reproduce the phenomena observed. With the application of machine learning techniques, the mechanical properties of concrete and rebar and their bonding over the entire RC structure should be determined quantitatively to replicate the observational information. In addition, new inspection technologies, such as those that use drones, must be utilized to obtain required observational information more efficiently. To address this challenging task, it is of vital importance to further integrate various advanced technologies and properly consider the uncertainties involved in the estimation and evaluation of each stage of deterioration and its propagation. In this study, a probabilistic framework for estimating the structural performance of corroded RC structures using observational information is presented using the associated core technologies in the literature, which include: (a) X-ray and digital image processing techniques to understand spatial steel corrosion, the product generated from corrosion and the associated crack width distributions, (b) the finite element method to simulate the structural performance and cracking behavior of corroded RC members, (c) the stochastic simulation technique to reproduce the characteristics of spatial steel corrosion variation, and (d) Bayesian updating and machine learning methods to estimate the degradation state from observational information as an inverse problem. For illustrative purposes, the effect of the observed corrosion-induced crack width distribution on the probability density function of the structural capacity of corroded RC beams is investigated based on the proposed framework.

1 INTRODUCTION

For RC members located in an aggressively corrosive environment, structural degradation due to chloride attack depends on several uncertainties associated with the predictions of mechanical and environmental stressors (Akiyama et al. 2011, 2012, 2014, 2020; Biondini et al. 2006, 2008, 2016). It is important to further develop probabilistic life-cycle design and assessment methods for RC structures in harsh environments (e.g., chloride-laden environments). Over the past decades, many studies have been performed to evaluate the reliability of newly constructed RC structures. Mori & Ellingwood (1993) proposed a framework to estimate reliability-based service life for corroded concrete girders. Frangopol et al. (1997) developed the reliability assessment method of RC girders being damaged due to corrosion and investigated the influences of steel corrosion on both flexure and shear reliabilities. Stewart et al. (1998) presented the time-dependent reliability method

of analyzing RC bridge decks, which is used to investigate the long-term deterioration of RC bridge decks generated from the application of deicing salts as well as from exposure to a marine environment. Enright and Frangopol (1998, 1999) and Yang et al. (2004) predicted the service life of existing deteriorating concrete bridges using time-variant reliability, Bayesian updating and life-time functions. Biondini et al. (2004) presented a novel approach of durability analysis and service life assessment for deteriorating concrete structures, where the mechanical damage was coupled to the diffusion process caused by the use of aggressive environmental agents, modeled by cellular automata, and was evaluated by the application of suitable laws of material degradation.

A key to assessing the performance of existing RC structures under uncertainty is gathering and utilizing observational information obtained through visual inspection and monitoring and the spatial modeling of material properties. Observational information can help reduce epistemic uncertainties associated with the prediction of structural performances. Assuming the uniform corrosion of steel over the entire structure results in overestimating its structural performance and in underestimating the associated corrosion cracking and spalling extents of the covering concrete (Zhu et al. 2014). Several probabilistic models used to reproduce the spatial variation in steel corrosion in RC members have been proposed in the literature (e.g., Stewart 2004; Lim et al. 2016, 2017; Zhang 2019). The spatial variability associated with steel corrosion is caused by several uncontrollable parameters such as the spatial distribution of the aggregate and porous zone of the steel-concrete interface, concrete mixing and casting methods. Structural details such as the concrete cover and rebar diameter also contribute to the variability in the generation of steel corrosion. These factors are the genesis of uncertainty associated with steel corrosion and the corresponding corrosion crack width. Since cracks stemming from the corrosion process are caused by pressure from the expansion of the corrosion products generated by steel corrosion, there should exist a strong positive correlation between the width of corrosion cracks and the amount of corrosion of rebars. Theoretically, if the width of corrosion cracks can be measured, it should be possible to estimate the amount of steel corrosion and to estimate the load-bearing capacity of deteriorated RC members. However, it is still extremely difficult to estimate the load-bearing capacity from observational information on corrosion cracks due to the influence of the aforementioned uncontrollable parameters.

To solve this problem, it is necessary to study the following issues:

- understand the occurrence of steel corrosion and the associated distribution and shape of corrosion products along the cross-sectional and longitudinal directions of RC members;
- model the complex nonlinear relationship between corrosion cracks and rebar corrosion, e.g., by machine learning;
- develop artificially deteriorated RC members using stochastic simulation and numerical analysis based on the experimental evidence and use as a database for subsequent training of machine learning programs, since the acquisition of experimental data using deteriorated RC members is time consuming and costly;
- perform a reliability assessment that considers the various uncertainties involved in the acquisition of observational information compared to the performance of RC members; and
- use new techniques that can efficiently acquire observational information.

This study presents a framework for estimating the structural performance of corroded RC members using observational information with the core technologies. These technologies include: (a) X-ray and digital image processing techniques, (b) FE methods, (c) stochastic simulation techniques, and (d) Bayesian updating and machine learning methods. In an illustrative example, the probabilistic density function (PDF) associated with the flexural capacity of corroded RC beams based on the corrosion-induced crack width distribution is estimated.

2 FLOWCHART FOR PREDICTING THE REMAINING SERVICE LIFE OF DETERIORATED CONCRETE STRUCTURES

Figure 1 depicts the flowchart for predicting the remaining service life of deteriorated concrete structures using core technologies based on information provided via inspection. The

proposed procedure consists of two phases. In Phase I, steel weight loss and crack width distributions obtained from RC beams are experimentally investigated. The measured distributions of steel weight loss for the corroded RC members are applied to generate a dataset of the steel weight loss distributions using a two-dimensional (2D) stochastic simulation method. The crack width distributions are developed by the three-dimensional (3D) FE model using the dataset of the simulated steel weight loss distributions.

In Phase II, the datasets of steel weight loss and crack width distributions that were synthesized in Phase I were then used to train the machine learning model. Based on the trained machine learning model with the observed inspection results (e.g., corrosion crack width) obtained from the RC structures analyzed, the distributions of steel weight loss inside the members are predicted. Finally, the PDF of the structural capacity for aging RC members was estimated by performing a Monte Carlo simulation (MCS)-based 3D FE analysis.

The following Sections 2 to 6 introduce the experimental and analytical approaches related to Phases I and II. Section 7 presents a case study of performance evaluation of aging RC structures by using experimental evidence, stochastic simulation, FE analysis, and machine learning.

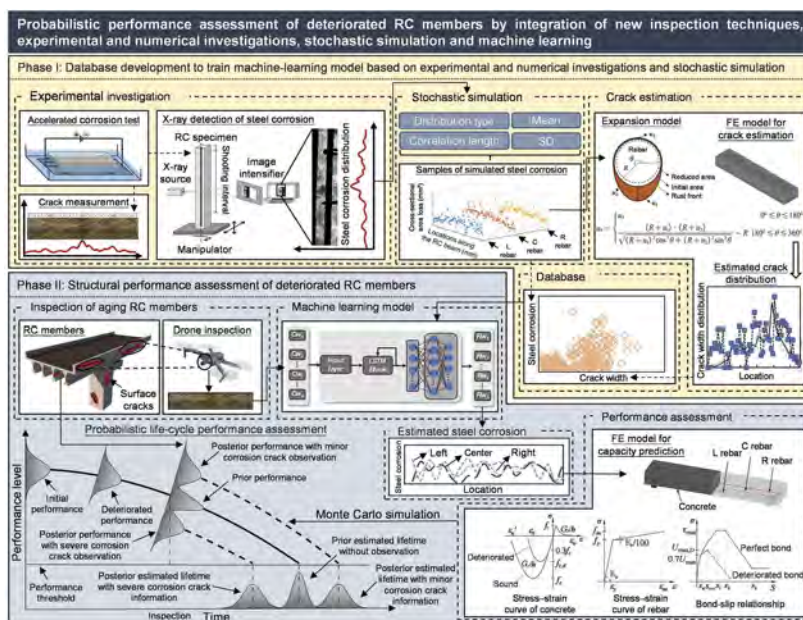

Figure 1. Flowchart for predicting the remaining service life of deteriorated concrete structures.

3 X-RAY AND DIGITAL IMAGE PROCESSING TECHNIQUE

It is essential to develop advanced measurement methods to detect and understand the spatio-temporal variability of nonuniform steel corrosion distributions. In recent years, obtaining information on the spatial steel corrosion of corroded RC members has become the focus of researchers (Lim et al. 2016, 2017; Gu et al. 2018; Zhang et al. 2019). Various methods, including weighing steel loss due to corrosion, measuring with Vernier calipers, drainage methods, and 3D scanning, have been applied to measure steel corrosion. However, since these methods require certain specimens to be demolished and removed to quantify the evolution of the steel corrosion in RC members, there is a high potential for experimental error owing to the difficulty in controlling for repeatable experimental conditions and other uncertainties.

To understand the development of steel corrosion and its spatial variability over time, continuous monitoring of steel corrosion based on a nondestructive evaluation technique is necessary. Akiyama & Frangopol (2012) demonstrated that an X-ray apparatus was a suitable tool for continuously investigating the weight loss of corroded rebar. Lim et al. (2017) further combined

X-ray and image processing techniques to monitor steel corrosion embedded in RC specimens. The nonuniform steel corrosion distribution along corroded rebars can be detected at different stages during the corrosion process. The steel weight loss per 5-mm length of rebar is determined by taking the average of each value of steel weight loss for each viewing angle as follows:

$$R_w = \frac{1}{k} \sum_{n=1}^k \frac{(W_{\theta_n} - W'_{\theta_n})}{W_{\theta_n}} \times 100\% \quad (1)$$

where R_w is the steel weight loss per 5-mm length of rebar, W_{θ_n} and W'_{θ_n} are the weights of the structurally intact sections and corroded sections of the steel rebars, respectively, and k is the number of viewing angles used (i.e., $k = 8$). A more detailed description of the method and analysis are given by Lim et al. (2017).

The general procedure applied in this study to investigate the nonuniformity of steel corrosion, as well as an example of the measured steel weight loss distribution of the rebar in a corroded RC specimen, are shown in Figure 2. Due to the shortage of experimental data, the obtained measurement results of steel weight loss are applied to the stochastic simulation method to generate a database of corrosion products and steel weight loss. This database is then utilized to obtain the crack width, using the 3D FE method, for training the machine learning model.

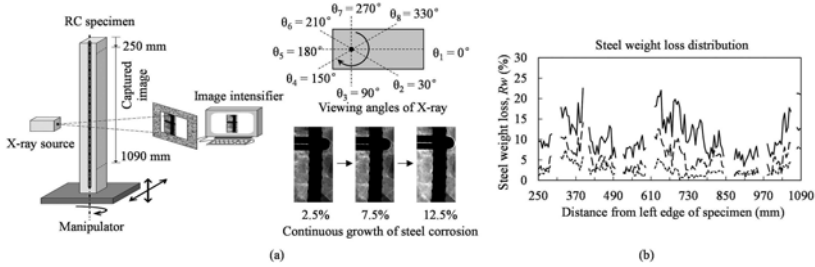

Figure 2. (a) Continuous evaluation of steel corrosion by X-ray and image processing techniques and (b) an example of the measured steel weight loss distribution.

4 TIME-DEPENDENT RELIABILITY ASSESSMENT OF CORRODED RC MEMBERS WITH STOCHASTIC SIMULATION

4.1 Stochastic simulation

Several methods are commonly utilized to generate random fields based on statistical information, such as covariance matrix decomposition (CMD) (Zhang et al. 2020; Ali et al. 2017), the spectral representation method (SRM) (Ma et al. 2020; Srivaranun et al. 2021), Karhunen–Loève expansion (KLE) (Wu et al. 2020) and the local average subdivision (LAS) method (Fenton et al. 1990). Among the stochastic simulation methods, SRM is a versatile method in terms of representing steel corrosion in RC members. The SRM can be utilized to simulate Gaussian and non-Gaussian random fields, univariate (UV) and multivariate (MV) random fields, and multidimensional random fields. The SRM for the simulation of UV and MV Gaussian random fields was introduced by Shinozuka & Jan (1972).

Further developments for the simulation of UV Gaussian random fields were proposed by Shinozuka & Deodatis (1991, 1996). For the simulation of UV non-Gaussian random fields, Yamazaki & Shinozuka (1988) proposed the SRM-based iterative methodology according to a target non-Gaussian spectral density function (SDF) and a target non-Gaussian marginal cumulative density function (CDF). Their method is based on Grigoriu’s translation field theory (Grigoriu et al. 1995). Since the methodology proposed by Yamazaki & Shinozuka (1988) was later confirmed to have less-than-ideal accuracy, Deodatis & Micaletti (2001) proposed some modifications using a “compatibility check” to confirm whether the target non-Gaussian SDF and the prescribed non-Gaussian marginal CDF are compatible. Their proposed method dramatically improved the accuracy of the simulation.

Shields & Deodatis (2011) developed the SRM-based iterative technique for generating UV non-Gaussian random fields. The proposed algorithm is conceptually much simpler and more computationally efficient. The applications of the UV non-Gaussian SRM have contributed to, for example, simulation of the corrosion process of steel beams (Christou et al. 2014) and simulation of the damage levels of bridges (Bocchini et al. 2011).

4.2 Life-cycle reliability assessment with stochastic simulation

Probabilistic concepts have been employed due to numerous sources of uncertainty in the degradation model, and the extent of damage is quantified by considering the spatial variability of the various parameters. Life-cycle reliability analysis of deteriorated RC structures should be performed in combination with stochastic simulation. A stochastic spatial-time-dependent analysis of chloride-induced corrosion in large RC structures was performed by Papakonstantinou & Shinozuka (2013). Spatial variation in the respective variables was represented by uni-variate, two-dimensional stochastic fields, simulated by the SRM. Shafei & Alipour (2015) developed an FE framework-based life-cycle prediction model of corrosion-affected RC members. Gaussian and non-Gaussian random fields were created using the SRM to consider the stochastic process of steel corrosion, which was used to reflect the spatial and temporal variability in material properties, structural properties, and exposure conditions.

Based on the experimental data (i.e., steel weight loss distributions identified by X-ray and digital image processing, as shown in Figure 2), Srivaranun et al. (2021) presented an application of the 2D stochastic simulation method using the SRM for estimating the reliability of aging RC structures that considered the effect of the interaction of corrosion pits among multiple tensile rebars. The interaction of corrosion pits among tensile rebar is represented by a transverse correlation parameter of steel weight loss distributions. To apply the SRM and simulate the MV random field, the Gaussian cross-spectral density matrix (CSDM) needs to be determined and should consider the cross-correlation of the corrosion in each component of the tensile rebar. The Gaussian CSDM of spatial steel weight loss distributions, $\mathbf{S}(\kappa)$, is expressed as follows (Deodatis et al. 1996):

$$\mathbf{S}(k) = \begin{bmatrix} S_{11}(k) & S_{12}(k) & \cdots & S_{1m}(k) \\ S_{21}(k) & S_{22}(k) & \cdots & S_{2m}(k) \\ \vdots & \vdots & \ddots & \vdots \\ S_{m1}(k) & S_{m2}(k) & \cdots & S_{mm}(k) \end{bmatrix} \quad (2)$$

where m is the number of spatial steel weight loss distributions, which is the same as the number of tensile rebars in the RC structure; κ is the wavenumber; and $S_{ij}(\kappa)$ represents the cross-SDF values, which is defined as:

$$S_{ij} = \gamma_{ij}(k) \sqrt{S_{ii}(k)S_{jj}(k)}, \quad i, j = 1, 2, \dots, m \quad (3)$$

where

$$\Delta k = \frac{\kappa_u}{N} \quad (4)$$

$$k = n\Delta k, \quad n = 0, 1, 2, \dots, N - 1$$

$S_{ii}(\kappa)$ and $S_{jj}(\kappa)$ are the auto-SDF of steel weight loss in rebars i and j , respectively; $\gamma_{ij}(\kappa)$ is the coherence function of steel weight loss between rebars i and j ; κ_u is the upper cutoff wavenumber beyond which the spectral density can be assumed to be zero; and N is a parameter defining the number of discretization points in the wavenumber domain. N is related to the number of discrete locations in a simulated steel weight loss distribution of a single rebar (M) because of the following anti-aliasing requirement: $M \geq 2N$.

Based on the measured steel weight loss distributions of the rebars in the RC specimen, the auto-SDF, $S_{ii}(\kappa)$, and coherence function, $\gamma_{ij}(\kappa)$, are determined empirically (Bendat & Piersol 2011). By considering the transverse correlation of the measured steel weight loss between

rebars i and j , a negative exponential functional form of the coherence function, $\gamma_{ij}(\kappa)$, is obtained by using the following equation:

$$\gamma_{ij}(k) = \exp\left(-\frac{k\sqrt{d_{ij}}}{2\pi C_3}\right) \quad (5)$$

where d_{ij} is the distance between rebars i and j ; and C_3 is the parameter associated with the degree of transverse correlation of steel weight loss distributions.

Based on the Gaussian CSDM, $S(\kappa)$, and the parameters of the standard deviation of steel weight loss and mean steel weight loss, the MV random field of steel weight loss for m corroded rebars can be simulated. The detailed procedure for simulating the MV random field using the SRM was provided in Bocchini (2008). Figure 3 presents the effect of the transverse correlation parameter C_3 on the simulated spatial steel weight loss distributions in the RC slab specimen with three tensile rebars assuming mean steel weight loss (MRW) = 10%. $C_3 = 0.05$ was determined experimentally. For comparative purposes, a value of $C_3 = 0.005$ was also used. As shown in Figure 3, the transverse correlation among the steel weight loss distributions of the three tensile rebars depends on the transverse correlation parameter C_3 . By applying the SRM to simulate the spatial steel weight loss distributions in MV random fields, the effects of the interaction of corrosion pits among tensile rebars can be considered.

Figure 3. Effect of the transverse correlation parameters (a) $C_3 = 0.005$ and (b) $C_3 = 0.05$ on the spatial steel weight loss distributions in the RC slab specimen assuming $MRW = 10\%$.

Numerical models that can account for the varying spatial amount of rebar corrosion in RC structures and for the associated material property of concrete and bond strength are necessary to evaluate structural performance. Simple cross-sectional analysis cannot provide good agreement with the test results from loading of RC beams (Zhang et al. 2020). The 3D FE method used to assess deteriorated RC structures is discussed in the following section.

5 FE CONSIDERING THE EFFECT OF STEEL CORROSION

The FE method is now widely used for investigating the structural performance of corroded RC structures. Cornelli et al. (2004) investigated the structural behavior of corroded RC beams by using FE analysis to deepen the understanding of the damage caused by corrosion and to appropriately evaluate the actual safety level of RC structures. The analyses performed in their study indicated that corrosion affects both the strength and the ductility of a structure. They pointed out that the bond conditions should be carefully assessed and modeled to predict the structural ductility, which is intimately associated with the mode of failure and, consequently, with the ultimate bearing capacity. El Maaddawy et al. (2005) proposed a new stress-slip model to predict the bond strengths of corroded beams at different levels of damage based on published data. Biondini et al. (2015) presented a three-dimensional RC beam finite element model for nonlinear analysis of concrete structures that are exposed to corrosion. Their formulation allows to model the damaging effects of uniform and pitting corrosion in terms of a reduction in the cross-sectional area of corroded rebars, a reduction in the ductility of reinforcing steel, deterioration of concrete strength and the presence of spalling in the concrete cover. The proposed model was validated with experimental results of RC specimens corroded with both accelerated and natural corrosion.

Both strength and ductility were affected mainly due to variability in the cross-sectional area loss of rebar along its length (François et al. 2013). It is essential to consider the effect of spatial steel corrosion when simulating the performance of corroded RC members. Lim et al. (2016)

developed a two-dimensional FE model that considered the variability in steel corrosion to simulate the responses of the corroded RC beams. Due to the difficulty in implementing the actual variability in steel corrosion in the numerical model, an alternative approach was applied by modeling the corroded rebar over a determined length based on the average cross-sectional area loss, together with empirical coefficients, to account for the reduction in strength and ductility of the corroded rebar attributed to the irregular cross-sectional area loss from corrosion along the length of the rebar. Lim et al. (2016) reported that with the residual bond stress–slip curve proposed by Kallias & Rafiq (2010), the results obtained from the FE model were in good agreement with those from a loading test performed on corroded RC beams.

Zhang et al. (2020) conducted FE analysis to investigate the effects of localized corrosion and the correlation of the steel corrosion distribution between adjacent rebars on the structural behavior of corroded RC beams. By comparing the computational results to experimental results, they concluded that the 3D FE model could better predict the behavior of the corroded RC beams than the 2D FE model, especially when the beam had a small correlation coefficient of cross-sectional area loss of rebar in the transverse direction.

6 INVERSE ANALYSIS: BAYESIAN UPDATING VS. MACHINE LEARNING

The corrosion-induced crack width can be the clearest visual indicator (Akiyama et al. 2010) to quantify the damage state of corroded RC structures. Many researchers have attempted to link the corrosion crack width and the amount of rebar corrosion. However, as mentioned previously, their relationship is unclear, making it difficult to accurately evaluate performance using the crack widths. There are two methods to evaluate the structural performance of existing RC members given corrosion crack information: Bayesian updating and machine learning methods.

6.1 *Bayesian updating*

It is well known that maintenance and repair decisions should be made based on inspection data and the results of performance prediction models (Frangopol et al. 2008). The models used to assess the deterioration status of RC members must be updated over time to revise the maintenance strategy based on how the structure is actually behaving in its lifespan. Within recent decades, several procedures have been presented for updating performance prediction models based on inspection results by applying the Bayesian updating method.

Akiyama et al. (2010) established a procedure to update time-dependent reliability using visual inspection (i.e., crack width and chloride concentration) for an existing RC slab in a marine environment by a particle filter (PF)-based method assuming the uniform distribution of reinforcement corrosion. To overcome this oversimplified assumption associated with steel corrosion, Srivaranun et al. (2022) proposed a framework for updating time-dependent reliability by incorporating the effect of the spatial corrosion distribution. The random variables associated with the corrosion prediction model, which are spatially correlated, are simulated in the random field context for the life-cycle reliability estimation. The random fields of the associated random variables are updated using the PF-based method. Jia et al. (2023) presented an inference framework for a stochastic volatility model conditioned on the time-dependent deflection of pre-stressed concrete (PC) bridges. In this framework, the augmented state space includes the full ranges of the unobserved state variables affecting the time-dependent deflection of PC bridges, which is modeled via the Wiener process. To utilize the latent structure of the stochastic volatility model, a cyclic Markov chain Monte Carlo (MCMC) sampler was proposed to draw samples from the joint posterior distribution of the unobserved state variables and volatility parameters.

6.2 *Machine learning*

Machine learning-based approaches have gained attention owing to their ability to simulate the complex physical process required for structural assessment. For instance, the feed-forward multi-layer perceptron (MLP) model, a classic artificial neural network (ANN), has been widely used in the field of civil engineering since it can identify complicated nonlinear relationships between inputs and outputs (Khandel et al. 2021; Most et al. 2007; Haddad et al. 2021; Xin et al. 2021).

The long short-term memory (LSTM) model, as an extension of the recurrent neural network (RNN), has the advantage of predicting data sequences by learning over long time sequences and retaining memory (Yu et al. 2020). Compared with empirical and mechanical models, it is expected that machine learning-based methods could provide a better solution for conducting inverse analysis that utilizes inspection information for the assessment of structural performance.

Recently, several researchers have developed machine learning and probabilistic-based approaches for estimating the steel weight loss distribution using the inspection information of the corrosion-induced crack width distribution. Zhang et al. (2021) adopted an LSTM network, as shown in Figure 4(a), to predict distribution possibilities of steel corrosion in RC beams with a single rebar due to the output sequence information from the LSTM model, which was then used to train a predictive model from the datasets of 1D spatial distributions of steel corrosion and the corresponding corrosion crack width. However, it was numerically and experimentally confirmed that rust expansion in corroded RC beams with multiple rebars can reduce the widths of corrosion cracks on the propagating concrete surface for adjacent rebars (Cheng et al. 2018). To consider the potential effect of multiple tensile rebars on the relationship between steel corrosion and corrosion crack width, a machine learning model (e.g., pix2pix, as shown in Figure 4(b)) capable of handling steel corrosion and corrosion cracks distributed in 2D space (Srivaranun et al. 2023) is needed. This model will be presented in the case study in the following section.

Figure 4. Flow diagram describing the training process of the (a) LSTM and (b) pix2pix models.

7 ILLUSTRATIVE EXAMPLE

An illustrative example of the probability-based structural performance assessment of corroded RC beams using machine learning is presented herein. Experimental data of steel weight loss and crack width distributions obtained from RC specimens were collected continuously during corrosion tests by both X-ray and image processing techniques, as introduced in Section 3.

A 3D FE model for estimating the corrosion-induced crack, as shown in Figure 5(a), was developed and then verified by the experimental results of crack width distributions for corroded RC beams. The elliptical corrosion expansion model proposed by Yuan & Ji (2009), shown in Figure 5(b), was utilized in this study to calculate the corrosion product thickness (u_θ), which was imposed on the holes to simulate the expansion stress on the concrete due to the formation of corrosion products. By inputting the steel weight loss distribution into the 3D FE model, numerical results of the distribution of the corrosion crack width were obtained and then verified by comparing those results to the experimental results.

A dataset with a certain number of samples is necessary for training the machine learning model. Due to the limited amount of experimental data of corroded RC beams available, the datasets of steel weight loss and crack width distributions were synthesized. Because steel corrosion over the length of RC beams was spatially distributed and subjected to several uncertain parameters and environmental factors, steel weight loss distributions were simulated by random field theory using statistical parameters. The measurement results of steel weight loss distributions for corroded RC beams were applied to obtain statistical parameters and then to generate the dataset of steel weight loss distributions in the 2D random field. Based on the generated steel weight loss distribution, the dataset of the corresponding crack width distributions was developed using the verified 3D FE model.

Figure 5. (a) 3D FE model for estimating the distributions of the corrosion crack width for the RC beam and (b) illustration of the mechanism of corrosion-induced stress expansion on concrete in the longitudinal direction and around the rebar cross section.

As a machine learning model, the pix2pix network is used to train the predictive model for the corrosion of RC beams. The flow diagram describing the training process of the pix2pix network is shown in Figure 4(b). The PDF of the flexural capacity for RC beams was estimated based on the predicted corrosion distributions by using MCS-based 3D FE analysis. Model errors associated with machine learning and FE modeling were taken into account. Figure 6 presents the estimation results of histograms and fitting lognormal PDF of the flexural capacity and the corresponding loading test result. It can be confirmed that the framework of the probability-based structural performance assessment using machine learning presented in this study can provide relevant and quantitative information on the possible deterioration level of aging RC structures based on the observational corrosion-induced crack width distribution.

8 CONCLUSIONS

The following conclusions are drawn:

1. A framework for predicting the life-cycle performance of deteriorating RC members using inspection information by integrating new inspection techniques, experimental and numerical investigations, stochastic simulation and machine learning is presented. The associated state-of-the-art existing core technologies in the literature were comprehensively introduced.
2. As an illustrative example, the PDF of the flexural capacity of deteriorated RC beams was obtained, given the corrosion crack widths, and distributed in two-dimensional space. The machine learning model pix2pix was trained using the artificial database of deteriorated RC beams constructed by stochastic simulation. 3D FE model analysis was performed repeatedly in the MCS to obtain the PDF of the flexural capacity, and model uncertainties were taken into account.

This study presents a load-bearing capacity estimation using corrosion crack widths. Recently, load tests on bridges have also been conducted (Lantsoght et al. 2022), and structural performance can be evaluated using the results of these tests. In addition, optimization can be incorporated into the framework presented in this study to provide an optimal maintenance strategy for deteriorated RC structures, which should be addressed in the future (Frangopol 1995, Frangopol et al. 1997; Yang & Frangopol 2018).

The structural life of a Cathedral and the worksites of the Duomo di Milano

F. Canali

Veneranda Fabbrica del Duomo di Milano, Milan, Italy

D. Coronelli

Politecnico di Milano, Milan, Italy

ABSTRACT: The life of Milan Cathedral is described with the evolution of the structural system and the restorations carried out throughout the centuries. The organization of the Veneranda Fabbrica del Duomo di Milano is outlined, with the latest restoration interventions. The case study of the construction and restorations of the Tiburio with its supporting pillars is analyzed, from the initial design to the dramatic damage in the 20th century. The rebirth of the Cathedral was the fruit of restorations preserving the structural identity of the monument up to the present. The conclusions address the study of damage and maintenance and repair operations of monumental heritage buildings within a life cycle perspective, in relation to the underlying societal values.

1 INTRODUCTION

The Cathedral of Milan represents an example of a century long structural life, characterised by a long construction and ongoing restoration history. A central event along the period of time between the start of the Fabbrica in 1386 and the present is the risk of collapse of the Tiburio and the “rebirth” - as defined by the former Architect of the Fabbrica, Carlo Ferrari da Passano (1988) - that occurred in the 20th century.

Novel approaches in life-cycle assessment, maintenance planning, and optimal design of structural systems (Biondini and Frangopol, 2016) foresee their extension to built heritage. Historic structures must be restored according to general conservation criteria (Roca, 2011). Also the safety of people and the integrity of the possible artistic contents pose certain requirements on structural reliability. While facing these two main challenges, the design and the management of such a specific activity has to often deal with uncertainties of the most intimate static and mechanical behavior of the monument. The result is a complex engineering problem aiming to optimal solutions which, while granting the reliability requirements, cause the minimum possible alteration to the original features of the structure. And, as a matter of fact, the experience acquired day after day on the scaffoldings and while designing, should be preserved as a most valuable knowledge increase by the means of specific organisations established in order to take care of the monument through the centuries.

The case-study of the structural life of the Tiburio of the Cathedral is here presented to link this history to central topics of life cycle assessment: the damage of existing structures, its evolution in time, restoration interventions and the safety requirements of historic buildings for their present function. Moreover this case demonstrates that the conservation or the restoration of a heritage property can be oriented to preserve its authenticity (Roca 2011).

The Veneranda fabbrica del Duomo is described as the active institution carrying out the operations needed for the preservation of the life of the Cathedral. Whereas modern design

and scientific concepts aim to a reference design service life of 50 or 100 years, heritage constructions often span a 5 to 10 times longer lifetime. Thus the survey and modelling of deterioration and time-variant structural performance meet a different temporal dimension, encompassing a past and often complex structural evolution. In addition these differences highlight the importance of maintenance within a life-cycle perspective, and the social and moral values of a society determining rules for this process.

2 THE FABBRICA DEL DUOMO AND THE TIBURIO RESTORATION CASE STUDY

2.1 *The Veneranda Fabbrica del Duomo*

The singular history of this institution is such that a brief summary is necessary. The Fabbrica of the Duomo of Milan (Venerable as dating back to the late XIV century) is the institution responsible for the conservation and development, as well as the maintenance of the cathedral. This is an ecclesiastical body endowed with legal authority by ancient statutory determination, for the purpose of worship and religion. It excludes all profit making activities.

There is a Board of Directors composed of 7 members who remain in office for 3 years, one of whom is elected President. Two are appointed by the diocesan ordinary and 5 by the ministry of the Interior, with the consent of the Archbishop.

Needless to say works of such entity, today as in the past demand large resources. In the course of its history the Fabbrica has been sustained by the donations of citizens, and by the introits of an important real estate patrimony formed by the numerous bequests made by those wishing to be remembered as associated with this great undertaking. The yields from these properties providing the necessary funds for the realization of such works arising from time to time.

However in the early years of the xviii century this efficient system of self-support fell victim, so to say, of History. On his arrival in Milan Napoleon, finding the Cathedral far from completion ordered the Fabbrica to sell of the entire property patrimony in order to speedily obtain the necessary resources in order to complete the facade.

There followed a very difficult period, with the Fabbrica obliged to recur to the Administrative Authority of the time for financial support, receiving which, to greater or lesser extent according to the interlocutors they were faced with, and within the historical context. Today faced once more with dramatic urgency to find new forms of financial support, for the first time in over 600 years the “Infinite Fabbrica” would run the risk of closure. From the tickets sold for guided tours and entry to the Terrazze in particular, together with specific fundraising campaigns (Adopt a spire, Adopt a statue) an adequate answer to the difficulties has been found.

As in every operative organisation the personnel employed on the front line (the 3 work sites, and the assistance to visitors and tourists) depend on the support of others to organise the work (from management to planning, to personnel and to logistics). The Fabbrica counts circa 200 employees subdivided in the following areas (Table 1).

The particular maintenance work on the cathedral can only be carried out by direct control of skilled workers of the Veneranda Fabbrica. There are approximately 100 people divided between 3 worksites, that of the Candoglia quarry, the marble carvers and the cathedral worksite, employees of the Institute founded by the Duke of Milan, Gian Galeazzo Visconti, in 1387; and from that time engaged, up to 1965, in the construction and particular maintenance (from 1842 to this day) of the cathedral.

The components of the Fabbrica work in the closest coordination, a delay in the chain of purchases has immediate effect on the possibility to proceed with work on the scaffolds; while unsatisfactory programming on the sites may compromise the visits of the faithful or visitors.

An error in daily consultation of the archives may compromise the research of scholars, or the necessary verifications regarding the worksites. Each of the areas listed above has its own work plan and procedures codified from time back, so that it is sought to combine the original procedures while keeping up to date, as regards the management profile. this is also true for all the extraordinary organisms of the Fabbricerias, Italian and European. Between which there is an ever growing network of contacts and the sharing of knowledge (see section 4).

Table 1. Fabbrica del Duomo - Areas of activity.

2.2 The restoration of the Tiburio

March 2016 saw the start to erect scaffolding around the cathedral Tiburio. Despite delays caused by the SaRs-CoV-2 epidemic the intensity and precision of the work to date indicate the possible completion of this very demanding restoration by the end of 2024.

Figure 1. The scaffolding for the Tiburio restoration.

A few figures may serve to understand the complexity of the undertaking:

- 3.600 tons weight of the tiburio developed over 55 metres height, supported within the span of a system of 4 arches.
- The absence of precise mechanical and geometrical data about the nature and function of the supporting arch system, which was conceived and realised during the mid XV century and the first 20 years of the XVI (see section 3).
- A 35 year period during which the conception and the actuation of the supporting structural system was conceived.
- A workforce consisting of 96 men a day on the scaffolding.

- 480 man hours to mount and erect it.
- 1.750 man hours estimated for the restoration work
- 72 hours topographical monitoring calculated to control the the functionality of the structural system during restoration work.
- 8 load cells installed and controlled daily to govern the weight distribution of the provisional structure on the architecture of the tiburio.
- 95 man days to consult the Archives with an end to obtain necessary information for the development of the work
- 6 million euro the estimated cost of the intervention.
- 20 cubic metres of Candoglia marble for substitution and 200 cubic metres of marble restored in situ at a medium height of 75 m from the cathedral square.
- 76 marble statues restored

The ensuing activities required a workforce which at the lowest level received a 2 year formation period before they could operate with a certain degree of autonomy, in a team type formed by 3 men, one of whom being the supervisor.

It was possible to develop the work by virtue of a series of hoisting towers, designed for the purpose and constantly checked and maintained by specialised personnel, and with the additional efficiency of the site store depot, while operating right in the heart of Milan’s historic centre.

3 HISTORY AND STRUCTURAL LIFE OF THE DUOMO

The great Milan cathedral (il Duomo) is a most imposing monument built in the Gothic style. Construction began in 1386. Late Gothic (the French style born some 200 years previously), was adopted more from political and economic motives than from architectural sensibilities. Almost as if to say that the social and economic field of reference was that north of the Alps.

The fact of being the 4th largest cathedral in the world for extension, and the 3rd in height, for the internal dimensions of the main nave, make it a very particular structure. The vertical system from floor to the terraces is built of buttresses, walls and piers of brick and blocks of serizzo, faced with Candoglia marble. The vaults are made of brick, with Candoglia ribs; the lateral buttressing is provided by diaphragm walls and iron ties (Coronelli et al., 2015). The upper part, from the terraces to the summit of the great spire, entirely built of Candoglia marble. This is a crystalline marble only extracted from the quarry of the same name as the town at the entrance to Val d’Ossola. Beautiful as it is to behold the marble presents structural problems: the presence of pyrite, plus the iron ties used over the centuries to join the units, frequently provoke sudden internal fracturing.

The history of the construction is here described underlining the different phases in time, followed by restoration. The sources used are mainly the writings of Ferrari da Passano (1988), Architect of the Fabbrica del Duomo from 1964 to 1988; these are based on this Author’s experience and the Annales of the Fabbrica del Duomo, a unique record of the worksite activities from 1386 to the present. A description of the overall structural configuration can be found in Coronelli et al. (2015).

3.1 Construction history

3.1.1 The Apse

The construction started in 1386 with the apse proceeding from East to West, containing the choir. The geometry of the apse (Figure 2) is a half octagon in plan, covered by a half dome with triangular cells, and six interior pillars supporting the half dome are placed along the perimeter. These members together with six vertical buttresses, support five quadripartite vaults of trapezium shape in the deambulatory. Here the apse is closed by large decorated windows. The dimensions of these openings together with the slenderness of the buttresses raised the concern of the French consultant Mignot, that originated a documented controversy (Ferrari da Passano, 1988). The statements of the constructors underlined the key role of pointed arches and iron ties for the stability.

The choir is flanked by the sacristies on either side with perimetral walls, connected to the buttresses on the exterior perimeter, constituting a firm system with lateral load bearing capacity, that was the first part of the construction.

The following part constructed was the crossing with a structure with one nave and two aisles very similar to that of the longitudinal body, with a main nave and four aisles. The buttressing is provided by diaphragm walls and lateral buttresses walls, combined with iron ties (Coronelli et al., 2015).

Figure 2. Parts of the Cathedral and years of construction.

3.1.2 The Tiburio and Dome

The construction of the tiburio began with foundations and four pillars slightly larger than those of the other vertical members. At the beginning of the 15th century these were built, supporting the four 19.6m span pointed arches, the walls above the arches, the pendentives and the decorations. The choir backed by the apse, the transepts and the first bay of the nave and aisles surrounded this part of the fabric.

The discussion developed with foreign and Italian experts including Leonardo Da Vinci and Bramante amongst others. The solution adopted was proposed by Lombard personalities, first Giovanni Solari from 1452 and then Guiniforte Solari, who took the lead of the construction starting from 1459. This consists of four semi-circular arches hidden behind the walls above the pointed arches (Figure 3). Conceptually these act as load-relieving arches for the pointed arches.

The intrados radius is 8,6 m, a great depth and width of the cross section, ensuring a wide load path for the loads of the dome: at the crown 160 by 180cm, and increasing moving towards the supports. The cross-section is obtained with voissiors in radial position, in a ring of constant depth (1,6m). Above this blocks are laid horizontally, reaching an extrados drawn by a circular line with a radius of nearly 18m and a centre at the springing line of the pointed arches. The material used is serizzo, a strong metamorphic stone quarried in Lombardy and Val d'Ossola.

Figure 3. Arches supporting the Tiburio.

The choice was made to build the arches supported on the pillars of the crossing, without demolishing the walls above the pointed arches; hence the arches lie in an off-set position (Figure 3, plan view) (Ferrari da Passano and Brivio, 1967). This layout increases the eccentricity of the reactions of the arches on top of the pillars (Ferrari da Passano, 1988).

As a consequence very relevant problems arose in the construction after the removal of the centering, as the pillar tops were displaced outwards under the arch thrusts. The ties of the Gothic arches below were all broken. The structures surrounding the Tiburio were damaged. As a consequence the construction was stopped around year 1470.

The system at the time was bearing only the weight of the new Roman arches and the masonry walls above. The arches were buttressed against the surrounding structure of the transepts, choir and nave. The walls in the choir and sacristies in particular definitely played a role in the lateral stability. Despite the damage the structure reached a new equilibrium that was the basis for the future of the construction.

This was undertaken under the guidance of Amadeo and Dolcebuono, and the dome was completed in year 1500. The whole structure was supported by the system of Gothic and Roman arches described above and is based on an octagonal geometric scheme, leading to concentrating the load on the drum in eight locations, interior to the span of the arches below.

The dome (Figure 4) was built with the same characteristics of the existing construction – the half-dome of the apse in particular, with the same arches and vaults (Ferrari da Passano and Brivio, 1967). The plan is octagonal, connected to the square of the crossing with pendentives. The dimensions are the same of the apse with a span of 32 braccia (19,2 m), and the crown at 19,2m from that of the pointed arches of the crossing. The interior vaults are made of brick, with eight cells, and Candoglia marble ribs meeting in a central ring of brick and marble. Walls made

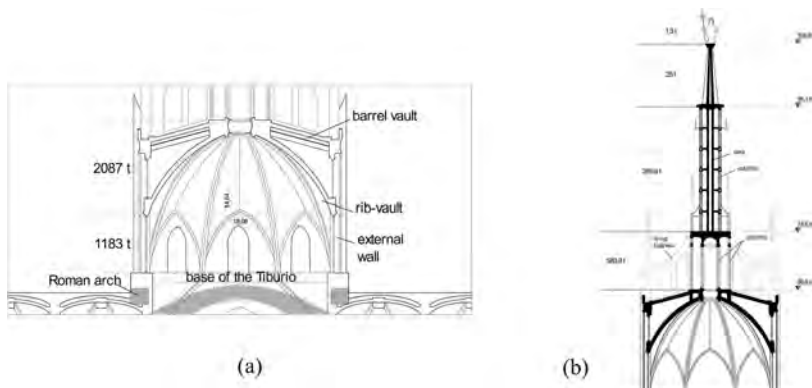

Figure 4. (a) Structure and weight of the Tiburio and Dome and (b) Tiburio with the main Spire.

of brick in vertical planes bear on the base and extend radially above each rib, creating a fan and connecting at the central ring. Barrel vaults span between adjacent radial walls at the top, to support the stone roof, and creating a chamber above the dome inner vaults. This is the same scheme used for the double vaults to support the roof above the naves (Coronelli et al, 2015).

The dome is enclosed within exterior vertical walls, along the perimeter of the octagon. Windows open at two levels, one looking into the interior of the church and the other into the chambers between the two vault systems. The walls connecting in the vertexes of the octagon form eight vertical members, with spires placed at their top. The weight of the walls sums with the forces transferred by the dome at the supports, bearing on the base of the Tiburio. The outwards components of these forces are balanced by steel ties lying in the horizontal octagonal ring at the base of the dome. The vertical components are transferred by vertical walls onto the semi-circular arches of the crossing.

Thus, following the history of the construction, the intensity and distribution of the loads on the semi-circular arches changed between years 1490 and 1500 with the construction of the tiburio, with increasing vertical forces and lateral thrusts on the underlying pillars. But further stages and changes were still to take place.

3.1.3 The main spire and gugliotti

The project to build a spire to crown the building dates back to the beginning of the construction (Ferrari da Passano, 1988). The main spire, “la Gran Guglia” was built in the 18th century, after studies to ascertain the safety for the underlying construction (Brivio and Repishti, 1998).

The final design (Figure 4b) was presented by Francesco Croce in 1764. Its base is at the level of 65,6m and reaches 104,9m at the feet of the statue of the Madonna. The spire is a rather light structure, with a central marble cylindrical tube, and pillars on the outer perimeter. All the stone works are connected by a complicated system of iron ties, with longitudinal elements within the central void and transverse fastenings. The total weight bearing on the top of the tiburio is 884 tons.

The four gugliotti (Figure 1) are small towers with spires at the top, placed on the roof at the four corners of the square corresponding to the perimeter of the crossing. The first was built between 1507 and 1518 and the others followed much later in the second half of the 19th century. Their position corresponds to the pillars of the crossing, and their load flows directly onto these members. The overall axial force of each pillar increases by 100-150 tons, less than 5% of the total axial load, approximately equal to 3000 tons at the base of each pillar. Nevertheless significant damage showed in these vertical members with cracking of the outer Candoglia ring. This led to the closing of the Duomo at the end of the 19th century for restoration works, showing that these members were already close to their safety limit at the time.

3.2 Restoration history

Any action aiming to the conservation or the restoration of a heritage property should be oriented to preserve its authenticity (Roca 2011). In this perspective, this section provides a synthesis of the

main structural restoration works related to the Tiburio and the piers of the crossing in the period ranging from the end of the 19th century until today. These have been the object of detailed reports by Ferrari da Passano and Brivio (1967) and Ferrari da Passano (1988).

The size of the cross-section, and the type and quality of construction were at the origin of the distress in the piers of the crossing. The cross-section is made of an outer ring of Candoglia marble; the thickness of this part is varying without a precise rule along the height. The interior is filled with mixed materials, including serizzo blocks, brick and mortar. The building of the Tiburio in the 16th century and then of the main Spire in the 18th century added high loads on these members. The configuration of the Roman arches caused eccentricity of these loads and lateral displacements of the pier.

In the second half of the 19th century, the piers of the crossing showed signs of severe damage. This indicates that the load effects were such to approach critical conditions for these members. Restorations were carried out extracting the damaged voissiors, filling with lead the inner voids, and replacing new marble units.

In the 20th century the soil water table was lowered by 20m between 1950 and 1970 by the industrial water consumption in Milano. The soil subsidence caused settlements of the foundations. Measurements of the differential settlements over a period of 5 years from 1965 to 1970 showed rates higher than 1mm/year between points at 20m distance (Ferrari da Passano, 1988).

A survey of the piers in the crossing (Figure 5) and in the choir showed compression cracks in the blocks of the outer Candoglia skin, with an approximately vertical orientation. Monitoring showed a dramatic progression of phenomena, with crack widths were increasing in time and the formation of new damage and spalling of parts of the units.

Figure 5. Survey before restoration: sketch of deterioration pattern of blocks and photograph of cracking.

To face the emergency a commission was formed in 1965 by the Fabbrica del Duomo and the Politecnico di Milano. The piers of the crossing were provisionally encased in reinforced concrete, while those of the choir with a steel structure. A geotechnical study showed that the load bearing capacity of the foundations was not the cause of the phenomena, whereas the settlements were compatible with a theoretic calculation of the effects of subsidence.

The interpretation of the conditions was carried out at the ISMES laboratory, resorting to a scaled experimental model of the whole Tiburio with the surrounding vaults and supporting vertical members (Ferrari da Passano and Oberti, 1983). Imposing differential foundation settlements, a redistribution of forces with overloading of the northern piers with respect to the southern was shown (Ferrari da Passano, 1988).

To stop the causes of the phenomena, the use of water was banned from industries surrounding the central part of Milan, hence stopping the lowering of the water table. This in turn gradually stopped the ground settlements.

The study of a restoration technique then started. Scaled masonry models of the piers were built and tested (Ferrari da Passano and Oberti, 1983). The solution adopted for the four

Figure 6. Survey and restoration: damaged and replaced units.

main piers of the crossing, proposed by the Architect of the Veneranda Fabbrica, Carlo Ferrari da Passano, was inspired by the concept of maintaining the identity of the Cathedral by preserving its original structure.

After a detailed survey of the thickness of the outer Candoglia ring and of the damaged units (Figure 6), these were gradually replaced with new pieces of the same material and profile, penetrating deeper radially in to the core of the pier and thus providing an increased resistance. To provide safety to the operations, the reinforced concrete outer skin was gradually removed, exposing only the parts being restored. By 1980 the four piers supporting the Tiburio appeared sound again.

Another intervention on the Tiburio structure was the placing of steel ties connecting the four piers of the crossing, anchored within the walls of the transepts. These correspond to the original design of the crossing, where iron ties had been used before the failure caused during the construction of the Tiburio (see Section 3.1). Finally, displacement monitoring on relevant points of the building began, and has been carried out with a period of six months up to today, highlighting essentially stable conditions.

It must be remarked that these choices reflect the concepts on the relation between structure and authenticity outlined by Roca (2011). The conditions of the piers were successfully improved by the restoration works described in this section; these members have been now in service for more than thirty years, and the elegance of the cathedral was restored (Figure 7).

Explanation of these past phenomena though was only partial. The experimental scaled model (Ferrari da Passano and Oberti, 1983) being elastic, made of materials obtained with epoxy resins, lead to estimates of the redistribution of loads with the ground settlements. These events could be examined and understood more deeply by numerical analysis with nonlinear constitutive models for the materials (Roca et al., 2013; Angjeliu et al., 2020). Another aspect to which attention should be devoted are creep effects (Binda, 2008). The effect of soil settlements evolution in time should be included. Thus a more thorough explanation of the phenomena that nearly led to the collapse of the Tiburio could be reached, and the present and future evolutions followed.

The last step in the 21st century is the restoration of the Tiburio (see Section 2). With the scaffolding in position maintenance operations have been carried out on the sculpture and decorations. Units of masonry of the walls above the supporting arches has been replaced, and the mortar beds maintained. The ties connecting this system have been inspected, showing good conditions.

4 INSPECTION AND MAINTENANCE

4.1 *The technical table of the Italian Fabbricerie*

One of the main aims of a restoration of a heritage structure is ascertaining the safety of people using or visiting the structure, with the possible risks limited to acceptable levels (Roca, 2011). Following the dramatic incident in Florence, in the Santa Croce cathedral, on the 20th October 2017, the leading technicians of the principal Italian Fabbricerie within AFI (Associazione Fabbricerie Italiane) decided to confront one another on their respective experiences and activities, to discuss

Figure 7. Section of the crossing.

the possibility of defining a code of practice for maintenance of such complex architectural organisms. For 18 months of monthly encounters and consultations, a document was formulated to underline the fundamental importance of periodical inspections; defining the operational modalities and criteria for the management and programming of the same inspections and verifications on all the elements at quota, characteristic of every monumental fabric, the degradation of which could present a danger to the public and private incolumity.

This was considered to be the prime, inexorable object to be reached, propedeutic to the definition of a code for programmed maintenance, to which each Fabbrica should comply according to the capacities and economical and financial possibilities of each.

To follow, a resume of the chief considerations which emerged in conclusion of the Technical table, regarding both the content and necessary action to be taken, in order to render the guidelines for inspection of cathedrals, fully operative.

4.2 *The conclusions of the AFI 2018-2019 activities*

With reference to public safety precautions, each Fabbrica possesses specifications which make it different, and has specific problems. Even though the type of problem is similar. Those of a structural nature (overloading, cracking, settlements etc.) being too different in the various cases must however be dealt with and resolved by each single Fabbrica.

On the other hand damage to decorative elements such as tiling, plaster or stone fragments of various dimensions, are a common phenomenon, constituting possible negative consequences for safety, and are by no way inferior to the structural problems.

Therefore it was agreed that in order to confront these problems from the safety point of view, monitoring of the architectural surfaces is fundamental. This can be undertaken essentially, by periodical visual inspection, eventually from hoists, or by workers specialised in operating at heights; the frequency and modality varying from case to case.

Each inspection is to be documented graphically, illustrating the area (prospects or parts of these, covering, characterising elements etc) and the architectonic or decorative elements of which they are composed or characterised by. The amount of detail will vary naturally, for each monumental fabric, but may also vary within the structure, as each possess intrinsic characteristics.

The evaluation must furnish a quantitative result, not only the conceptual. To this end the technical table has elaborated a procedure which, on the basis of inspection results, (that is the state of conservation in the inspected area), the estimated duration of the manufactured components of the same, and of the level of risk relative to its exposition, must report the degree of alert and establish the frequency of verifications to be made. To complete the evaluation it is essential to establish the expected duration of the manufacture defining the architectural surface, distinguished according to form, material and exposition.

5 CONCLUSIONS

In a life cycle analysis perspective, the study highlighted the description of damage, its evolution in time and the study of the causes. Two aspects that differentiate the structure of heritage buildings from modern construction are the higher uncertainties related to the geometrical complexity and of the materials effectively used. The case of the piers in the crossing of Milan Cathedral is emblematic with the differences between external and internal geometry and materials.

A specific type and pattern of mechanical damage, showing in the 19th and 20th century, related to overloading of the piers and their masonry texture, has been documented. This shows the need for the development of numerical structural and constitutive models capable of predicting effects of masonry creep in relation to different materials and textures. The engineering problem, tackled by the experts of the time, leading to successful restoration intervention and a true rebirth of the Cathedral at the end of the last century has been described.

The 21st century restoration activities on the Tiburio show the solution of a different type of damage, of relevant importance for monumental buildings and their present use. Operations carried out to maintain the decorations and sculptures, contemporarily provide means to avoid dramatic accidents, that have been the object of a technical discussion table of the Italian Fabbricerie.

When the concept of maintenance of the cultural patrimony assumes the aspect of physical care to an architecture (that is, to any expression of the building capacity of Man) the study of the best way to fulfil such an arduous task is enriched by certain, perhaps surprising observations for those who do not habitually frequent the scaffolding of a building site, or the tables at which restoration projects, or the economic aspects and financing of such, are planned.

One of the observations which is brought to the attention of those studying these processes, regards the realization that the significance of testimonies that vert on the cultural patrimony is seen to be in the majority of cases centered on a single case, independently of its nature or dimensions, be it a commemorative monument or building. Single constructions, were erected in the distant past, using building techniques and suffer the effects not only of the times when they were erected but also of the regional uses to which they were put, so that when faced with their conservation we have little information, or few designs to describe their constitution.

The knowledge and experience gathered by whomsoever has done conservation work on these goes to form a valuable capital, allowing to consider the best way to invest in the sector. Knowledge is often gained from past errors, or from verifications made during the intervention, or from fortunate intuition during the course of the works; this together with the experience gained, leading inevitably to an affection towards the object, as well as satisfaction over

a successful intervention, or a desire to improve on this when not entirely successful at a first attempt. It is natural that we strive toward improvement in our professional practice.

How are we to avoid the loss of such capital? How to make it more fruitful? By the formation of a group of persons essentially drawn from skilled operators, for the constant maintenance of a chosen cultural object. A group of workers, of varied experience, according to the specifics of the monument, to acquire in depth and transmit the method of intervention, increasingly gaining understanding of the nature and characteristics of the same, and with a greater knowledge measure the resources necessary. Such a group to be composed, as fore-said, of skilled workers: that is to say, artisans specialized in the sector, allowing for them to develop and investigate modalities for the intervention, and to be in a condition in which to dedicate themselves with serenity, to the monument in question, without having to submit to managerial impositions.

The management, for commercial reasons and bearing in mind the above mentioned difficulties incurred in intervention (unusual techniques of the times, lack of specific technical information, etc.) must find an economic balance which however could sometimes penalize the quality of the intervention. Small scale public or private administrations, as well as great cultural institutions such as Museums or Foundations could make the most of their most significant assets, finding in an economy of scale solutions to questions of costs and benefits.

The permanent maintenance group must certainly be enriched by the indispensable contribution of the design engineers; but these may be autonomous professionals, accustomed to operating in the market. The commissioning body must formulate clearly the request to supervise activities of the workforce, while taking a long view, as the planning of the maintenance operations at the very best will be projected for tens of years, and for centuries to come. Therefore inevitably a period beyond that of individual involvement. An unimaginable stimulus this, to give of one's best.

ACKNOWLEDGEMENTS

The Authors are grateful to Prof. Fabio Biondini and the IALCCE Association for the invitation to present the keynote lecture outlined in this paper.

Field and laboratory tests for corrosion assessment of existing concrete bridges

M. Carsana & E. Redaelli

F. Biondini

Department of Civil and Environmental Engineering, Politecnico di Milano, Milan, Italy

ABSTRACT: Many existing Reinforced Concrete (RC) structures built around the middle of the last century have now reached the end of service life and require maintenance interventions to repair degradation-induced damage, especially due to steel corrosion. The conservation of existing structures and infrastructural facilities is therefore a relevant and urgent problem, particularly bridges and viaducts in view of their social and economic importance. In order to correctly define the restoration interventions and fulfill safety, robustness, and durability requirements, it is necessary to inspect RC structures and assess the state of degradation of materials and corrosion of embedded steel. This paper is aimed at contributing to effective methods, procedures, and criteria for corrosion assessment of existing RC bridges and viaducts. To this purpose, the results of inspections and diagnostics carried out on structural members of bridges subjected to corrosion and exposed to different environmental conditions and microclimates will be presented by focusing on in-field non-destructive testing as well as on chemical, physical and microstructural analyses.

1 INTRODUCTION

Structures and infrastructure systems are exposed to aging and deterioration processes. Among other structures, many existing Reinforced Concrete (RC) bridges built around the middle of the last century have now reached the end of service life and require significant maintenance interventions to repair damage, especially due to concrete degradation and corrosion of steel reinforcement (Bertolini 2008, Biondini & Frangopol 2016). The conservation of existing structures and infrastructural facilities such as bridges and viaducts, that due to their social and economic importance, are included among the most critical assets of cultural heritage, is therefore a relevant and urgent problem. In order to correctly define the restoration interventions and fulfill safety, robustness, and durability requirements, it is necessary to monitor RC structures and assess their state of degradation paying special attention to corrosion of embedded steel and related concrete damage (Bertolini et al. 2013, Biondini & Frangopol 2019).

Maintenance of existing RC structures is an important challenge that may be coped with through suitable criteria, methods and procedures for structural condition assessment. The developments and results presented in this paper are part of the contributions to this field given in recent years by a synergy of research activities ongoing at Politecnico di Milano within the mCD Concrete Durability group of the Department of Chemistry, Materials and Chemical Engineering on corrosion assessment and Department of Civil and Environmental Engineering on life-cycle of bridges and viaducts. After analyzing the mechanisms of corrosion of steel in RC structures and the main factors affecting corrosion, the paper describes methods and procedures for structural condition assessment of RC bridges, with emphasis on characterization of corrosion damage of the materials. Special attention is paid to field non-destructive testing as well as sampling of materials in order to perform laboratory tests including both chemical and microstructural analyses on concrete, complemented by electrochemical

tests on steel reinforcement. To this purpose, the results of inspections carried out on structural members of bridges or viaduct subjected to corrosion and exposed to different exposure conditions and microclimates are presented, including some selected results obtained within the BRIDGE|50 research project (Carsana et al. 2022). This project is carried out by Politecnico di Milano and Politecnico di Torino in collaboration with several public authorities and private companies to investigate the residual structural performance of a 50-year-old concrete bridge recently dismantled in Italy (Biondini et al. 2020, 2021, Savino et al. 2023). A set of 29 precast prestressed beams and two pier caps are stored in a testing site at Politecnico di Torino for non-destructive testing, full-scale load tests, and extraction of a large number of samples from the tested structural elements for laboratory tests. Figure 1 provides an example of corrosion-induced degradation of a pier cap of the viaduct before dismantling. Figure 2 shows a series of deck beams (Figure 2a) and a pier cap (Figure 2b) stored in the testing site.

Figure 1. Corrosion-induced degradation of a pier cap of the bridge before dismantling (Biondini et al. 2020).

Figure 2. Bridge elements stored in the testing site: (a) deck beams; (b) pier cap (Biondini et al. 2020).

2 CORROSION IN RC STRUCTURES

Experience has shown that corrosion is frequently the main cause of degradation of RC over time. As a consequence of the typical urban or industrial exposure conditions of RC bridges and viaducts, they often suffer damage due to carbonation-induced corrosion of reinforcement and/or chloride-induced corrosion if exposed to de-icing salts or marine environments. Moreover, on high-strength steel used in prestressed concrete under very specific conditions, hydrogen embrittlement can also occur. Figure 3 shows the typical evolution in time of corrosion in RC structures, adapted from Tuutti (1982), due to carbonation-induced corrosion (black line), chloride-induced corrosion (orange line), and hydrogen-induced stress corrosion cracking (red line).

Figure 3. Evolution of the degradation of a RC element due to corrosion (adaptation of Tuutti’s diagram).

2.1 Mechanism of corrosion and consequences

Steel in concrete is normally protected by the alkaline solution contained in the pores of the hydrated cement paste (with pH values higher than 13) which promotes passivation, i.e. the spontaneous formation of a thin oxide film on the surface of the steel. Passivation guarantees negligible corrosion rate (i_{corr}) values, typically lower than 1 mA/m^2 , corresponding to a depletion of about $1 \text{ }\mu\text{m/year}$ (Bertolini et al. 2013), regardless of the presence of oxygen and moisture in the concrete pores.

Corrosion on the steel bars takes place if the passive film is removed or is locally damaged. This usually occurs due to carbonation of concrete or chloride penetration. Carbonation is the neutralization of alkalinity of concrete due to carbon dioxide in the atmosphere. It brings about a drop in the pH of concrete from alkaline values to neutrality, with consequent loss of stability of the passive film on the steel bars. Consequently, rebars can corrode, if oxygen and moisture are available. Chloride ions may locally break the passive film even in alkaline concrete. This occurs when chloride ions, which are contained for instance in seawater or in common de-icing salts, penetrate the concrete cover and reach a critical threshold level at the depth of the reinforcement. Pitting corrosion thus initiates and may propagate if moisture and oxygen are available at the steel surface. Corrosion of steel bars in chloride-contaminated concrete is usually more severe than carbonation-induced corrosion, leading to much higher corrosion rates for given conditions of moisture content and temperature.

Although carbonation and chloride penetration are the most frequent causes of corrosion initiation in RC structures, it is worth recalling that, under specific circumstances, other forms of corrosion could take place. DC stray currents may promote corrosion initiation or propagation, e.g. in structures of railway networks (Bertolini et al. 2007), whilst high strength steels used in pre-stressed concrete may be highly vulnerable to the effects of corrosion (Page & Page 2007). In fact, corrosion can have serious consequences when it occurs in pre-stressed or post-tensioned concrete structures. Due to high loads applied to the tendons or bars and low fracture toughness that characterize the high strength steels, the consequences of corrosion attacks are more dangerous than in the case of conventional reinforced structures. As a matter of fact, even tiny localized attacks can determine the failure under service of tendons or bars. In the case of pre-tensioned structures, as shown in Figure 4, corrosion can be brought about by the penetration of carbonation or chlorides through the concrete cover (Figure 4a), while in post-tensioned structures corrosion usually arises as a consequence of ineffective filling of ducts with cement grouts (Figure 4b) or other protective materials. Under specific conditions, localized attacks (Figure 4c) can degenerate into cracks promoted by hydrogen embrittlement and brittle failure can take place.

Figure 4. Examples of (a) strand conditions in pre-stressed beam (Carsana et al. 2021), (b) segregated grout in the external post-tensioning tendons in contact with strand with severe corrosion attacks (Carsana & Bertolini 2015), and (c) localized corrosion attacks.

2.2 *Factors affecting corrosion*

Many factors can influence the corrosion behavior of steel in RC structures. They are related mainly with aggressiveness of exposure conditions, concrete quality, and thickness of concrete cover (Bertolini 2008). Environmental aggressiveness is a function of numerous factors not always independent of each other, such as humidity of the environment and its variability in time and place (the latter connected with macroclimate and local microclimatic conditions), presence of chlorides and oxygen, and temperature.

In case of carbonated concrete that does not contain chlorides, rebars can corrode if oxygen and moisture are available. Corrosion rate of steel increases as the moisture of concrete increases (Bertolini et al. 2013), and only when the moisture content approaches saturation the corrosion rate decreases due to lack of oxygen.

Chloride-induced corrosion occurs when chloride ions penetrate the concrete cover and reach a critical threshold level at the depth of the reinforcement. In presence of chlorides, the environment may be aggressive if the R.H. remains above 50% (or even 40% if the chloride content is very high and hygroscopic chlorides such as magnesium or ammonium chloride are present). Aggressiveness increases with humidity, chloride content, and temperature.

The resistance of RC elements against corrosion strongly depends on quality of concrete. The penetration of carbon dioxide and chlorides depends on the permeability of concrete. All factors that promote a dense, low-porosity microstructure of the cement paste (e.g. low water/cement ratio, careful placing, compaction and curing), allow obtaining a concrete with high resistance to carbonation and chlorides penetration (Bertolini 2011).

In addition to concrete quality, also a minimum value of concrete cover has to be prescribed. An increase in the thickness of the concrete cover increases the barrier to the various aggressive species moving towards the reinforcement and increases the time for corrosion initiation.

3 INSPECTION PROCEDURES

Regular inspection of RC structures and infrastructural facilities is fundamental to detect signs of deterioration and, if necessary, application of remedial measures in an early stage of damage. There are many reasons why inspection or condition assessment of RC structures are performed. Firstly, inspection activity is part of management operations of many large-scale structures (Carsana et al. 2023b, Bertolini et al. 2011). Based on the observation of signs of deterioration, a proper follow up can be taken before damage is too large. Structures with damage due to incidents, such as fires and collisions, need to be inspected for establishing proper corrective measures. Damaged RC structures need to be repaired in order they can reach the expected service life or prolong the residual lifetime (Bertolini et al. 2016). With respect to corrosion damages, a condition assessment of the structure has to be performed in order to find the optimum repair solution and to avoid further corrosion problems in the future. This evaluation consists into preliminary visual inspections (§3.1) that should allow for planning other detailed survey (§3.2 and §3.4).

3.1 *Visual inspections*

Visual inspection is the preliminary step in any survey. It should give a first indication of the nature of degradation problems and the extent of damages. Figure 5 shows typical effects of concrete degradation and steel corrosion, which may affect serviceability and safety of RC structures. Cracking, spalling or delamination of the concrete cover may take place due to tensile stresses induced by corrosion products growing at the steel surface, especially in case of inadequate thickness of concrete cover (Figure 5a). Further problem that is often observed on RC structures is the concrete segregation (Figure 5b). Evidences of macro-voids observed on the concrete surface suggest that concrete has not been properly compacted during casting phases. This phenomenon may cause premature corrosion initiation with consequent

detachments. Thus, prevention of steel corrosion should be further developed as the concrete is mixed, placed, compacted and cured. Moreover, even simple design details should be taken into account in order to prevent significant degradation of RC structures. Such significant signs can often be observed in those parts of the structural elements that were exposed to wetting (Figure 5c) in absence of adequate systems of collection of water coming mainly from the bridge platform.

Figure 5. Effects of steel corrosion and concrete degradation: (a) cracking and spalling or delamination; (b) concrete segregation; (c) degradation of structural parts exposed to wetting; (d) efflorescence; (e) pitting corrosion; (f) corrosion of steel strands at the anchor head.

Visual inspection can highlight the presence of signs of degradation due to phenomena of efflorescence for the use of de-icing salts (Figure 5d). In the case of chloride-induced pitting corrosion, the cross-section of the reinforcing bars can significantly be reduced (Figure 5e) and thus the mechanical characteristics of structural members, including load-bearing capacity, ductility, and fatigue strength, may be affected, even before any cracking takes place in the concrete cover. Visual observation could also concern corrosion of external post-tensioning tendon (Figure 5f).

3.2 *Non-destructive tests*

Visual inspection is often combined with several non-destructive tests (NDTs), as shown in Figure 6. NDTs include Schmidt rebound hammer and ultrasonic pulse tests carried out on concrete surface of structural elements to estimate mechanical properties and, in this way, detect the possible presence of zones where the concrete is unsound. Examples of frequency distributions of concrete strength, estimated through the Schmidt rebound hammer test for different structural elements, i.e., a pier cap, a box beam, and an I-beam investigated after dismantling of the viaduct (Figure 1), are illustrated in Figure 7. Additional NDT results can be found in Anghileri et al. (2021).

Average values of concrete strength around 50-55 MPa have been found, confirming a comparable design strength for concrete used to realize these different elements. Anyway, the wide range of variation of values measured on the pier cap highlights the possible presence of weak zones, such as those close to cracking and spalling of concrete surface (Figure 1).

As far as NDTs are concerned, the measure of concrete cover by magnetic-type instrument is also essential in order to explain why some areas of a structure are corroding and to identify those of future corrosion risk. In fact, low cover will favor the onset of corrosion because carbonation or chlorides reach the rebars more rapidly. Figure 8 shows the frequency distributions of concrete cover of the outermost reinforcement (stirrup bars) and internal longitudinal rebars of a RC element and it highlights the variability associated with this parameter.

Figure 6. Examples of non-destructive tests: (a, b), electrochemical inspection techniques; (c) concrete cover measurement; (d, e) Schmidt rebound hammer and ultrasonic pulse tests.

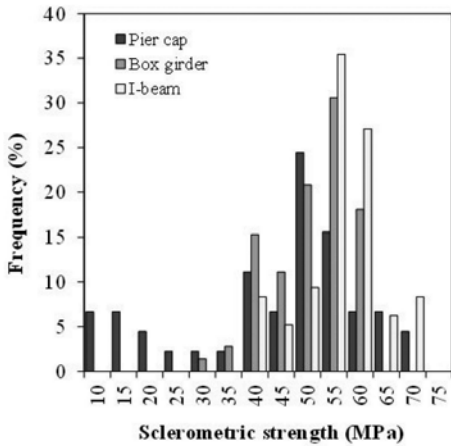

Figure 7. Frequency distribution of concrete strength estimated by means of Schmidt rebound hammer test (Carsana et al. 2022).

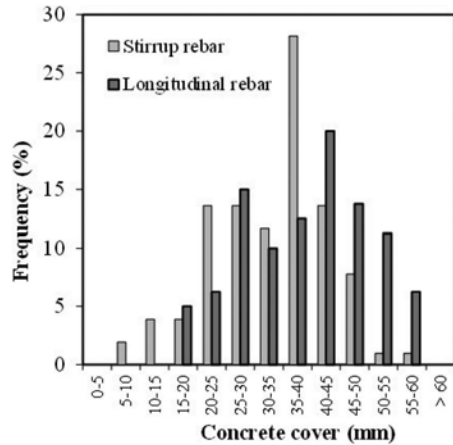

Figure 8. Frequency distribution of concrete cover thickness measured onsite for stirrups and longitudinal steel bars of a RC element.

Since corrosion is an electrochemical process, electrochemical techniques are most suited to assess the corrosion state of the reinforcement, to highlight corrosion sites and to monitor the corrosion propagation. Potential mapping is the only widely recognized and standardized NDT for assessing the corrosion state of rebars in concrete structures. To facilitate the interpretation of half-cell potential measurements of large bridge elements (Elsener 1995, Elsener et al. 2003), the most suitable approach of representing the data has been found to be a color map of the corrosion potential field (E_{corr}) based on the criterion of the American Standard ASTM C876 (1991), as shown in Figure 9a. According to this criterion, for $E_{corr} > -200$ mV vs CSE (Copper Sulphate Electrode) the probability of corrosion is less than 10% while for $E_{corr} < -350$ mV vs CSE the probability of corrosion is higher than 90%. However, the interpretation of the corrosion potential is not so obvious because the concrete cover and its resistivity, in addition to the actual corrosion potential of the steel, influence the readings at the concrete surface at the inspection time. Important information can be obtained by combining results from half-cell potential mapping and resistivity measurements. Figure 9b shows the relationship between the corrosion potential of steel and the electrical resistivity of concrete measured on a box beam.

The regions with very negative corrosion potentials and low electrical resistivities represent wet corroding zones, where steel bars are in contact with carbonated or/and chloride-contaminated concrete, while those with positive potentials and high resistivity indicate dry conditions and passive zones. The points where low resistivity yet positive potential are measured can be interpreted as the areas at risk of future corrosion. Electrochemical inspection techniques include also corrosion rate measurement carried out by means of polarization resistance method (Bertolini et al. 2013), which presents some difficulties when performed onsite (Andrade & Alonso 2004).

Figure 9. (a) Half-cell potential contour map. (b) Corrosion potential of steel reinforcement vs concrete electrical resistivity measured at different depths from top of a box beam (Carsana et al. 2020).

Certainly, the interpretation of available electrochemical parameters should be associated with further analyses aimed at assessing the actual state of steel bars embedded in concrete. In particular, concrete samples should be collected during inspection phase in order to evaluate also the carbonation depth and chloride content of concrete at the time of measurement and to predict future deterioration of the structure or to assess residual lifetime.

3.3 Sampling

Based on visual inspections, several zones of the structural elements of a bridge can be located for sampling. Inspection, condition assessment and prediction of the future service life require information both on concrete and on steel reinforcement. Thus, different types of samples have to be collected (Figure 10). Such samples are dedicated to several types of analyses that may help in the characterization of concrete, steel reinforcement and their resistance to aggressive agents.

Figure 10. Different sampling procedures during onsite inspections: (a) concrete fragments, (b) concrete cores, (c) concrete powders, and (d) samples of steel reinforcement.

3.4 Laboratory analyses

3.4.1 Carbonation depth

For determining carbonation depth it is essential to spray freshly broken concrete surfaces with a phenolphthalein solution (pH indicator) which will remain colorless where concrete is carbonated, while it will turn pink where concrete is still alkaline (Figure 11). The depth of carbonation can be measured also by spraying the same solution on concrete powders that are collected by drilling at increasing depth with a tip. The latter method is slightly less accurate than taking a concrete core, but it is less invasive as well. Usually the square-root formula is used to describe the penetration of carbonation in concrete ($d = k \cdot t^{0.5}$, where k is carbonation coefficient that is a function of concrete and environmental conditions). For real structures exposed to atmosphere (Bertolini et al. 2013) k ranges between 2 and 15 $\text{mm}/\text{y}^{0.5}$ (indicatively $2 < k < 6$ for concrete of low porosity, and $k > 9$ for highly porous concrete). Based on results obtained from inspection of deck beams after 53 years (Carsana et al. 2023), it has been observed that the carbonation depth shows a certain variability due to different local properties of concrete. In fact, carbonation depth measured on a core collected next to a segregation

zone is higher than that obtained on a sample cored in an undamaged zone of the same front. Figure 12 shows the progress in time of the carbonation depth for the values of k obtained for the investigated deck beams with and without segregation (respectively equal to 3.2 and 6.2 $\text{mm}/\text{y}^{0.5}$, grey lines). It can be deduced that the carbonation depth is less than 22-23 mm (average thickness of concrete cover of ordinary reinforcement in the deck beams) after 50 years only if k ranges between 2 and 3.2. This means that 22-23 mm of concrete cover for ordinary rebars in the inspected beams lead to an initiation time of over 50 years only in dense concrete. Strands, which are in depth at an average cover depth of 40 mm, are protected after 50 years in a concrete with k equal to 3.2 only in absence of segregation.

Figure 11. Phenolphthalein test on concrete core and concrete powders.

Figure 12. Carbonation depth vs time and carbonation coefficient k .

3.4.2 Chlorides content

Chlorides can be transported in concrete from the environment due to seawater exposure or to de-icing salts. Thus, chloride depth profiles should be determined in order to value the actual chloride level at the reinforcement and possible corrosion initiation and propagation. Chlorides contents can be measured by different methods. It is preferable to carry out laboratory tests which are more accurate than field tests (Colleparidi 1995). Figure 13 shows the chloride profiles measured on concrete samples after being digested in hot nitric acid for several type of deck beams inspected after 53 years of service life (Figure 1). The chloride content, measured by means of potentiometric titration, has been expressed as percentage of the dry concrete. Chloride profiles have been interpolated based on the “erf function” obtained from the analytical solution of the one-dimensional Fick’s second law of diffusion (Colleparidi et al. 1972). From Figure 13 it can be observed that the chloride profile measured on a pier cap overcome the critical chlorides threshold for carbon steel (0.05-0.125% in mass of concrete)

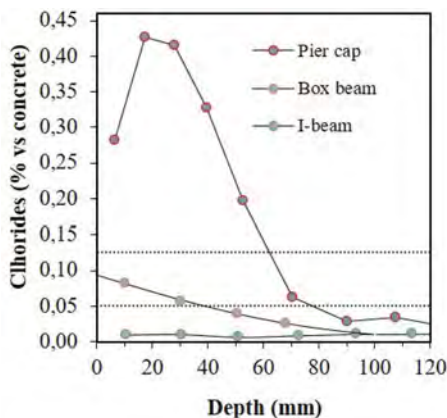

Figure 13. Chlorides profiles on bridge elements: I-beam, box beam, pier cap (Carsana et. al 2023). Dotted lines indicate critical chloride thresholds.

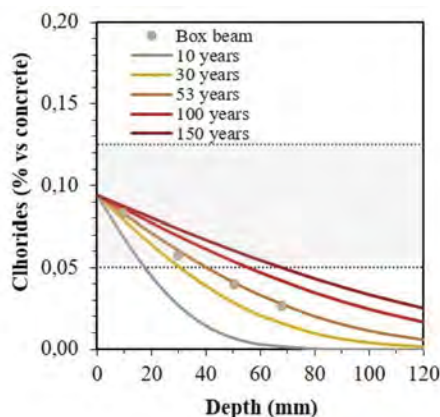

Figure 14. Chlorides profiles calculated after different time of exposure (10-100 years), based on experimental data from a box beam (Figure 13).

also far beyond typical minimum concrete cover thickness (for example 20 mm) with maximum values of 0.42% vs concrete mass. Conversely, for deck beams the risk of chlorides-induced corrosion shall be considered low at inspection time. In fact, chlorides content is below critical chlorides threshold at any concrete depth.

The diffusion equation considered to fit experimental data can be also used for the evaluation of the initiation time of corrosion. As shown in Figure 14, by assuming constant exposure conditions, the evolution with time of the chlorides profile in concrete can be evaluated.

3.4.3 Physical, microstructural and chemical analyses

To predict future deterioration of RC elements of bridges and viaducts due to corrosion phenomena, several measurements of the electrochemical parameters in time are usually needed in order to take into account daily and seasonal variations due to change in temperature and relative humidity. However, if this is not feasible, the interpretation of the available data deriving from electrochemical techniques can be improved by measuring physical properties of cores and samples collected from inspected structure (such as density in dry and water-saturated conditions and water absorption). In fact, it is well known that the electrical resistivity of concrete and cement paste depends on pore volume and pore-size distribution of cement paste, the pore-water composition and moisture content. Depending on exposure conditions and chemical and microstructural properties of concrete, resistivity can vary of several orders of magnitude. For instance, Figure 15 shows the relationship between the moisture content of concrete and its resistivity, obtained from laboratory tests on cores taken from transversal (T) and longitudinal (L) fronts of some deck beams of the viaduct shown in Figure 1. Resistivity of these cores has been measured in different conditions: “as received”, after (o during) wetting and drying.

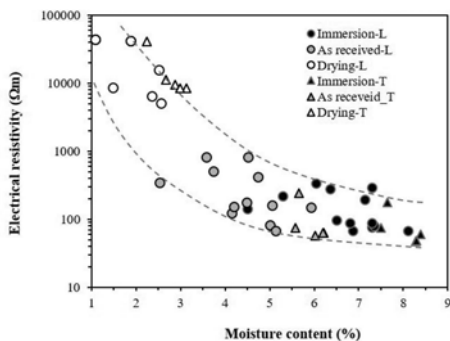

Figure 15. Electrical resistivity vs moisture content measured on some concrete cores taken from several deck beams of the viaduct shown in Figure 1.

Moreover, to investigate the composition, microstructure, and thus the protection given by concrete (or grout in case of post-tensioning tendons) to embedded steel, further laboratory analyses can be carried out on selected samples. Firstly, X-ray diffraction analysis is performed in order to identify crystalline compounds of cementitious materials or corrosion products. The ICP-OES technique by plasma emission spectrometry is used to analyze the elemental composition of concrete or grout and of reinforcement in terms of oxides. Finally, the microstructure of concrete samples, grout or reinforcement can be also observed under stereomicroscope and environmental scanning electron microscope with an EDS X-ray spectrometer (Carsana & Bertolini 2016).

As an example, Figure 16 shows evidence of phenomena of efflorescence on a concrete sample collected from the surface of a box beam, by means of stereo-microscope and scanning electron microscope. In particular, Figure 16b shows the morphology of crystallization products and highlights main elements such as sodium (Na), sulfur (S) and oxygen (O) and traces of chlorine (Cl), thus confirming the presence of chloride and sulfate salts.

As far as steel reinforcements are concerned, by analyzing a polished section of a rebar with stereo-microscope and scanning electron microscope, as shown in Figure 17, its microstructure and the thickness of the oxide layer can be estimated.

Stereo-microscope and scanning electron microscope allow also to observe fracture surfaces of samples of steel. For instance, Figure 18 shows the failure of a wire, which took place in correspondence of a localized corrosion attack. At the scanning electron microscope (SEM), the fracture surface, where it is not masked by corrosion products, seems ductile and characterized by the presence of elongated dimples (Carsana & Bertolini 2015). Microstructural observations allow to investigate on the possible presence of hydrogen-induced stress corrosion cracks, as reported in Carsana & Bertolini (2015).

4 CONCLUSIONS

The paper has introduced some of the key aspects of inspection procedures for corrosion assessment of RC bridges and viaducts. Methodologies and results from several field and laboratory tests have been presented and exemplified, illustrating the procedures and tools available in order to perform both chemical and microstructural analyses on concrete, complemented by electrochemical tests on steel reinforcement.

A summary of the results of recent studies and research investigations carried out by the authors have been presented. In particular, a wide campaign of investigations has been considered to evaluate statistically various electrochemical, physical and microstructural parameters of real scale elements. These outcomes, in agreement with the results reported by many other researchers, have allowed defining a procedural approach aimed at assessing the state of materials degradation and corrosion conditions of structural members with emphasis on bridge structural components. These investigations have highlighted mainly the effects of both carbonation and chlorides-induced corrosion on reinforcing and prestressing steel of concrete structural elements and how to consider the results of surveys for preliminary evaluating the evolution with time of such degradation phenomena. The collected data will also be used in future research investigations for the development of database and inventories for condition evaluation and structural assessment and of the life-cycle performance and residual lifetime of in-service structures and infrastructure facilities.

Bayesian assessment of existing concrete structures: Exploiting the full power of combined information

R. Caspeele & W. Botte
Ghent University, Ghent, Belgium

ABSTRACT: When assessing existing concrete structures, an adequate prediction of the time-dependent structural performance is crucial. Unfortunately, the degradation process is associated with large uncertainties and when executing additional investigations and measurements, significant model and measurement uncertainties play a dominant role in the reliability-based performance prediction. Bayesian updating techniques provide a unique engineering tool to adequately combine and fully exploit the power of combined available information, enabling to make inferences where classical statistical approaches fail. Among others, uncertainties on degradation parameters and variables in structural reliability calculations can be updated on the basis of combined information from measurements, monitoring and visual inspections. Even the effect of quality control can be taken into account. Consequently, these updated uncertainties can be taken into account in full-probabilistic structural reliability calculations, or partial factors for the structural verification can be adjusted according to the posterior probabilistic models. In this contribution, the integration of these approaches into the practical assessment process is briefly explained and an outlook is given on future engineering challenges to integrate such approaches further in the life-cycle assessment of existing concrete structures.

1 INTRODUCTION

An increasing amount of the current activities in the construction sector are oriented towards the assessment of existing structures and the associated repair and upgrading interventions. Although the last decennia significant progress has been made to analytically and numerically simulate the degradation process of concrete structures and their associated structural performance prediction in time, structural engineers are challenged to deal with the large uncertainties involved. Besides a typical lack of information, the degradation processes are associated with large uncertainties and when executing additional investigations and measurements, significant model and measurement uncertainties play a dominant role in the reliability-based performance prediction. Intentions to generalize and internationally fix variables and parameters involved in the assessment of existing concrete structures appear difficult to achieve. Hence, a solution to this problem is rather to be found in the application of Bayesian updating techniques that enables to take into account the specific situation of the structure and its environment. This Bayesian updating provides a unique engineering tool to adequately combine and fully exploit the power of combined available information, enabling to make inferences where classical statistical approaches fail.

After revisiting some basics on Bayesian approaches, it is explained and illustrated how Bayesian updating techniques provide an undeniable advantage in several steps of the assessment process. It is explained how degradation models whose parameters generally are difficult to find consensus about, can gradually be updated when more information becomes available. Variables in structural reliability calculations can be updated on the basis of direct as well as indirect measurement data. Sources of information contained in different types of measurements or even visual inspections can be combined in order to make much more informed inferences and to reduce

uncertainties in the reliability-based performance assessment, compared to when such data is analysed separately. Even, although often forgotten, the positive effect of quality control can be taken into account when assessing the structural reliability. After updating the uncertainties of the variables involved, these posterior distributions can be taken into account in full-probabilistic structural reliability calculations, or partial factors used in semi-probabilistic assessment approaches can be adjusted on the basis of updated uncertainties (fib 2016). Finally, the paper ends with an outlook to future engineering challenges to integrate such approaches further in the life-cycle assessment of existing concrete structures.

2 BAYESIAN INFERENCE

The basic theory behind Bayesian statistics dates already from 1763 with the famous paper (posthumously published) by the reverend Thomas Bayes in order to solve the question how to assess the probability of a certain value of not observable quantities, given a set of related measurements. Note that this is exactly the challenge we are often faced with as structural engineers. However, it is only the last decennia that this Bayesian point of view is used extensively due to the advances in computational abilities and the development of more efficient numerical algorithms to solve the mathematical difficulties associated with Bayesian statistics. Many fields of research have recognized the importance of Bayesian statistics, which has led to new research perspectives, for sure also in the field of structural engineering. Although already common practice to tackle research challenges, the methodology has still not yet fully found its way into practical applications by practitioners where frequentistic approaches still dominate statistical inference to deal with uncertainties. A challenge ahead is hence to make the *Bayesian way of thinking* more accessible.

The Bayesian definition of the probability $P[A]$ of an event A is formulated as a degree of belief that A will occur. Hence, Bayesian inference probabilities are a measure of our state of knowledge about nature, not a measure of nature itself (Gregory 2005). The degree of belief can hence be a reflection of the state of mind of the individual person in terms of experience, expertise and preferences. In this respect the Bayesian interpretation of probability is subjective. However, this subjective nature is not a big issue, as we can require that observers with the same amount of information should come to the same conclusion (Verdoolaege 2006). More specifically, it is possible to suppose as little as possible and *let the data speak for themselves* by using non-informative priors. However, the ability to include prior information is of large importance in structural engineering problems, especially when confronted with limited data.

The Bayes' theorem to calculate the probability P of an event E_i given the observation A (i.e. the posterior probability of E_i) is given by Equation (1):

$$P[E_i|A] = \frac{P[A|E_i]P[E_i]}{P[A]} \quad (1)$$

where $P[E_i|A]$ is called the posterior probability of E_i , $P[A|E_i]$ is often referred to as the likelihood (i.e. the probability of observing a certain outcome given a certain cause) and $P[E_i]$ is called the prior probability of the event E_i (i.e. prior to the knowledge about event A). Hence, Bayes' theorem enables to update probabilities, based on new information.

In case of continuous distributions, the continuum formulation of Bayes' theorem can be used. Consider a random variable X which has a probability density function $f_X(x|\theta)$ depending on a parameter vector θ . In case new information becomes available, the prior distribution function $f'_{\Theta}(\theta)$ of the parameters θ can be updated towards a posterior distribution function $f''_{\Theta}(\theta)$ (Gelman et al. 2004):

$$f''_{\Theta}(\theta) \equiv f(\theta|\mathbf{I}) = \frac{L(\theta|\mathbf{I}) \cdot f'_{\Theta}(\theta)}{\int L(\theta|\mathbf{I}) \cdot f'_{\Theta}(\theta) d\theta} = c \cdot L(\theta|\mathbf{I}) \cdot f'_{\Theta}(\theta) \quad (2)$$

where c is a normalizing constant, $L(\theta|\mathbf{I})$ is the likelihood function, i.e. the likelihood of the parameters θ based on the new information \mathbf{I} . Assume for example that n independent results x_i are observed, then the likelihood associated with this new information is given by the probability:

$$L(\theta|\mathbf{I}) \equiv L(\theta|x_1, \dots, x_n) = \prod_{i=1}^n f_X(x_i|\theta) \quad (3)$$

In case of correlated observations, the likelihood can be extended to a multivariate distribution including the correlation between variables.

In contrast to the classical or frequentistic approach, prior information can be taken into account through the prior density function of the parameters, i.e. $f_{\theta}(\theta)$. The way in which this influences the posterior density function is depending on the relative importance of the prior information compared to the new information (i.e. the likelihood function). In order to *let the data speak for themselves* most often non-informative or vague priors are used, which maximize the information provided by the likelihood function (see e.g. Box & Tiao 1973, Gelman et al. 2004)

When calculating the posterior distribution, computational difficulties arise due to the necessary evaluation of high-dimensional integrals. This was the main obstacle for the use of Bayesian methods in the previous century. Together with the advances in computational efficiency, a group of so-called Markov Chain Monte Carlo methods (MCMC) were developed (see e.g. Gelman et al. 2004) for the numerical determination of the posterior probabilities.

3 APPLICATION OF BAYESIAN UPDATING TECHNIQUES IN THE ASSESSMENT OF EXISTING CONCRETE STRUCTURES

3.1 *The Bayesian way of thinking in all steps of the assessment and rehabilitation process*

The assessment process commonly consists of several steps, encompassing condition assessment, performance prediction, monitoring, performance updating and an optimization of interventions (Figure 1). Uncertainties are involved in all of these steps, and Bayesian updating can play a role in each of the steps to adjust lacking knowledge when more information becomes available.

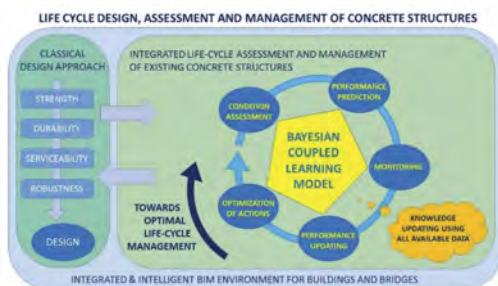

Figure 1. Principle of life-cycle design, assessment and management of concrete structures and the place of Bayesian approaches to update within and in-between all aspects.

In particular, parameters that are difficult to be fixed in general (e.g. degradation parameters such as diffusion coefficients and carbonation resistance, environmental conditions, direct and indirect costs, etc.), can be updated when more information becomes available and as such bypass the often occurring conundrum when trying to fix model parameters in general for all cases.

Moreover, while often forgotten, also the interaction between the different steps in the assessment process plays an important role when updating uncertainties and the combination of this kind of information can lead to a significant improvement of the posterior uncertainties. Monitoring data can for example also be used to update degradation models used in the condition assessment. Structural analysis models can be extended by random fields that enable to update degradation models and their spatial variability – which is often not quantitatively accounted for as most models are 1D models – when test and monitoring data becomes available.

In the following, several more specific aspects on how to exploit Bayesian updating in the framework of assessment of existing concrete structures are highlighted.

3.2 Updating variables in structural reliability calculations

3.2.1 Updating of variables on the basis of direct associated measurements

Bayesian updating methods based on prior information are already widely applied for the assessment of existing concrete structures (see e.g. Strauss et al. 2008). In case of the assessment of concrete strength, quantitative prior knowledge on concrete strength distributions can be found in literature (see e.g. Rackwitz 1983), and similarly for other variables (see e.g. JCSS 2001). Prior information can for example be modelled, based on normal-gamma or lognormal-gamma distributions. These types of distributions are natural conjugate priors for updating the mean and standard deviation of the normal or lognormal concrete strength distribution, which enables to find simple analytical expressions for updating the parameters of the strength distribution function in a Bayesian framework. When for example the characteristic concrete strength has to be estimated from a limited number of test samples, the use of a combined vague-informative prior is of particular interest (Caspellee & Taerwe 2012). Prior knowledge on the standard deviation can be taken into account, leading to a reduction in the standard deviation of the predictive strength distribution and a more realistic estimation of the characteristic concrete strength in cases where only a limited number of test results are available. A similar approach can be followed for other variables.

3.2.2 Data from in-situ static load tests

Data obtained from static load tests can be used to update the probabilistic distributions of variables which are of significant importance when assessing the behaviour of concrete structures. Such static load tests can be executed in situ on (part of) the structure or in laboratory on representative elements which have been taken from the structure to be assessed. In such cases, the observed data $\bar{\mathbf{d}}$ can according to (Simoen et al. 2015) be written as:

$$\bar{\mathbf{d}} = M(\boldsymbol{\theta}) + \boldsymbol{\eta}_G + \boldsymbol{\eta}_D \quad (4)$$

where, $M(\boldsymbol{\theta})$ is a model with input parameters $\boldsymbol{\theta}$ used to predict the data $\bar{\mathbf{d}}$, $\boldsymbol{\eta}_G$ is a modelling error and $\boldsymbol{\eta}_D$ is the measurement error. Assuming a normal distribution with zero mean and covariance matrices $\boldsymbol{\Sigma}_D$ and $\boldsymbol{\Sigma}_G$ for the latter, the likelihood can be expressed as:

$$L \sim (\det(\boldsymbol{\Sigma}_D + \boldsymbol{\Sigma}_G))^{1/2} \exp\left(-\frac{1}{2} F_{ML}\right) \quad (5)$$

where F_{ML} is the maximum likelihood function, which can be formulated as:

$$F_{ML} = (M(\boldsymbol{\theta}) - \bar{\mathbf{d}})^T (\boldsymbol{\Sigma}_D + \boldsymbol{\Sigma}_G)^{-1} (M(\boldsymbol{\theta}) - \bar{\mathbf{d}}) \quad (6)$$

When looking into the incorporation of information of monitoring data based on static load tests on infrastructure, the approach followed in (Vereecken et al. 2023) illustrates the possibility to use the data of strains and displacements collected during a static load test on a reinforced concrete slab bridge in Amsterdam (The Netherlands) to update the spatial distribution of the stiffness of the deck along the bridge (Figure 2). In case of strains and considering $\boldsymbol{\Sigma}_G = \mathbf{0}$, the likelihood function can be rewritten as (Vereecken et al. 2022b):

$$F_{ML} = \sum_{j=1}^N \frac{1}{\sigma_\varepsilon^2} (\bar{\varepsilon}_j - \varepsilon_j(\boldsymbol{\theta}))^2 \quad (7)$$

where N is the number of measurements, σ_ε is the standard deviation of the measurement error, $\bar{\varepsilon}_j$ are the measured strains and $\varepsilon_j(\boldsymbol{\theta})$ are the strains obtained from a numerical model with input parameters $\boldsymbol{\theta}$.

In (Vereecken et al. 2023), the aim was to determine the best posterior model based on MCMC in combination with surrogate modelling in order to limit the computational cost. Therefore, the influence of different models for the prediction error, as in (Simoen et al. 2013),

the model bias, and the influence of different definitions of the stiffness of the structural model, was investigated on an actual engineering structure. Bayesian-based model selection was performed both based on log evidence and posterior predictive capabilities. As an example, the posterior distributions of the stiffness along the deck of the bridge is illustrated in Figure 2 for two models: one adopting two possibilities for the stiffness (cracked and uncracked) and one adopting for more flexibility in the stiffness distribution along the length. A more flexible model for the stiffness distribution was found to be preferred over a model allowing less spatial variability.

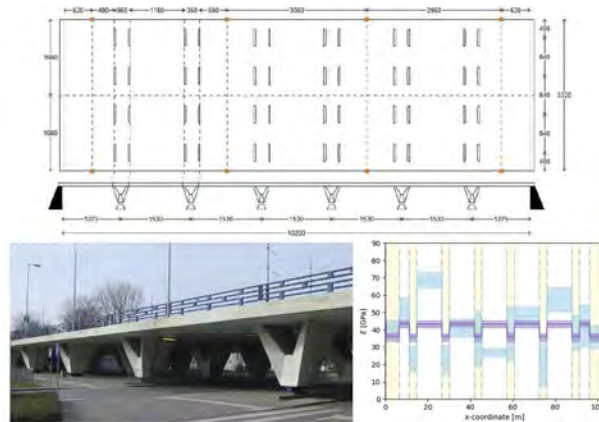

Figure 2. Picture, top and side view of bridge 705 with its main dimensions in [cm] (Rozsas et al. 2022) and posterior distribution of the stiffness along the deck for two *situations*: 2 discrete stiffness distributions (purple) and a spatially variable stiffness distribution (blue). The solid/dashed line represents the posterior mean and the hatched area represents the posterior 90% HDI (Vereecken et al. 2023).

3.2.3 Data from laboratory static load tests

Bayesian updating can also play a significant role when analysing results from a limited number of (e.g. large-scale) tests. In this regard, the approach developed in (Botte et al. 2021) is of particular interest, adopting a two-step Bayesian framework in combination with non-linear finite element modelling in order to assess the remaining prestress and associated uncertainties in post-tensioned concrete beams from the 1940's. In the first step, the distributions of material characteristics such as the compressive strength, tensile strength, Young's modulus and density of concrete as well as the Young's modulus of the prestressing steel were updated using MCMC and based on direct measurements of those properties. Prior information was selected from the JCSS Probabilistic Model Code (JCSS 2001) based on historical documentation regarding the design. Considering these updated distributions for the material properties, a vague prior distribution of the remaining prestress was consecutively updated based on the information obtained from large-scale load tests in laboratory. In particular the cracking moment, moment of reopening of cracks and behaviour in the non-linear branch of the load-displacement diagram contain in that regard very valuable information, since these depend significantly on the remaining prestress level.

Figure 3. Static load test on a primary beam and the corresponding posterior distribution of the remaining prestress including the 90% HDI (Botte et al. 2021).

3.2.4 Ambient vibration data

Model-based structural health monitoring is often executed through vibration-based finite element model updating. It is based on the assumption that local structural damage results in a local reduction of stiffness. The presence of damage can be detected, located and quantified (Simoen et al. 2015). The natural frequencies identified in a modal test only provide global information, whereas localization of damage requires the identification of mode shape displacements. However, mode shapes are usually characterized by a larger identification uncertainty and they are not extremely sensitive to moderate changes in structure stiffness (Simoen et al. 2015). Hence, additional properties can be measured which are more sensitive to changes in stiffness, such as modal flexibilities (Catbas et al. 2008), modal curvatures (Pandey et al. 1991) and modal strain energies (Jaishi & Ren 2007).

In case eigenvalues and mode shapes are used in a Bayesian model updating procedure and considering $\Sigma_G = \mathbf{0}$, the likelihood function can be written as:

$$F_{ML} = \sum_{j=1}^N \frac{(\bar{\lambda}_j - \lambda_j(\boldsymbol{\theta}))^2}{\sigma_{\lambda_j}^2} + \sum_{j=1}^N \frac{(\bar{\phi}_j - \phi_j(\boldsymbol{\theta}))^2}{\sigma_{\phi_j}^2} \quad (8)$$

where N is the number of modes considered, $\bar{\lambda}_j$ and $\bar{\phi}_j$ are the measured eigenvalues and mode shape vectors and $\sigma_{\lambda_j}^2$ and $\sigma_{\phi_j}^2$ are the standard deviations of the error related to the measured frequency and mode shape respectively.

3.2.5 Visual inspections

Visual inspections are the most frequently occurring types of inspections since these are relatively simple to execute. These inspections provide rough indications whether there is a risk related to human safety or whether there are any alarming time-dependent evolutions in the structural behaviour. Regarding corrosion, the most important visual observations are the presence of rust stains, corrosion cracks or concrete spalling. If any of these signs are present, it can be concluded that the reinforcement at that location has started to corrode. In Figure 4 it is illustrated how visual observations can influence the distribution of the initiation period. If at t_{insp} it is observed that rust stains are present, the initiation time T_i should be lower than t_{insp} . Hence, the distribution of the initiation time can be updated as follows (Botte, 2017):

- In case inspection reveals that corrosion has initiated at some point in time before t_{insp} :

$$F''_{T_i}(t) = \frac{F'_{T_i}(t)}{F'_{T_i}(t_{insp})} \quad (9)$$

- In case inspection reveals corrosion has not yet initiated at t_{insp} :

$$F''_{T_i}(t) = \frac{F'_{T_i}(t) - F'_{T_i}(t_{insp})}{1 - F'_{T_i}(t_{insp})} \quad (10)$$

Figure 4. Influence of a visual observation of corrosion on the PDF of the initiation period.

In addition, this visual data can be used to supplement the static and/or dynamic data as it – through the application of the Bayesian updating approach – can lead to inferences on the origin of the stiffness reduction. Furthermore, models to predict the crack width or time to

cracking can be updated based on the observed crack locations or crack widths according to the approach which will be explained in section 3.3. It should be pointed out that visual inspections can also suffer significantly from operator bias. If such bias is present, this bias should and can be accounted for when evaluating the information from the visual inspections.

3.2.6 Combining different sources of information

Each of the mentioned test methods and corresponding data types has its advantages and limitations. Nevertheless, in a Bayesian context, the different types of data can be combined in a smart way in order to optimize the assessment procedure. A possible solution consists of first localizing the critical elements of the structure based on the modal data so that these can be prioritized when strain data are collected under proof-loading. Combining the data of both measurements will lead to reduced identification uncertainties when compared to the case where the measurements are considered separately. A conceptual illustration of the advantage of combining both sources of information is provided in Figure 5.

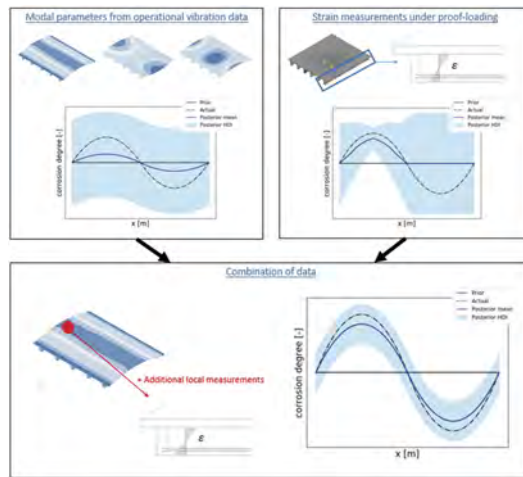

Figure 5. Concept of updating the corrosion degree based on strain data from proof-loading and modal data from ambient acceleration measurements and the improved predictability considering both sources of information (Vereecken et al. 2022b).

In (Vereecken 2022a) the advantage of updating on the basis of combined information with or without the information from visual observations is illustrated in relation to the posterior distribution of the corrosion degree of reinforcement in a concrete beam, see Figure 6.

Figure 6. Posterior corrosion degree of a simply supported beam when measuring the strains under proof loading (a) without visual observation, (b) with visual observation of rust stains. For more detailed information, see (Vereecken 2022a).

3.3 Updating of degradation models

The principle provided by Bayes' rule can also be applied in regression analysis. This way, previously obtained information regarding regression parameters of degradation models can be

updated towards posterior distributions of the regression parameters, taking into account experimental data. The fact that prior information can be taken into account, moreover enables to make sure that relevant regression models can be obtained even in case of very limited information, which provides a significant advantage compared to other statistical approaches.

Assume that the true value of the response variable \tilde{y} can be predicted by a mathematical or numerical model $M(\cdot)$ which is a non-linear function of R regression parameters β_i and depends on a vector \mathbf{x} which represents a m -dimensional set of input parameters. If this model would be perfect and the true values $\tilde{\mathbf{x}}$ are exactly known, this model would predict the true response value \tilde{y} . However, due to the existence of uncertainties, the true value is given by:

$$\tilde{y} = y + \varepsilon = M(\mathbf{x}) + \varepsilon \quad (11)$$

where the error term is usually considered as a realization of a Gaussian random variable with mean 0 and standard deviation σ_ε , representing the measurement and model uncertainties.

If N independent test results y_i are available for the response variable of N sets of corresponding input parameters \mathbf{x}_i , the likelihood of the experimental data can in general be written as:

$$L(y_1, \dots, y_N | \mathbf{x}_1, \dots, \mathbf{x}_N) = \prod_{i=1}^N \frac{1}{\sigma_\varepsilon} \phi\left(\frac{y_i - M(\mathbf{x}_i)}{\sigma_\varepsilon}\right) \quad (12)$$

where $\phi(\cdot)$ is the probability density function of the standard normal distribution.

Based on the Bayesian principle, the prior information is given as the joint prior distribution $f'_B(\sigma_\varepsilon, \beta_1, \dots, \beta_R)$ regarding the standard deviation σ_ε of the error term and the regression parameters $(\beta_1, \dots, \beta_R)$. This prior distribution can be updated towards a posterior distribution, using the likelihood function, i.e.:

$$f''_B(\sigma_\varepsilon, \beta_1, \dots, \beta_R) = c \cdot f'_B(\sigma_\varepsilon, \beta_1, \dots, \beta_R) \cdot L(y_1, \dots, y_N | \mathbf{x}_1, \dots, \mathbf{x}_N) \quad (13)$$

where c is a normalizing constant.

When now considering again the situation with degradation models, a common discussion relates to fixing model parameters for the corrosion propagation phase in concrete. Rather than trying to fix these parameters in general for all cases, this Bayesian regression approach can be incorporated in the updating process when additional information becomes available. Consider for example the empirical model to predict the corrosion rate presented in (Vu & Stewart 2000) and (Stewart and Suo 2009):

$$M(\mathbf{x}) = i_{corr}(t_p) = i_{corr}(1) \cdot a \cdot t_p^b \quad (14)$$

$$i_{corr}(1) = \frac{d \cdot (1 - WC)^e}{C} \quad (15)$$

where t_p is the propagation time, $i_{corr}(1)$ is the corrosion rate at the start of corrosion propagation, WC is the water-cement ratio, C is the concrete cover, and a , b , d and e are regression parameters (with default values $a = 0.85$, $b = -0.3$, $d = 27$ and $e = -1.64$ according to (Stewart and Suo 2009)). In case N measurements of the corrosion rate $i_{corr,j}$ and associated input vectors $\mathbf{x}_j = (WC, C, t_p)_j$ are available, the likelihood function (12) and posterior distribution (13) yield respectively:

$$L(i_{corr,1}, \dots, i_{corr,N} | \mathbf{x}_1, \dots, \mathbf{x}_N) = \prod_{j=1}^N \frac{1}{\sigma_\varepsilon} \phi\left(\frac{i_{corr,j} - M(\mathbf{x}_j)}{\sigma_\varepsilon}\right) \quad (16)$$

$$f''_B(\sigma_\varepsilon, a, b, d, e) = c \cdot f'_B(\sigma_\varepsilon, a, b, d, e) \cdot L(i_{corr,1}, \dots, i_{corr,N} | \mathbf{x}_1, \dots, \mathbf{x}_N) \quad (17)$$

The likelihood and probability distributions can simply be added to the likelihood and distribution in relation to other variables and updated together. Prior information can moreover be based on literature data (such as mentioned for this specific case) or be based on vague prior information or information based on expert judgement. Finally, it is also important to notice that in case the corrosion rate is not measured directly, indirect measures may be used as for example corrosion

degrees, deflections, crack widths, etc. to infer indirectly about the corrosion rates. In such case also the model uncertainties or model parameters can be taken into account in the likelihood function and the updating can be performed together with all other uncertainties. In doing so the power of Bayesian updating is fully exploited in a way that is not comparable to other statistical methods.

3.4 Updating on the basis of information from quantitative quality control

The most important objective of quality control is to verify whether the delivered product or service complies with the specifications requested by the client. In general, quality control has a favourable effect due to the fact that the existence of quality requirements (such as conformity criteria) compels producers to deliver high quality products in order to avoid rejection by quality assessment. This effect has an influence on the probabilistic modelling of e.g. concrete properties of accepted concrete lots and also influences the structural reliability analysis of concrete structures. Bayesian approaches can be used to quantify this effect (Caspeele & Taerwe 2013).

For an assumed property (e.g. the concrete strength distribution) and for a given conformity criterion, one can calculate the probability that a concrete lot, characterized by a fraction defectives θ , is accepted. This probability is called the probability of acceptance and denoted as P_a . An example of such an operating characteristic curve is shown in Figure 7 in case of conformity criteria for concrete strength.

Figure 7. OC-line corresponding to different conformity criteria (Caspeele et al. 2014).

The filter effect of a conformity criterion is related to the probability of acceptance associated to the applied conformity control scheme. Due to the lower acceptance probability of a strength population with a high fraction defectives, the population of strength distributions shifts towards lower fractions defectives (which correspond to a higher quality with respect to e.g. concrete strength). Bayesian statistics provide the probabilistic framework for updating the (strength) distribution after conformity control, thus enabling to quantify the so-called filter effect, as follows:

$$f_{\theta,o}(\theta) = \frac{P_a(\theta) f_{\theta,i}(\theta)}{P_a(\theta) f_{\theta,i}(\theta) d\theta} \quad (18)$$

with $f_{\theta,i}(\theta)$ the prior distribution of the fraction defectives in incoming lots (designated 'i') and $f_{\theta,o}(\theta)$ the posterior distribution of the fraction defectives in outgoing or accepted lots (designated 'o'). In case of structural reliability calculations, it is however more relevant to update the parameters of the strength distribution (i.e. the mean and standard deviation of e.g. the concrete strength). In (Caspeele et al. 2014) a semi-analytical approach was developed to assess the filtering effect of complex conformity criteria accounting for autocorrelation between consecutive test results. Consider the following model for the concrete compressive strength X :

$$X = X_m + X_l \quad (19)$$

where X_m is a quantity describing the variation of the mean strength of different lots, i.e. X_m is normally distributed with mean μ_m and standard deviation σ_m , and X_l is a quantity describing the variation of the strength within a certain concrete lot, i.e. X_l is normally distributed with mean 0 and standard deviation σ_l . The mean and standard deviation of the offered (incoming) lots can be written as Equations (20) and (21) respectively:

$$\mu_i = \mu_m \quad (20)$$

$$\sigma_i = \sqrt{\sigma_m^2 + \sigma_l^2} \quad (21)$$

After conformity control, the posterior density function of X_m is given by:

$$f_o(x_m) = \frac{\frac{1}{\sigma_m} \phi\left(\frac{x_m - \mu_m}{\sigma_m}\right) P_a(x_m | \dots)}{\int_{-\infty}^{\infty} \frac{1}{\sigma_m} \phi\left(\frac{x_m - \mu_m}{\sigma_m}\right) P_a(x_m | \dots) dx_m} \quad (22)$$

where $\phi(\cdot)$ is the probability density function of the standard normal distribution and $P_a(x_m | \dots)$ is the probability that a concrete lot with mean strength x_m is accepted by the conformity criteria.

Further, the posterior predictive distribution of the concrete strength can then be calculated according to Equation (23) in case of the model outlined in Equations (19)–(22):

$$f_o(x) = \int_{-\infty}^{\infty} f(x|x_m, \sigma_l) \cdot f_o(x_m) dx_m = \int_{-\infty}^{\infty} \frac{1}{\sigma_l} \phi\left(\frac{x - x_m}{\sigma_l}\right) \cdot f_o(x_m) dx_m \quad (23)$$

where $f(\cdot)$ is the prior probability density function of X .

In (Caspele et al. 2014) and (Caspele 2014), the influence of quality control of concrete on structural reliability has been assessed based on the procedure outlined above. It was shown that due to conformity control, a more uniform reliability is obtained in function of the incoming fraction defectives. Thus, conformity control reduces the dependency of the reliability index with respect to the parameter uncertainties of concrete strength distributions. In Figure 8a, the filter effect is illustrated for the reliability of a concrete column subjected to compression. Similar results were obtained in (Botte et al. 2017) in case of conformity control of reinforcing steel. The influence of the latter on the reliability of a concrete beam subjected to bending is shown in Figure 8b.

Figure 8. Influence of conformity control on the reliability index of a concrete (a) column subjected to compression and (b) beam subjected to bending: incoming and outgoing reliability indices β_i and β_o as a function of incoming fraction defectives θ_i and load ratio χ .

4 OUTLOOK

From the above overview it is clear that Bayesian updating techniques provide a unique tool for engineers in order to incorporate additional direct and indirect information about structures in all steps of the life-cycle assessment framework. Nevertheless, several challenges remain to be tackled the coming decades in order to bring these new developments into practical applications and convey the *Bayesian way of thinking* into everyday engineering practice.

At the research level, more efforts need to be undertaken to develop easy-to-use engineering tools that enable to disguise the often complex numerical and probabilistic calculations and simulations that are involved. There is an urgent need for the development of commercial FEM software for structural analysis that enables to incorporate localized information about the structure such as

measured concrete properties, monitoring data, durability parameters, etc. and automatically integrate this in a Bayesian calculation scheme enabling to make spatial predictions of the structural behaviour. Further, it is also necessary to orient research efforts to the quantification of suitable prior information in relation to measurement and model errors, as the current vague information that is available on this matter prevents more accurate posterior prediction of the structural behaviour. Especially in relation to degradation processes, research should step away from the intention of proposing generally applicable probabilistic models for the degradation process (which is very case specific) and orient towards updating degradation models along the lifetime of the structure.

At the level of practical applications, efforts should be oriented to develop a suitable assessment framework incorporating these Bayesian updating techniques. The optimization of investments in testing, monitoring and interventions is feasible with such techniques (see e.g. Vereecken et al. 2020) and should be more intensively exploited in order to come to cost-efficient, but adequate structural assessment and rehabilitation. There is an urgent need to step away from prescribing an extensive testing program without looking at the Value of Information (VoI) this data provides for the structural analysis to be performed. Frequently, investments in testing and monitoring can more adequately be spent if the VoI is properly considered, i.e. by quantifying the influence of the additional information on the posterior uncertainties and the associated decision making through a pre-posterior analysis (see e.g. Vereecken et al. 2021). Finally, in order to exploit the updating feasibilities during the lifetime, efforts and investments during the exploitation of the structures should be oriented to more frequent material testing rather than only making point-wise investigations and assessments in time. In this way, the Bayesian updating of the life-cycle performance becomes more effective and a more accurate estimation of the end of lifetime can be obtained.

5 CONCLUSIONS

Bayesian updating techniques have proven to be of undeniable importance when requiring to incorporate different sources of information into the assessment process of concrete structures. Although the last decennia significant progress has been made to analytically and numerically simulate the degradation process of concrete structures and their associated structural performance prediction in time, dealing with the large uncertainties involved requires the use of updating techniques that enable to incorporate direct and indirect information from inspection, testing and monitoring when these become available. Moreover, the combined integration of this information into the performance prediction proves to enable much more accurate predictions compared to the situation when this data is analysed separately. Also the need to step away from classical ad-hoc testing approaches and the formulation of testing and measurement campaigns considering the Value of Information is stressed. Further, it was also identified that several challenges still remain in relation to the development of such Bayesian updating methodologies, not least the quantification of suitable prior information as well as the values of model and measurement uncertainties to be considered. The integration of these approaches into the practical assessment process is however proven to be feasible and an outlook was presented on challenges to be tackled in the coming years in order to integrate such approaches further in commercial FEM software. As such, a more accessible and easy-to-use platform can be created in order to introduce the *Bayesian way of thinking* in all steps of the life-cycle assessment process of concrete structures.

ACKNOWLEDGEMENTS

The financial support from FWO-Flanders on the FWO SBO project lifeMACS “Multi-layer Bayesian life-cycle Methodology for the Assessment of Existing Concrete Structures” is highly appreciated (FWO-SBO project S001021N).

Safety assessment of civil infrastructure assets subjected to extreme events

M. Ghosn

The City College of New York, The City University of New York, New York, USA

ABSTRACT: Civil infrastructure systems are exposed to various types of human-made, environmental, and climatic hazards within their service lives. Reliability-based approaches and probabilistic risk-informed methods have long been used for assessing the safety of such systems and developing design standards and specifications to account for the random nature of these hazards, their intensities and rates of occurrence, and possible compounding effects. Specifically, current design standards provide reliability-calibrated design load maps and tables as well as load combination factors for use in engineering practice during a structure’s safety check process. These maps and associated procedures are based on historical data assuming that the underlying processes are unchanging over time where observed variations in the historical data are only random oscillations around underlying stationary statistical properties. However, ageing processes, growth in economic activities, and climate change are causing increases in the frequencies and intensities of human-made and environmental hazards, raising the risk to infrastructure systems and their users.

This presentation reviews the fundamental principles behind structural code developments and their underlying assumptions. It also examines analytical methods to assess the safety of structural systems accounting for the nonstationary nature of hazards. The presentation discusses approaches for adjusting current structural design specifications in view of anticipated climate change scenarios. A numerical example illustrates the application of these approaches during the safety assessment and the design of structural systems.

1 INTRODUCTION

The failure of civil infrastructure systems is associated with severe safety and financial consequences to their users, owners, and the surrounding community. For these reasons, the design and construction of structural systems must meet strict criteria stipulated in design codes and standards. As explained in NEHRP (2020), “structures designed according to modern codes are targeted to have low probabilities of collapse when extreme hazards occur while ensuring that construction costs remain within a level that does not discourage development. A critical function of code writing authorities is finding a proper balance between these conflicting considerations”.

Because assessing the potential for structural collapse is difficult, traditional structural design processes are mostly based on checking the safety of each individual member of a structural system for a single limit state or one failure mode at a time. However, structures are composed of many members, each of which may fail in a different mode and the reliability of the structural system is a function of the reliability of all its components. The target performance is set in design codes to minimize risk which provides a means to consider the performance of structural members or that of the system including the probability of structural failure, P_f , which is defined as the probability of exceeding a pre-defined limit state and the resulting consequences where in the most basic formulation, Risk is considered to be the product of the probability of failure and the consequences of failure (Ang and Tang, 2006):

$$\text{Risk} = P_f \times \text{consequence of failure} \quad (1)$$

It is most common to express the consequence of failure in terms of costs. These may include direct costs, such as the cost of replacing or repairing the structure and loss of life, as well as indirect and user costs including downtime, economic losses, environmental, societal, and political costs. The expression for risk, or the probability of loss due to damage caused by a single or multiple hazards, can be conceptually presented as:

$$Risk = P(loss) = \sum_H \sum_D \sum_{LS} P(loss|D)P(D|LS)P(LS|H)P(H) \quad (2)$$

where *loss* is any appropriate loss metric; $P(H)$ is the probability of occurrence of an input intensity level of a hazard within a structure's service period; $P(LS|H)$ is the conditional probability of exceeding a structural limit state, *LS*, given the hazard intensity, *H*; $P(D|LS)$ is the conditional probability of a damage state, *D*, given the exceedance of the structural limit state, *LS*; and $P(loss|D)$ is the conditional probability of a loss given the damage state, *D*.

The last two terms which express the probability of reaching a limit state define the probability of failure which itself can be conceptually presented as:

$$P_f = \sum_H P(LS|H)P(H) \quad (3)$$

For the probabilistic assessment of structural members, P_f gives the probability that capacity represented by strength capacity, *R*, is less than demand represented by the applied load effects, *S*, or the probability that the limit state function $Z=R-S$ is less than zero (Ang & Tang, 2006, Melchers & Beck, 2018):

$$P_f = \Pr(Z < 0) = \Pr(R < S) \quad (4)$$

where the load effect, *S*, is related to the maximum hazard intensity, H_T , that may occur within the service life, *T*, of the structure. The relationship between load effect and the maximum hazard can be represented through an Influence Function, $IF(\dots)$, such that $S=IF(H_T)$ represents the structural analysis process that converts hazard intensities into applied load effects such as bending moments, shearing forces, curvatures, or displacements.

Depending on methods of structural analysis and the ease of their implementation, it has been traditional to use different limit states for different applications. For example, for the analysis of most hazards, ASCE 7 (2021) and most structural design codes and standards require assessing the structural response of individual members such that the limit state function in Eqs. 3 & 4 represents the margin of safety between a member's resistance and applied load effect. On the other hand, seismic design may consider the probability of structural collapse allowing for nonlinear structural behavior and the associated redistribution of forces between components.

As expressed in Eq. (3), evaluating the probability of failure, whether failure is set in terms of member limit state or in terms of structural collapse, involves a three-step process: 1) establishing a hazard curve, which expresses the rates at which different amplitudes of a hazard are exceeded; 2) developing a fragility curve for the structure, each point of which represents the conditional probability of failure given that a certain amplitude of the hazard has occurred, $P(LS|H)$; and 3) Integrating the hazard and fragility curves to compute the unconditional probability of structural failure, P_f . The safety assessment process is based on evaluating the probability distribution of the maximum hazard intensity expected to occur within the base line service life of the structure. For example, for buildings the base line service life is usually set at 50 years while for bridges it is set at 75 years (ASCE, 2021; AASHTO, 2020).

Design codes specify load and resistance factors and magnitudes of hazards for use in the design process to ensure that structural members designed according to the specifications provide a minimum risk of failure related to a pre-set probability of failure or a target reliability index, β , defined as:

$$\beta = -\Phi^{-1}(P_f) \quad (5)$$

where $\Phi^{-1}(\dots)$ is the inverse of the cumulative normal probability distribution function.

For example, ASCE 7 sets the target probability of member failure for most buildings under gravity loads at $P_f=0.135\%$ in 50 years or at $\beta=3.0$. For other buildings categories, the target reliability index varies between $\beta=2.50$ to 3.50 . For bridges, the target reliability index is $\beta=3.5$ for a 75-year design period. These criteria were set based on extensive reliability analyses of previous generation of structural systems that demonstrated that the best performing structural systems provided this level of reliability in the respective base-line service lives (50-yr and 75-yr). By calibrating the target reliability to the successful performance of previous generation of structures, the target probability of failure in a service life reflects the risk level tolerated by society giving indirect consideration of cost, safety, and our ability to adequately characterize safety. Thus, the explicit calculation of risk is avoided.

While the reliability analysis in Eqs. 3 and 4 involves the probability distribution of the maximum expected hazard within the base line service life, H_T , the intensities of the design hazards are usually expressed in terms of return periods, T_R , also known as Mean Recurrence Intervals (MRI). The return periods are set in the codes for use during the calculation of the nominal resistance of structural members. These return periods are calibrated based on the annual probability of exceedance. In fact, recognizing the large uncertainties in estimating hazard intensities, scientists and engineers have represented yearly maximum hazards with cumulative probability distribution functions, $F_{H1}(\dots)$, using historic data on hazard frequencies and intensities. In many cases, Gumbel or Generalized Extreme Value (GEV) distribution functions have been adopted because they modeled the distributions of yearly maximum hazards quite well.

The cumulative distribution for the maximum hazard event in a period of time T depends on the number of loading events, N , that occur during this period of time. These events are designated as $H_1, H_2, \dots H_N$. The maximum of these N events, call it H_T , is represented by:

$$H_T = \max_{i=1}^N (H_i) \quad (6)$$

The probability that H_T is smaller than some value, h , implies that each of $H_1, H_2, \dots H_N$ is smaller than h . Assuming the events are statistically independent, the cumulative probability distribution of H_T , $F_{H_T}(\dots) = P(H_T < h)$ can be obtained from:

$$F_{H_T}(h) = F_{H_1}(h) \times F_{H_2}(h) \times \dots \times F_{H_N}(h) \quad (7)$$

If one assumes that the probability distributions of the annual maximum events are stationary represented by the same CDF so that $F_{H_1}(h) = F_{H_2}(h) = \dots = F_{H_N}(h)$, Eq. (7) reduces to:

$$F_{H_T}(h) = [F_{H_1}(h)]^N \quad (8)$$

While Eq. (7) is always valid assuming independence, Eq. (8) is only valid if in addition the CDF are identical, which implies that the process generating the hazard is stationary.

When the distribution $F_{H1}(h)$ is that of the maximum yearly event, the number of events, N , used in Eq. 8 is equal to the number of years in the structure service period and $N=T$. The calculation of the probability of failure and the reliability index can then proceed for different possible member resistances using Eqs. 4. The process is described as shown in Figure 1 where the maximum load effect increases assuming a stationary distribution of the load effects. The resistance that produces a reliability index equal to the target is subsequently used to calibrate a Load and Resistance Factor Design (LRFD) equation that takes the form:

$$\phi R_n = \sum \gamma_i S_{ni} \quad (9)$$

where R_n is the nominal member resistance, ϕ is the resistance factor, γ_i is the load factor for load i and S_{ni} is the nominal design load effect of hazard i where $S_{ni} = IF(H_n^*)_i$, with H_n^* being the design intensity of hazard i . The calibration of the load factors and H_n^* seek to ensure that Eq. 4 leads to reliability index values equal to the target for the entire applicable range of structure dimensions.

For environmental and climatic hazards, the design hazard intensity H_n^* are typically expressed in terms of the probability, $1/T_R$, that the design hazard is exceeded in any

Figure 1. Safety assessment process for stationary conditions.

Figure 2. Variation of probability distribution of hazards with service life.

given year, in which T_R is the return period or the Mean Recurrence Interval (MRI). Thus, the distribution of the yearly maximum value is used to determine the nominal value for a design hazard, H_n^* , such that:

$$H_n^* = F_{H_1}^{-1}\left(1 - \frac{1}{T_R}\right) \quad (10)$$

where $F_{H_1}^{-1}(\dots)$ is the inverse of the cumulative probability distribution function (CDF) of the yearly maximum hazard intensity, H_1 .

T_R in Eq. (10) may or may not coincide with the base line design life of the structure. If T_R is equal to the base line design life (e.g. 50 or 75-years), the live load factor γ_i is usually associated with a factor greater than 1.0 to ensure that Eq. (9) leads to designs that meet the target reliability index. In fact, Eqs. (10) and (8) indicate that if T_R is equal to the base line service life, the probability that the hazard will exceed the design hazard will be equal to 63.2% which would lead to an unacceptably high probability of failure unless a relatively high load factor is applied. For example, early versions of wind-resistant design standards specified 50-year design wind speed contour maps with a load factor equal to 1.6 for the design of ordinary building occupancies. Design standards that assign the same return period to define the amplitude of a nominal load without considering the probabilistic nature of other design variables are said to follow a *uniform hazard* approach.

More recently, it was determined that the presence of regional variations in the probability distributions of environmental and climatic hazards meant that the target reliability index was not uniformly achieved when the return period coincided with the base line design life. Instead, it was determined that using a live load factor $\gamma_i=1.0$ with high return periods led to more uniform reliability indices for the different regions in the US and the range of structural types. For example, McAllister et al. (2018) observed that achieving the target reliability levels $\beta = 2.5$, $\beta = 3.0$, $\beta = 3.25$ and $\beta = 3.5$ for the wind design of buildings as set in ASCE 7 (2021) would require respectively return periods of 300 years, 700, years, 1700 years and 3000 years for the four building categories whose member failure is not sudden and does not lead to wide-spread progression of damage. Table 1 summarizes the relationship between the target reliabilities and the return periods specified in ASCE 7 associated with a load factor equal to 1.0.

Table 1. Return periods for wind design load in ASCE-7 for members whose failure is not sudden and does not lead to wide-spread progression of damage.

Basis Period	Target reliability	Return period
50 years	$\beta = 2.50$	300 yrs
50 years	$\beta = 3.00$	700 yrs
50 years	$\beta = 3.25$	1700 yrs
50 years	$\beta = 3.50$	3000 yrs

2 APPLICATIONS TO CLIMATE CHANGE

As explained in Section 1 and illustrated in Figure 1, current structural design standards are based on the assumption that environmental and climatic hazards are stationary and that any observed oscillations in their intensities are natural random variations around stationary statistical parameters. Existing research indicates that due to climate change, the intensities of several types of climatic hazards will increase over time in various regions of the world. As a matter of fact, over the past few years, an international team of climate scientists, economists and energy systems modelers have built a range of “pathway” scenarios that examine how global society, demographics and economics might change over the current century. These scenarios, known as the “Shared Socioeconomic Pathways” (SSPs) are associated with future CO₂ and other global greenhouse gas emissions. Climate scientists are using these SSPs as inputs for developing climate models as described in the Intergovernmental Panel on Climate Change (IPCC, 2022).

Table 2. Shared Socio-economic Pathways, SSPs, and associated temperature changes, IPCC (2022).

SSP	Scenario	Estimated (2041–2060)	Estimated (2081–2100)	Very likely (2081–2100)
SSP1-1.9	very low GHG emissions: CO ₂ emissions cut to net zero around 2050	1.6 °C	1.4 °C	1.0 – 1.8
SSP1-2.6	low GHG emissions: CO ₂ emissions cut to net zero around 2075	1.7 °C	1.8 °C	1.3 – 2.4
SSP2-4.5	intermediate GHG emissions: CO ₂ emissions around current levels until 2050, then falling by 2100	2.0 °C	2.7 °C	2.1 – 3.5
SSP3-7.0	high GHG emissions: CO ₂ emissions double by 2100	2.1 °C	3.6 °C	2.8 – 4.6
SSP5-8.5	very high GHG emissions: CO ₂ emissions triple by 2075	2.4 °C	4.4 °C	3.3 – 5.7

Table 2 lists the five IPCC pathways and the corresponding temperature rise relative to pre-industrial times. As shown in Table 1, every SSP is also associated with a “Representative Concentration Pathway” (RCP) value that predicts how concentrations of CO₂ in the atmosphere will change in the future as a result of human activities. The numerical values of these RCPs (1.5, 2.6, 4.5, 7.0 and 8.5) refer to greenhouse gas emissions and concentrations and their combined radiative forcing in Watt/m² in the year 2100. Figures 3 and 4, extracted from the IPCC report, illustrate how the CO₂ concentrations are expected to change over the years and their respective global warming estimates by the year 2100 relative to 1986-2005 period. Although, the IPCC (2022) report did not give precise estimates of the likelihoods of the scenarios, it described the most severe scenario SSP5-8.5 as highly unlikely, SSP3-7.0 as unlikely, and SSP2-4.5 as likely. In addition to using these RCP’s to project future changes in temperature, they are used as bases for projecting future changes in the intensities of various climatic hazards such as precipitations, and wind which can be subsequently used to study the effect of future climate-related hazards, such as sea level rise, floods, wind storms and hurricanes, rain, snow and ice, on structures and infrastructure systems.

Global warming is expected to lead to significant changes in several hazards such as sea level rise, precipitation, hurricanes, storm surges and floods that inflict severe risk on society and civil infrastructure systems. Yet, current structural design codes and standards assume that past history is sufficient to describe future events and the data used to obtain the probability distributions of the relevant hazards for reliability assessment and design purposes as expressed in Eqs. (8) and (10) are based on historic data. The assumption is that any oscillations in observed extreme events are due to natural variations and that the past will represent the future. However, as schematically presented in Figure 5, global warming may be causing severe changes in both the expected maximum intensities of future events and the confidence

Figure 3. Atmospheric CO₂ concentrations by SSP across the 21st century (IPCC, 2022).

Figure 4. Projection of temperature change for RCP 2.6 and 8.5 scenarios (IPCC, 2022).

Figure 5. Schematic representation of non-stationary hazard intensity.

Figure 6. Observed differences in Jan. & July’s maximum and minimum wind speeds (Klink, 1999).

bounds in our estimates. The reduced confidence is not only due to the random nature of hazards but also to the limited ability of climate science to model future changes and the large uncertainties in predicting society’s response to the scientific community’s dire warnings about the need to reduce greenhouse gas emissions to reduce climate change trends.

Ongoing studies are providing information on expected changes in global climate and related hazard levels, as well as assessments of uncertainties associated with the projection of future climatic hazards. However, one should note that most climate science studies seek only to project typical trends in hazard intensities which would give the “average load effect” illustrated in the solid lines of Figure 4 rather than analyzing the trends in the extreme events which form the bases for structural design and safety assessment as explained earlier. As an example, Figure 6 extracted from the data by Klink (1999) illustrates how historic maximum and minimum monthly 1-minute wind speeds in different directions leading to practically no change in the mean wind speed in Albuquerque, New Mexico. Hence, as shown in Figure 1, providing trends on potential changes in the mean values of any hazard could be misleading when it comes to analyzing the ability of our infrastructure to sustain future extreme events. Therefore, much work is still needed to coordinate between what climate science reports are providing as compared to the needs of the structural engineering community.

If available, projections of changes in the extreme intensities of relevant hazards during the base line service life of structural systems, can be used to implement the same uniform risk concepts described in Section 1 for the safety assessment of structures and the adjustment of current design standards to account for the effect of changing climatic hazards.

3 ILLUSTRATIVE FLOOD WALL DESIGN EXAMPLE

A simple example is provided to illustrate how the analysis of climate hazard data, specifically riverine flooding, would be performed for the safety assessment of a flood wall to account for changes in flood intensities over time. As explained in Section 1, evaluating the safety of structures exposed to potential riverine floods requires a hazard assessment process that models the maximum intensity of the hazard over the service life of the structure accounting for future

changes in the hazard. This can be done using two approaches: 1) performing a direct study of historical changes of extreme floods at a given river location over time, modeling the correlation of these changes to other controlling factors such as CO₂ emissions, as well as changes in temperature and precipitations over time and performing a statistical projection of these factors to estimate future floods, or 2) modeling changes in the primary climate parameters such as temperature and precipitation and using these models to project their influence on flooding hazards at the specified location using a combined topographical/hydrological/hydraulic model. The first approach requires the availability of a long historical record at specific locations of all the pertinent climatic factors, the availability of future projections of the basic primary climate factors and assumes that the correlation between observed maximum floods and the primary factors will continue at the same historic trend. The second approach requires an integrated model that relates the intensity of the riverine floods to the underlying climate parameters (Xue et al., 2018).

Because at this stage future projections of floods are not readily available for either of the statistical or the integrated model, in this example we use historical data on hydraulic discharge rates collected for the Schoharie Creek USGS Station 01350000 at Prattsville, NY (Molodecka, et al. 2020) to describe how the safety assessment of a flood wall can be undertaken for cases where flooding hazards are changing over time.

The statistical analysis of the historic upward trend in the maximum yearly flood event shown in Figure 7 indicates that the maximum yearly discharge rate starting with the year 1908 can be modeled as a Gumbel distribution with a location parameter, u_t , and a scale parameter, β_t , both of which are observed to have increased over time. A statistical analysis shows that both u_t and β_t are linearly increasing over time, t , measured in years, such that:

$$u_t = 10,371 + 51.71 * t \quad (11)$$

$$\beta_t = 5,869 + 43.30 * t \quad (12)$$

where the discharge rate is in ft³/sec (1ft³/sec = 0.0283168 m³/s). The data plotted in Figure 7 show that the rate of change for the location parameter per year equals 0.50%/year and for the scale parameter it is 0.74%/yr.

Maximum hydraulic events used in design are usually represented by the flood having a return period $T_R=100$ years. If the Gumbel distribution is used in Eq. (10) for a return period $T_R=100$ years, using the statistics of the first year, the design flood would have a discharge rate equal to 37,332 ft³/sec (1,057 m³/sec). Table 3 compares the results obtained for the maximum 100-year discharge rate assuming stationary (Eq. 9) or nonstationary (Eq. 8) models based on the statistical models in Eqs. (11) and (12). The calculations show that the application of Eq. 8 would produce a probability distribution for the maximum 100-year flood that can be approximated by a Gumbel distribution. Thus, accounting for the increase in the flood discharge rates over the 100 years beginning in 1908 leads to an expected maximum discharge rate equal to 57,000 ft³/sec (1,614 m³/sec) with a coefficient of variation (COV) of 20.3%. This value is 40% higher than the one predicted assuming no change over the years as implied in Eq. (9).

The data plotted in Figure 7 indicate that the calculated expected maximum 100-year discharge rate covers all the actual measured peaks in the 100-year period starting in 1908 except for the data from the 2011 Hurricane Irene when the discharge rate is almost six standard deviations above the mean, presenting an anomaly to the statistical trends observed over the period of data collection. It has been observed that the high discharge rate was due to the combination of heavy precipitations from another storm that coincided with Irene. Table 3 also shows that even under stationary assumptions, the flood with 100-yr return period for this river data would underestimate the mean value of the maximum 100-year flood by about 9%. As shown in the last two rows of the table, using the end year's data to conservatively develop design standards to account for climate change, as some researchers have advocated, would lead to over-conservative designs. Alternatively, using the average yearly statistics would underestimate the maximum flood rate by about 5%.

Figure 7. Analysis of historical trends for Schoharie Creek peak streamflow (a) with and (b) without the effect of hurricane Irene. (Molodecka, et al. 2020).

The effects of riverine floods on structures are related to: 1) flood depth, 2) flood velocity, 3) structural exposure, and 4) type and depth of their foundations. Good estimates of flood depth and velocity are obtained based on flood discharge rate data as well as the topographical profile of the river and flooded zone and the type of soils in the vicinity of the structure using computationally intensive or sometimes simplified hydraulic models (Xue et al.; 2018; Ghosn, et al. 2003). As an example, the discharge rate, Q , at a cross-section of a river is computed by dividing the cross-section into “ n ” elements (Genc et al., 2015):

$$Q = \sum_{i=1}^n U_i d_i \Delta w_i \quad (13)$$

where U_i , d_i and Δw_i are the mean velocity, mean flood depth and width in cross sectional element, i , respectively. The flow velocity can be estimated from Manning’s equation:

$$U_i = \frac{R_i^{2/3} S_i^{2/3}}{n_i} \quad (14)$$

where $R_i = A_i/P_i$ is the hydraulic radius of section i of the channel with A_i being the cross section area, and P_i the wetted perimeter; S_i is the friction slope, which is equal to the bed slope for a steady uniform flow; n_i is Manning’s coefficient.

Given a value for Q , the solution of Eqs. (13) and (14) leads to the determination of the flood depth and velocity in each flooded sub-area of width Δw_i . As shown in Figure 8, the flood depths and velocities are used to study hydraulic effects of a flood on a structure which are of two types: 1) hydraulic forces on structural components and foundations, and 2) foundation scour. (Lagasse et al., 2013).

Flood water pressure at each point of a submerged structural component is due to hydrostatic and hydrodynamic effects, such that:

$$p = \rho g z + \frac{1}{2} \rho a U^2 \quad (15)$$

where ρ is the density of water, g is the gravity, z is the depth below the water surface at the point where the pressure is evaluated, U is the average water velocity and a is a drag coefficient or shape factor.

The structure may also be subject to impact forces from debris carried by a flooded river. However, the difficulty of determining the type of debris being carried may require the consideration of various site-specific scenarios. A more complex situation arises when openings between different structural elements (or different structures) are obstructed by large size debris causing a blockage of water flow which can itself collect smaller debris resulting in a debris jam. The blockage adds to the forces applied on the structural elements at contact debris-structure areas.

Table 3. Comparison of projected 100-year maximum flood rates for stationary and nonstationary cases.

Case	Yearly Dist., Location ft ³ /sec	Yearly Dist., Scale ft ³ /sec	Yearly Mean ft ³ /sec	Yearly Standard dev. ft ³ /sec	Mean of 100-yr max. ft ³ /sec	Std. dev of 100-yr max. ft ³ /sec	COV of 100-yr max.	100 yr return Q _r , ft ³ /sec
Stationary with stats. from year 1908	10,371	5,869	13,754	7,517	40,745	7,517	18.4%	37,332
Stationary with average stats. 1908-2007	12,938	7,808	17,560	10,271	54,438	10,271	18.9%	49,775
Stationary w stats. from year 2007	15,505	10,155	21,366	13,024	68,130	13,024	19.1%	62,218
Nonstationary					57,000	11,548	20.3%	

NB: 1,000 ft³/sec = 28.32 m³/sec

Ignoring the effects of debris related forces, a simple free body diagram of a submerged structural component may be represented as shown in Figure 8 where d_w is the water depth. The structure may fail due to bending or shearing forces or due to general equilibrium instability, or from foundation scour.

In this simplified example, we demonstrate the analysis of the effect of the static water pressure on a hypothetical reinforced concrete flood wall that is built in the flood plain of the Schoharie River at Prattsville, NY in the vicinity of the site where the data of Eq. (11) and (12) were collected. The schematics of the flooded area and the protective flood wall are shown in Figure 9.

The hydraulic static force and the corresponding moment at the base of the flood wall per unit wall width will be respectively equal to $F = \rho g d_w^2 / 2$ and $M = \rho g d_w^3 / 6$ where d_w is the height of the water level in the flood plain. According to the USGS web site, <https://fim.wim.usgs.gov/fim/>, the implementation of Eqs. (11) and (12) with the site specific values of river channel dimensions, bed slope, and Manning coefficient lead to a rating curve that can be approximated by the following relationship between the total flood depth, d , in feet and the discharge rate Q in ft³/sec:

$$d = 12\text{ft} + d_w = 0.66 Q^{0.31} \quad (16)$$

where 12 ft is the overtopping water depth in the channel.

The design and safety assessment of the flood wall must consider various failure modes including shear and bending moment failures, sliding and overturning, foundation failures, etc. In this example, we demonstrate the design and reliability analysis for bending moment at the base of the concrete flood wall. The required moment capacity per unit wall width is obtained as:

$$0.9 M_{cap} > 1.6 \rho g d_w^3 / 6 \quad (17)$$

where $\phi = 0.9$ is the resistance factor and $\gamma_w = 1.6$ is the load factor. As shown in Table 3, assuming that the engineer ignores the effects of climate change, the design flood corresponding to a 100-year return period is obtained as $Q_{design} = 37,332$ ft³/sec, leading to water depth at the wall level equal to 5.25 ft. Using the specific weight for water equal to 62.4 lb/ft³, the required moment capacity per unit width is obtained as $M_{cap} = 2.675$ kip-ft/ft.

Figure 8. Free Body diagram of a submerged simple structure.

Table 3 shows that a yearly maximum discharge rate $Q_f=13,754 \text{ ft}^3/\text{sec}$ yields a 100-year maximum discharge rate $Q_{100}=40,745 \text{ ft}^3/\text{sec}$ with a standard deviation= $7,517 \text{ ft}^3/\text{sec}$. This yields a mean value for $d_w= 5.67 \text{ ft}$ and a COV= 17% . Given a bias equal to 1.14 and a COV= 13% for the bending strength of reinforced concrete members, the probability of failure for a wall built to meet the $M_{cap}=2.675 \text{ kip-ft/ft}$ is equal to $P_f=16.3\%$ or a reliability index $\beta = 0.98$. This low reliability index associated with a design discharge rate obtained for a 100-year return period that has a probability of occurrence equal to 63.2% is a reflection of the cubic power for the depth in Eq. (14) indicating that a live load factor of 1.6 is not adequate even without considering climate change.

As shown in Table 3, accounting for climate change, the 100-year maximum discharge rate has a mean $Q_{100}=57,000 \text{ ft}^3/\text{sec}$ with a standard deviation= $11,548 \text{ ft}^3/\text{sec}$. The probability of failure for a wall built to meet the $M_{cap}=2.675 \text{ kip-ft/ft}$ obtained for the stationary case is equal to $P_f=78.2\%$ or a reliability index $\beta = -0.78$. Raising the reliability index to $\beta = 0.98$ obtained for the stationary assumption will require a design moment capacity $M_{cap} = 6.20 \text{ kip-ft/ft}$ which is associated with a design depth $d_w=6.95 \text{ ft}$ or a design discharge rate $Q_{design} = 50,945 \text{ ft}^3/\text{sec}$. This design discharge corresponds to a probability of exceedance in a 100-yr period equal to 66.7% . If one uses the probability of exceedance of 63.2% to define the design discharge rate, then Q_{design} would have been $51,805 \text{ ft}^3/\text{sec}$ which is less than 2% more conservative than what is required to give the same reliability index as that obtained when the river is not exposed to climate change. The 63.2% probability of exceedance is equivalent to the probability obtained if the process were stationary and where the design load is obtained from the hazard having a return period $T_R=100$ years.

Figure 9. Schematic representation of river cross section and floodwall free body diagram.

4 IMPLICATION FOR DEVELOPMENT OF DESIGN STANDARDS

The theoretical review presented in Sections 1 and 2 about the process of developing structural design standards and specifications and how the effect of climate change can be accounted for during the development of the next generation of standards along with the simple illustrative example presented in Section 3, present important observations worthy of consideration.

4.1 *Inapplicability of return periods*

Current standards for the design of bridges, buildings and other structures specify design load intensities for climatic hazards (e.g. temperature, snow, wind, floods) based on return periods presented in maps or tables that account for pertinent regional differences. The design load S_{ni}^* for return period, T_R , has a probability of being exceeded in any one year equal to $1/T_R$ (e.g. = $1/50$) but has 63.2% probability of exceedance in T_R years. The high probability of exceedance necessitates the application of load factors or else the use of return periods significantly higher than the base line service life that would lead to much lower probabilities of exceedance (e.g. 700 years for a 5-year base line service life) so that the design of structures for wind loads achieve a target reliability index $\beta = 3.0$. However, the concept of using return periods imply that the hazards are stationary and that their statistical parameters do not change over time and that their probability density functions over the years are well represented by that of a single year. Hence, in view of climate change, the concept of using return periods to define design loads is no longer applicable. Instead, codes and standards should calibrate design loads based on the probability of occurrence of a maximum hazard in the specified base line service life.

4.2 *Alternative approaches for defining hazard maps*

Given the inapplicability of specifying return periods for design hazards when the hazards are not stationary, it is recommended that design standards develop hazard contour maps based on the target reliability and base line service period. For example, instead of providing wind maps for 300 years, 700, years, 1700 years and 3000 years return periods, the maps should provide contours of hazard intensities that achieve specified target reliabilities in base line service periods. Specifically, code writers could develop load hazard maps in terms of a target reliability index and design period basis rather than in terms of specific return periods and label these maps accordingly (e.g. $\beta = 2.5$ in 50-years, $\beta = 3.0$ in 50-years, $\beta = 3.25$ in 50-years and $\beta = 3.5$ in 50-years).

In the meantime and until such design hazard maps are developed, the numerical example presented in this paper as well as others presented by Ghosn & Ellingwood (2022) demonstrate that engineers can adjust a design performed using existing standards and design hazard by simply scaling up the required design capacity in the inverse ratio of the design load calculated using current hazard maps to the a load value obtained from a hazard that has an intensity with the same implied probability of exceedance within the specified base line service life. Eq. (7) in this paper provides an approach to find this hazard intensity. Of course, this would require the availability of projections describing how the maximum hazard intensities would be changing over the specified base line service life, which for many hazards may not yet be available. In fact, due to computer limitations and other factors, climate scientists have been traditionally projecting average trends rather than extreme events.

It is also observed that using the hazard data from the most conservative year as the basis for defining the design intensity as many researchers have recently proposed would lead to very conservative designs which may lead to unjustifiable high costs for rehabilitating existing structures or designing new structures. Such tendencies to be over-conservative are likely be rejected by developers and infrastructure owners because of the implied additional costs. More importantly, an excessive over-conservatism could lead to the rejection of any future consideration of the problem.

5 CONCLUSIONS

This paper reviewed how the safety and reliability of structures exposed to climatic hazards that may be changing due to global warming should be analyzed to maintain a uniform and consistent levels of risk and reliability. The concepts are applied in a numerical example demonstrating the safety analysis of a wall designed to protect from riverine floods. The example illustrates how a structure's safety may be affected by increases in river discharge rates over time. The simple example demonstrates that maintaining the same target reliability level set in

current design standards would require a major change in the specified design flood loads. For the particular case analyzed, it appears that using a design flood that achieves the same probability of exceedance within the specified base line service life of the structure as that obtained from current standards if climate change effects are ignored, would lead to reliability levels similar to those currently specified. Specifically, if one uses for design flood the discharge rate that has 63.2% probability of exceedance within a 100-year period accounting for climate change, the reliability index would be similar to the one obtained by using in design the flood corresponding to a 100-year return period assuming stationary flood discharge rates. This situation appears to be valid as long as the COV of the maximum design-life-flood under climate change remains reasonably close to the COV for the stationary condition. Additional work is needed to verify the validity of this observation for various limit states and conditions.

Digital transition in asset management of bridges – Advantages and challenges

J. Sandager Jensen

COWI A/S, Kongens Lyngby, Denmark

ABSTRACT: Operation and Maintenance (O&M) of bridges are undergoing a digital transformation, and with better technical and more cost-beneficial equipment (drones, sensors, software, etc.), the digital transition accommodates environmental, economic, and technical benefits. Today, most inspections of civil structures are done on-site challenged by traffic restrictions, difficult access- and working conditions, and high initial costs (lift, rope access, etc.). With high-quality RGB - and thermal imagery captured by drones etc., a Reality Model or a visual Digital Twin of the structure may be created, and a Virtual Inspection can be carried out revisiting the structure when needed. The thermal imagery is used in combination with the RGB photo to detect hidden defects in the structure such as delaminations, honeycombing and water ingress. In asset management, the key interest is to find the optimal point in time to repair or replace structural elements considering the Key Performance Indicators (KPIs) that are important to the asset manager or operator. Combining the Reality Model with Artificial Intelligence (AI) for damage detection and monitoring data from implemented sensors on a web-based platform might be the solution to find the optimal point in time for repair, increase the level of safety (for bridge users and O&M personnel), and minimize traffic disturbance. Working with a Reality Model may also decrease the level of subjectivity and increase the level of transparency in decision-making as well as provide efficient means of communication. Despite the many advantages, some challenges remain. They are related to e.g., the reality capture process, AI training, data processing, -presentation, and -integration (also with data-enriched 3D BIM models for recent bridges) in current asset management systems.

1 INTRODUCTION

In general, there has been a great focus on the Operation and Maintenance (O&M) of bridges the recent years originating from e.g., bridge collapses, environmental advancement; ‘repair instead of replacing’, and the attention to service life and Life Cycle Cost of structures and materials.

Asset managers of bridges perform or outsource visual inspections of bridges. The traditional inspections are challenged by e.g., traffic restrictions, high initial costs (rope access, platform, lift, etc.), subjectivity and consistency in documentation (Moore et al., 2001), and access - and working conditions. The inspections are usually reported using condition rating, which is a somewhat ‘weak’ measure loosely correlated to safety and serviceability (COST TU1406, 2018).

The construction sector’s digital maturity was reported as very low back in 2016 (McKinsey 2016). When compared to other industries there seems to be great potential in terms of both technical and economic benefits of the digital transition in the construction sector, and O&M is no exception.

The use of Unmanned Aerial Vehicles (UAVs) has accelerated in the construction sector the recent years, and with high-quality sensors (e.g., thermos cameras) and improved software, it is possible to establish detailed 3D Reality Capture Models and carry out a Virtual Inspection. RGB photogrammetry is used with Artificial Intelligence (AI) to detect visual defects e.g., cracks, spalling, corrosion, etc. (Avendaño et al., 2022) and thermal imagery is used to detect hidden defects e.g., delamination, repairs, and water ingress. UAV-based photogrammetry

has proven safe, cost –, and technically efficient on multiple bridge projects with the use of both RGB – and thermal imagery (Linneberg et. al. 2022).

The digital transition and market within asset management is rapidly improving, and this paper provides a review of three case studies the last five years and a look at the prospects within virtual inspections and the digitalization of O&M.

2 ASSET MANAGEMENT OF BRIDGES

In Denmark, bridge managers are obligated to perform principal inspections every sixth year. The inspections are mostly outsourced to consultancy companies performing a visual inspection of the bridge which is cost-effective when performed by qualified personnel. The inspectors should be able to acknowledge when to upgrade the principal visual inspection to a special inspection to detect non-visible defects, perform load capacity assessment, proof-loading, etc.

The observations from the principal inspections are translated into a condition rate for each structural element class (intermediate piers, abutment, pavement, bearings, etc.) by following a manual and are documented in a report including selected photos. The inspector also provides a timing and cost estimates of needed repair or replacement works. The asset manager plans for future repair work based on this principal inspection report.

The condition rating is a somewhat “weak” measure loosely correlated to safety and serviceability, and ref. (COST TU1406, 2018, Linneberg, 2020) proposes a transition from condition to performance assessment using one or several Key Performance Indicators (KPIs). For the asset manager, the key interest is to find the ‘optimal point in time’ for the repair and replacement work of structural elements considering a range of KPIs. The COST TU1406 project (COST TU1406, 2018) has defined a set of orthogonal (non-overlapping) KPIs relevant for bridge management considering the service life of the bridge:

Reliability (fit for purpose or probability of structural failure, operational failure, or any other failure mode), *Availability* (proportion of time the system is in a functioning condition), *Safety* (minimizing or eliminating the harm to people, i.e. loss of life and limb and not structural failure), *Economy* (minimizing the long-term costs of maintenance activities), and *Environment* (sustainability, minimizing the harm to the environment) (Linneberg et al., 2022).

The KPIs can be translated into monetary units to set up different maintenance scenarios with adjacent long-term costs to find the ‘optimal point in time’ being the lowest long-term cost (Linneberg et al., 2022). Considering the monetary units, the ‘optimal point in time’ could be identified using a risk-based analysis, ranking different maintenance scenarios considering likelihood and monetized consequences.

Many portfolios Bridge Management Systems (BMS) cannot accommodate the integration of Structural Health Monitoring Systems (SHMS), load situations, and defect modelling in 3D which is key input to the decision-making considering multiple KPIs. Such improvement of the current portfolio BMS incl. full integration of a risk-based management system considering multiple maintenance scenarios (and KPIs) is technically challenging and costly. Therefore, the digital transition is only improved gradually.

3 REALITY CAPTURE MODELS AND VIRTUAL INSPECTIONS

3.1 Introduction

One of the important first steps towards the digital transition within bridge management is to establish a Reality Capture Model or Virtual Twin. The model is created from photogrammetrically processed images efficiently collected using camera-mounted UAVs. Establishing a detailed 3D mesh model which in combination with high-quality RGB – and thermal images creates the Reality Capture Model used for visual (virtual) inspections.

It requires domain knowledge within reality capture (data collection, flight plans, light conditions, data processing, etc.) and within bridge condition assessment (vulnerable zones,

damage mechanisms, resolution needed for defect finding, etc.) to establish a detailed 3D model suitable for visual (virtual) inspections.

3.2 *Workflow of virtual inspections*

When the Reality Capture Model is established, it is imported into COWI Virtual Inspection or similar commercial software. Artificial Intelligence (AI) is applied to detect common defects and damages e.g., cracks, corrosion, spalling, graffiti etc. The damages are then reviewed by an experienced engineer to sort the damages. The AI models are in general trained with the mindset, that false positives are accepted (they are sorted out later during the manual visual inspection), but a false negative of a given size or in vulnerable regions (e.g., shear cracks in bridge half joints) is not accepted. In addition, it is important to use AI models that are trained for similar damage types and image resolution.

The manual visual (virtual) inspection is then carried out, and all significant damages are registered and annotated directly in the model. The thermal imagery is used as a supplement to the RGB photos and can identify areas with temperature changes at the surface of the concrete e.g., delamination, certain cracks and joints, concrete repair, and water ingress which may not be visible on RGB photos.

Some of the benefits of having a Reality Capture Model are that it can have multiple viewers, several specialists can be consulted during the inspection process, the structure can be revisited when needed, and all the annotated damages and defects can be reported to the asset manager within the model and as conventional reports summarizing finding.

The asset manager is provided with a 3D Reality Capture Model with annotated damages and defects. The model may be used to plan future repairs and replacements of structural elements, for daily operation, and assist contractors before repairs and replacements.

3.3 *Introduction to case studies*

Three case studies from Denmark emphasize the development within use and integration of UAVs and Reality Capture Models from 2018 to 2022. The New Little Belt Bridge project consists of a UAV-based Reality Capture Model and handheld thermographic screening of the concrete approach spans. The Faroe Bridges project consists of several UAV flights to establish a Reality Capture Model of both bridges, RGB photogrammetry of concrete emergency walkways and both RGB – and thermal imagery of all concrete piers.

In the pilot project of the Queen Alexandrines Bridge, UAVs captured RGB photogrammetry and thermal imagery in one flight, and a complete virtual inspection is completed on the Reality Capture Model in COWI Virtual Inspection software.

In only five years the process is improved, and the Reality Capture Models become easier to establish due to high-quality sensors. The use of UAV for inspection purposes maximize availability and reduce the time on-site, especially when access is difficult e.g., bridges across water or deep valleys.

3.4 *The New Little Belt Bridge*

The New Little Belt Bridge connects Funen and Jutland in Denmark. The bridge opened to traffic in 1970 and is built as a six-lane highway connection with a total length of 1,700 m, and with a main span of 600 m between the two pylons and with a clearance from the sea of 44 m (Linneberg et al., 2022).

The bridge is owned and operated by the Danish Road Directorate. COWI A/S has provided consultancy services related to the operation and maintenance of the bridge. The New Little Belt bridge is shown in Figure 1. In 2018, the Danish Road Directorate commissioned COWI A/S to perform a safety inspection of selected concrete approach spans. The key concern was delamination of the superstructure to recreation-al areas below the bridge in relation to public safety. A Reality Capture Model was established using UAV-based RGB photogrammetry and is shown in Figure 2.

Figure 1. The New Little Belt Bridge.

Figure 2. Reality capture of approach spans at the New Little Belt Bridge.

Figure 3. Potential areas with delaminated concrete (thermography at 10 m distance).

Figure 4. Delaminated concrete removed.

The second investigation comprised a handheld thermographic screening from 2--10 m distance from the concrete surface to find delaminated areas. The areas with delaminations were confirmed and removed by contractors from an under-bridge inspection gantry. An example of an identified area is shown in thermography Figure 3, and the removed concrete from same identified area is shown in Figure 4. Defects that were not captured during the visual inspection were also identified.

3.5 *The Faroe Bridges*

The Faroe Bridges connect Falster and Zealand across the Faroe Island in Denmark. The bridges opened to traffic in 1985 and is carrying four lanes of highway traffic. The connection consists of a cable stayed bridge in South from Falster to Faroe with a length of 1,726 m and a main span of 290 m with a clearance from the sea of 26 m and a concrete beam bridge (orthotropic steel box girder) in North from Faroe to Zealand with a total length of 1,596 m and a clearance from the sea of 20 m (Linneberg et al. 2022).

The bridge is owned and operated by the Danish Road Directorate. COWI A/S has provided consultancy services related to the operation and maintenance of the bridge. The Cable stayed bridge is shown in Figure 5. In 2020, the Danish Road Directorate commissioned COWI A/S to establish a Reality Capture Model of both bridges to be used for operation in general and for presentation of principal inspection of concrete emergency walkways (more than 6.5 km) and bridge piers (34 in total).

In total four UAV flights were performed: The first flight established reference points. The second flight established RGB photogrammetry for the whole model. The third flight established close-up photos of emergency walkways. The fourth flight established close-up photos incl. thermal imagery of all bridge piers.

The Reality Capture Model was imported into COWI Virtual Inspection software, and a visual inspection is carried out using both RGB – and thermal imagery. Examples of two areas with defects are identified in RGB – and thermal imagery in Figures 6 and 7. After a virtual visual inspection, an inspection of six bridge piers using rope access were carried out.

The inspectors found the same significant defect (delaminated areas of similar size) as the virtual inspection alongside minor defects as cracking and poor in-situ grouting of voids from the removal of scaffolding. In addition, the virtual inspection identified few defects in the splash zones not accessible to rope access.

Figure 5. The Faroe Bridges (Cable Stayed Bridge in South).

3.6 *The Queen Alexandrines Bridge*

The Queen Alexandrines Bridge, also known as the Moen Bridge, connects Zealand with Moen in Denmark. The bridge opened to traffic in 1943 and is carrying two lanes of traffic and two pedestrian walkways with a total length of 745,5 m, and a main span of 127,5 m with a clearance from the sea of 26 m (The Danish Road Directorate, 2022). The construction is an open arch bridge with five approach spans cast in reinforced concrete on each side of the main arch span constructed in steel.

Figure 6. Potential areas with delaminated concrete (verified by rope-access personnel).

Figure 7. Potential areas with delaminated concrete - captured using thermography.

The bridge is owned and operated by the Danish Road Directorate. COWI A/S has provided consultancy services related to the operation and maintenance of the bridge. The Queen Alexandrines Bridge is shown in Figure 8. In 2022, the Danish Road Directorate commissioned COWI A/S to establish a reality capture model of one approach span and integrate the model in COWI Virtual Inspection as part of a pilot project for visual inspections.

The Reality Capture Model of the bridge is based on both RGB – and thermal imagery captured simultaneously with the use of a drone without any traffic restrictions.

The Reality Capture Model is imported into COWI Virtual Inspection, and a principal inspection is carried out using annotations in the model to illustrate visible damages e.g., cracks, spalling, organic growth, graffiti, etc. The annotations are directly linked to the specific area of the model and are easy to revisit to e.g., consult or verify with a specialist.

Thermal imagery identifies areas with possible delamination that have a temperature difference down to 0.1-0.2 degrees Celsius compared to the surrounding structure. Three identified areas are shown in the RGB photo in Figure 9 and thermography in Figure 10. Two areas located in the bottom of the concrete arch show concrete repair works, and another area close to the granite parament show delamination on the thermal imagery. The identified areas were subsequently verified by contractors with a hammer test and repaired as part of a larger maintenance project on the pile caps in 2022 and 2023.

The Danish Road Directorate can access the model and hereby get full documentation of the bridge related to the principal inspection. A screen dump from the COWI Virtual Inspection software is shown in Figure 11.

The Reality Model may also be used to e.g., annotate daily operation jobs for operation personnel, plan future repair works, etc. The model creates a solid foundation for collaboration with all stakeholders incl. owners, contractors, and consultants without being present at the bridge site and without possible traffic restrictions.

Figure 8. The Queen Alexandrines Bridge.

Figure 9. RGB photo of potential delaminated areas on concrete bridge pier.

Figure 10. Thermography of potential delaminated areas on concrete bridge pier.

4 ADVANTAGES AND CHALLENGES

4.1 *Virtual inspections*

Working with virtual inspections proposes many advantages related to the reality capture process, the inspection itself, and future use of the Reality Capture Model. Using UAVs leads to reduced traffic disturbance and a short time on site which overall reduce the initial cost e.g., truck mounted under bridge inspection units, rope access, lifts, etc. for visual inspections.

Figure 11. Screen dump of one approach span in COWI Virtual Inspection software.

The COWI Virtual Inspection platform allows multiple specialists to take part in the visual inspection leading to transparency in decision-making and less subjectivity. The bridge is inspected with well-rested personnel, and it is possible to revisit structural elements to look for repetition patterns in defects. The asset manager is provided with full photo-realistic 3D documentation of the bridge and with a Reality Capture Model providing an efficient means of communication with various stakeholders incl. operational personnel.

Though many advantages have been pointed out, some challenges remain: The data collecting process still requires highly trained personnel to establish a detailed photo-realistic 3D model and depends on the quality of sensors (cameras etc.), traffic laws, and restrictions when flying with UAVs, flight plans, lighting conditions, weather, and temperature (when using thermal imagery).

The implementation of the Reality Capture Model in ‘codified’ procedures and manuals, and in current BMS software remains one of the greater challenges.

4.2 Future perspectives

Companies specialized in asset management have acknowledged the great potential for digitalization within Operation and Maintenance (O&M), and UAVs, AI models, and Bridge Management systems are rapidly improving.

When delivering a new bridge, BIM models can be handed over as part of the As-built information if specified by contract requirements. At the same time, a ‘Birth Certificate’ of the bridge (incl. a Reality Capture Model) should be established and linked to the BIM model. This model ‘environment’ may later be supplemented with information from O&M incl. sensor data in a complete asset management system to predict repairs and replacements of structures.

Furthermore, new types of drones that can “bump” into obstacles when capturing images and thereby get close to full coverage of the bridge structure including e.g., tight spaced areas, hangers, and bearings has been developed. UAV’s can fly autonomously, and soon AI-assisted flying will be implemented e.g., a drone being a part of the daily operations and inspections fully integrated into the asset management system and updating the adjacent Reality Capture Model.

5 CONCLUSIONS

Operation and Maintenance (O&M) of bridges are undergoing a digital transformation, and with better technical and more cost-beneficial equipment (drones, sensors, software, etc.), the digital transition accommodates environmental, economic, and technical benefits.

Combining the newest UAV technology (incl. carry-on equipment) and trained AI-based models with the knowledge of experienced engineers is one of the keys to success toward a digital transition of bridge inspections and their relation to bridge management.

Data processing requires domain knowledge to establish a detailed Reality Capture Model suitable for visual virtual inspections. Digitalization in general comes with a cost and requires certain competences within an organization to be a part of the digital transition.

With improved sensors, software, and autonomously UAVs, the data collection -and integration process becomes less time consuming and more cost beneficial. Virtual inspections performed on Reality Capture Models delivers less subjectivity and full 3D documentation in an improved workflow with full transparency. In addition, UAV-based inspections increase bridge availability, increase safety for bridge users and workers – with less environmental impacts from emissions.

The workflow of Virtual Inspections is tested and improved over three bridges presented in this paper with both RGB and thermal imagery to detect visual and certain non-visual (hidden) defects. It is important to calibrate virtual inspection results with manual hands-on inspections.

The integration of the Reality Capture Model within the principal inspection regime improves workflow and supports finding the ‘optimal point in time’ to repair and replace structural elements considering multiple Key Performance Indicators for bridge owners and operators.

ACKNOWLEDGEMENTS

A huge thanks to the Danish Road Directorate, for allowing us to work with the three bridges presented in this paper. We look forward to future collaboration when expanding the pilot project on the Queen Alexandrines Bridge to include a full virtual principal inspection of the bridge in 2023.

Life-cycle sea-crossing bridge operation under strong winds in severe weather

Ho-Kyung Kim & Hyeong-Yun Cheon
Seoul National University, Republic of Korea

Sejin Kim
University of Michigan, USA

ABSTRACT: This study addresses the challenge of maintaining the stability of running vehicles on sea-crossing bridges in the presence of strong side winds. To ensure safety, bridge operators often limit speed or close bridges when wind speeds reach predetermined criteria. However, critical wind speeds vary from bridge to bridge due to influential factors such as geometrical shape and road surface conditions. This study proposes a framework to determine critical wind speeds, considering rain or icing road conditions during severe weather. The study also reports on two overturning accidents on double-deck suspension and cable-stayed bridges and extends the procedure to probabilistic risk assessment for the bridge's lifetime. The results provide guidelines for bridge operators to balance driving safety and mobility in hazardous weather conditions.

1 INTRODUCTION

The Korean peninsula is frequently affected by typhoons, and the over 90 cable-supported sea-crossing bridges in the region are often subjected to strong side winds. While most bridges are closed at wind speeds above 25 m/s on a 10-minute average, speed control protocols vary based on bridge-specific experiences or benchmarks. However, bridge operators face challenges in taking timely actions, such as bridge closure, due to the need for advanced discussion with the police department and site preparation, coupled with unpredictable fluctuations in wind speed (Lim et al. 2022). Additionally, vehicle speed control or bridge closure protocols may not be relevant for specific bridges (Kim et al. 2022a, b, Kim et al. 2021, Kim et al. 2020, Kim et al. 2016).

This paper presents two case studies of bridges, a suspension bridge (GAB) and a cable-stayed bridge (SHB), which experienced rollover accidents in almost the same locations. The study applied a risk assessment procedure to determine the root cause of the accidents and compared potential measures to mitigate the risk index.

The study emphasizes that a comprehensive vulnerability assessment of driving safety on sea-crossing bridges must consider several factors, including bridge geometry, wind and traffic data, and road surface conditions during severe weather, throughout the life cycle of the bridge. The results of the study highlight the importance of such assessments in ensuring the safety of vehicles on cable-supported bridges during strong side winds and can provide guidance for bridge operators in developing effective strategies for managing the safety of sea-crossing bridges considering different road surface conditions.

2 EXAMINED BRIDGES

2.1 GAB – a double-deck suspension bridge

Figure 1 provides an overview of GAB, including its main span and approach spans. Notably, the lower deck at the approaching spans, marked in Figure 1(a), was the exact location of

consecutive rollover accidents that occurred in 2012, with only an hour interval between them. After identifying the corner points along the approaching spans as vulnerable spots, a risk assessment framework needs to be employed to determine the root cause of the consecutive roll-over accidents that occurred at this location.

Figure 1. GAB (a) bridge overview (b) A roll-over accident (c) Another roll-over accident.

2.2 SHB – a cable-stayed bridge with approach spans with a transition region

Figure 2(a) provides an overview of the SHB, including its main and approach spans, while Figure 2(b) shows a sudden change in deck width at the transition region. A rollover accident occurred in 2012 at this location, as illustrated in Figure 2(c). CCTV footage revealed that all vehicles hesitated to cross the transition spots and the overturned truck had come to a stop just before the accident. These observations suggest that the transition region was indeed vulnerable to accelerated wind conditions.

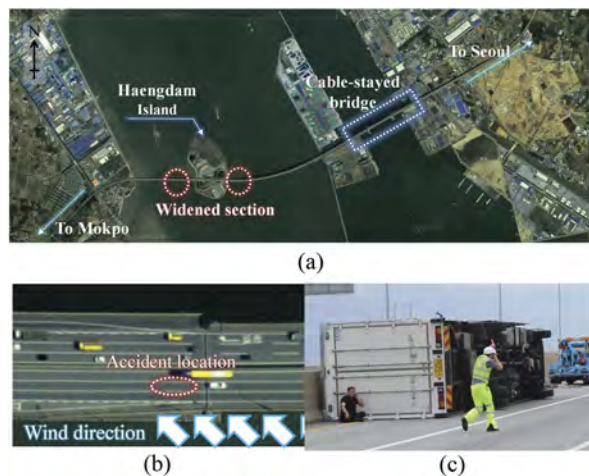

Figure 2. SHB (a) bridge overview (b) transition region (c) A roll-over accident.

3 RISK ASSESSMENT FRAMEWORK

Figure 3 shows the risk assessment framework for the root cause analysis and mitigation strategy for the whole life. The framework includes a wind tunnel test, vehicle analysis, wind-environment analysis with long-term wind data, fragility analysis, and risk assessment.

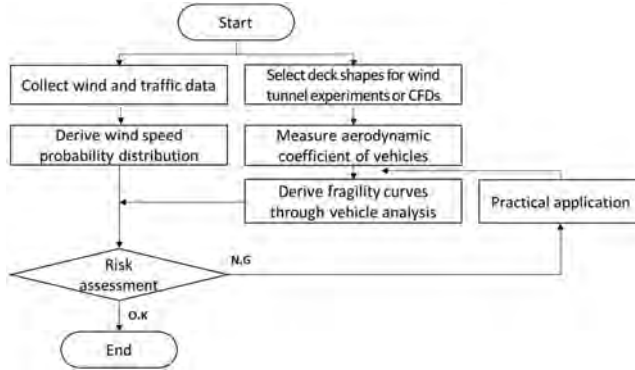

Figure 3. Risk assessment framework (KBRC 2021).

3.1 Wind tunnel test

A wind tunnel test was conducted using scaled-down bridge and vehicle models to estimate aerodynamic coefficients, which considered the effect of girder shape. Six different aerodynamic loads acting on the vehicle models were measured on each traffic lane using a small-size six-axis load cell. A special jig system (shown in Figure 4(a)) was used to measure the coefficients according to the incident wind angle by rotating the bridge model from -40° to $+40^\circ$ along the vertical axis (as shown in Figure 4(b)). The variations of aerodynamic coefficients for all wind directions were obtained through sine curve fitting (Figure 4(c)).

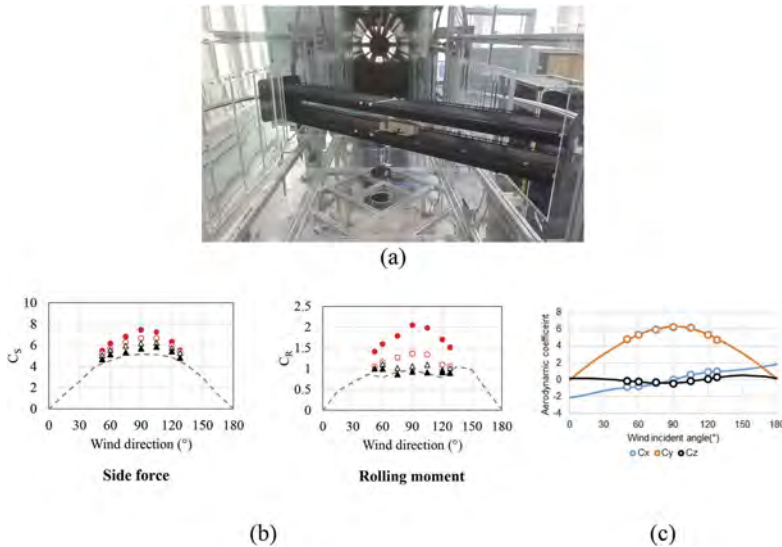

Figure 4. (a) Wind tunnel test using jig (b) measured coefficients (c) fitted coefficients result.

3.2 Critical wind speed curves (CWCs)

The authors used a dynamic simulation of running vehicles to estimate the critical wind speeds (CWCs) of vehicles. This was done using software such as TruckSim/CarSim and Simulink, which allowed for the simulation of vehicle models, running speeds, wind conditions, road geometries, and surface conditions. The quasi-static procedure (Batista & Perkovič 2014, Kim & Kim 2019) was also adopted for simplicity, and critical wind speeds were estimated by considering two accident types: rollover and side slip.

The CWCs were estimated based on the tire reaction forces and calculated for both the main and approach spans. Figure 5 shows a sample of the estimated CWCs for a truck on the lower deck of an approaching span of the GAB when the vehicle speed is restricted to under three different speeds. The traffic control wind speed can be determined for all vehicle types by selecting the lowest value of CWC.

Figure 5. Example of dangerous wind speed curves according to Speed Limit (vehicle type: truck, accident probability: 5%).

3.3 Risk assessment

The authors estimated the risk index by analyzing the wind environment using long-term wind data collected from nearby weather stations. The probability distribution functions of wind speed were evaluated for 16 wind directions. Based on the previously estimated CWCs, the annual accident occurrence frequency (NE) was calculated.

$$N_E = 365 \times A \times Q_d \times R_v \times R_L \times \sum_{i=0}^{16} P_i \times P_{E|dir=i} \quad (1)$$

where Q_d is the annual average daily traffic, R_v is the vehicle type ratio, and R_L is the ratio of traffic volume for traffic lanes. A is the modification factor, which can be smaller than 1.0 considering the empty and closed container vehicle ratios. P_i is the ratio of the occurrence frequency of wind speed by the wind direction and can be calculated through wind environment analysis. $P_{E|dir=i}$ is the accident probability for the i -th wind direction and can be calculated based on the driving restriction wind speed applied to the bridge.

4 RISK REDUCTION STRATEGY DURING THE WHOLE LIFE OPERATION

4.1 The GAB

A series of wind tunnel tests demonstrated the wind tunneling effect, revealing an acceleration in wind speed between the upper and lower decks (Kim et al. 2020). This effect was found to be more pronounced in the approaching spans that lacked truss members between decks. The increased vehicle side force and rolling moment at the lower deck were identified as the primary causes of the consecutive rollover accidents in 2012. Analysis results indicated that the truck was the most vulnerable vehicle type, with an annual accident frequency risk index of 0.34.

To reduce the risk index, traffic control measures following Table 1 can be implemented as an effective solution (Kim et al. 2022b). While the construction of a windscreen on the vulnerable point of the bridge would be demanding, it is a viable option with the limited range required for the corner part of the approach span when the dominant wind direction is included in the risk assessment. Figure 6 illustrates the effectiveness of the windscreen in reducing the risk index, with the second bar indicating the windscreen case for one side of the road and the third bar for both sides (Kim et al. 2022b). However, after another recent rollover accident, the bridge owner has temporarily reduced the speed limit for wind speed.

Table 1. Proposal for improvement of traffic control strategy for the GAB.

	Response	Wind speed (existing)	Wind speed (improved)
Level 0	Speed limit 110 km/h	0~14 m/s	0~16 m/s
Level 1	Speed limit 80 km/h	14~21 m/s	16~19 m/s
Level 2	Speed limit 50 km/h	21~25 m/s	19~22 m/s
Level 3	Bridge closure	25 m/s~	22 m/s~

Figure 6. Changes in the risk index of the truck according to the installation location of the windscreen.

4.2 The SHB

A series of wind tunnel tests were conducted to understand the variation of wind speed at the transition region. The structural details, including the double installation of roadside barriers, induced an acceleration in wind speed over the open deck, increasing the side force and roll-over moment three to four times that of the general approach spans. To adhere to the Korean guideline (KBRC 2021), the proposed risk assessment procedure suggested lowering the traffic control wind speed by 1~3 m/s, as shown in Table 2 (Kim et al. 2022b).

Figure 7 demonstrates the risk index based on the traffic control plans for the transition section, where the risk index decreases with the decrease of the restricted wind speed. It is more meaningful to adopt the second or third plan instead of the first one, which has no significant difference from the current one (Kim et al. 2022b). Moreover, a windscreen installation in the transient region could be more effective from a mobility standpoint, as indicated in Figure 8.

Table 2. Proposal for improvement of traffic control strategy for the SHB.

Response	10-minute-average wind speed		
	Strategy 1 (-1 m/s)	Strategy 2 (-2 m/s)	Strategy 3 (-3 m/s)
Level 0	Speed limit 80 km/h	14 m/s	
Level 1	Speed limit 50 km/h	19 m/s	17 m/s
Level 2	Bridge closure	24 m/s	22 m/s

Figure 7. Changes in the risk index according to the improvement plan for the SHB.

Figure 8. Changes in the risk index according to the windscreen installation on the transition section.

5 EFFECT OF ROAD CONDITIONS IN A SEVERE WEATHER

5.1 Measuring road surface roughness coefficients in severe weather conditions for GAB

Given the significant impact of road surface roughness coefficients on vehicle stability, Busan Infrastructure Corporation measured them during rainy conditions. Specifically, we analyzed the relationship between hydroplaning depth and the corresponding surface roughness coefficients measured on GAB, as illustrated in Figure 9. The field measurements of the roughness coefficients were conducted seven times between May and November 2020. Our findings indicate that the roughness coefficients decreased from 0.8-0.85 to 0.60-0.70, depending on the rainfall intensity. Notably, when the hydroplaning depth exceeded 2 mm, the roughness coefficients stabilized at 0.6.

Figure 9. Hydroplaning depth and measured road surface roughness coefficients.

5.2 Traffic control wind speed according to road surface conditions

To facilitate our analysis, we assumed the roughness coefficient to be 0.85 under dry conditions, 0.50 under wet conditions, and 0.20 under icing conditions, as we did not have access to direct measurements of the latter. Figures 10 and 11 demonstrate how the varying road surface conditions affected the critical wind speed (CWC) at two different driving speeds: 80 km/hr. and 40 km/hr. Our analysis revealed that the surface conditions significantly impacted CWCs, particularly for passenger vehicles, which were more susceptible to road conditions. For instance, at a driving speed of 80 km/hr., the CWC decreased from 22 m/s to 17 m/s and 7 m/s for wet and icing conditions, respectively. Conversely, the truck was less affected, with the CWC decreasing from 14 m/s to 14 m/s and 8 m/s under the same conditions. This difference can be attributed to surface conditions primarily affecting side slip accidents.

Figure 10. CWCs of passenger cars for three road conditions and two vehicle speeds on the lower deck of GAB.

Figure 11. CWCs of trucks for three road conditions and two vehicle speeds on the lower deck of GAB.

6 CONCLUSIONS

This study highlights the significance of employing a probabilistic risk assessment procedure to determine the appropriate traffic control strategy for ensuring the safety of crossing vehicles during strong side winds. Our proposed risk assessment framework successfully identified the root causes of the rollover accidents that occurred on two examined bridges. Interestingly, we found that the vulnerable spots were not always in the main span of the sea-crossing bridges with high altitudes and more exposure to open space. Instead, weak spots were identified in the approach span, contrary to our initial expectations. Our analysis indicated that the geometrical characteristics of the bridge deck, particularly double deck configuration and road width transition regions along the sea-crossing bridges, were the most influential parameters that affected the risk of overturning accidents. Additionally, the evaluation of long-term wind

speed, with consideration of wind direction, was found to be an essential component of the assessment. These findings emphasize that traffic control or bridge closure during strong side winds should be determined for each bridge, considering its geometry, alignment, traffic volume, wind environment, and road conditions in severe weather conditions at the site for the entire lifespan of the bridge. We proposed traffic control strategies for the examined bridges. However, considering the bridge's serviceability and the driving mobility of bridge users, we recommend the use of a windscreen for vulnerable spots as a long-term operational measure for the bridge's life cycle.

ACKNOWLEDGMENT

This research was supported by a Grant (RS-2023-00250727) from the Ministry of Land, Infrastructure and Transport of the Korean Government. The authors thank Principal Engineer Young-Kook Kim, the Bridge Management Team leader of Busan Infrastructure Corporation, for field-measured wind and roughness data and his comments on this study.

Resilient structures: Materials | Components | Systems

Mark P. Sarkisian

Partner, Skidmore, Owings & Merrill, San Francisco, CA, USA

ABSTRACT: Materials, components, and systems are all essential to creating resilient structural systems. Historical, materials have been used based on technologies of the time including an understanding of mathematics, physics, and engineering. Modest-strength materials, when assembled creatively can provide significant resistance to gravity and lateral loads. When intelligently placed, these materials can form structures that are even self-stabilizing during construction without the need for forming systems. Structural components designed for maximum life and performance can transform brittle structures into those with ductility where damage can be reduced when subjected to extreme loadings such as those created from seismicity. Structural systems can be comprised of multiple types of materials and can be assembled into efficient structures at all scales. New advancements in design include super-elastic materials that can be used to dissipate energy during seismic events and even provide self-centering of structures after strong ground motions.

Several building examples will be described and presented. These examples will be based on fundamental concepts of life-cycle engineering including ideas that help reduce embodied carbon through initial construction and long-term behavior. Ideas include structures that incorporate seismic isolation, friction fuse devices, and even new concepts using Shape Memory Alloys (SMA).

1 INTRODUCTION

Resilience is arguably the most important aspect of life-cycle civil engineering. Even though code-based design inherent provides a reasonable approach to resilient structures primarily due to a life-safety considerations, it falls short of achieving optimal performance in areas of risk especially those with high potential seismicity. For example, many buildings in Christchurch, New Zealand were designed to recent building codes and proved to be life-safe during the 2011 earthquake. However, many buildings were significantly damaged and proved to be unfit for continued operation even with a magnitude earthquake of 6.3 on the Richter Scale. These buildings were demolished as a result causing significant financial loss and major disruptions to businesses in the city of Christchurch (Figure 1).

Environmental impacts due to the emission of carbon dioxide and carbon dioxide equivalents has proven to be an important consideration in life-cycle civil engineering. The carbon associated with building construction is perhaps the most significant contributor accounting for approximately 50% of emitted carbon when considering initial construction and building operations (Figure 2). Approximately one half of these emissions are associated with initial construction and embodied. Urban developments around the world can sometimes occur over a limited period of time.

Without careful planning, these developments (Figure 3) can have enormous impact on the emission of carbon not just during the initial construction but throughout the development's life where resilient materials, components, and systems are important to minimize impact. In areas of environment risks (ie. seismicity), the amount of embodied carbon can significantly increase over time due to the need for repairs or in extreme cases demolition and new construction.

2 MATERIALS

For thousands of years, mankind has invented ways of using materials based on a specific understanding of applications known at the time. First developed for shelter and later of a wide range of uses, structures incorporated ingenuity that was largely informed by construction trial and error and near-term/long-term environmental conditions. Structures originally were constructed by found materials (i.e. stone) and later by fabricated materials. In early applications using fabricated materials, raw materials used were largely those resourced directly from the earth such as clay. These materials could be fired for increased strength and when used in pure compression with modest loads, could be used for large structures (Figure 4).

Within the last few hundred years, masonry has been widely used in major structures in Europe and in many of those structures, timber vaults were used to span significant distances. Timber vaults are unique since these structures are typically constructed without formwork (geometric guides only) and are self-stabilizing (Figure 5).

The disadvantage to these structures is they typically perform poorly in significant seismic events where masonry materials are subjected to tension and cyclic loadings. A major earthquake in April 2015 in Nepal led schools, constructed of brick or stone, to collapse (Carroll, 2015). Techniques to retrofit these buildings so that they can withstand seismic loading are strongly needed. While reinforcement attempts have increased over the last decades (Foraboschi, 2004) (Shrive, 2006) (Ramaglia, 2016), the reinforcement of buildings made from solid masonry, such as brick, stone, adobe blocks and hollow clay tile, remains an ill-mastered technique for which no standard procedure has been developed. SOM research done in

Figure 4. Stacked masonry – Lima, Peru. Figure 5. Masonry timbrel vault construction.

collaboration with the University of Alcalá, Madrid and Taller de Bóvedas has resulted in more highly resilient timbrel vaults when subjected to lateral loading while using modest materials such as fiberglass to reinforce the masonry.

Analysis of arches, a segment of idealized vaults, focused on the onset of mechanisms when four hinges are formed. Analysis and physical testing considered unreinforced and reinforced masonry vaults (Figure 6).

Figure 6. Masonry arches on shake table – reinforced on left, unreinforced on right.

Given that the supports of the arch were pinned in the numerical model, predicted collapse would occur when two hinges form within the arch. Lateral analyses of unreinforced arches when subjected to lateral acceleration using frame elements is shown in Figure 7.

The distance e between the centroid of the section and the location of the force resultant in the section is given by the following formula: $e = \frac{M}{P}$ (1), where M is the strong axis bending moment and P is the axial force. Therefore, the condition for a hinge to form is represented by the following formula: $e \geq \frac{h}{2}$ (2), where h is the section height.

The unreinforced arch was originally considered for a unidirectional lateral acceleration starting at 0.1g. Using equation (2), the first hinge was predicted to appear at an acceleration of 0.2g between elements 7 and 8. Collapse was predicted at 0.23g, when a second hinge formed between elements 2 and 3 and the original hinge moved to the joint between bricks 8 and 9 (Figure 7).

To validate the predicted hinge locations, the bricks were modelled as shell elements and the stress distribution in the shell elements was evaluated. Similar to the frame element model, the interface between bricks was modelled as a continuum. In this model, compressive stresses were

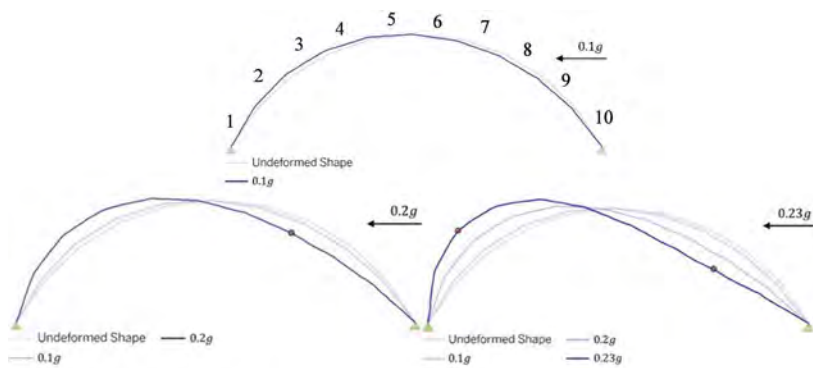

Figure 7. Masonry arch deformation at 0.1g, 0.2g, and 0.23g (numbers indicate frame element labels and red circles indicate hinges).

concentrated on one the side of the section at the hinge locations. On the other side of the section, tensile stresses were observed, indicating that the adjacent brick sections had separated. The stress distribution and the predicted hinge locations at 0.23 g is presented in Figure 8.

Figure 8. Stress distribution in arch 1 at 0.23g.

Figure 9. Extrados – reinforced arch.

Reinforcement was introduced into the model with another layer of elastic frame elements offset from the elements representing the bricks (Figure 9). The reinforcement elements were assigned low values of inertial stiffness so that they mainly resisted axial loads. The two layers of frame elements were connected through rigid frame elements. The deformation at a similar level of acceleration was found to be more pronounced for the unreinforced arch than it was for the extrados-reinforced arch (Figure 10). When collapse occurred in Arch 1 with the formation of two hinges within the span, the reinforcement in Arch 2 prevented hinges from forming on the intrados, allowing it to resist higher levels of acceleration.

Figure 10. Deformation comparison between the unreinforced arch (green) and the extrados – reinforced arch (blue) under 0.23g.

In addition to the improved lateral load resilience of modestly reinforced masonry arches, principles of structural optimization were applied to the masonry vaults. For the installation of works at the College of Architecture Madrid (COAM), density optimization was applied to a structure that was built as part of the exhibition. The goal was to create a timber vault that could minimize the use of materials and therefore embodied carbon. Construction would be faster since less materials would be placed. The concept of the vault was one that could be

scales to larger structures when carbon emissions associated with materials and construction would be much more significant. Topology optimization analyses led to mapping of states of stress with areas in red having highest compressive stress and areas in light blue where stress was minimal, and material could be removed (Figure 11).

Figure 11. Topology optimization of masonry timber vault.

Figure 12. Constructed masonry timber vault indicating material removal and overall geometry.

Skilled, increasingly rarely available labor to build such vaults led to imagining that geometrically specific, self-stabilizing structures could be built with an automated process where three-dimensional space could be defined, and the material could be placed by robots. Alternate materials, still exhibiting good compressive characteristics, could be used to replace conventional masonry elements. SOM collaborated with Princeton University to create a glass vault assembled jointly by robots and humans. The structure was built using two robots placed on a platform to avoid arm interference and allowing for the placement of glass block material in predetermined three-dimensional space (Figure 13).

Figure 13. Geometric definition and constructed self – stabilized glass vault.

3 COMPONENTS

The original request for proposal (RFP) for the design-build Long Beach California Civic Center Project (Figure 14) stated four design objectives for a design level seismic event – 1. Experience few or no injuries; 2. Reoccupy the new facility within a week; 3. Have full functionality within 30 days; and 4. Experience less than 5% financial loss (as compared to the replacement value). For a public facility this criterion was a welcomed framework for resilient design. Initial ideas led to concepts of replacement traditional plastic yielding mechanisms of shear wall cores with an innovative concept of using a central base bearing at the base of core walls to allow for controlled mechanisms to occur during a seismic event while limiting damage.

Figure 14. Rendering of Long Beach civic center project with core wall bearing concept.

For cost and schedule reasons, the final design included a creative alternative idea that used a more conventional approach where staggered openings in core walls were used so no link beams were required, therefore eliminating damage for these otherwise sacrificial elements during a seismic event. In addition, non-structural components were carefully considered for seismic displacement. For instance, partition walls typically did not span between each floor level but were otherwise interconnected only at the base of walls allowing for tops to move freely.

Advancements to friction joints within seismic resistance structures have led to an innovative approach to increase seismic resilience of the Sanyi Irotech Towers in Guangzhou (Figure 15). Seismic fuses were introduced into offset exterior braced frames. The fuses use bolted friction connections designed to slip during a major earthquake while protecting the base building material from plastic deformations/permanent damage. This resilient system does not move during typical service conditions when the towers are subjected to wind and moderate seismic events.

Figure 15. Rendering, idealized frame elevation, and enlarged view of offset frame joint.

High strength slip-critical bolts and steel friction shims are used to create the fused joints within the frame. Slip is considered through vertical slip in the joints. Conventional steel building components are used in each joint and the structural frame is exposed without cladding (Figure 16).

The combination of structural steel and heavy timber is a solution to reducing seismic mass while providing a ductile lateral load-resisting system. As part of the Long Beach Civic Center Project, a public library name the Billie Jean King Library was designed and built. This ultra-low

carbon structure was built over an existing parking structure where load was balanced through the removal of heavy landscaping and the addition of a lightweight steel and timber structure.

Figure 16. Modeled movement and components of frame friction joints.

This approach resulted in only modest seismic upgrades to the existing parking structure while creating long-span, flexible library spaces above. Steel braced frames and steel columns are interconnected with repetitive timber construction used for all of the floor systems (Figure 17).

Figure 17. Combination of steel and timber – Billie Jean King library.

Components were further developed in the recently designed County Office Building 3 (COB3) Project for San Mateo County (Figure 18). Structural steel was also incorporated into

Figure 18. COB3 project under construction and typical beam-to-column connection detail.

the timber structure with wood typically used for columns instead of steel. Connections were prefabricated and proved to be essential to the rapid on-site assembly. Instead of conventional steel braced frames, unbonded steel braces were used in the core areas for seismic resistance. These braces can be replaced after a significant seismic event.

4 SYSTEMS

The Cathedral of Christ the Light in Oakland (Figure 19), California is an excellent example of a resilient, low embodied carbon structure. Seismic isolation is central to the design approach with the timber and steel structure supported on stainless steel friction pendulum bearings.

Figure 19. The cathedral of Christ the light under construction and the seismic isolation design.

A similar systematic approach was used for the design of Los Angeles County Museum of Art (LACMA) expansion project in collaboration with architect Peter Zumthor. This structure, currently under construction, consists of long cantilevers (up to 25 meters) as well as a clear span condition at the existing Wilshire Blvd. Seismic isolation is used to protect the artwork and create a resilient structure that is designed to minimize and damage due to potentially high seismicity.

Figure 20. Rendering and cross-section of structure for the LACMA museum.

The superstructure consists for reinforced concrete ribs and post-tensioning that sandwiches and top and bottom slab systems. Slabs are also post-tensioned. Art House walls interconnect the floor framing sandwich systems at the exhibition floor and the roof. Art Tower reinforced concrete shear wall cores house services and support the framing systems and are ultimately supported on 3 meter-diameter friction pendulum bearings. Post-tensioning is also used in the art house walls to transfer gravity loads from the framing to the Art Tower walls (Figure 21).

Significant advancements have been made for framed systems for all building structures. Based on the concept of the Michell Truss, the theoretically most correct and efficient use of materials in a cantilevered structure when subjected to lateral loads, several design

advancements have been made. Instead of concentrically braced frames, those that consist of a high-waisted asymmetrical system results in a more efficient structure achieving target strength and displacements with far less material. 800 West Fulton Market in Chicago (Figure 22) incorporates this system. A steel brace frame provides the lateral system for an otherwise reinforced concrete structure.

Figure 21. LACMA framing system concepts and cross section of wall system.

Figure 22. Lateral frame concept and final construction of 800 West Fulton Market, Chicago.

The important attribute to the Michell Truss concept is its application to horizontal framed structures such as the pedestrian bridge for Emery Cancer Center in Atlanta, Georgia (Figure 23). This concept can be used for pedestrian or vehicle bridges as well as long-span floor framing systems that can be used in repetition structures of all heights.

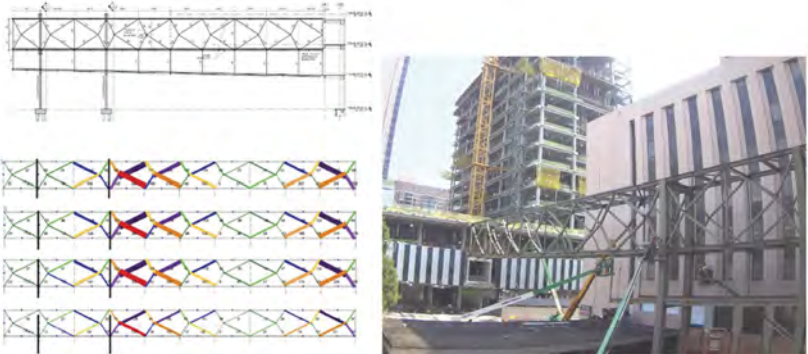

Figure 23. Emery cancer hospital pedestrian bridge drawing, analysis, and on-site photograph.

Bracing systems with seismic fuses provide an excellent solution to creating ductility in a potentially otherwise non-ductile seismic system. For the University of California, Berkeley, Bechtel Engineering Center fuses are introduced into the perimeter steel tension-only bracing system. What is unique about the system for the Bechtel Center is that the fuses are comprised

of super elastic Shape Memory Alloy (SMA) devices (Figure 24). The overall concept is to create an ultra-lightweight structure that is supported on an existing reinforced concrete building while minimizing any seismic retrofit to the existing building. The SMA devices deform during an extreme seismic event, dissipate energy, and then act to restore the building to its original position after the event (Figure 25).

Figure 24. UC Berkeley Bechtel center rendering and location SMA seismic fuses.

Figure 25. SMA Fuses – Elevation drawing and stress – strain relationship of material.

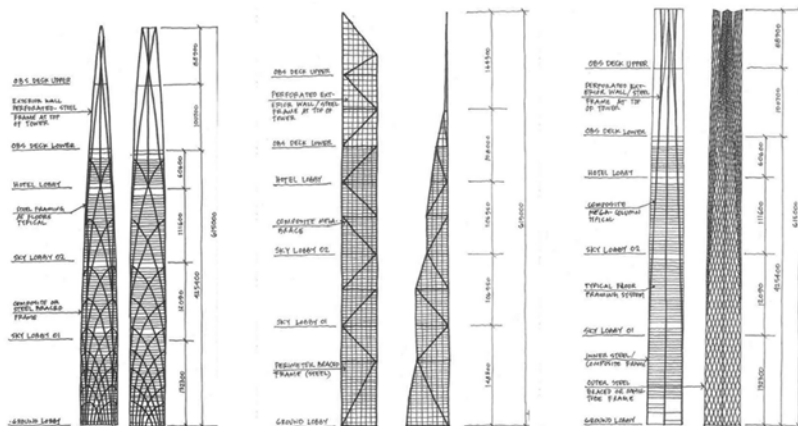

Figure 26. Structural system concept sketches for the Grand Rama tower – Bangkok.

5 CONCLUSION

Resilient design can be accomplished at all scales. Careful considerations of materials, components, and systems are all essential to efficient, low-carbon emitting structures that optimally perform over a projected building life. Combined concepts are important and when designing structures at great scale all attributes can be combined with great benefits. Mapping natural force flows is important resulting in structures that are elegant and potentially expressive (Figure 26).

Risk and decision-making for extreme events: What terrorism and climate change have in common

M.G. Stewart

University of Technology, Sydney, Australia

ABSTRACT: Terrorism and climate change debates are often characterized by worst-case thinking, cost neglect, probability neglect, and avoidance of the notion of acceptable risk. This is not unexpected when dealing with extreme events. However, it can result in a frightened public, costly policy outcomes, and wasteful expenditures. The paper will describe how risk-based and cost-benefit approaches are well suited to infrastructure decision-making in these uncertain environments.

1 INTRODUCTION

Cyclones, earthquakes, tsunami and floods are natural hazards that cause significant loss of life, and economic and social losses. Added to this are ‘man-made’ hazards such as climate change and terrorism. These hazards are low probability - high consequence events which in recent times are more commonly referred to as ‘extreme events’. There is much hyperbole in the media and other sources that terrorism and more recently climate change are (or can be) reaching dangerous levels, are apocalyptic, or even existential. This characterisation of extreme events can result in a frightened public, costly policy outcomes, and wasteful expenditures. Hence, extreme events illicit extreme reactions – risk aversion, probability neglect, cost neglect, worst-case thinking – that may distort the decision-making process in an effort by policy makers to be seen to be ‘doing something’ irrespective of the actual risks involved.

Terrorism and climate change are extreme events of much interest. They can engender fear in the community, and predictions of impending doom are often overstated. Many terrorism and climate change ‘risk’ and ‘risk management’ reports dwell on lists of vulnerabilities and consequences. There is seldom mention of probabilities, or quantitative measures of vulnerability, or the likelihood of losses. While useful for initial risk screening, intuitive and judgement-based risk assessments are of limited utility to complex decision-making since there are often a number of climate or threat scenarios, adaptation or counterterrorism options, limited funds and doubts about the cost-effectiveness of protective measures. In this case, the decision-maker may still be uncertain about the best course of action. For this reason, there is a need for sound system and probabilistic modelling that integrates the performance of infrastructure systems with the latest developments in stochastic modelling, structural reliability, and decision theory.

Civil Engineering infrastructure such as houses, buildings, bridges, roads, pipelines, dams, etc. are vulnerable to terrorism and climate change. Over the past century building standards have been developed and continually improved – with the prevention of building collapse and catastrophic loss (ultimate limit state) the main driver for change. And while uncertainties and knowledge gaps still exist, disaster risks in the developed world are, in general, at an acceptable level. Hence, new infrastructure is, in general, built to modern codes of practice and so are less vulnerable to these extreme events. However, risks are generally higher for ageing or deteriorating infrastructure.

Risk-based approaches are well suited to optimising decisions related to extreme events (e.g., Stewart and Rosowsky 2022), in this case, climate adaptation strategies and counterterrorism measures. Stochastic methods may be used to model threat likelihood, vulnerability, resilience, effectiveness of protective strategies, exposure, and costs. Probabilistic terrorism risk assessment methods have been developed to assess the risks of terrorism, and effectiveness of risk reducing

measures (Mueller and Stewart 2011, 2015). Risk-based assessments of climate adaptation measures have also been developed (e.g., Bastidas-Arteaga and Stewart 2019). While the jargon may differ, the decision support approaches to counterterrorism and climate adaptation measures have much in common, as are the challenges. This paper aims to draw out these issues in more detail, with a particular focus on the pitfalls often encountered when assessing the threats, hazards, vulnerabilities and consequences of counter-terrorism measures, and climate change mitigation and adaptation.

2 CLIMATE ADAPTATION ENGINEERING

In recent years climate change seems to have displaced terrorism as the extreme event of most concern to public and governments. There is increasing research that takes into account the changing climate risks and life-cycle costs in engineering to reduce carbon emissions and/or reduce the vulnerability or increase the resiliency of infrastructure – this may be referred to as ‘climate adaptation engineering’. Climate adaptation engineering is defined as measures taken to:

- (i) reduce CO₂ emissions during the life cycle of design, construction, operation and end-of-life of infrastructure that may include decarbonisation measures such as more sustainable (low carbon) materials, enhanced operation efficiency (e.g., more thermally efficient buildings), and changes to inspection and maintenance regimes, and/or
- (ii) reduce the vulnerability or increase the resiliency of built infrastructure to storms, floods, fire, heat and other climate hazards, this may include, for example, enhancement of design standards (higher design loads or flood levels), retrofitting or strengthening of existing structures, or use of hazard resistant materials such as fire-resistant cladding.

Figure 1 shows a schematic to help illustrate the concept of climate adaptation engineering.

The political imperative to “act” on climate change is to reduce CO₂ emissions with a recent push for renewable energy, electric vehicles and other sustainability measures. However, while these measures are needed, their impact on the near to mid-term climate-related losses is miniscule. Whereas measures to reduce vulnerability and enhance resiliency of infrastructure provides a more immediate reduction in climate-related losses.

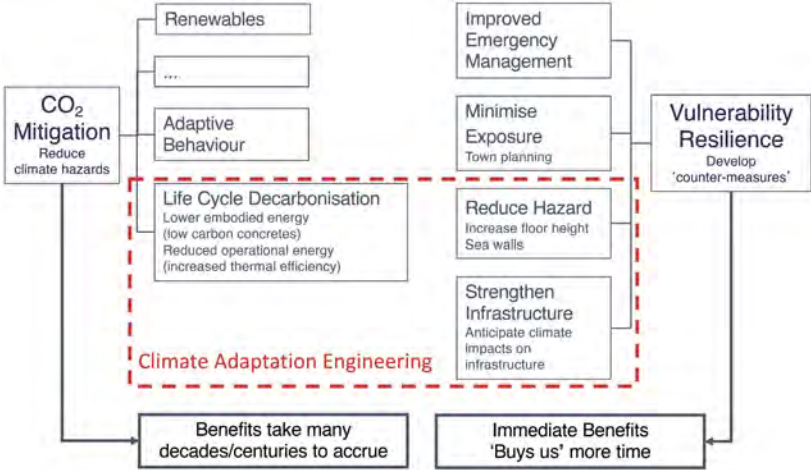

Figure 1. Illustration of climate adaptation engineering.

3 DECISION CHALLENGES: TERRORISM AND CLIMATE CHANGE

There are a number of issues and questions related to controversial and emotive issues such as terrorism, climate change, and other extreme events, and are discussed as follows.

3.1 *Worst-case thinking*

The media are replete with stories and articles that the world has never been more dangerous, and this is exacerbated by worst-case thinking and hyperbole expressed by many climate change and terrorism experts. In 2008, Department of Homeland Security (DHS) Secretary, Michael Chertoff proclaimed the “struggle” against terrorism to be a “significant existential” one. In 2021 U.S. President Joe Biden said that climate change poses a “global existential crisis”. These are not isolated examples, as similar remarks have been made by Boris Johnson, the United Nations General Secretary, and other world leaders and senior government officials. However, with the exception of all-out nuclear war or an asteroid impacting earth, other threats existential to humanity are hard to fathom.

If business as usual predictions are biased towards impending doom, then this justifies any response no matter the cost in loss of civil liberties, quality of life, and treasure. It can lead to wasteful expenditures for a threat or hazard that is possible, not probable. Sunstein (2007) notes that “For public officials no less than the rest of us, the probability of harm matters a great deal, and it is foolish to attend exclusively to the worst-case scenario”. A more rational approach is to focus on estimating the likelihood of costs and benefits when assessing the need for protective measures. This of course, is the essence of risk assessment.

Worst-case thinking can also lead to excessive spending on programs with little benefit, and ignoring other programs with large benefits. The current U.S. budget for domestic homeland security is approximately \$120 billion per year (Stewart and Mueller 2018). Mueller and Stewart (2011) estimated that U.S. counter-terrorism costs are 5-75 times higher than any benefits – i.e., one dollar buys less than 20 cents in benefits. A panel of more than 40 international experts assembled by Bjorn Lomborg found that a \$2 billion investment could save more than 1.5 million lives by expanded immunisation coverage and community-based nutrition programs (Lomborg 2009). Hence, if a miserly \$2 billion were redirected from the homeland security budget to these more effective risk reducing measures, the likelihood and consequences of terror attacks would hardly change, but 300 to 60,000 more lives would be saved.

3.2 *Cost neglect*

While it is not difficult to list threats and vulnerabilities, what is more challenging is to ascertain the cost to reduce these threats and vulnerabilities. And to decide who pays, and when. There is a notion that safety is infinitely good, and no cost is too high. There is no attempt to compare costs against benefits.

For example, it is not unusual for books on counter-terrorism to provide exhaustive lists of vulnerabilities and the need for enhanced security measures such as explosive detection systems, surveillance cameras, armed guards, etc. – yet often there is no entry for cost in the index (for examples see Mueller and Stewart 2011).

3.3 *Probability neglect*

Many analysts base their findings on threats or scenarios that they assume will occur. There is no consideration of the likelihood of a terrorist attack, that a specific CO₂ emission scenario will occur, or that adaptation will be effective. For example, a U.S. 2014 climate risk assessment report predicts trillions in dollars of damage due to climate change for the business as usual scenario – i.e., the U.S. continues in its current path assuming a RCP8.5 (known more recently as SSP8.5) emission scenario (Risky Business 2014). This IPCC emissions scenario assumes that emissions will continue unabated for the next 85 years including 6.5 more coal being used in 2100 as it is today¹. This is very much a worse-case scenario, and might be better characterised as unrealistic and implausible as it ignores that CO₂ mitigation measures will be implemented, that adaptation measures are implemented, or the impact of improved or game-changing technologies.

1. A more realistic scenario is RCP 2.6 – this corresponds to the Paris Agreement which aims to hold the increase in the global average temperature to below 2 degrees Celsius above pre-industrial levels.

Sunstein (2003) terms this as ‘probability neglect’ and that “people’s attention is focused on the bad outcome itself, and they are inattentive to the fact that it is unlikely to occur.” There is no certainty with predictions, nicely summed up by physicist Niels Bohr: “Prediction is very difficult, especially if it’s about the future.”

3.4 *Opportunity costs*

Policy-makers that act before they carefully consider the implications of their actions can result in undesirable outcomes which are often referred to as ‘opportunity costs’. For example, increased delays and added costs at U.S. airports due to new security procedures provide incentive for many short-haul passengers to drive to their destination rather than flying, and, since driving is far riskier than air travel, the extra automobile traffic generated has been estimated to result in 500 or more extra road fatalities per year (Blalock et al. 2007). Using DHS-mandated value of statistical life of \$7.5 million (Robinson et al. 2010), this equates to a loss of \$3.75 billion per year.

A CO₂ mitigation strategy that reduces economic growth, particularly in developing countries, may reduce their ability to adapt and other indirect impacts. In the 50 years since 1970, the natural hazard fatality rates have reduced by over 90% for low income countries (Ritchie et al. 2022a). This shows that economic development is a key driver in reducing the impact of natural hazards, and climate change mitigation or adaptation measure that reduce economic growth may have a significant opportunity cost.

Further, according to the charity ActionAid, the increased use of industrial biofuels (fuels made on an industrial scale from agricultural crops) have been a major cause of the food and hunger crisis in the developing world – filling an SUV with one tank of biofuel requires over 450 pounds of corn, which contains enough calories for a person for a year (ActionAid 2010). Rising energy costs also mostly affects the poor.

3.5 *Acceptable risk*

The notion of acceptable risk is rarely raised in public discussions. The world is not risk free. The generally accepted level of annual fatality risk is 1 in a million (e.g. Stewart and Melchers 1997). The probability that an American will be killed by a hurricane stands at about one in 7 million per year, and one in 2.8 million per year for a heat-related death. The probability that an American will be killed by a terrorist in the United States, with the events of 2001 included in the count, stands at about one in 4 million per year (Mueller and Stewart 2015), and is one in 39 million since 9/11. In Western Europe the odds are higher at one in 9 million, but still considerable lower than one in a million. The annual likelihood worldwide that a person will be killed in an airliner by a terrorist is approximately 1 in 320 million for the period since 9/11. To put some of these data in context, a person would need to fly once per day for 30,000 years before being involved in a terrorist attack (Stewart and Mueller 2018). By comparison, an American’s chance of being killed in an automobile crash is about one in 9,500 a year, the chance of being a victim of homicide is about one in 20,000, and the chance of being killed by lightning is one in 10 million (Stewart and Mueller 2018). How much should we be willing to reduce a risk, and is the risk reduction worth the cost?

In the past decade, the chance of being killed in a natural disaster in the United States is one in a million per year, in Western Europe is one in 500,000. However, for the world the odds are significantly higher at one in 150,000 per year (Ritchie et al. 2022b). In the 50 years since 1970, the natural hazard fatality rates have reduced globally by 75%, and by over 90% for low income countries (Ritchie et al. 2022a).

The above data shows that the world is not becoming any more dangerous or vulnerable. There is evidence to suggest that the opposite holds true – it can be argued that the world has never been healthier, wealthier and more educated leading to more resilient societies that can better cope with natural and manmade disasters (for a full discussion see Stewart 2022). While vulnerabilities remain, people and infrastructure are showing increased resilience. Though staggering losses may still occur, they can be ameliorated with targeted strategies to reduce vulnerability, increase resilience or reduce exposure of infrastructure and people to extreme events.

4 LIFE CYCLE ANALYSIS

The decision challenges discussed in the previous section are also mostly relevant for life-cycle analysis for civil engineering infrastructure. These include:

4.1 *Opportunity costs*

Direct costs to an asset owner or manager are, in general, relatively straightforward to estimate for design, construction maintenance, repair, etc. However, opportunity costs are normally harder to quantify and require awareness of unintended impacts to a community. For example, opportunity costs may be considerable if a road or bridge is closed for maintenance and repair, such as delayed response by ambulances reducing the odds of timely life-safety interventions, or occurrence of an extreme hazard (earthquake, bushfire) will hinder emergency vehicle access and safe evacuation routes for residents.

4.2 *Probability neglect*

The world is not deterministic. The timing and severity of natural hazards, loads, deterioration, maintenance, repair, etc. associated with the life-cycle of infrastructure are highly variable and uncertain. Added to this is the uncertainty and incomplete knowledge of how infrastructure is vulnerable and damaged by these hazards, and the ability for economic or societal infrastructure to be resilient and for communities to recover. Infrastructure comprises of interlinked sectors and networks which adds uncertainty about how the performance of each component affects overall system behaviour.

Uncertainty and incomplete knowledge may be modelled by probabilistic (stochastic) methods. It provides a normative measure of uncertainty that may be quantified from field, laboratory or historical data and/or advanced computer simulation models. While the former can help ascertain past or current vulnerabilities and resiliency, it has very little predictive capability if the network or system changes over time to suit increases in demand and shifting community demographics, or if the infrastructure degrades over time, or if the likelihood or severity of natural hazards increases due to climate change. These stochastic methods allow risk to be quantified, such as the likelihood and extent of infrastructure damage and recovery for future scenarios of hazard, vulnerability or resiliency.

An area of particular difficulty for decision-making is where the potential consequences are extremely large or severe yet the probability of these consequences actually occurring is estimated to be extremely low. These are termed “low probability – high consequence” events or hazards, or more recently, as “extreme events”. As discussed above, a probabilistic risk analysis based on sound system and probabilistic modeling is well suited to predicting life saving and damage risks for extreme events. This probabilistic framework provides practical guidance; for example, developing disaster risk reduction measures, safety and load rating assessment of bridges, asset management of pipelines, tunnel safety from vehicle fires, safety cases for offshore platforms and chemical process plants, reliability of electricity infrastructure, and it underpins the development of safety factors and design loads for civil engineering design codes and standards. The next section will describe how risk-based decision support may be applied to life-cycle assessment of infrastructure.

The outcomes of probabilistic risk analysis include: (i) likelihood and extent of infrastructure damage and losses to the owner, users, community and other stakeholders, (ii) influence that infrastructure resiliency has on the time to renewal and follow-on consequences and losses, (iii) effect of risk mitigating measures on predicted damage and losses, and (iv) cost-benefit or similar decision analysis used to assess the probability that a decision option (risk mitigating measure) will yield a benefit to one or more stakeholders. The robustness of decisions can be explored through scenario and sensitivity analyses. Since the outcomes of a probabilistic risk assessment can affect significantly the safety and operations of infrastructure, it is important that an independent and critical review be conducted by recognised experts, and the findings discussed at workshops involving all stakeholders.

Not surprisingly, learned academies such as the Royal Academy of Engineering (RAE) and the Australian Academy of Technological Sciences and Engineering (ATSE) understands the importance of probabilistic thinking: “Regulations and design standards are evidently in need of revision to reflect the uncertain climatic conditions that will be experienced in coming decades, setting probabilistic standards rather than absolute requirements for performance” (RAE 2011) and “The Academy considers evidence-based tools, such as probabilistic risk assessments. . . to be fundamental for building resilience into Australia’s future planning processes” (ATSE 2022). However, they note an understandable concern: “The lack of understanding of probabilistic scenarios by politicians and the media could be particularly problematic” (RAE 2011). This is an ongoing challenge to the engineering profession, where engineers need to explain probabilistic concepts to the government, media and the public in a way that allows for more informed and rational decision-making.

5 RISK-BASED DECISION SUPPORT

Decision criteria for extreme events are typically based on (i) annual fatality risk, and (ii) cost-effectiveness of protective measures. Risk for a system exposed to a threat is

$$E(L) = \sum \Pr(T)\Pr(H|T)\Pr(D|H)\Pr(L|D)L \quad (1)$$

where $\Pr(T)$ is the annual probability that a specific threat will occur (a terrorist attack, an emission scenario), $\Pr(H|T)$ is the annual probability of a hazard (wind, heat, explosion) conditional on the threat, $\Pr(D|H)$ is the probability of damage or other undesired effect conditional on the hazard (also known as vulnerability or fragility) for the baseline case of no extra protection (i.e. ‘business as usual’), $\Pr(L|D)$ is the conditional probability of a loss (economic loss, loss of life, etc.) given occurrence of the damage (resilience), and L is the loss or consequence if full damage occurs. In some cases, ‘damage’ may equate to ‘loss’ and so a vulnerability function may be expressed as $\Pr(L|H)$ which is equal to the product $\Pr(D|H)\Pr(L|D)$. The summation sign in Equation (1) refers to the number of possible threats, hazards, damage levels and losses. If the loss refers to a monetary loss, then $E(L)$ represents an economic risk. If the loss refers to fatalities, then $E(L)$ represents an annual fatality risk (AFR).

If we modify Equation (1) where ΔR is the reduction in risk caused by protective measures (e.g., climate adaptation or counterterrorism measures) then expected loss after protection is

$$E_{\text{protect}}(L) = \sum (1 - \Delta R)E(L) - \Delta B \quad (2)$$

where ΔR is the reduction in risk caused by the protective measure, $E(L)$ is the ‘business as usual’ expected loss (risk) given by Equation (1), and ΔB is the co-benefit such as reduced losses to other hazards, increased energy efficiency of new materials, etc. If there is an opportunity cost associated with a new measure, then ΔB becomes a negative value. Protective measures should result in risk reduction (ΔR) that may arise from a combination of reduced likelihood of the hazard, damage states, safety hazards and and/or people exposed to the safety hazard.

The challenging aspect of risk-based decision theory is predicting values of $\Pr(T)$, $\Pr(H|T)$, $\Pr(D|H)$, $\Pr(L|D)$ and ΔR . This information may be inferred from expert opinions, scenario analysis, and statistical analysis of prior performance data, as well as system and reliability modelling. Since there is uncertainty associated with such predictions, the use of probability distributions to describe mean, variance and distribution type is recommended.

If the AFR lies in the generally tolerable region (e.g., 1×10^{-4} to 1×10^{-6}) then several criteria may be used to assess if the benefits of protective measures exceed their cost:

1. Net Present Value (NPV)
2. Probability of cost-effectiveness or $\Pr(\text{NPV} > 0)$

The ‘benefit’ of a protective measure is the reduction in damages or losses associated with the protective strategy, and the ‘cost’ is the cost of the protective strategy. The net benefit or net present value (NPV) is equal to benefit minus the cost. The decision problem is to maximise the net present value

$$NPV = \sum E(L)\Delta R + \Delta B - C_{\text{protect}} \quad (3)$$

where C_{protect} is the protection cost including opportunity costs that reduces risk by ΔR . Figure 2 shows how protective costs increase with risk reduction, while benefits increase. The optimal protection occurs when NPV is a maximum, leading to optimal risk reduction. Relevant is what level of expenditure and risk reduction gives the greatest benefit and when does the law of diminishing returns kick in. The first dollars spent on protective measures are likely to be worthwhile, even if the last is not.

The above discussion is related to the concept of life-cycle cost analysis for infrastructure where design, construction, operation, failure, and end of use costs are summed and the optimal configuration selected based on minimal life-cycle cost or other decision criteria.

Governments and their regulatory agencies normally exhibit risk-neutral attitudes in their decision-making as described by the above equations. Utility theory can be used if the decision maker wishes to explicitly factor risk attitudes such as risk aversion or proneness into the decision process (e.g. Stewart et al. 2011, Qin and Stewart 2021).

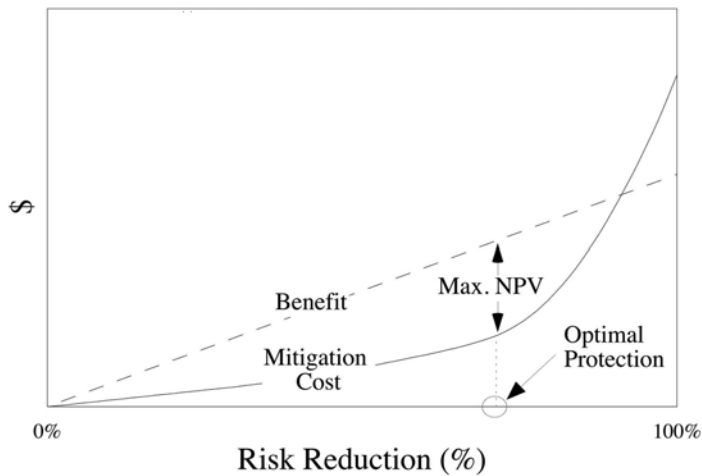

Figure 2. Schematic of net present value (NPV) showing optimal protection.

If parameters $\text{Pr}(T)$, $\text{Pr}(H|T)$, $\text{Pr}(D|H)$, $\text{Pr}(L|D)$, L , ΔR , ΔB and/or C_{protect} are random variables then the output of the analysis (NPV) is also variable. This allows confidence bounds of NPV to be calculated, as well as the probability that an adaptation measure is cost-effective denoted herein as $\text{Pr}(NPV > 0)$. If $NPV > 0$ then there is a net benefit and so the protective measure is cost-effective. Other notations and formulae can be used to provide optimal protection, but ultimately these also mostly rely on maximising NPV.

If the probability that a specific threat will occur $\text{Pr}(T)$ is too unreliable, then a decision analysis based on scenario analysis where threat probability is decoupled from Equation (1) provides an alternative decision-making criteria based on expected costs. The above equations can be generalised for any time period, discounting of future costs and more detailed time-dependent cost and damage consequences.

Threat, vulnerability, loss and protective costs are subject to considerable uncertainty due to lack of available data and models. For this reason, calculations of risks, costs and benefits will be imprecise. Hence, a ‘break-even’ analysis may be useful where minimum threat probability, minimum risk reduction or maximum protective cost necessary for protective measures to be cost-effective is selected such that there is 50% probability that benefits equal cost – i.e. $\text{mean}(NPV) = 0$. For example, if the actual cost of protection exceeds the predicted break-even value, then protection is not cost-effective. Decision-makers can then judge whether a protective strategy meets these break-even values.

Ultimately however, the outcomes of risk-informed decision analysis will be to inform decision makers as not all decisions can be made on technical merits alone. It also helps to inform government, infrastructure asset and network owners and operators, community and individuals of the trade-offs between risk, benefits and cost when making decisions on how best to protect communities.

6 CONCLUSIONS

Terrorism and climate change are extreme events that engender fear and anxiety in the community. Policy makers are also susceptible to these emotions. Risk-based approaches are suitable to assess the acceptability of risks, and the cost-effectiveness of measures to reduce terrorism and climate impact risks.

The design and development of a demountable and reconfigurable segmented fan concrete shell flooring system

M. Nuh & J. Orr

University of Cambridge, Cambridge, UK

R. Oval

Princeton University, Princeton, USA

ABSTRACT: The structural floor of typical concrete frame buildings contributes a significant portion to the total embodied carbon of the superstructure by its sheer mass. In addition, the monolithic nature of in-situ concrete and the frequent use of grouting for prefabricated components result in structures which are often difficult to disassemble, creating barriers towards reuse. We present a novel segmented thin-shell concrete flooring system which facilitates component reuse and reconfiguration compatible with a circular economy for construction. By leveraging the funicular potential of shell structures and the geometry of masonry fan vaults, a lightweight materially efficient flooring system which can be disassembled without the need to cut through concrete or grout is proposed. Fabrication and assembly of a scale prototype spanning 2 m by 2 m were carried out as a proof-of-concept, leveraging digital fabrication techniques to create the curved vault profile.

1 INTRODUCTION

The construction industry contributes an estimated 38% of worldwide energy and process-related emissions (United Nations Environment Programme, 2020), emphasising the need for increased efforts to reduce the environmental impact of our built environment. A potential means which has gained renewed interest for reducing the carbon impact of building structures is the reuse of structural building components to extend their lifespan. However, various projects which implement concrete reuse have often faced challenges in terms of making them economical (Durmisevic, 2019; Eklund et al., 2003; Glias, 2013; Roth, 2005; te Dorsthorst & Kowalczyk, 2005); having to cut away sections manually is a labour-intensive process which typically leads to increased cost premiums, making it an economically unattractive practice.

We present a novel flooring system which is designed for disassembly, component reuse, and reconfigurability. Concrete segments can be assembled without the use of any grout through a compression-dominated segmentation plan. A geometry inspired by masonry fan vaults facilitates this segmentation while also allowing reconfiguration to span different distances. This paper will detail the design conceptualisation and form-finding approach for the shell, the potential for reconfigurability in the context of a circular economy of construction, the fabrication and assembly of a quarter-scale prototype, and, lastly, a sustainability assessment of the flooring system.

2 CONCEPTUAL AND STRUCTURAL DESIGN

A segmented shell flooring system offers several advantages related to carbon savings compared to conventional flat slab concrete flooring. Firstly, the funicular nature of a shell (i.e., mainly acting in compression) is highly compatible with brittle materials with low tensile capacity such as plain concrete. As such, less concrete is needed to span distances and there is no need to embed steel reinforcement within the concrete to resolve tensile stresses. Rather, the thrust of the vault can be resolved externally, either through buttresses (as is the case in Gothic cathedrals) or through external ties, creating a physical separation between the materials which

is conducive for disassembly and reuse. Secondly, segmentation allows for accurate prefabrication of the curved components, thereby reducing the amount of on-site concrete required. This leads to less material wastage due to the more controlled factory environment compared to on-site casting. Lastly, the compressive nature of the shell combined with the segmentation allows for dry joints under compression between segments. This facilitates disassembly as there is no need to manually cut out elements using saws or to remove grouting. As a trade-off, the complexity lies in the assembly and disassembly process of the shell which is more involved compared to the fabrication of prismatic formwork or assembly of prefabricated flat slabs.

The use of dry joints in segmented shells for flooring systems is not a novel concept: a 3D sand-printed floor using 5 discrete segments has been prototype (Rippmann et al., 2018) and a nine-segment concrete floor demonstrator spanning a 4.5 m by 4.5 m bay (Oval et al., 2023) all validates that it is a structurally feasible system. However, the primary focus of these prototypes was not on the potential for disassembly and circularity of the structure; the segmentation was typically a by-product of size constraints imposed by transportation or digital fabrication print area limitations. Reconfiguration of the structure to span different distances was also not considered as it is challenging for a form-found shell; changing the distance spanned will affect membrane action and introduce bending unless the curvature of the structure is adjusted.

To further leverage the disassembly potential of a segmented concrete shell for circularity, therefore increasing its lifespan and reducing its environmental impact, the form-finding and segmentation plan of the shell must be taken into consideration. The two are intimately interlinked to each other as the shape of the shell will affect the ‘optimal’ locations of interfaces. The criteria for an optimal interface were defined as follows:

1. Compression dominated to avoid opening of interfaces and hinge formation, and
2. Minimal shear forces along the surface of the interface to avoid slipping.

To satisfy both criteria, it follows that interfaces should be oriented with their normal aligned with the principal compressive stress direction.

2.1 *Fan vault concept*

The masonry fan vault presents a base for the shell geometry which allows for a simple segmentation plan that is both optimal and allows for reconfigurability. The geometry of the fan vault is characterised by surfaces of revolutions which form conoids which may intersect with one another, with the central region (if there are any) filled by a spandrel—a shallow or flat segment acting as a keystone. The manner in which the conoids intersect with each other defines the class of fan vault (Bagi, 2021). Here, we are mainly interested in fan vaults where the conoids do not intersect with each other, to avoid trimming segments that would become harder to reuse. The surface of revolution also allows for increased repetition of segments along the hoop direction, facilitating prefabrication and modularity.

Membrane analysis can be performed to determine a state of stresses on the conoids following plasticity’s lower-bound theorem (Heyman, 1967), shown in Figure 1. Taking a strip along the conoid and applying a radially symmetric load at the top, the analysis shows that, with a sufficiently large spandrel load, the structure experiences no tensile stresses. In this radially symmetric load case, the compressive stresses flow along the strip direction with the other principal stress direction found along the hoop-wise direction of the conoids, providing an evident and simple segmentation plan. While the true loading clearly does not take the form of a constant, radially symmetric load, this provides a good starting point for the segmentation plan. In addition, the locations of interfaces having minimal shear forces will inevitably vary depending on the loading due to asymmetric load cases, making optimisation of a segmentation plan against one load case an unproductive exercise. The shear which will be present in the interfaces can be minimised by the inclusion of interlocking shear keys between segments to resist slippage. Staggering can also aid in this, although was not considered for this design as it introduces complexity to the fabrication process.

The spandrel and the conoid of the fan vault inspired shell can be separated into two parts of the system, allowing them to be uncoupled to span different distances, as shown in Figure 2. Shorter distances can be spanned by removing the sections of the upper conoids and

Figure 1. Conoid membrane analysis of the fan vault informing the segmentation plan for the shell.

installing a new spandrel while larger distances can be spanned by installing a larger spandrel. For the latter, the increased loading may not be sufficiently resisted by the conoids. In such cases, it may be necessary to reinforce the conoids (e.g., using carbon fibre plates or wraps) unless the shell was already pre-designed for a larger span. Note that if a different distance is to be spanned, this requires the fabrication of a new spandrel, leading to waste. However, the flexibility the system affords for future reuse cases may prove beneficial; while it has been suggested that a *form follows availability* approach should be taken for a design using reused components (Brütting et al., 2019), increased flexibility in the distance spanned allows designers more freedom in the final form and may lower the barrier towards reuse.

Figure 2. Reuse of a segmented fan concrete shell to span different bay sizes.

2.2 Form finding and structural optimisation

Form finding of the segmented fan concrete shell was performed by firstly parametrising the geometry into the thicknesses at various locations and the curve profile of the conoid, illustrated in Figure 3. This was performed in the Grasshopper visual programming environment (Rutten et al., 2007). The shape of the curve was controlled by a Bézier curve with 4 control points, with the two endpoints set by the shell width and depth. The coordinates for the Bézier curve's profile were limited to the upper triangle to ensure a concave profile. The thickness in the conoid was allowed to vary linearly (against the u-direction shown in Figure 3) from the base to the top and a separate constant thickness was allowed for the spandrel. The span of this shell was set as a constant 8 m and the distance from the mid-depth of the spandrel to the mid-depth of the conoid base was set to 800 mm. This was selected as a representative span and depth, although different spans can be easily optimised for using the same approach. Segmentation along the strip direction was done every 1 m as this is assumed to provide a sufficiently small resolution for reconfiguration purposes while avoiding too many segmentations which results in a lower structural capacity. As it is envisioned that the smallest distance between columns will be at least 4 m, the segments in a 2 m vicinity from each corner were merged. M24 steel ties were connected at the corners to resolve the horizontal thrust of the shell.

Figure 3. Parametrized geometry model.

Using the shell geometry parametrised into 7 variables (with the two points deconstructed into their coordinate values), a finite element model in Karamba3D (Preisinger & Heimrath, 2014) was created using shell elements to ensure that the element stresses are within the material limits and that the shell is stable. In addition to the gravitational loading, a uniform imposed load of 1 kPa and a live load of 1.5 kPa were applied. The lower live load was selected based on work by Orr (2018) which suggested it is a more representative loading for a typical office building. Various area loading was applied to the shell and preliminary investigations show that the uniform live load case was likely to be critical. As such, optimisation was carried out based on that load case.

A unique modelling approach for the interfaces was taken, inspired by one developed for a rigid body analysis (Galassi et al., 2018). At the interface, stiff beam elements are connected to nodes located at the extreme fibre locations. The beams are removed if tensile forces are transmitted across the nodes, allowing 1) a hinge to form at the interface and 2) the segments to fully detach themselves. The beam elements are added back in if the nodes are detected to penetrate each other, signifying a closing of the interface. The use of a stiff beam element is due to the lack of rigid links in Karamba3D. Analysis was performed by incrementally increasing the loading by 10% for a linear elastic model where the interface elements were modified for each iteration. Note that this is not a non-linear analysis, but rather a set of linear elastic analyses where the previous analysis informs the state of the joints of the next. As such, it will not fully capture the behaviour of the structure, especially in cases where many hinges form as the model will exhibit large rotations and displacements. A fully non-linear analysis incorporating contact behaviour using commercial software such as 3DEC and LS-DYNA is expected to be able to capture the behaviour of the shell. However, the long computation time is not conducive for optimisation purposes, often taking several days to compute a single shell.

The Wallacei Grasshopper plugin (Makki et al., 2021), which implements the NSGA-II multi-objective evolutionary algorithm (Deb et al., 2002) was used to optimise the shell against two objectives: maximised buckling load factor and minimised mass (which was used as a surrogate metric for the embodied carbon of the structure). Once the algorithm converged, a set of Pareto front solutions was obtained which provides a minimum mass structure given a certain buckling load factor. Due to the limitations of the linear elastic analysis used, as well as to account for manufacturing tolerances, a candidate with a large buckling load factor of 10 (the properties of which are tabulated in Table 1) was selected for the basis of design for the fabricated quarter-scale prototype spanning 2 m by 2 m. As the thicknesses of the quarter-scale prototype were quite thin (being merely 18 mm at the top of the conoid), all the thicknesses were doubled to accommodate fabrication process tolerances and prevent significant damage from storage and handling.

3 FABRICATION

Fabrication of variable-thickness curved concrete shells poses challenges on two fronts: the manufacturing of the formwork and the deposition of the material. The Automated Robotic Concrete Spraying fabrication process (Nuh et al., 2022) was developed to address these challenges and was used to fabricate the curved conoid segments (Figure 4). Using a target spraying surface constructed using a wooden frame and a shape-reconfigurable pin-bed, a robot arm connected to a glass fibre reinforced concrete (GFRC) spraying station deposits the

Table 1. Selected candidate from form finding optimisation.

	Selected candidate's properties

Bézier point 2 [p_2]	(3.48, 0.70) m

material where it is required. The shear keys were formed by including their negatives within the wooden frame. As the spandrel was of a flat profile, it was not manufactured using this process and was instead cast in a conventional manner using wooden formwork. Further details regarding the GFRC mix can be found in Nuh et al. (2022) and the unreinforced spandrel was cast using a standard C30/37 class concrete mix.

Figure 4. Digital fabrication setup (left) used to fabricate the sprayed GFRC conoid segments (right).

4 ASSEMBLY AND DISASSEMBLY

The assembly of the segmented fan concrete shell requires that all pieces are placed in their correct position before being decentred. As opposed to masonry structures which often require intricate falsework and scaffolding due to the large number of bricks, the shell's larger segments mean that telescopic props and standard scaffolding can be used to position the structure as needed. The addition of shear keys also aids in the erection process as they align adjacent segments together. A similar method was used to great effect by Oval et al. (2023) to assemble their nine-segment shell demonstrator.

The detailed procedure for the assembly of the prototype shell is as follows, also illustrated in Figure 5:

1. Position all segments in their appropriate location using props and jacks,
2. Tighten the steel ties to resolve the horizontal thrust from the shell's self-weight, and
3. Remove the props.

For the prototype, the fabrication tolerances of the hand-made wooden side frames were found to be lacking. This resulted in gaps between segments, which ranged from effectively flush to 1 cm (i.e., approximately 2% of their size), hindering solid contact and arch action formation. Therefore, fine sand was added between the interfaces prior to tightening the steel

ties. This was found to sufficiently stabilise the shell while still being demountable. The fully assembled shell is shown in Figure 6.

The disassembly process of the shell follows the same procedure as the assembly process but in reverse; by adding props and slightly pushing on the segments, the tie can be safely loosened, and the segments lifted off one by one.

Figure 5. Assembly and disassembly process for the shell.

5 SUSTAINABILITY ASSESSMENT

The embodied carbon impacts from *cradle-to-gate* (Modules A1 to A3 of the BS EN 15798 life cycle stages) of various flooring systems were compared to provide a quantitative comparison of their carbon impact. The selected flooring systems compared are:

1. Flat concrete slab,
2. BubbleDeck (a voided hollow deck system), and
3. Segmented fan concrete shell.

Combined embodied carbon factors for the relevant materials are tabulated in Table 2. For this analysis, the flat concrete slab, BubbleDeck, and the flat spandrel of the segmented shell were designed using C30/37 class concrete with 35% cement replacement and reinforcement bars having a yield stress of 500 MPa. The design was based on an 8 m by 8 m bay under the same loading as the segmented shell based on Eurocode 2 for the flat slab and recommendations from the BubbleDeck manufacturer for the voided hollow deck system (BubbleDeck, 2006). The HDPE bubble thickness used to form the BubbleDeck voids was assumed to be 5 mm. Excluded from the calculation is the raised flooring—which will be used to create a level surface for the shell like the demonstrator shell by Oval et al. (2023)—as it is assumed that all flooring systems will include them to accommodate services. The resulting masses and the embodied carbon equivalents of the three flooring systems are tabulated in Table 3.

The analysis shows that the segmented fan concrete shell has a lower embodied carbon impact compared to the other options, albeit only a 13.6% saving compared to the reference flat slab. This is mainly due to the high embodied carbon of the GFRC mix which has a high proportion of cement. This saving can be further increased by using larger aggregates and by adding cement replacement as binder. Conversely, the 8 m by 8 m span used to design the flat slab and BubbleDeck are not optimal spans for those systems; shorter spans have been shown to reduce the initial embodied carbon contribution of these reinforced concrete systems (Drewniok, 2020) making them potentially competitive with the segmented fan concrete shell. However, one clear benefit of

the shell is the large mass savings of 71% over the baseline flat slab. This can result in drastic savings in the material of the columns and footings of the structure, leading to further carbon savings elsewhere in the structure. In addition, the potential for reconfiguration and design for reuse for different spans remains a strong benefit of the shell system for sustainability reasons.

6 CONCLUSIONS

The segmented fan concrete shell presented is a novel concrete flooring system which is designed for reuse in a circular economy. Using the revolution geometry of the fan vault provides a simple segmentation plan which facilitates reconfiguration into different spans. The quarter-scale prototype demonstrates that the system is structurally sound and can be assembled and disassembled using simple props.

To validate the modelling approach as well as investigate the structural capacity and reconfigurability of the system, an experimental testing program is currently underway. Further

work is required to reduce the tolerance of the segments to provide better contact at interfaces for future prototypes. Lastly, further improvements to the mix design of the GFRC material can lead to further reductions to the cradle-to-gate embodied carbon of the structure.

Can we reuse plasterboards?

S. Kitayama & O. Iuorio
University of Leeds, Leeds, UK

ABSTRACT: Gypsum turns plaster when it is dehydrated, and it returns to gypsum when it is hydrated. Because of this, gypsum is 100 % recyclable in theory. However, in reality, only 4% (in mass) of the plasterboard is from recycled plasterboard. This is because of the substances, other than fresh gypsum from quarries, to make plasterboard, and the current demolition methods that cause material contamination. The current practice of manufacturing, construction, and deconstruction of plasterboard necessitates significant resource extraction and carbon emissions, and the situation is unlikely to change in the foreseeable future. Reusing, instead of recycling, construction material is effective in reducing resource extraction and carbon emissions, however, it has not been investigated at all for plasterboard. Thus, this paper explores the potential and feasibility of reusing plasterboard used for exterior infill walls, which is made of plasterboards and an increasingly used façade construction method in the UK.

1 INTRODUCTION

Exterior lightweight infill walls (see Figure 1) are increasingly used in building façade construction in the UK (SCI, 2019a). These walls are often replaced during the refurbishment of buildings to adapt spaces to new functions or to comply with new energy efficiency or humidity control targets (Morgan & Stevenson, 2005). The replacement typically occurs every 30 years (ARUP, 2022), even though most of the components could maintain their good performance generally much longer than 30 years.

The authors of this article have recently evaluated the carbon emission from the exterior lightweight infill wall construction/deconstruction, using lifecycle assessment procedures (RICS, 2017) of an actual building (located in the Greater Manchester area, UK). The authors found that the construction and deconstruction of exterior lightweight infill walls could contribute significantly to the amount of carbon emission (more than 20% of embodied carbon emitted from the entire building). Thus, the authors have investigated the potential of disassembly of infill wall components for future reuse.

The earlier work by the authors investigated the potential for the disassembly and reuse of lightweight cold-formed steel (CFS) members within the infill wall (Kitayama and Iuorio, 2022). The steel frame members in infill walls are the major contributor to the carbon emission from the construction and deconstruction of infill walls. However, the exterior infill walls are made up of, not only steel frames, but several other components, including internal plasterboards, cavity insulation, external plasterboard, external insulation, and cladding. The contributions of carbon emissions from the construction and deconstruction of these components are significant. Also, the current practice of construction and deconstruction of any of these components has not established circular practice (i.e., reuse or energy-efficient recycling). Moreover, past research and practice focused on recycling to improve the efficient use of materials and carbon reduction, however, a significant improvement in material use and carbon reduction from recycling has not been achieved and will not be achieved in the foreseeable future.

Reusing, instead of recycling, construction material can be effective in reducing resource extraction and carbon emissions, however, it has not been investigated at all for plasterboard, which is one of the main components of infill walls. Thus, this paper first examines the potential for the disassembly and reuse of gypsum plasterboard based on available publications, including journal articles, technical reports, Environmental Product Declarations (EDPs) and other company documents. The examination follows the order of lifecycle stages specified in BS EN 15978 (BSI, 2011), which are: product stage, construction process stage, use stage, and end-of-life stage. Subsequently, the feasibility of disassembly and reuse of plasterboard is discussed by looking at three different aspects: connections between plasterboard and steel profiles, available experimental data, and construction methods used for infill walls.

Figure 1. Exterior infill wall: (left) notations of infill wall components; (right) notations of lightweight cold-formed steel members and surrounding primary structure.

2 LIFECYCLE STAGES OF PLASTERBOARD

2.1 Product stage

According to Etex's EDP (Etex, 2018), the product of plasterboard consists of plasterboard (94.8%), paper liner (3.6%) and additives (1.6%). Among the 94.8% of the plasterboard, 36% is from mineral quarrying, 60% is from by-products from a coal-burning power station, and 4% is from recycled plasterboard (Etex, 2018). The rate of recycled gypsum in new plasterboards is limited to only 4%. This is due to the presence of impurities, introduced with the use of additives and the lining paper. There is an ongoing research program in the UK and abroad that aims to increase the recycled gypsum content in new plasterboards by increasing the purity rate of the collected gypsum waste (Erbs et al., 2018; Castro-Díaz et al., 2021). However, usually, the development and implementation of new technologies take a long time (Allwood et al., 2019).

2.2 Construction process stage

For the construction of exterior infill walls, the plasterboards are fixed to the studs of a lightweight steel frame, using self-drilling screws (Siniat, 2021). Screws are used at a minimum of 13mm from cut edges. The screws for the infill wall linings are used at a maximum distance of 300 mm (Siniat, 2021). The plasterboards should not be screwed to the head track, to avoid compromising the free movement relative to the structure (SCI, 2019a). One or two plasterboards are used for the internal linings for the infill walls depending on the designed performance for fire resistance, sound and heat insulations, and strength to wind load and cladding weight.

2.3 Use stage

The plasterboards do not need maintenance, repair, replacement, or refurbishment during the use stage. Plasterboards can be used in UK and European buildings for 50-60 years (Etex,

2018, 2021). While the expected life of the plasterboards is long (50-60 years), the infill walls, of which plasterboards are parts, are usually replaced every 30 years (ARUP, 2022) during the refurbishment of the building to adapt spaces to new functions or to comply with new energy efficiency or humidity control targets. The warranty period of plasterboard for some prefabricated types of infill walls is 30 years (Etex, 2020) but the warranty may be set to target the typical replacement period and it is not representative of the plasterboard's actual functional period. Indeed, warranties issued by manufacturers are often much shorter in their lifetime than the expected service life (Hartwell et al., 2021).

2.4 *End-of-life stage*

Most of the plasterboards (83% in mass) are landfilled or recycled and used for other purposes (e.g., agriculture), and the rest (17%) is sent for recycling to manufacture new plasterboard (Etex, 2018). Landfilling the plasterboard generates hydrogen sulphide, a toxic and foul-smelling gas, and incinerating the plasterboard results in the release of sulphur gas, a contributor to acid rain formation (Ndukwe & Yuan, 2016). In the UK, the method of landfilling plasterboard waste is getting stricter (DEFRA, 2010), and the landfill tax is increasing (DEFRA, 2013). Among the 83% of plasterboards that are either sent to landfilled or reused, the rate of landfilled plasterboard is declining due to the agreement with all stakeholders to reduce the waste sent to landfill (Jiménez-Rivero & García-Navarro, 2017). The low rate of recycling (17%) is due to the impurities of the collected plasterboard. The amount of recyclable post-consumer plasterboard may be increased when the plasterboard is dismantled and segregated from other wastes at the deconstruction site (Jiménez-Rivero, 2016).

In summary, the rate of recycled plasterboard in newly manufactured plasterboard is very low and the technology to increase it is still under development, the amount of landfilled plasterboard needs to be reduced due to the cost and detrimental environmental effect, and plasterboard used for infill walls can be used longer (50-60 years) than they are typically used for (30 years). The first two demonstrates the necessity of alternative way of improving resource efficiency and reducing carbon emissions from recycling and landfilling plasterboard. The third point demonstrates the potential of plasterboard being reused to extend the life of the plasterboard that is used in place. It is also clear that for the reuse of plasterboard to be practical and implemented in the near future, the technology must already exist or, at most, minor modifications of current technologies need to be conceived, as the development and implementation of totally new technologies take time (Allwood et al., 2019).

3 CAN WE REUSE PLASTERBOARD?

The reuse of plasterboard is beneficial as it can reduce the carbon emission from the production of the plasterboard. It also reduces the extraction of gypsum from quarries. Thus, we want to know if the plasterboards can be reused. In this section, the feasibility of reusing the plasterboard is discussed from three aspects: (i) Connections in plasterboard, (ii) Experiment of plasterboard, and (iii) prefabricated systems to respond to the question, "Can we reuse plasterboard?"

3.1 *Connections in plasterboard*

To disassemble and reuse plasterboards, the connections between the board and light steel frames need to be disconnected. As described in the previous section, the connections are made using screws between the plasterboard and studs, and between the plasterboard and base track. The connections need to have sufficient stiffness and strength to stabilise the infill wall. According to the company EDPs, the screws can be removed, and other screws can be used at the same location where the hole already exists, although some repair actions may be necessary. This is because when the screws are used in the pre-existing screw holes, the stability

of the screw may be weak and needs to strengthen the connection. Specifically, the manufacturer of weather defence board (external plasterboard) recognises the situation when the screws are used at the pre-existing screw holes, “Multiple attempts to fix a screw may create holes, inspect for holes carefully and seal” (Siniat, 2021).

When it is not feasible to remove the screws between the plasterboard and steel frame members due to the difficulty in finding their locations (e.g., the screws are not visible because the wallpapers hide them), the plasterboard may be locally cut to find the connections. This is deemed possible as there is an established repair method of plasterboard for up to certain areas of damage. The manufacturer of plasterboard specified the following repair options for different levels of damage (Siniat, 2021):

- Small areas of damage, up to 15mm x 15mm and a maximum of 3mm deep, may be patched using Siniat Fire Rated Silicone Sealant or Siniat Weather Defence™ Joint Tape.
- Areas up to 300mm x 300mm and a maximum of 5mm deep, may be filled with Siniat Aquamix water-resistant compound.
- An area larger than 300mm x 300mm or if the board has been perforated by damage must be replaced. Additional metal noggins or straps may be required to support the board.

The EDP for the internal plasterboard from the same company also states that a certain amount of damage is repairable (Etex, 2019): “Mechanical damage can be repaired using jointing compound, due to the easy repair associated with the plasterboards and without any adverse effects on function. Plasterboards can be easily replaced with new boards in the event of more extensive damage.”

Other methods may be introduced to ease the separation of plasterboard from the steel frames, for example, by developing a connection between the plasterboard and steel frame using a hooking or hanging mechanism, developing easily detachable adhesives, or using dot snap fasteners, Velcro strips, or magnetic strips. These connections need to be satisfactory to the essential structural functions of the infill walls, i.e., support the weight of the cladding and resist the shear and pull-out force induced by wind load. However, developing and implementing such new ideas in the practice may take time.

3.2 *Experiment of plasterboard*

The material properties of various types of plasterboards and the strength, stiffness and ductility of connections between plasterboard and lightweight cold-formed steel members have been investigated by many researchers (Iuorio 2009, 2017; Chen et al., 2016; Petrone et al., 2016; Ye et al., 2016; Selvaraj & Madhavan, 2019a; Abeyasiriwardena et al., 2021; Kyprianou et al., 2021; Stergiopoulos et al., 2022). The lightweight wall systems (plasterboard attached to either stud-only or studs and tracks) were also experimentally investigated by many (Bewick, 2013; Vieira et al., 2013; Liu et al., 2014; Peterman et al., 2014; Petrone et al., 2016; Landolfo et al., 2019; Selvaraj & Madhavan, 2018, 2019b; Kyprianou et al., 2021; Peiris & Mahendran, 2022).

The experimental results provide the material properties of the plasterboard and the strength of the walls (plasterboard + lightweight steel frame members). The information about the elastic range indicates that the wall systems or wall components are undamaged, therefore if carefully disassembled, they could be in a suitable condition for reuse. Recent research on structural members, other than exterior walls, at the connections of beam-to-slab, beam-to-column, and column-to-column, used the experimental results, in terms of the relationship between the deformation and strength, to discuss the feasibility of reusing the connected members (Uy et al, 2017.). These studies set 40% of the ultimate (peak) strength as the limit of reusability of the structural members. The 40% of the ultimate (peak) strength corresponds to the elastic deformation of the structural systems being deformed or stressed without damage. This type of experimental investigation, or re-evaluation of existing experimental results, provides further guidance on the feasibility of reusing the infill wall systems or plasterboards. A guideline document may be developed based on these test results to facilitate the reuse of plasterboard and wall systems. For other popular structural members, such as structural steel, for example, a guideline for assessment, testing and design of reclaimed members

exists (SCI, 2019b). According to this, straightness, loss of section, signs of damage, signs of fire exposure, plastic strain, etc. are checked for reuse of structural steel members. Similarly, a guideline document could be developed for the assessment of plasterboard panels for the determination of re-usability.

3.3 Prefabricated systems

Infill walls are often site assembled from lightweight cold-formed steel members that are delivered cut-to-length, followed by installation of plasterboard and other components (see Figure 1), or can be prefabricated as storey-high units (SCI, 2012). The disassembly of prefabricated, modules, in general, provides great opportunities for the refurbishment and reuse of modules or the recycling of materials and components used in the modules (SCI, 2001). Figure 2 shows the photos of prefabricated infill walls (SCI, 2008). Figure 3 presents the prefabricated panelised infill walls that were used in the construction of a school building in the Greater Manchester area, UK.

There are several advantages of using the prefabricated, panelised infill walls over other ways of constructing infill walls, such as (a) enhanced safety of installation workers (installation from inside the structure, reducing working externally at height), (b) reduced costs (reduced mast climber and scaffolding requirements; the crane is not necessary), and (c) reduced site waste.

Figure 2. Installation of lightweight infill wall in a primary structural frame (images from SCI, 2008), (left): Prefabricated infill wall with cladding, windows, and light steel frame, and (right) prefabricated infill wall with exterior plasterboard, windows, and light steel frame.

Figure 3. Prefabricated panelised infill wall with exterior plasterboard (photos taken by the authors on December 2021 in the Greater Manchester area, UK).

3.4 *Can we reuse plasterboard?*

Based on the discussions in this section, the authors consider that the plasterboards can be reused, and this can be done today. The reuse of plasterboard is done at the usual refurbishment time that takes place after 30 years of building construction. Currently, the plasterboard is reported to be functional for about 50-60 years, so the plasterboards can be reused once. Primarily, there are two ways of reusing the plasterboard: (a) removing plasterboard from steel frames and using it to construct another infill wall (or any other systems, i.e., internal partition walls, ceilings, etc.), and (b) keeping them attached to the steel frames and reusing the infill walls as prefabricated walls (see Figures 2 and 3). For (b), the plasterboards do not need to be separated from the steel frames. As discussed in the previous sections, any damage caused by the removal of plasterboard or prefabricated infill walls, or transportation processes, can be repaired by the existing technologies by manufacturers. In case the prefabricated infill walls are reused in other buildings, the size (width and height) of primary frames (steel or reinforced concrete frames) may be different from that of the original one. This is not a problem because the height and width of the infill walls are adjustable (i.e., the connection between studs and head track are adjustable; there are some spaces between the stud and column of the primary frame that are filled by insulation). Due to the advantages discussed in Section 3.3, prefabricated panelised infill walls may be most feasible for reusing plasterboard.

4 CONCLUSIONS

This paper first discussed the potential of reusing plasterboard. It showed that currently the rate of recycled plasterboard in the newly manufactured plasterboard is very low, the amount of landfilled plasterboard needs to be reduced, and plasterboard used for infill walls can be used longer than they are typically used. It then discussed the feasibility of reusing the plasterboard, looking at the feasibility of disassembling current connection systems, available experimental data, and prefabricated systems. Based on the developed analysis, the authors conclude that plasterboards have a high potential and feasibility to be reused, and the reuse of plasterboards can be done using existing technologies. Additionally, the authors consider that the prefabricated panelised infill walls are most suitable for the reuse of plasterboard due to their size and construction method. In the future experimental tests will be developed to provide further evidence of feasibility.

ACKNOWLEDGEMENT

This research is funded by EPSRC through the Interdisciplinary Circular Economy Centre for Mineral-Based Construction Materials from the UK Research and Innovation (EPSRC Reference: EP/V011820/1). The authors thank Etex for sharing the information regarding the topic in this paper.

Re-use of existing load-bearing structural components in new design

R.P.H. Vergoossen, G.J. van Eck & D.H.J.M. Jilissen

Royal HaskoningDHV, Rotterdam, South Holland, The Netherlands

ABSTRACT: One of the main contributions to meet the goals of circularity, i.e. reduce Carbon emissions and use of primary materials, is the re-use of load bearing structural components from existing structures into new structures. In the last years, as a result of the Dutch Concrete Act, different projects on re-use of structural components in new structures are executed in the Netherlands. On the other hand, the first steps in eliminating the barriers for a shift from linear to circular design and construction have been taken. One of these steps is the drafting of guidelines and codes (CB'23, NTA Steel, CROW-CUR guideline for concrete and National Annexes to Eurocodes) to make re-use of existing load-bearing components in new structures possible within the Dutch Building Act. Disseminating of knowledge through publicizing lessons-learned from executed projects is another. In this paper both points are described, with a focus on Dutch infrastructures (bridges and overpasses). Not only the technical challenges will be addressed but also the mutual influence of architectural design, road design and social safety on circular design with re-use of structural components. A framework is proposed for investing in more material and/or costs including environmental costs for easier and cheaper deconstruction depending on the most likely envisioned lifespan of the structure with regard to maintenance costs.

1 INTRODUCTION

The Dutch construction industry is believed [Ministry 2016] to use approximately half of all raw materials and 40% of the total energy in the Netherlands. Additionally, the industry is a major contributor to waste production, accounting for up to 40%, as well as CO₂ emissions, at almost 35%. The Dutch Concrete Agreement [Ministry 2018], supported by the Dutch government, states that CO₂ emissions must be reduced with 49% compared to 1990 and that all concrete waste must be recycled in new concrete by 2030. Innovations in the construction sector are needed to achieve these goals. One of the solutions is to reuse structural elements from bridges/overpasses to be demolished and to use them in new structures to be built. It sounds simple, though it isn't done in practice. From a study [Donker 2021] it was concluded a few barriers are present.

2 FIRST BARRIER: NO GUIDELINES

One of the key barriers is the lack of standards and guidelines for the reuse of structural elements. For example, the Eurocodes are currently fully focused on new construction. However, from the Building Act, a construction to be erected must often comply with it, or deviations must be made in agreement with the authority. Various guidelines (CB'23 [Platform CB'23 2020], NTA Steel [NTA 8713 2023], CROW-CUR guideline for concrete [CUR-Aanbeveling 127 2021]) have been drawn up to provide guidance. A draft version of the CUR guideline for the reuse of structural

elements [CROW-CUR, 2023] is already available. Which should eventually lead to guidelines for reuse in the National Annexes of the Eurocodes. In international connection with the new FIB modelcode 2020 end-of-life scenarios and re-use are for the first time in history (pre)codified.

Deconstruction of structural elements from an existing structure currently costs (far) more than traditional demolition. This means that there must be a party that makes a pre-financing, extra investment, to dismantle the elements instead of crushing them into concrete aggregate. A contractor is often commissioned to demolish an existing viaduct and build a new one. For the contractor, the reuse of constructive elements and making an extra investment is therefore only interesting if it is certain that the elements can be reused or sold in the foreseeable future. At the same time, when a new viaduct is being built, one wants to be certain that these reused elements will be released in time and that they can be provided with a quality declaration (assurance of delivery) after disassembly and, if necessary, modification and repair. In addition, both parties benefit from knowing whether, and in what capacity, the elements can be reused. For this, a structural assessment must be carried out, which also requires pre-financing. When a client in a country or region has a large part of the (main) infrastructure, it is obvious that the pre-financing and matchmaking is done by the client. The client can stimulate dismantling and reuse through contracts and has an overview of constructions that will expire and where new constructions are required.

At the moment there is no stock of deconstructed elements. When elements are deconstructed from various bridges and overpasses over time, a stock is built up. Ideally, this stock will consist of various elements with different lengths, angles of skew and load bearing capacities. In this way, the elements can be most efficiently matched to the preconditions of the new overpass to be built.

3 THE SECOND BARRIER: DISSEMINATING OF KNOWLEDGE

Reuse of concrete components in new construction has already been applied in various projects in recent years [Küpfer 2023]. However, the reuse of structural elements in new bridges has not been done before.

Rijkswaterstaat, the Dutch Ministry of Infrastructure, has asked the market through a Strategic Business Innovation Research (SBIR) assignment to come up with ideas for Circular Viaducts in order to achieve its goal of being climate neutral and fully circular by 2030. The consortium with Royal HaskoningDHV with reuse of prefab girders was chosen by an independent assessment committee to realize a tested prototype after the feasibility study showed it was feasible.

In Groningen, a large-scale conversion of the southern ring road is taking place. The contractor had been commissioned to demolish the viaduct KW21 Europaplein. Instead of demolishing the entire viaduct and grinding it into aggregate, it was decided, in the context of circular construction, to reuse the 26 prefabricated prestressed girders from the main spans.

Figure 1. Deconstruction of prefab girders in Groningen (left) and girders in temporary storage (right).

A temporary access bridge (Oling 5) had to be built at the location of a temporary residential area in Appingedam (near Groningen). Seven girders from the former Groningen viaduct were used for this. But before the girders could be reused, the girders were stripped of the in-situ deck and the tooth support in a temporary storage facility. The original design was based on three shorter spans. To be as circular as possible, the design has been adapted to the available beams from Groningen. The access bridge now consists of a single span, retaining the original beam length of 18.2m. In addition to the beams, the tubular piles, sheet piles and H-profiles for the substructure have also been reused. In short, only the in-situ deck and the handrail were new for this bridge.

Figure 2. Temporary access bridge Oling 5: reused girders, sheet piles and purlins.

Within the SBIR project the project team was looking for a project in which a new overpass has to be constructed. Project partner Dura Vermeer has been awarded the tender of the replacement of the 60-year-old overpass Hoog Burel over the A1 motorway. The tender design consisted of a fully new overpass with 4 spans and an angle of skew of 30 degrees. The project team of Liggers2.0 went looking to several projects in construction if girders were to be demolished with lengths that could fit. In the project Southern Ring Road Groningen such an overpass was found. But that overpass had girders of 13 m and 19 m (with half joints) were the overpass Hoog Burel needed girders of 34 m and 14.4 m. The contact demands of the new overpass Hoog Burel were such that the length of the girders wasn't allowed to change. Therefore, it was decided to investigate if the main spans of 19 m could be shortened to the desired length of 14.4 m. One of the challenges was that the original shop drawings of the girders from the overpass in Groningen were lost. Another challenge was that because of the demands of the number of construction joints, the girders had to be supported indirectly to provide sufficient vertical support reaction for the bearings to resist horizontal forces and movements. All actions to prove that the girders could be adapted and fulfill the structural safety requirements of a new structure are described in [Vergoossen 2022]. In order to prove the quality of the elements, tests on bored cylinders were performed in the laboratory. Strength (both compression and tensile splitting), chloride ingress, carbonation and alkali-aggregate reaction were tested. All tests showed very high performance with almost zero ingress of aggressive agents after 40 years. Based on these results a remaining service life of hundreds of years is predicted according to FIB modelcode on service life design [CEB-FIP fib 2006]. As these are one of the first elements which are being reused these tests were performed as part of a the SBIR pilot project to demonstrate that the remaining service life generally is no problem for these elements. In the future less or no tests are required. The girders were placed under a large audience from Rijkswaterstaat and Ligger2.0 project partners. These girders are the first re-used girders within the acreage of Rijkswaterstaat. Although, it was proven that the girders can be adapted this project was far from ideal from a circularity viewpoint. As the girders had to be shorten for about 30% of their original length, and the skew angle had to be increase from 8 to 30 degrees. Also, the indirect support resulted in a lot of extra engineering

work and some extra reinforcement and extra roughening of the webs of the girders. On the other hand, because of the many extra challenges in this project, it can be said that because all these challenges were successfully solved all girders can be adapted. Despite all these modifications still a huge environmental saving in terms of CO₂-eq of 96% has been achieved when compared purely to newly-cast girders.

A previous case study [Vergoossen 2021] has shown that a saving of more than 40% CO₂-eq can be achieved when looking at a viaduct by only reusing girders instead of making new girders. As 26 girders were dismantled and 16+7=23 girders were used in the above-described project, still three girders are available. Although, there were some promising contacts for a new pedestrian bridge, it was decided to keep these girders into storage. Therefore, these girders were transported to the Urban Miner facility in 's Gravendeel of project partner Dura Vermeer. The girders are also placed at the digital marketplace Bridgebank, so interested parties can find the properties of the girders. The project partners of Ligger2.0 are currently investigating a new pilot bridge where the original inverted-T-beams are transformed into H-beams, which can be connected together with transversely post-tensioned prestressing without bond. In that way a fully re-useable structure can be made, without waste and the need of sawing or drilling.

During the feasibility phase of the SBIR project, the project team of Liggers2.0 investigated which structures with girders were to be demolished in the next years. One of these structures was planned to be demolished before the submission date of the tender. The project team reacted agile and decided to invest into the dismantlement of 6 of the 40 girders, as an option for a pilot project if the project was awarded. On the other hand, the dismantlement helped the feasibility study as it proved it is possible to save girders from demolition. Although the project was awarded, the girders weren't suitable for the above-mentioned project Hoog Burel. So, the project team went on searching for another possible location.

Figure 3. Placing the reused girders in Hoog Burel.

That was found to be the new bridge in the provincial road N386. In that road a new water and fauna underpass had to be designed. The reference design consisted of a two-span bridge with spans of 10 m. As the existing girders from the overpass in the A9 Motorway had a length of 22 m it was decided to change the design into a single span of 21.5 m. On this way even extra width of the fauna and a better water run-off could be made. As there were only 6 girders saved and the width of the N386 needed 8 girders to fit, the new structures will consist of a combination of 2 new girders and 6 re-used ones. In this contract the project partner Haitsma Beton, which is the largest prefabrication producer of the Netherlands, will produce

the two new girders as well as deliver the 6 re-used girders as a client delivery to the contractor. The project is planned to be constructed this year.

Contractor Dura Vermeer deconstructed a 45-year-old pedestrian overpass in the city of Zoetermeer. The I-girders were in such a good shape that it was decided to save these girders and put them into a storage. For a project for a new sports facility in Amsterdam near the Johan Cruijf Arena a new temporary pedestrian bridge was planned. That project was also awarded to Dura Vermeer. Therefore, together with Royal HaskoningDHV it was decided to design the new bridge based on the available I girders from the overpass in Zoetermeer. After the completion of the design, the total project unfortunately was stopped because of lack of funds for the total project. Therefore the design still only exists on paper. The girders are still in a storage and the availability of the girders is made publicly via the platform Bridgebank www.bruggenbank.nl.

Figure 4. a) former pedestrian overpass Zoetermeer (left) and b) girders in storage (right).

Figure 5. Longitudinal section of the design with the reused girder.

Figure 6. Cross-section of the design with the reused girder.

For the Floriade in Almere three new pedestrian bridges were needed. It was decided that these bridges should be designed as circular as possible. It was proposed by Dura Vermeer to build one of these bridge as a ‘second life bridge’. Shortly before the Floriade project started, Dura Vermeer was commissioned to remove the pedestrian overpass “Bolgerijnse Kade” over motorway 27. It was decided to re-use four of the main girders in the new bridge at the Floriade. The other elements of the Floriade bridge also consisted of re-used elements [Doorn 2021]. The other six girders are placed in a storage and their availability is made publicly by the Bridgebank.

Together with Rijkswaterstaat and the consortium Closing the Loop, who was also awarded a SBIR pilot overpass, the partners of Liggers2.0 are investigating the re-use of up to 1500 girders which are to be demolished within the A9 motorway project. The first success is that about 40 girders are dismantled for re-use of an overpass over the A76 for Rijkswaterstaat. Another success is that a letter of intent between Rijkswaterstaat and the province of Noord-Holland was signed to dismantle at least 32 girders for two new bridges in de provinciale road N201. A feasibility study is conducted to structural assess all the girders if they can fulfill the demands for new structures in new motorways for Rijkswaterstaat. As the costs of dismantlement usually are much higher than demolition, someone has to invest in the dismantlement. In many cases at that time there isn't any assurance that the girders can be re-used. To gain more assurance the first step is to perform structural assessments to check if the girders can meet the requirements. In some cases, a second step is to perform laboratory tests on drilled cylinders from the structure to assess the ingress of carbonation and chlorides and the susceptibility of Alkali-Aggregate-reaction within the concrete. Although for most of the prefabricated pretensioned concrete girders there aren't any serious deterioration mechanisms as the concrete strength and quality is very high and therefore the concrete is very dense.

4 DISCUSSION

In addition to the assessment level for new construction from the Eurocodes, the Netherlands has from the Dutch standard NEN 8700 the levels for reconstruction, usage and disapproval for assessing existing structures. The lack of a specified level for reuse has led to a discussion as to which level should be maintained for reused structural elements. The divisions that can be made here are everything at new construction level (Eurocodes), loads and partial safety factors at new construction level (Eurocodes) with the capacity following the NEN 8700 for existing structures (add shear capacity of concrete share and stirrups), and loads and partial safety factors reconstruction level (NEN 8700) with the capacity following the NEN 8700 again. First, one could always assume new construction. If this level cannot be met, the capacity according to NEN 8700 can be assumed. In this way, the safety philosophy of the design (reliability index) is maintained. Based on the FIB model code 2020 one could use the principle of "economic value" for decision-making. For example, in the case of an inverted T-girder with an in-situ deck where the deck is not removed, one could assume that the reconstruction level is used. Structurally, nothing changes to the element and the economic investment is relatively limited. In practice, the in-situ deck will have to be removed in order to obtain a single bridge deck again after casting a new in-situ deck on site and due to the mediocre quality of the old concrete. In that case, structural changes do occur in the element to be reused and a relatively large investment must be made. The most economic value is then obtained by making the relatively small additional investment to meet the assessment level for new structures.

The structural design of an overpass or bridge is generally determined by conditions like the road layout, the desired location and number of supports (and therefore the length of the spans), the maximum length of the structure and the construction height of the deck. One is used to designing a construction and ordering the structural elements project-specifically. From the design point of view the highest efficiency is achieved with "taylor fit" elements. Reused elements must then be modified to be used in a new bridge or overpass. In addition, there is a good chance that newly produced project-specific elements will have to be adapted for future reuse. The most circular would be to reuse elements as they are deconstructed. This means that one has to design with the elements that are available. This does depend on the stock and the contract requirements of the owner of the construction to be deconstructed. In addition, a contractor prefers to reuse elements as quickly as possible in order to save on storage costs.

5 CONCLUSIONS

The various projects described in this paper show that it is very well possible to reuse structural elements from existing overpasses in new overpasses to be built, both demand and

supply driven. It is possible to modify elements to enable application within the design of the structure to be realized. However, it is most circular to reuse elements with only minimal adjustments, so this is preferable. This means that one has to design based on the elements that are or will become available.

In many cases, reused structural elements are still more expensive than the traditional demolition and production of new elements. Costs for deconstruction, storage and modification can still be optimized. The reuse of structural elements does make a significant contribution to the circularity goals. In this way a contribution is made to moving away from the throw-away society.

Quality assurance process for reuse of building components

A. Räsänen & J. Lahdensivu

Tampere University, Tampere, Finland

ABSTRACT: Reusing building components has generated discussion increasingly. Current guidelines and practices are not suitable for the reuse process, and therefore new guidelines need to be developed. With new guidelines the quality of reuse can be ensured. The quality assurance process can be divided in five different stages including pre-deconstruction audit, structural condition investigation, deconstruction design and deconstruction, demands for redesign in new building and product approval and authorization. In the process, overall perspective of the building and its structures is required. This can be achieved by studying old documents and doing structural condition investigation. With the results, more exact information about the structural properties of the building components can be obtained. These results can be used in redesigning the components and in product approval. Also, the quality of the deconstruction stage needs to be ensured in order to avoid any effects on the structural properties of reusable building components.

1 INTRODUCTION

Construction industry consumes a vast amount of natural resources globally. In addition to natural resources, construction industry produces over 35 % of the EU's total waste generation. Also, greenhouse gas (GHG) emissions are estimated to be 5-12 % of total national GHG emissions. GHG emissions includes material extraction, manufacturing of new construction products, construction and renovation of buildings. Therefore, saving natural resources is one essential means of curbing climate change. (European Commission 2022)

In a Finnish apartment building carbon footprint from construction materials is average 26 % of the whole life cycle of the building. Most of the carbon footprint consist of energy consumption, which is approximately 63 %, since buildings requires heating during cold periods and cooling in hot periods in Finland. The carbon footprint of the whole service life may differ from this average value in individual cases, because it depends on energy efficiency of the building, carbon footprint of the energy production and the materials used in the building. (Ymparisto 2016) Currently zero-energy buildings have become more common and the emissions of energy production have been decreased. Therefore, the material emissions of the whole life cycle increase in proportion to the emissions of a whole building. Construction product industry has developed several construction products by which the carbon footprint of buildings can be decreased. With low-carbon concrete the carbon footprint of an usual apartment building can be decreased 34 % (Lahdensivu & Lahdensivu 2021). Reusing building components is one potential way to decrease the carbon footprint even more, because the carbon footprint of a product stage (A1-A3) is zero according to Finnish national guideline (Kuittinen 2019). According to German studies carbon footprint (A1-A3) of reused concrete elements is between 3 and 5 % (Mettke 2010). The product stage A1-A3 includes material supply, transport and manufacturing according to information modules of assessment of environmental, social and economic performance of the construction works in European standard SFS-EN 15643:2021.

Figure 1. The progress of negative values for reuse of hollow-core slabs in the future compared to demolition and recycling (Naber 2012, p. 135).

Buildings are designed to service several decades. In Finland facades are designed typically for 50 years while frame and foundation structures are designed to service at least 100 years. However, industrial and office buildings have been demolished notably under designed service-life, typically after 20 to 40 years (Huuhka & Lahdensivu 2014). Therefore, building components have several decades of service-life left at demolition stage and potential for reuse.

According to European Union's directive 2008/98/EC of 19 November 2008 on waste and repealing certain Directives, reuse, recycling and other material recovery of construction and demolition waste should have been increased to a minimum of 70 % by weight by 2020. This varies between EU's member countries, but the most common way is using the waste as a substitutive material in land construction or as an aggregate in concrete. However, recycling is inferior to reusing in waste hierarchy in 2008/98/EC. Also, by reusing building components, for example concrete components, the carbon footprint and energy consumption can be decreased 96-98 % compared to a new product (Mettke 2010, ReCreate 2022).

Reuse of building components have been studied previously by several researchers (Mettke 2010, Lahdensivu et al. 2015, Huuhka et al. 2018, van den Brink 2020, RE:Source 2021, Zhu et al. 2022). From previous studies it can be concluded that reusing is possible. However, a main challenge found in previous studies is quality assurance process (Re:Source 2021, Zhu et al. 2022). The challenge includes especially ensuring safety and healthiness of the reusable building components and methods for investigate these.

Building components may deteriorate or material properties may change in-use. Also, the components may get damaged in deconstruction. Several national guidelines for condition assessment of façade structures have been developed (Lahdensivu et al. 2019, Lahdensivu et al. 2021), but for load-bearing structures there are no as united whole guidelines. This structural assessment is an essential stage for reuse process of building components since the properties and reusable components can be discovered before deconstruction. A problem is a lack of established practices of reuse, which increases negative values as costs, time, environment impact and social factors of reuse. These negative values may increase higher than in recycling and new construction. In the future after getting more utilized practices, negative values are assumed to decrease lower than demolition and new construction (Figure 1). (van den Brink 2020)

This paper presents a concept of quality assurance process for reuse of pre-cast concrete elements. The aim of the study is to create a practical process which can be used to ensure the quality of the reuse of building components. The current quality assurance processes are for

new construction and for example in concrete industry these are for concrete batching. However, the properties of concrete vary in time and the properties in old structures may differ from the age of batching. Therefore, new processes need to be developed for old reusable components. The process in this study is supposed to promote the reuse of building components by providing a base for development of practices. This process will be developed during the Reusing precast concrete for a circular economy (ReCreate) project by using it in practice.

2 REUSE PROCESS

Several different further actions may be done after building's service life. The further action depends on the owner's decision of what is the future of the plot or the building. The decision may be maintenance, repair or upgrading works, demolition or deconstruction for reuse of building components. The deconstruction process differs significantly from usual demolition and new construction as far as designing and building practices. (Bertino et al. 2021)

Reuse process can be divided in four different stages: deconstruction, transport, storage and building. All these stages differ from new construction and should be considered in the reuse process as they increase the challenges of reusing without established practices. (Bertino et al. 2021) The current challenges in the whole reuse process are costs, design, regulation, market and deconstruction. The costs may be three to five times higher in reuse than in new construction, because deconstruction and design stages being unusual and thus taking more time (Rakhshan et al. 2020). Furthermore, the costs in reuse process may be lower than in new construction if labor costs are small and the deconstructed components have demand (da Rocha & Sattler 2009). In addition to these challenges, one of the main challenges, which must not be forgotten, is the quality assurance of the reusable building components as mentioned in the introduction. The quality assurance process will be discussed further in the following section.

3 QUALITY ASSURANCE PROCESS

There are several different stages in quality assurance process. Each of these stages are essential to consider in reuse process for safe and reliable reuse of building components. The process starts before deconstruction and ends to product approval after the deconstruction of the building. General flow diagram of the quality assurance process is illustrated in Figure 2.

3.1 *Pre-deconstruction audit*

Before deconstruction stage, it is essential to decide what needs to be done with the building. The decision may be to maintain the current building by renovating or deconstruct the building and reuse the components in a new building. Regardless of the decision, the properties of structures should be assessed in both cases. Only the scope and extent of investigation vary. There are no any strict rules for decision-making as the decision varies between individual cases, but before the decision, the structures of the building should be always studied. This study can also be helpful and support the decision-making.

Overall, at this stage it is essential to get a general overview of the building and its structures. This can be done by studying design basis, previous inspections and maintain records and occurred irregularities to get information about the properties and factors as dimensions, environment, joints etc. that affect to service life, deconstruction work and reusability of the structures. This stage is also known as pre-deconstruction audit.

3.2 *Structural condition investigation*

One of the essential stage in reuse process is to ensure reusability of building components. This includes mechanical properties for structural capacity design, durability properties for

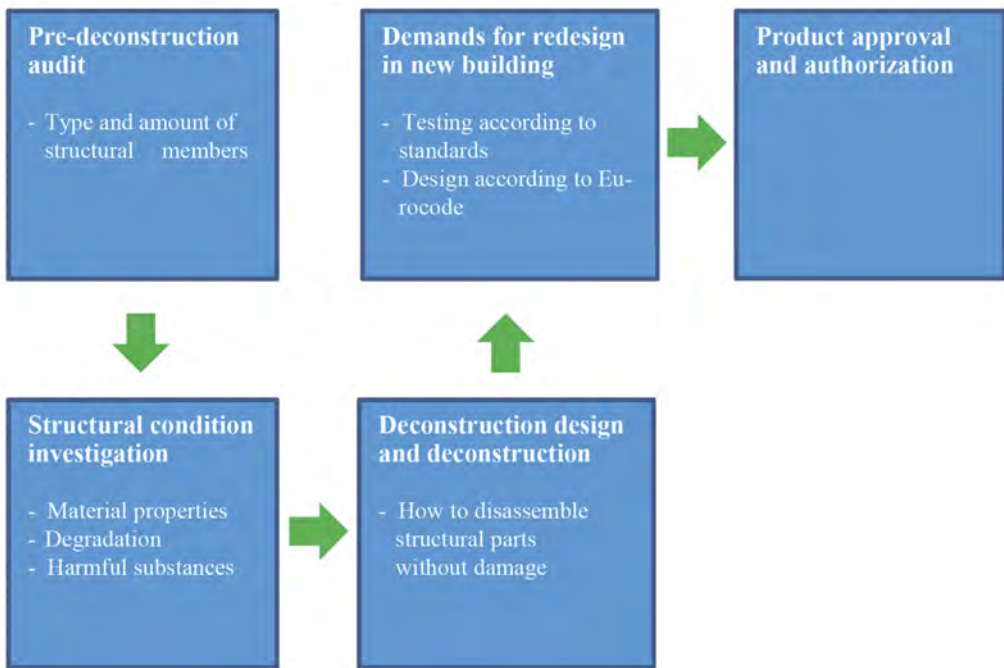

Figure 2. Quality assurance process for reuse of building components.

service-life assessment and hazardous substances for safe and healthy deconstruction work and reuse. These affects to the design process for a new building as well as to the product approval and authorization before the reuse. The properties can be assessed by structural condition investigation and assessment.

For a successful condition assessment, careful pre-planning is required. In the pre-planning it is essential to decide test methods, sampling spots and sample size for each test. Decision-making for testing reusable building components differs from usual condition assessment of a building, since the components are going to be redesigned according to current requirements and standards. For condition assessment of a building, the minimum performance requirement can be decided by the owner of the building, but in the reuse process, the minimum performance requirement is defined in standards and design guidelines for a new building. Thus, representative of test results, reliability of testing and threshold values for different deterioration mechanisms are emphasized in the structural condition investigation of reusable building components.

To get reliable and representative results, it is important to know every factor affecting to the results. For example, different non-destructive test methods (NDT) for testing bricks have uncertainty, and it is therefore important to select the right methods and sample sizes for each property (Räsänen et al. 2022). Also sampling spot and sampling should be considered in pre-planning, since they have a significant influence for example on the testing results in concrete structures (Haavisto et al. 2021). In addition to these examples mentioned above, other factors as location of the sampling spot and used equipment should be considered as well depending on the structure and building.

Threshold values for corrosion of reinforcement in concrete, for example, needs to be decided according to the demands from new building. The testing procedure needs to be as accurate as possible, since the threshold value is essential information for the service-life assessment. This procedure varies for different deterioration mechanisms. Therefore, it is very important to know if there are any ongoing deteriorating and what is the primary deterioration mechanism to be investigated and assessed. Deterioration mechanisms are not the only

thing, since the components are going to be redesigned. The most important thing being the structural properties as strength and stiffness. These are the essential information for design and therefore the values for these must be as accurate as possible.

To achieve accurate results, on-site inspection is required. Visual inspections, non-destructive testing and destructive testing should be done to get a representative picture of all the structures. Using these methods mentioned above alone or together, this representative picture can be achieved. After having the results of the tests, the results need to be analyzed and assessed by a qualified person who can identify any factors of uncertainty.

3.3 *Deconstruction design and deconstruction*

Deconstruction process relates to occupational safety and is therefore essential stage in the quality assurance process. This requires thorough design process where every affecting factor to the occupational safety need to be considered. In the reuse process, it is also essential to design the deconstruction so that the properties of the building components are not being affected. The factors are for example deconstruction order, working method, support structures, lifting equipment and joints of the structures.

Before actual deconstruction work, the condition investigation results need to be assessed at general level. The reason for this is that possible damages before and after deconstruction must be separated so that the main reason and influence of the damage on the properties of structure can be assessed. At least visual inspection is required before and after deconstruction. Also, need for further investigations must be clarified, if needed.

In addition to the deconstruction of the building, storage and transport conditions must be considered. These conditions may have significant effect on the properties of structures, and it is essential factor. For example, in-door structures may have problems with freeze-thaw durability in cold climates if they are not protected sufficiently from moisture or cold air. Further investigations and assessment are required if there are any doubts of deterioration during storage or transportation.

3.4 *Demands for redesign in new building*

As mentioned before, reusable building components are designed according to current standards and guidelines. The values for these can be determined by condition investigation and assessment which cannot be over-emphasized in the reuse process. In the redesign of the components, reliability of the results from condition investigation is essential and needs to be considered by the designer. The reused building components cannot risk sustainability of the new building.

The current design equations may not represent the real performance in the structure, if the structure has been damaged. Thus, the factors in the design equations may require adjustment in the redesign stage. The way how these factors have been influenced by the damage need to be investigated and assessed. This requires expertise to understand the design equations and factors which may have been affected. In addition to the design equations, the joints may require full demolition, or they may be damaged during deconstruction, and therefore new joints and details may be needed. This may require more creative thinking because typical joints in new construction may not be practicable with reused components.

In addition to the structural properties, the designer must understand the meaning of fire and sound insulation of the structures. The requirements for these have changed during time, and reusable components may not fulfill these requirements without any improvement. All these demands must be considered for reusable components as in new construction with new components.

These factors affecting to the redesign of the reusable building components are just a few examples from several affecting factors. This indicates that there are several challenges in the reuse process, and it requires a lot of understanding to consider all the affecting factors. Also experience from practice will point out the typical challenges in the redesign stage in the future.

3.5 Product approval and authorization

Currently CE marking is required for new materials and components in EU. However, this is only for products manufactured after 2013, and therefore, for reusable building components manufactured before that, the CE marking is not required. Local and national authorities may still require product approval for ensuring safe reuse. This can be done by following each stage of the quality assurance process in Figure 2.

For a product approval it is highly recommended to create a document from each stage which can be used as an aid for proving the usability of the reused components. In these documents the results and decisions need to be stated. The documents are also helpful for designer who tries to figure out the uncertainty of the material properties and select the usable property value in design. Therefore, any uncertainty in different stages need to be considered in the documentation.

4 CONCLUSIONS

The quality assurance process of reusable building components has several stages. Each of these stages needs to be done with care, since they affect to the next steps and the whole process. The pre-deconstruction audit is important to get a general picture of the building and reusable components. This is an aid for designing structural condition investigation and assessment stage, which is a very important stage in the whole process. By the results of the condition investigation, the reusability of the components can be ensured. The requirements for the condition investigation comes from the demands from the new building because the building need to be designed according to the current standards and guidelines. To ensure that the components satisfy the demands for the new building, the deconstruction needs to be taken with care. In addition to the components, occupational safety is an essential perspective at this stage. At the end of the process, reusability of the building components can be ensured by following these stages above.

FUNDING

The study was conducted in the Reusing precast concrete for a circular economy (ReCreate) project. The project has received funding from the European Union Horizon 2020 research and innovation programme under grant agreement No 958200.

Calculating embodied carbon for reused structural components with laser scanning

B.S. Byers, M. Gordon & C. De Wolf
ETH Zurich, Zurich, Switzerland

O. Iuorio
University of Leeds, Leeds, UK

ABSTRACT: The global warming potential (GWP) of reused building elements can be evaluated based on two variables: structural material quantity (SMQ) and embodied carbon coefficient (ECC). The volume of the SMQ can often be unknown, however, and it is not clear how to best estimate the ECC of a reused element. This paper illustrates a method for extracting the volume of reused metal structural elements to calculate their GWP in buildings that lack documentation. The authors use laser scanning and voxelization to extract the volume and a method based on the Swiss Society of Engineers and Architects (SIA) 2032 norms for calculating the GWP of reused materials. The reality capture method is accurate enough to approximate structural material volume, although it requires exposed structures. The results are important for building managers to understand the relative environmental impact savings from reused versus new building elements.

1 INTRODUCTION

New structural design methods are needed to achieve many industrial and governmental goals for sustainable construction. In the closed material system of planet Earth, it is imperative to be more efficient with building resources and to understand how to use what is already available. Circular construction and the reuse of building elements is a growing approach for minimizing environmental impacts through lowering embodied emissions in the product stage of the construction process. One approach for measuring embodied emissions is through measuring global warming potential (GWP), a sub-factor of a traditional life cycle assessment. There are existing methods for measuring GWP in new projects but measuring GWP in the current building stock is limited due to a dearth of as-built drawings and further information on existing building stock. Two challenges prevent understanding of how reused building components affect the net environmental impact: no consensus on a method currently exists for calculating the GWP of reused components, and documentation is usually lacking the volume and material data of existing components in buildings. From these issues, the research question arises: how can we extract the estimated volume of metal structural elements to calculate their GWP in buildings with no documentation?

1.1 *Review: Reality capture for reuse and volume estimation*

Reality capture technologies, such as Lidar laser scanning and photogrammetry (photographic image analysis), are increasingly used in the architecture, engineering, and construction industry for applications such as construction progress monitoring (Dimitrov and Golparvar-Fard 2014, Bosché *et al.* 2015), continuous site inspection (Hutter *et al.* 2018), interior mapping (Tchapmi *et al.* 2017), and scan-to-BIM (Pătrăucean *et al.* 2015, Iglesias *et al.* 2019). Although work is emerging on reality capture for circular construction (Xiong *et al.* 2022), building component volume estimation has yet to be thoroughly explored (Xu *et al.* 2021).

A common volumetric application of Lidar is for estimating volume change over time in planar surfaces by integrating point-to-point distances (Puente *et al.* 2013). Similar bulk volume estimation, such as for stockpiles or excavation, is built from the summation or integration of a resulting digital surface model (Manish *et al.* 2022). For geometries with clear axes, volumes are estimated through a series of slices and profiles along their length (Chang *et al.* 2017, Terryn *et al.* 2022). For more complex geometries, volumes are read from an intermediate mesh, generated, for example, by Delauney triangulation (Zhang and Yang 2019), convex hulls and alpha shapes (Terryn *et al.* 2022), or Poisson surface reconstruction (Ma *et al.* 2020). Voxel-based (volumetric cubic grid) approaches have been applied in domains with irregular density complexity (Kim *et al.* 2016). Finally, additional domain information may be integrated, such as by combining surface segmentation with associated material volumes for typical building typologies, such as the depth of different materials in walls (Heisel *et al.* 2022). Due to the difficult geometry of the web and flanges of structural metal, a voxel-based approach is best suited and explored in this paper.

1.2 *Review: Calculating embodied carbon of reused components*

One output from the life cycle assessment of structures is the GWP, measured in carbon dioxide equivalent emissions (CO₂-eq). Embodied carbon is the sum of greenhouse gas emissions released outside of the operation stage. It is used interchangeably with GWP in this paper, as both measure the relative impact of a given greenhouse gas on global warming. Existing research has explored how to measure the embodied carbon values of specific building structures to aid early design-stage decisions (De Wolf *et al.* 2014, Iuorio *et al.* 2015). An exposition of relative environmental savings in reusing steel elements demonstrates environmental savings and the relatively low impact of transportation (Brütting, Vandervaeren, *et al.* 2020). A consensus is lacking, however, on how to best calculate and compare the environmental impact of reused building elements (Hoxha and Fivet 2018, De Wolf *et al.* 2020).

This research focuses on the reuse of structural metal components due to the existing research precedent, modularity, and ease of disassembly. Although structural steel typically consists of a very high amount of recycled content (Iuorio *et al.* 2019), there are continuing efforts to focus on component reuse to remove the added energy demands of melting and recasting. Validation of the process of reusing steel components can be found in various case study analyses (Pongiglione and Calderini 2014, Drewniok *et al.* 2017).

1.3 *The contributions of the work*

How to best assess environmental impact for reused building elements is not agreed upon, but reusing structural building elements has undoubted environmental benefits. This research aims to use Lidar scanning to collect data for estimating volume and GWP savings of in-situ reused structural elements relative to new elements. As mesh-based analysis methods have low accuracy and would be difficult to use for this domain, a voxel-based volume estimation method is explored, compared to ground truth volumes, and after testing on a site with known structural volumes applied to a more difficult site. The results of this research will contribute to a growing body of knowledge on the relative environmental impacts of reusing steel building components as well as how component volume calculations can be supplemented with laser scanning.

2 CASE STUDY DESCRIPTION

This research examines two different structures of reused structural elements, the first being a recent steel construction with known structural volumes used as a baseline for the volume estimation techniques. The Kopfbau Halle 118 building (K118) is a building expansion project in Winterthur, Switzerland completed in 2021 under the architecture firm Baubüro in situ AG. Reusing structural and facade materials in the expansion reduced the carbon footprint from construction by around 60%. K118 uses a standard steel girder system with a maximum span of 8.5 m, 1.4 m on center, and a total floor plan area of 230.4 m². Prior work in (Brütting, Senatore, *et al.* 2020) looked into the design process using the same stock of steel elements used in K118.

The second structure is in the Grand Café Horta in Antwerp, Belgium, which includes a unique iron portal frame structure in art nouveau style. The café's Art Nouveau Room contains nine cast iron portal frames of differing heights and degrees of completeness, and three half-portals originally designed by the architect Victor Horta from 1895–1899 for the Maison de Peuple. Documentation of the frame is limited. The original Maison du Peuple was deconstructed in 1965, and the trusses were eventually reused in the construction of the Art Nouveau Room in 2000. The current structure is 46.1 m long, 16.3 m wide, and 10.5 m high. Each truss is an open web non-continuous portal frame, spaced 5.2 meters apart. Although the design styles and materials differ, these buildings were chosen because they both had exposed frames of reused structural metal and the developed method can be used on both to explore GWP.

3 METHODOLOGY

3.1 *Data collection and processing*

The volume estimation strategy of structural metal for the embodied carbon calculation employed here covers three main steps. First, raw point cloud data is collected using terrestrial Lidar scanners. This data is then classified and segmented to separate only the points representing the metal structure. Automated segmentation was considered outside this study's scope; the clouds were manually segmented to correspond to the best possible output from automated segmentation. Lastly, the subset of the cloud is geometrically analyzed to produce the final volume estimation

3.1.1 *Approach for K118*

One floor of the K118 building was selected as the test site, wherein most of the steel structure was left exposed with relatively little interior clutter (Figure 1). Scanning was conducted using a Leica RTC360 Lidar scanner. 24 captures were taken over two hours, with a total raw cloud size of 102 million points. The manufacturer software Leica Cyclone was used for registration. Reflection noise was cleaned by manual cropping, and no downsampling was performed as it may have induced aliasing errors with the voxel analysis strategy. The cloud was manually segmented to produce a test cloud containing only the steel points, resulting in 10 million points for analysis (Figure 1). The ground truth steel volume was derived from the original construction drawings, extracted from a model produced with Revit.

Figure 1. Interior view (left) and captured point cloud (right) for K118 (edited for steel visibility).

3.1.2 *Approach for Café Horta*

The Art Nouveau Room was captured using a RIEGL VZ-400i terrestrial laser scanner. The space was captured across 32 scans in two hours, producing a raw point cloud of 580 million points. The manufacturer software RiSCAN Pro 2.0 was used for registration. The cloud was manually cleaned and segmented to retain the iron portals. This site contained more prevalent occlusions both at the bases of the trusses and near the ceiling, which the estimation method does not attempt to account for. This resulted in a cloud of 39.9 million points for analysis (Figure 2).

There was significantly less accessible documentation for this site than for K118. The baseline 3D model was instead based on existing historic modeling work drawing on a combination of

Figure 2. Café Horta, interior view (left), captured point cloud after steel segmentation (right).

archival documentation and on-site photogrammetry (Van Laere 2003, Vaeck 2006, De Prins 2016). Typical details were then adapted to the changes in base height along the length of the site.

3.2 Point cloud volume extraction

Given the concave complexity and prevalence of self-occlusions in metal structural geometry, the visible points were directly measured using a voxelization method. Herein, the total space was divided into equal cubic volumes, which were considered filled if they contained any scanned points. The sum of these volumes was considered the raw volume value. The point clouds were pre-rotated to align the major walls to the world axes to reduce aliasing errors. The size of the voxel grid is critical to this estimation, and a range of possible sizes was evaluated between 1 mm and 100 mm. As the ideal size was found to correlate closely with the average web and flange thickness, a heuristic was determined wherein the operator would manually measure a typical element as input. Figure 3 demonstrates the influence of voxel size selection. The middle example is similar to the determined voxel sizes used for the test sites.

Figure 3. Example beam point cloud voxelization: (left to right) under sized, usefully sized, and oversized.

3.3 Global warming potential calculations

Full life cycle assessments are broad in inventory requirements and impact assessment scope, but focusing the assessment to a single impact factor, GWP, increases accessibility for industry to make informed decisions about relative carbon footprint of building materials (Bala *et al.* 2010, De Wolf *et al.* 2014, 2020). Cradle-to-gate GWP of structures can be calculated by multiplying two variables: structural material quantity (SMQ) and embodied carbon coefficients (ECC), as demonstrated in Equation (1) below (De Wolf *et al.* 2014):

$$SMQ (kg_m/m^2) * ECC (kg_{CO_2e}/kg_m) = GWP (kg_{CO_2e}/m^2) \quad (1)$$

SMQ can be calculated from the volume of material, the density of the material, and the floor area of the structural system. The ECCs, in this case, capture only the embodied emissions in the product life cycle stages A1–A3 (SIA 2020). ECCs differ depending on the data source. To stay consistent with the chosen environmental impact method and location for one of the buildings, the ECCs used are from the Swiss KBOB (Koordinationskonferenz der Bau- und Liegenschaftsorgane der öffentlichen Bauherren) database.

The method for calculating the GWP of reused components is not straightforward. Research done by De Wolf *et al.* (2020) compares six different environmental impact allocation methods for building components reused over n life cycles. This paper used one method derived from the Swiss Society of Engineers and Architects (SIA) 2032 norms to demonstrate the GWP reduction

associated with reusing building components. The adapted SIA 2032 method compares the total time of use to the time of expected use (design use) as a factor for the ECC. For calculating the environmental allocation of previous life cycle(s), one takes the percentage of actual use over design use. For the current life cycle, if combined actual use has exceeded design use, then the allocation is zero. If combined actual use is less than design use, then the allocation is proportional to the projected remaining years of actual use over design use.

Additionally, using the SIA 2032 norms, all building components have a maximum of 60 years of design use (SIA 2020). This value is arbitrary and may not correspond to actual life cycle but helps normalize comparisons. The first life cycle of the Café Horta structure was in use for 66 years until it was dismantled in 1965. Its second life cycle (in use since 2000) equates to an extra 22 years at the time of this study. The structural steel used in K118 was only in use for 15 years in its first life cycle and has been in use since 2021 for its second life cycle. Therefore, considering a 60-year design life, significant GWP is allocated in the reused K118 building elements due to its very short initial life span.

4 RESULTS

4.1 Validation of the volume estimation approach

While testing voxel sizes between 1 mm and 100 mm, 10 mm was found to produce the least error for K118. This roughly correlates with the typical web and flange size on site, matching the chosen heuristic measurement. The density of structural steel is approximately 7850 kg/m^3 , thus the total mass of steel reused in the K118 site is approximately 13,229 kg. In the Grand Café Horta site, the best voxel size was found to be 7 mm, likewise in the range of flange sizes present on the site. The best-estimated volume from existing records was calculated at 4.168 m^3 , while the best voxel volume estimate was 3.771 m^3 . However, the volume from estimated records had lower confidence due to less documentation. Table 1 shows a summary of the volume values extracted from documentation of both buildings compared to the estimated volume from the scanning method, plus a percentage error.

Table 1. Comparison of estimated and calculated structural metal volume.

	Raw Point Count	Segmented Point Count	Volume from Documentation	Volume from Scan	Volume Error
Project	millions	millions	m^3	m^3	%
K118	102	10.2	1.698470	1.685224	0.78
Café Horta	580	39.9	4.168164	3.771370	9.51

4.2 Results from GWP analysis

4.2.1 SMQ calculation

For the structural material quantities, information had to be collected not only on the total volume of the structural metals but also on the floor plan area and material density. The floor

Table 2. Structural material quantities per project.

Project	Location	Structural Material	Material Density	Total Volume	Floor Plan	SMQ
			kg/m^3	m^3	m^2	kg/m^2
K118	Switzerland	Steel	7850	1.69847	230.4	57.87
Café Horta	Belgium	Cast Iron	7300	4.16816	751.4	40.49

plans from the architects of K118 and some general information on the Café Horta building were used to calculate the floorplan. The results can be seen in Table 2 below:

4.2.2 GWP results for new material verse reused

Following Equation 1, the GWP of the structures assuming new material was used and calculated by multiplying the ECC and SMQ of the materials. The ECC values used for the GWP calculation are drawn from the 2022 life cycle assessment data published by KBOB. The product stage emissions for steel profiles are 0.731 kg CO₂-eq/kg_m, and the product stage emissions for cast iron are 2.1 kg CO₂-eq/kg_m. Note the emissions for cast iron are based off current production values, likely, the impact from the original manufacturing at the end of the 18th century would be worse. The resulting GWP calculations for the structural systems assuming new components were used are reported below in Figure 4. The GWP values assuming new building components are 42.30 kg CO₂-eq/m² for K118 and 85.04 kg CO₂-eq/m² for Café Horta. Figure 4 shows the calculated GWP of the actual structures with reused components with the method adapted from SIA 2032. The GWP values of the actual reused building components are 31.73 kg CO₂-eq/m² for K118 and 0.00 kg CO₂-eq/m² for Café Horta. Reusing elements reduces GWP by 25% and 100% for K118 and Café Horta, respectively.

Figure 4. Global warming potential for new and reused components per project.

5 DISCUSSION

The estimation method achieves good accuracy in a setting with strong point coverage on all surfaces for K118. The voxel method's reliance on visible areas and lack of extrapolation necessitates taking many scans on site to avoid high occlusion scenes. While the method would not be strongly affected by small amounts of noise in the segmentation, consistent confusion by the model would quickly compound across the entire cloud. The effects of high occlusion were evident in the higher error for Café Horta, and the unseen points are consistent with the volume underestimation, which probably contributed to the 9.51% error. Additionally, though the chosen 7 mm voxel size falls within the set of flange sizes for this site, increasing component variation typically necessitates increasingly frequent spot checks for verification.

The design specifics also affect the necessity of the method. While a single-story space with standard components such as K118 could be measured and calculated manually, structures with significant height and complexity would be less tenable and benefit more from automation.

A thorough embodied carbon analysis of reused building elements should account for other stages in the life cycle. Hidden carbon costs include intermediate transportation and potential remanufacturing, which are neglected when using the SIA 2032 method for reuse. However, research demonstrates transportation has a relatively low impact on the total embodied carbon of building components (Seo *et al.* 2015, De Wolf *et al.* 2018, Brütting, Vandervaeren, *et al.* 2020).

The use of the adapted SIA 2032 method prioritizes reusing building components that have already served longer lifespans: when the predicted service life is surpassed, GWP impacts on additional life cycles are nullified. The calculations within this paper show that with the chosen allocation method, the reuse of the Café Horta structural elements contributed no additional environmental impact, thus incentivizing its reuse and preserving cultural heritage. In contrast, the beams in K118 were only in use for about 15 years, thus allocating more GWP to

its recent life cycle. Lastly, although the chosen structures for this work are both exposed metal frames, **a 1-to-1 comparison of GWP between the buildings is not reasonable** because material choice affects the ECC, the intended structural use case and optimization are different.

5.1 Limitations of the approach

Although the findings of the proposed approach are promising, there are some limitations in the method. Laser scanning requires the structural components to be visible, but the elements are encased in many structural systems, thus preventing this approach. In addition, the developed technique for volumetric analysis contains opportunities for human error during the scanning, spot checks, and manual segmentation. Lastly, our approach was only used for homogenous materials; calculating GWP for hybrid structural systems would be more complex.

6 CONCLUSION

This paper demonstrated how to calculate the environmental savings from reused structural metal without prior documentation on the components. Lidar scanning helped capture the point cloud of exposed structural elements and develop a method to extract the component volume. (Previous literature focused on using Lidar as a method for tracking more raw material volumes, but Lidar had not been used for component volume extraction.) The second part of this paper conducted a GWP analysis of the scanned components and compared the savings of carbon dioxide equivalent emissions from reusing the components relative to using new components of the same volume. The latter work supplements existing literature by providing case-study applications and demonstrates the impacts of reusing structural components.

The calculation of material volume partially informs post hoc embodied carbon analyses of structures with lost or no prior documentation. This work aims to inspire future work on models based on artificial intelligence (AI) for structural point cloud segmentation and volume estimation for a more rapid analysis of buildings. Future research will focus on the automation and error resistance of the process. Deep learning approaches, currently applied for various interior classes, can be evaluated for automatic classification and segmentation of structural elements in different contexts. Semantic analysis of the voxel grid may allow for automatic calculation of the ideal voxel size without manual spot checks, as well as the detection and mitigation of occlusion areas. This work successfully demonstrates a reality capture workflow to estimate in-situ building component volumes in order to calculate GWP savings from reusing components.

Reuse of existing reinforced concrete beams: Exploration of residual mechanical characteristics and measure of environmental impact

ABSTRACT: With a view to developing reuse, reinforced concrete beams were retrieved from a deconstructed building, and tested by 3-point bending tests in order to measure their residual strength. With a residual strength of about 70% of the presumed initial strength in the worst case, deconstruction by beam sawing appears to be an interesting solution for the recovery of deconstructed buildings. For a low resistance loss, LCA of these solutions highlights that the reused beam has globally less impact than a new beam. Additional studies need to be conducted to increase the robustness of these conclusions.

1 INTRODUCTION

Scientific literature shows that the building materials sector is the third most CO₂-emitting industrial sector in the world and in the European Union. Parrot (2002) states that the building materials sector is responsible for 10% of total anthropogenic greenhouse gas (GHG) emissions, the majority of which being related to concrete manufacturing.

Moreover, concrete is a material that is extensively used around the world, particularly in the construction industry. In France in 2018, more than 40 million cubic meters of ready-mix concrete (RMC) were produced, representing 6.8% more than in 2010 (UNICEM & SNBPE 2020).

In order to mitigate the resource-intensive consumption of this sector (and all sectors in general), waste hierarchy has been introduced by European Union since 2008 (European Parliament 2008). It prioritizes reuse of waste over recycling. Hence, reuse seems to be the best waste recovery method and is promoted by governments. Moreover, scientific literature identifies numerous examples of reuse in history (Benoit et al. 2018; Ghyoot et al. 2018).

The reuse in buildings affects lots of parts, from the interior installation to the structural work while passing (in a non-exhaustive way) by the frontages, the joineries, the grounds, the partitions and the technical elements. Nevertheless, the reuse of structural elements are less common (Küpfer & Fivet 2021).

For cast-in-place concrete elements (and more broadly, structural concrete elements), reuse is an “exceptional practice”. However, for reasons of deconstruction in dense urban areas, “careful dismantling” (Küpfer & Fivet 2021) techniques have been developed.

In this context, concrete seems to be a strategic candidate for reuse: its manufacture has a high environmental impact and it is widely used. Thereby the objective is to reduce the quantity of waste, as well as the use of natural resources (aggregates and cement) which induces reduction of GHG emissions from natural resources production.

This study aims to show to what extent reuse of reinforced-concrete structures from deconstruction is environmentally friendly.

First, an exploratory study on the residual strength of a deconstructed beam is undertaken: two beams are subjected to a 3-point bending test. Then, a Life Cycle Assessment (LCA) of different scenarios of beams construction is carried out, allowing to compare a reused beam to a new beam with the same functional unit (same resistance).

2 DETERMINATION OF THE RESIDUAL RESISTANCE OF A DECONSTRUCTED CONCRETE BEAM

To evaluate the environmental impact through the LCA, a functional unit has to be defined in order to compare end of life scenarios. Consequently, the mechanical resistance of structure deconstructed should be preliminary determined. This exploratory study is based on a case study of a cast-in-place concrete beam which has been deconstructed from a building under renovation in France (Figure 1). No particular protocol is set up in relation to a deconstructed beam for landfill for this case study.

Figure 1. Picture of the building during partial dismantling (a), dismantling process of the concrete beams (b) (pictures A. Lachat).

2.1 3-point bending test

The objective of this study is to obtain a first value of loss of resistance of such element and to determine the behavior of a deconstructed element from loading to failure (elastic and plastic limits, and cracking mechanism). To this end, 3-point bending tests were carried out (Figure 2) using a hydraulic press of 450 kN at the Navier Laboratory. Figure 3 presents the beam on the test device.

Figure 2. Instrumentation diagram of the 3-point bending test.

The instrumentation of the device is as follows:

- The force F applied by the cylinder, measured by the press;
- The deflection f at the center of the beam and at two points halfway between the center and the supports, measured by Linear Variable Differential Transformer (LVDT) displacement transducers with a stroke of 2 cm (LVDT 1, 4 and 5);
- The parasitic displacements at the supports (LVDT 2 and LVDT 3).

This test provides an estimation of the residual strength of the beam. The force-displacement curve is shown in Figure 4. Three unloading were performed during the test.

The curve is consistent with the bending studies performed on new elements (Ajdukiewicz & Kliszczewicz 2007, Omary et al. 2014) and theoretical studies (Fleury & Mouterde 2019, Mosley et al. 1996). Three main phases can be identified:

- **Quasi-elastic phase** (phase 1): At low loading, concrete and steel materials are in the linear elastic domain. The shear force is taken up by the vertical reinforcement (frames). During this phase, the displacement is almost reversible.
- **Elastic steel phase** (phase 1 bis): Cracks appear and propagate within the beam. The deflection becomes more important. The displacements are irreversible; a residual deflection is observed after unloading. The cracks are oriented at about 45° , reflecting the combined shear force and bending moment.
- **Plastics steel phase** (phase 2): The cracks widen more strongly and the deflection increases more significantly. Tensile reinforcements go through a plastic phase.
- **Beam failure**: In the face of tensile cracking, the compressed concrete section becomes too small. The concrete cracks in compression at the level of the upper fiber. The beam gradually loses strength.

Figure 3. Picture of the instrumented test device (picture A. Lachat).

Beam failure appears at 426 kN, compared with the theoretical value 494 kN (according to the EN 1992-1-1 standard (EUROCODE 2 2005)). The loss of resistance is at most of 14% for this beam. This value represents an upper bound due to uncertainty on the quality of the reinforcing steel (if $R_e = 500\text{MPa}$). For a more probable value of steel resistance ($R_e = 450\text{MPa}$), the loss of resistance of the beam is only 8%. The same test was carried out with a similar beam, and the upper bound loss was less than 30% (the uncertainties regarding the layout of reinforcing steel were higher). These tests (resistance and durability) show that deconstructed beams have an interesting mechanical potential for reuse. The implementation of a rigorous protocol for deconstruction, transport and reconstruction would allow for the reliability and optimization of the residual strength.

2.2 Carbonation test

In addition to the residual strength evaluation, phenolphthalein tests were performed in order to assess the durability of the beam. These tests consist in measuring punctually the progress of carbonation on the beams, and thus to estimate the risk of corrosion.

Figure 4. Value of the force applied as a function of the displacement for the central LVDT sensor and highlighting of phases.

The phenolphthalein test is carried out on the exposed faces of the beam: top face (ground side) (Figure 5a) and bottom face (ceiling side of the lower floor) (Figure 5b). It can be seen on these photographs that the carbonate section (none colored) is very small: less than 0.5 mm. However, the coating of the reinforcement is 2 cm which leaves a margin of evolution of the carbonation of more than 1 cm before there is a risk of initiation of corrosion.

(a)

(b)

Figure 5. Photograph of phenolphthalein tests: (a) surface mortar, upper part of the beams (on the flooring side); (b) concrete on the underside of the beam (on the false ceiling side) (test realization: Cerema; pictures: A. Lachat).

3 EVALUATION OF ENVIRONMENTAL IMPACT

The exploratory mechanical study presented in the previous section enabled to prove that reuse of concrete structures (concrete beams) is mechanically feasible, and to quantify the corresponding loss of resistance. Evaluation of the environmental impacts is consequently now achievable. Reuse solution will be compared with a new construction solution.

3.1 Materials and methods

The objective of this part is to compare, resorting to the Life Cycle Assessment (LCA), these three following fictitious beams:

- A reused beam, named *Breu* (Beam reused),
- A new constructed beam made from raw materials, named *Bvir* (virgin),
- A new constructed beam made with recycled aggregates, named *Brec* (recycled).

The functional Unit chosen is “to construct/ install a beam allowing to cross a span of 1.80 m and to support a maximum load (point in its center) equal to that of the reused beam (426 kN) for a minimum life span of 50 years”.

The value of resistance is extracted from the case study detailed in section 2. We use the most probable loss of resistance i.e. 8%. New beams are designed according to EUROCODE 2 (2005) and the height of the beam is fixed at 0.36 m.

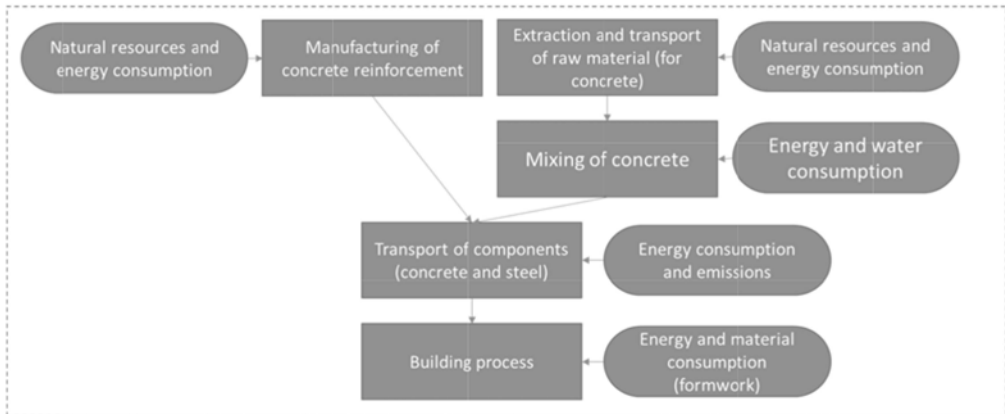

Figure 6. Boundaries of the system for the construction of a new beam from new or recycled aggregates.

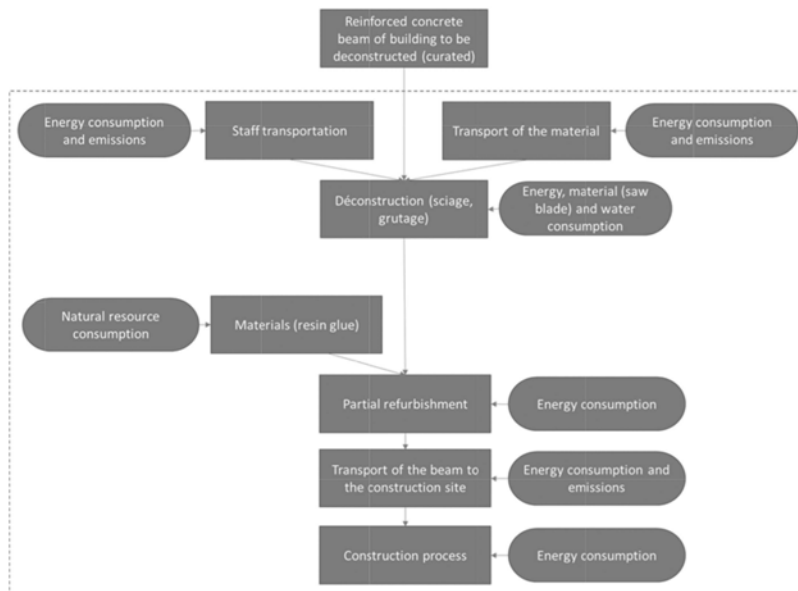

Figure 7. Boundaries of the system for the dismantling and the construction of a reused beam.

The LCA model is constructed according the standard NF EN 15804 and the impact method is NF EN 15804+A1/CN. Modeling is made on the software OpenLCA 1.10 applied on the database Ecoinvent 3.5.

System boundaries are represented on the Figure 7 for the new constructed beams and the Figure 7 for the reused beam.

The intermediate processes are derived from:

- Data from the deconstruction sites of the beams to be re-used;
- Ben Fraj & Idir (2017) for the recycling of aggregates and concrete;
- The SNBPE’s BETie tool (product declaration sheet generator) for new beam construction;
- Bertin (2020) and Brière (2016) for additional data on reuse.

3.2 Results

Results of this LCA are presented on the Figure 8. Reuse solution is the least impacting solution for 5 out of 9 indicators: *soil and water acidification, climate change, water pollution, depletion of abiotic resources (fossils + elements)*. For climate change, the reuse scenario is more than 50% less impactful than the most impactful scenario (new with recycled aggregate) and 50% less impactful than the virgin scenario. Nevertheless, the reuse scenario has a biggest impact on the *photochemical ozone formation* indicator by more than 10% compared to the other scenarios (about 20%). For the three remaining indicators: *ozone depletion, air pollution and eutrophication*, the reuse scenario is of the same order of magnitude as the recycled scenario, taking into account a 10% uncertainty.

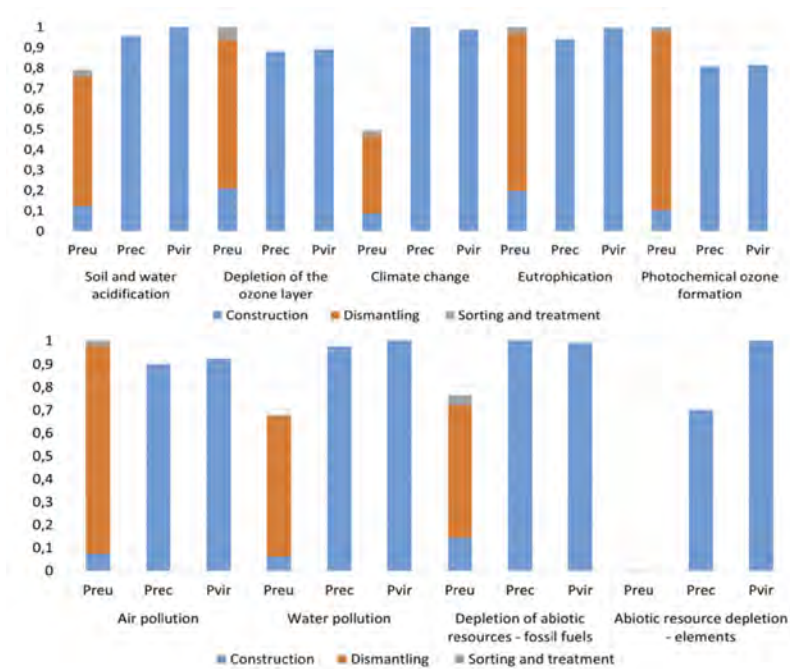

Figure 8. Relative impact of the three scenarios according to NF EN 15804+A1 impact indicators.

Thus, it can be said that the reuse of reinforced concrete structural beam seems beneficial for most indicators. However, it is necessary to conduct more studies to determine the loss of strength of the beam after deconstruction. Indeed, if the loss is too high, the fabrication of the new beam (with less material) could be equivalent to the reused beam. This is the subject of a sensitivity study in section 3.3.

The impact for the reuse scenario is mostly related to the end of life of the structure within the previous building (sorting and treatment). The construction phase contributes at most 24% of the total impact (for the *water pollution* indicator). This is consistent with the principle of reuse which, by definition, requires limited reconditioning. Consequently, in order to limit

the impact of reuse scenario, it is necessary to think about the deconstruction phase and in particular on the impact of sawing (or more broadly of the dismantling method).

3.3 Sensibility analysis

Previously, it has been highlighted that, for some indicators, the reused beam is not more virtuous than the new beam. However, the impact of the new beam is strongly linked to the manufacturing of the beam and in particular to its formulation. Thus, the impact may vary if the geometry or the required resistance changes. This sensitivity analysis aims at highlighting the consequences on the result of a modification of the residual resistance of the reused beam (and thus a new beam with different dimension). This is all the more important as the loss of resistance currently used is linked only to a single feedback.

Two alternative scenarios have therefore been constructed:

- *Bvir 0% loss*: a very optimistic scenario where there is no loss when the beam is reused. The equivalent new beam is therefore built identically to the reused beam during its first life (beam resistance of 463 kN).
- *Bvir 15% loss*: a pessimistic scenario where the loss of resistance is almost doubled (15% loss) (beam resistance of 393 kN).

The results of these scenarios are presented on Figure 9. Very strong variations are observed, especially for the scenario without loss of resistance where the increase in *climate change* can reach 50% for the virgin beams. Moreover, with this scenario (*Bvir 0% loss*), reuse becomes less impactful or equal for all indicators (equivalent impact for *photochemical ozone formation*). The scenario with a 15% loss in resistance makes the new beam more competitive with the reused beam.

Figure 9. Sensitivity analysis on the strength loss of the reused beam, relativized according to the reused solution except for the last indicator (*Bvir* = 8% loss).

Thus, the new beam becomes less impactful for *eutrophication* and equivalent for *water pollution*. This scenario remains significantly more impactful for the *climate change* indicator. For this indicator, equivalence could be reached for a loss of resistance of about 30%.

The determination of the strength loss has a strong influence on the environmental benefit of the reuse. It is therefore important to determine the residual strength of a reused beam as accurately as possible, which requires a more detailed technical study.

4 CONCLUSION

In order to develop reuse, 3-point bending tests were undertaken on reinforced concrete beams from a deconstructed building in order to measure their residual strength. With a residual strength of about 70% of the initial strength in the worst case, deconstruction by beam sawing appears to be an interesting solution for the recovery of deconstructed buildings.

For low resistance loss, LCA of these solutions highlights the fact that the reused beam has globally less impact than a new beam particularly for the *climate change* indicator but there is a transfer of impact for *water pollution* and *photochemical ozone formation*. Nevertheless, the good result is highly depending on the dismantling process and the loss of resistance.

The reuse of reinforced concrete structural elements is therefore a potential alternative to concrete recycling. Additional studies, including a broader experimental campaign on existing beams and a focus on the influence of the dismantling process, need to be conducted to increase the robustness of the results presented here.

Designing with recovered precast concrete elements

T.S.K. Lambrechts, F.J. Mudge, S.N.M. Wijte & P.M. Teuffel

Technical University of Eindhoven, Eindhoven, The Netherlands

ABSTRACT: In The Netherlands, two shortcomings of the country's building stock have become increasingly prevalent in recent years: high vacancy rates of office buildings (8.2% as of 2022) and a high demand for residential buildings (shortage of up to 315,000 dwellings as of 2022). This paper investigates how the reuse of whole precast concrete elements from office buildings can lead to more sustainable residential building designs. As a case study, suitable 'donor' office buildings and an apartment building design are identified. First, the apartment building design is modified to employ as many suitable recovered elements as possible (while maintaining the original building geometry). This leads to a 69% reduction of new concrete used and a 46% reduction of CO₂ output. Second, the design is adjusted to an optimal grid layout for maximal component reuse. This further improves the outcome to 90% and 60% respectively.

1 INTRODUCTION

The construction industry is considered to be a major contributor to global environmental degradation (Bossink & Brouwers, 1996) – responsible for 42% of annual worldwide natural resource consumption and 30-40% of solid waste generation (de Wit et al., 2020)(Jin et al., 2019). Within the construction sector, the production of concrete requires more raw materials and generates more CO₂ emissions than any other sub-sector (Herczeg & Klaassens, 2014). The production of cement generates 8% of the CO₂ emission by humans (Florea, 2016).

While downcycling concrete (e.g., using crushed concrete in road layer works or as coarse aggregate in new concrete) is a common practice, this does not prevent new concrete and more particular new cement from being used in construction (Durmisevic Elma., 2006). Therefore, it is more effective to reuse the material for the same function or in the highest possible value function. Keeping elements in their original shape may prevent the need for certain steps of the preparation and production process, however, this may cause challenges for conventional transport and storage equipment and processes. This paper investigates possibilities for making the concrete sector more sustainable by exploring the possibilities for reuse of pre-fabricated structural concrete elements.

Previous literature provides inspiration towards this goal. The first case where structural concrete elements were reused on a large scale was in Gothenburg, Sweden, in 1984 where elements from apartment buildings were reused in the construction of freestanding homes (Huuhka et al., 2019). Similarly, in 1986 the five top floors of a residential building in Middelburg, The Netherlands, were deconstructed and the elements used for new housing (Coenen et al., 1990). Another project in The Netherlands took place in Maassluis in 2000, which revealed substantial synchronization issues between deconstruction and reconstruction, thus indicating a need for a set process for determining which buildings are optimal to deconstruct and what the optimal deconstruction process is.

In The Netherlands, there is a relatively high vacancy of office buildings (8.2% as of 2022) (Verhaegh, 2022), while there is a pressing need for housing (shortage of up to 315,000 dwellings as of 2022) (Ministerie van binnenlandse zaken en koninkrijksrelaties, 2022). The best option to increase the number of houses is to transfer office buildings to apartment buildings.

The second best option is to disassemble vacant office buildings and reuse the harvested structural concrete elements in the structure of new apartment buildings. The case study discussed in this paper presents two design approaches for reusing such elements.

2 DESIGN APPROACH

In this study a re-design approach consisting of 8 steps has been developed and is summarized below:

1. Inventory of office buildings: The re-design process starts with an inventory of possible donor buildings. In this case it regards office buildings, which consist of structural precast concrete elements that are (or are expected to become) out of use in the near future. For this study, four office buildings (A to D), located in the Amstel III office park in Amsterdam, are considered. Due to low occupancy, the municipality of Amsterdam launched a project, where a substantial number of office buildings are going to be transformed to residential buildings.
2. Inventory of structural components: An inventory is created containing the precast concrete structural elements from the attained donor buildings. All structures of the four donor buildings use hollow-core slabs (HCS) as floor elements, three of them use precast beams and load bearing façade elements, of which two also use precast columns and walls. The remaining in-situ concrete elements are not considered for reuse. The available number of elements, derived from the inventory can be seen in Table 1.

Table 1. Inventory of available elements in four office buildings.

Building	Beam	Column	Wall	Façade	Slab
A	45	72	50	115	430
B	0	0	0	515	1169
C	138	60	34	131	686
D	84	84	0	0	165

3. Apartment design: An already existing apartment design with 19 units and three stories has been selected and used as the basis for the re-design of the building with a structure consisting of recovered structural elements. To make the process a little bit more challenging in terms of structural stability, the number of stories has been increased from three in the original design to five. The relatively regular floor layout can be seen in Figure 1.

Figure 1. Floor layout of apartment design (de Alliantie, 2019).

4. Determination of the structural characteristics of the apartment: The key structural requirements, such as spans of floor and stability system are determined.
5. Selection of suitable elements: An investigation based on step 4 is carried out, in which the suitable elements from the donor building(s) are selected. A distinction will be made between elements which meet the requirements, elements that need adaptations, and elements not suitable for re-use.
6. Start of re-design approach: This step has a more detailed focus on the structural requirements. A distinction can be made between the following two approaches:
 - a. Using recovered elements and following the intended design as close as possible
 - b. Using recovered elements and adapting the intended design to maximize the number of re-used elements
7. Re-evaluate the design: Once the initial implementation of re-used elements has been made, the whole design needs to be checked again as the elements influence the other parts of the building (e.g., extra load due to bigger dimensions of recovered elements).
8. Redesign 2: The final step entails the iteration of steps 6 and 7 to further maximize reuse potential and eliminate possible problems.

3 CASE STUDY

3.1 Available office buildings

The information on the four office buildings is retrieved from Alexandros Glias's master dissertation (Glias, 2013). The buildings range from three to eight floors and were built between 1983 and 1988.

3.2 Apartment design

The apartment design is based on a three-story apartment building in Eemnes. The structure consists of precast concrete walls and HCS. Stability is ensured by the walls, core and diaphragm action of the floors. As mentioned previously, the re-design consists of five floors instead of three.

3.3 Goals

The main goal is to put the two design approaches into practice in a case study. The first re-design approach is to match the original apartment building design as closely as possible. This makes it unlikely that a suitable replacement for every precast concrete element will be found or the need for large adaptations rises and the missing pieces will be filled in with newly constructed elements.

Table 2. Goals of design approach.

Aspect	Redesign approach 1	Redesign approach 2
Structural quality	The reused concrete structure is technically possible and full fills requirements with respect to safety and serviceability.	
Material use	Significant reduction in new material used.	Even larger reduction in new material used.
	Significant reduction of construction waste.	Even larger reduction in construction waste.
CO ₂ emissions	Significant reduction in CO ₂ emissions in total process.	Even larger reduction in CO ₂ emissions in total process.
Architectural Design quality	Equal architectural design quality to original design.	

In the second approach, the focus lies on achieving an even larger reduction in the use of new concrete, construction waste and CO₂ emissions. This is done by increasing the amount of re-used concrete and limiting element adaptation, by allowing for small alterations of the design grid geometry without compromising on layout functionality or structural integrity.

3.4 Reused elements

In both design approaches it is considered that recesses in wall elements can be partially or fully filled by applying concrete block masonry. Table 3 provides an overview of the number and type of elements that can be used based on the first design approach. From the hollow core slabs, 264 of the 365 are reused elements, originating from office B and office D. The HCS from office B were used in the roof and ground floor as they were only suitable for this. The HCS from office D will serve for the floors in between, leaving 92 HCS unaccounted for, for which newly constructed elements have to be used. The design requires 80 load-bearing wall elements, building A can supply 46 elements, leaving only four not viable for this design. New wall elements have to be used for the 34 remaining. Building B has 74 suitable façade elements, the remaining 36 have to be newly constructed. The main reason remaining elements were not suitable for reuse in this design, is that they do not meet the required dimensions and load capacity.

Table 3. Overview of reused elements for redesign one (reused/available).

Element	Required	Recovered				Total	New
		Office A	Office B	Office C	Office D		
Slabs	365	0/430	112/1169	0/686	152/165	264	92
Walls	80	46/50	n.a.	0/34	n.a.	46	34
Beams	0	0/45	n.a.	0/138	0/84	0	0
Columns	0	0/72	n.a.	0/60	0/84	0	0
Façade	110	0/115	74/515	0/131	n.a.	74	36

In the second redesign approach, reusing HCS is prioritized as those are the elements with the largest volume of concrete, thus contributing most to the CO₂ emissions when creating new elements. HCS reuse can be improved by taking less suitable slabs from another building and allowing minor changes to the layout of the planned building. In this second approach, slight alterations to the window sizes and positions were allowed, leading to significantly higher reuse ratio. Both redesigns of the apartment building can be seen in Figure 2 below.

Table 4 provides an overview of the number of recovered elements resulting from the redesign with the second approach. The number of HCS has increased to 333 elements, which will be sufficient for the whole building. All 50 of the wall elements from building A will be reused, leaving 30 to be filled in by new elements. The reuse of façade elements has increased significantly, going from 74 elements to 150 elements. Thus only 21 new façade elements will be constructed

3.5 Comparison to original design

The two design approaches are both compared to the original design on the amount of new concrete used and CO₂ emissions. Redesign based on the first approach uses 69.4% less new concrete while also using less concrete in total, this due to the possibility for thinner walls and floors. It has to be noted that using thinner walls and floors could require additional sound- and thermal insulation. Approach two uses 89.6% less new concrete than the original apartment design and 65.9% less new concrete than redesign one. The largest amount of concrete reduction originates from the increased reused of HCS and façade elements. Values used for the determination of percentage of concrete used can be seen in the Table 5. The values include concrete blocks to fill the openings in the walls and mortar used for the connections.

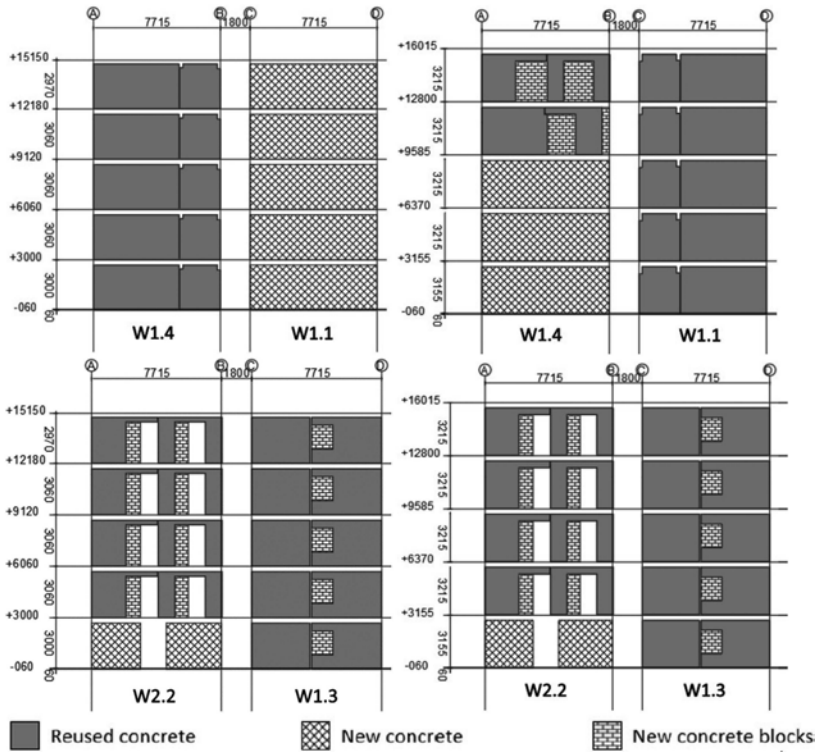

Figure 2. Configuration of façade elements in approach one (left) and approach two (right).

Table 4. Overview of reused elements for redesign two.

Element	Required	Recovered					Total	New
		Office A	Office B	Office C	Office D			
Slabs	333	0/430	333/1169	0/686	0/165	333	0	
Walls	80	50/50	n.a.	0/34	n.a.	50	30	
Beams	0	0/45	n.a.	0/138	0/84	0	0	
Columns	0	0/72	n.a.	0/60	0/84	0	0	
Façade	171	0/115	150/515	0/131	n.a.	150	21	

Table 5. Concrete usage in different design approaches.

Design	Reused/new	Concrete
		m3
Original	Reused	-
	New	1452.6
Redesign 1	Reused	886.2
	New	463.2
Redesign 2	Reused	1085.5
	New	152.6

In terms of CO₂ emissions, approach one saves 21.5% of CO₂ emissions at the end of life of the office building and 46.2% in the creation of the apartment building. Approach two saves 34.9% and 60.9% CO₂ emission respectively. The largest savings are made in both the demolition and production phase, and not so much in the construction phase. As previously mentioned, the HCS's cause most of the CO₂ emissions - this is also the case for transport emissions. For transport emissions, a hypothetical distance of 50 km is assumed between the deconstruction site and the building site for the apartment building. Values used for the determination of CO₂ emissions used can be seen in the Table 6.

Table 6. CO₂ emissions in different design approaches.

	Original design	Redesign 1	Redesign 2
Time	Ton CO ₂ equivalent	Ton CO ₂ equivalent	Ton CO ₂ equivalent
Creation of apartment	390.7	306.4	253.8
End of life of office building	489.5	263.0	191.2

3.6 Recommendations for general design approach

Based on the case study some recommendations for the general design approach can be derived. Giving precedence to reusing as many HCS as possible over other elements could provide benefits as HCS have the largest impact on material use and CO₂ emissions. Second, allowing for the window size and positions to be altered, could increase the number of façade elements that are reused, and limit their adaptation. Allowing alteration of the floor height to match the available façade and wall elements could prevent the need for adaptations, which will also allow for more finishing options such as a floating floor. Lastly, in some cases, limiting the reuse to not include odd-shaped elements could prevent the building process from becoming too complicated. An important note is that these recommendations, and all suggestions made in this paper, should be judged on a case-to-case basis.

4 CONCLUSION

From the literature study it can be concluded that concrete element reuse is possible, but remains to be optimized. Reusing precast concrete elements can lead to significant reduction in new concrete and steel whilst also reducing the amount of waste generated in the demolition process, which all contributes to a substantial reduction in CO₂ emissions. It is important to limit transport distances of reclaimed elements to further reduce the CO₂ emissions.

Creating a completely new design to optimize the reuse of available elements is favoured over redesigning an already existing design. However, this is not always possible, allowing for small adaptations in dimensions of elements and positions of openings could substantially increase the reuse capacity.

After the initial load calculation, the reused elements are chosen, these are unlikely to have the exact same dimensions of the elements of the initial calculation. Thus, it is necessary to perform a secondary load calculation after the element selection to check the influence of the elements. The creation of a list or database of available elements with their relevant properties would be beneficial to the design process.

ACKNOWLEDGEMENTS

I would like to acknowledge Bart van den Brink, he did the fundamental research on which this paper is based (van den Brink, 2020). Also, Rijk Blok who sadly passed away but was the supervisor for both Bart van den Brink and myself.

Building structures made of reused cut reinforced concrete slabs and walls: A case study

N. Widmer, M. Bastien-Masse & C. Fivet

Ecole Polytechnique Fédérale de Lausanne (EPFL), Fribourg, Switzerland

ABSTRACT: Reuse of reinforced concrete (RC) components reduces construction's environmental impacts and waste. Rather than crushing the concrete of an obsolete structure, its components are saw cut and later reassembled in a new structure. The theoretical feasibility of this method is demonstrated through a case study: the design of a residential building structure that reclaims cast-in-place RC components from two 60-year-old office buildings scheduled for demolition. Parts of the source buildings are allocated to an optimal position in the target building using an algorithm that minimizes the need for strengthening. Construction details are developed for the slab-wall connections and the bracing system. An alternative conventional cast-in-place RC design is proposed for comparison, as well as a hybrid design balancing environmental and cost savings with technical readiness. The assessment of the designs confirms that reusing RC components allows saving up to 75% of greenhouse gas emissions for similar costs, as long as demolition and disposal of obsolete source material are considered.

1 INTRODUCTION

Concrete is the most commonly used building material and the related production of cement is responsible for at least 9% of global CO₂ emissions (Monteiro et al. 2017). Cement and concrete production also consume large quantities of raw materials such as gravel, sand and limestone, which, in combination with an increasing concrete demand, will most likely lead to a shortage of these natural resources in the near future (Habert et al. 2010).

Meanwhile, construction and demolition waste correspond to about one third of all waste in Europe (Zhang et al. 2022) of which about 30% is concrete rubble (Giorgi et al. 2018). Nowadays, the demolition of buildings is usually not due to structural deficiencies but to changes of requirements – e.g. new functions, use intensification, or improved energy efficiency. During demolition, concrete is most often crushed and used as backfilling material (Zhang et al. 2022) or as a substitution for natural aggregates in a new, so-called recycled concrete. However, because both need similar amounts of cement, CO₂ emissions for recycled concrete are comparable to those for a conventional mix, especially if the rubble has to be transported over long distances before use (Marinkovic et al. 2010, Knoeri et al. 2013).

To reduce the detrimental environmental impacts (DEI) of concrete construction, the service life of existing structural components should be extended as much as possible through maintenance, renovation and strengthening. When none of these options are feasible anymore, deconstruction and component reuse is preferable to demolition. Reuse involves carefully dismantling the structure into smaller elements that are then reassembled in a new structure. This strategy delays the waste production and significantly reduces the need for new materials and the related CO₂ emissions.

Since the 1980s, there have been several examples where prefabricated concrete components were deconstructed and reused in new structures, many of which demonstrate a major reduction in DEI (Küpfer et al. 2022). The reuse of components extracted from cast-in-place reinforced

concrete (RC) structures is much less common. Recently, a pedestrian bridge named Re:Crete has been built from 25 reused blocks sawed out from concrete walls of a building undergoing renovation (Devènes et al. 2022). For this specific project, a 75% reduction in CO_{2eq} emissions was calculated when compared to a recycled concrete alternative.

Through a case study, this paper demonstrates the theoretical feasibility of constructing a residential *target* building with pre-existing cast-in-place RC components. The components are reclaimed from two *source* buildings that are expected to be demolished soon. The paper is organized as follows. Section 2 presents the design process specific to a RC-component-reuse project. The resulting design for the case study is given in section 3 including new construction details developed for connections. In addition to the reuse design, a conventional concrete construction alternative is developed, as well as a hybrid solution balancing environmental and cost savings with technical readiness. The alternatives are compared and assessed in terms of CO_{2eq} emissions and construction costs in section 4. Section 5 highlights the main conclusion of this work.

2 DESIGN METHODOLOGY

2.1 Design process

Figure 1 shows the 11 steps of the process for designing a load-bearing system from reclaimed cast-in-place RC components, including the required iterations. Step 1 consists in analyzing the source buildings to obtain the structural capacity of the different components available for reuse – e.g. bending-moment resistance for different slab parts and normal force resistance for walls and columns. In parallel, the floor plan of the target structure is defined and used to fix a preliminary load-bearing system – i.e. the layout of vertical load-bearing elements and the boundary conditions (step 2). The live loads are specified according to the space use while dead loads are set based on assumed structural thicknesses.

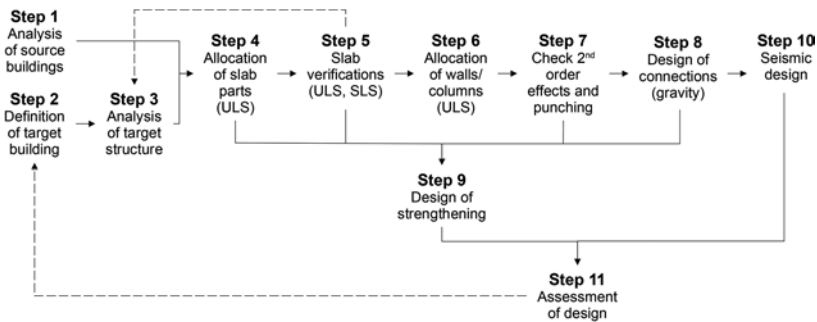

Figure 1. Selected design process.

In step 3, the target slab is divided into parts which are sought to be built in one piece – i.e. the position of joints in the target structure is defined. Different types of joints are considered, allowing or not the transmission of bending-moments or shear-forces (continuous, hinged, free, etc.). A Finite Element Model (FEM) of the target structure is created and joints are placed between the parts corresponding to their boundary condition. The action effects are calculated, which corresponds to the minimal resistance requirement of the target slab.

Subsequently, the dismantling and reassembly of floor slabs is planned. An algorithm is used in step 4 to allocate parts of the source slabs to the parts of the target slab defined in step 3. The allocation criterion is to minimize areas where structural strengthening is required to satisfy the bending-moment-resistance requirement at Ultimate Limit State (ULS). The shear-force-resistance requirement at ULS and deflections at the Serviceability Limit State (SLS) are subsequently checked in step 5. Deflections should not be larger than the limits fixed in in-force

design codes. In case the shear-force resistance of the allocated slab is insufficient or deflection limits are not met, the slab is either strengthened or the load-bearing system is modified – e.g. by adding supports or changing the type of joints to remove hinges. The latter is a first iteration looping between step 5 and step 3. Changing the load-bearing system will modify action effects and the corresponding resistance requirements for the target slab. Therefore, the allocation of source parts (step 4) should be redone to find a satisfactory solution.

If walls and columns are also sought to be built from reclaimed components, a similar approach as for slab parts is followed. The list of available vertical load-bearing parts made in step 1 is updated in step 6 to take into account the results of step 4. On top of the walls available in the source structures, parts of the source slabs which were not used to reassemble the target slab are considered as available stock for wall elements. This available stock is then allocated to a position in the target building according to structural resistance. Then, columns are checked for second order effects and punching resistance of the reassembled slab is also verified (step 7).

After allocation of all structural components, connections and the required strengthening of the slab are designed in steps 8 and 9 to resist gravity-action effects. Connections should ensure the force transmission conditions chosen for the joints in the structural model. Finally, the lateral bracing system is designed to resist seismic loads in step 10.

Once the structural design of the target structure is completed, it is assessed in step 11 regarding different criteria – e.g. DEI and construction costs (cf. section 2.2). If performance is not satisfactory, the design is modified at different stages, particularly by modifying the desired target structure to make better use of the available stock of reclaimed components.

2.2 *Assessment*

2.2.1 *Functional unit and system boundaries*

Life-cycle and cost assessments are dependent on a predefined functional unit and limits of the analysis. For this paper, the functional unit is the load-bearing system of one story – i.e. the RC slab with its vertical supports (RC columns and walls) – in the new target structure. Non-structural elements are not taken into account.

For the purpose of comparison, different design alternatives are developed and assessed: conventional construction with new materials; construction with reused structural components; hybrid construction. For all alternatives, processes related to the construction of the new building and the production of new materials are considered in the system. The end-of-life of the source buildings is taken into account as well. This is especially relevant for projects where existing buildings are to be demolished prior to the construction of a new building – i.e. a replacement project. For the variants applying reuse, all processes related to the deconstruction of building parts to be reused are included as well as those related to the demolition and disposal of the remaining material. For the conventional variant, the demolition and disposal of the entire source buildings is accounted for. The operation, maintenance, and end-of-life stages of the new target structure are not considered in the system. Moreover, construction processes expected to be the same for all variants – e.g. cranes, site specific installations, foundations, etc. – are excluded from the comparative assessment.

2.2.2 *Life Cycle Assessment*

In order to evaluate the environmental impacts of reusing structural RC elements, a comparative Life Cycle Assessment (LCA) is conducted (International Organization for Standardization 2006). LCA has been previously applied to evaluate reductions of DEI when reusing structural elements (Yeung et al. 2017, Brütting et al. 2020a, b, Devènes et al. 2022).

As introduced in section 2.2.1, the analysis includes the product stage and the construction process stage of the project (construction stages A1-A5) as well as the end-of-life of the source buildings (construction stages C1-C4) according to the European standard for Life Cycle Assessments (CEN 2011). The impacts associated with recycling materials or reusing components are allocated to the final product resulting from the processes, i.e. following a cut-off approach (Schrijvers et al. 2016).

In this paper, the global warming potential (GWP) is chosen as the indicator for comparing the variants, expressed in kilograms of equivalent carbon dioxide ($\text{kgCO}_{2\text{eq}}$). Emission factors for the different processes are mainly taken from the Swiss LCA database (KBOB 2022).

2.2.3 Construction costs

In order to evaluate the economical implications of reusing RC components, costs for dismantling the source structure and constructing the target structure are estimated for all variants. For this paper, unit prices for the reference year 2021 are used. They are mainly estimated from construction companies' bids, engineering office experience and average prices published in the Swiss Construction Price Index (FSO 2021).

3 CASE STUDY

3.1 Source and target buildings

The two source structures for the case study are cast-in-place RC slab-and-column systems of office buildings located on a former industrial site in the city of Basel, Switzerland, Figure 3. They were constructed in the late 1950's and are now destined to be dismantled following the urban re-qualification of the district.

The target building is shown in Figure 2. It is a 6-story residential building with an area of 606 m^2 per floor and a total height of 17.1 m above the ground. It is to be located on the same site as the source buildings.

Figure 2. Target building.

3.2 Design alternatives

For the sake of comparison, three different design alternatives are developed. The first one, “Reuse”, includes as many reclaimed RC components as possible. The details of this design are given in section 3.3. The second design alternative, “Conventional”, instead uses only newly cast-in-place RC and is used as a reference for conventional construction methods. The third alternative, “Hybrid”, is a combination of both variants that favors a simplified construction process for the bracing system: slabs and vertical supports are made of reclaimed components except for the bracing walls, i.e. the walls of the cores, that are made from new cast-in-place RC.

3.3 Reuse-driven design

3.3.1 Slab design

Figure 2b shows the division of the target floor slab into parts (step 3 of the design process, see Figure 1). For each part, a component of the source building must be allocated (step 4 of the design process, see Figure 1).

Figure 3 shows the floor plan of the considered source buildings. Color zones correspond to different bending-moment resistances which are used as an input for the allocation algorithm. Each zone is characterized by four values – i.e. positive and negative resisting bending-moment in x- and y-direction respectively. The final sawing position for every part allocated to the target slab, obtained after the design iterations, are also shown.

Figure 3. Distribution of bending-moment resistance across the source slabs and final sawing layout.

3.3.2 Strengthening and connection details

For the Reuse design variant of this case study, a layer of 20 to 35 mm of Ultra-High Performance Fiber Reinforced cementitious Composite (UHPFRC) is used to provide structural strengthening when necessary as well as continuity at the connections. The composite material is commonly used for rehabilitation of existing structures and allows bending as well as shear strengthening of the slab in all directions simultaneously (Habel et al. 2006, Bastien-Masse & Brühwiler 2016). The zones of the target building requiring a UHPFRC-layer are shown in Figure 4a. The blue zones illustrate bottom reinforcement, while the red zones are top reinforcement.

In the structural model of the target building, slabs are considered to be continuous over walls, meaning that there are negative bending moments over the supports. Therefore, as shown in Figure 4b., a layer of UHPFRC is applied on the upper surface of the slab in the joint region to transfer the tensile force from one slab element to the other.

Figure 4. Slab strengthening and slab-wall connection.

3.3.3 Lateral bracing system

The city of Basel, Switzerland, where the case study is located, has the second highest seismic risk in the country. Therefore, an adequate seismic design is required. For the Reuse design, bracing walls to resist seismic loads are sought to be built from reclaimed components as well. The analysis shows that the reclaimed components do not provide a sufficient cross-sectional resistance to resist lateral forces. Therefore, another bearing system is suggested, where each bracing wall is built as a truss system over the height of the whole building, as shown in Figure 5a. A compression strut forms in the reclaimed concrete walls, which is deviated by ties at each slab level. The connection between the walls is done as shown in Figures 5b, c, so that new reinforcement bars embedded inside cast-in-place concrete are introduced in between the reclaimed wall components as vertical and horizontal ties.

Figure 5. Design of new bracing system with reclaimed concrete walls to resist lateral forces.

4 ASSESSMENT RESULTS

4.1 Life Cycle Assessment

Figure 6 shows the comparison of the GWP for the three design variants. It is assumed that the components to reuse are stored on the same site as the deconstruction of the source buildings and the construction of the target structure. Therefore, no transportation of reclaimed elements is considered for the Reuse and Hybrid design variants.

If the demolition of the source buildings is not considered, greenhouse gas emissions of the Reuse and Hybrid variants are respectively 77% and 73% lower than those of the Conventional variant. If the end-of-life is included in the LCA, ratios become 75% for the Reuse variant and 72% for the Hybrid variant. The Hybrid variant is slightly less favorable in terms of GWP than the Reuse variant due to the larger quantity of newly poured concrete. For both variants using reclaimed materials, the largest share of GWP is caused by the UHPFRC structural strengthening of the slab which amounts to about 60-70%.

4.2 Construction costs

Figure 7 shows the comparison of the estimated construction costs for the three variants, with a $\pm 15\%$ precision. The ratio of costs between variants differs significantly depending on whether the end-of-life of the source buildings is taken into account or not. If the costs of demolishing the source buildings are attributed to a different project than the construction of the target building, then the costs of the Reuse and Hybrid variants are respectively 54% and 56% higher than for the Conventional variant.

However, if the end-of-life of the source buildings is included in the analysis, demolition and material disposal drive up the costs of the Conventional variant to a level comparable to the variants applying reuse. Under these assumptions, the Reuse and Hybrid variants have costs within the $\pm 15\%$ precision range of those for the Conventional variant.

For the Reuse and Hybrid variants, the biggest share of costs is due to the deconstruction of the components to reuse, i.e. related to sawing (30-40%) and to lifting components with a crane (10-20%). New materials needed for the bracing system only amount to around 2-3% of total costs.

Figure 6. Comparison of global warming potential per floor area for different design alternatives.

Figure 7. Comparison of construction costs per floor area for different design alternatives.

5 DISCUSSION AND CONCLUSION

The aim of this study is to investigate the technical feasibility as well as the benefits in terms of environmental impacts and costs of reusing RC components from obsolete structures in new constructions. To this end, the load-bearing structure of a residential building is designed with reclaimed cast-in-place RC components mined from two given source buildings. The final design is compared to an equivalent, conventionally built structure using new cast-in-place RC.

The study proves that technical solutions are available to design the structural system of a building floor from reclaimed cast-in-place RC elements. It is found that by reusing structural components greenhouse gas emissions are reduced by 75% compared to conventional construction techniques. Integrating a limited amount of newly cast-in-place RC in a structure mostly made from saw cut parts simplifies the construction process and at the same time achieves a similarly low level of global warming potential. In terms of construction costs, estimations show that reusing RC components competes with conventional construction methods only if the demolition and disposal of the source buildings are included in the analysis.

These are promising results, as they clearly show the potential of reuse to reduce the DEI of RC construction for a similar range of costs. Especially in times of supply bottlenecks and increasing material prices, when costs of conventional construction tend to increase, reuse becomes an interesting alternative that is beneficial not only from an ecological but also from a financial point of view. Yet, more studies like the present one are needed to support a widespread application of RC component reuse.

Reuse of fibrous tectonics as the secondary structure of the facade system

A. Ahmadnia, C. Monticelli, S. Viscuso & A. Zanelli

Politecnico di Milano, Milan, Italy

ABSTRACT: Fibrous structures are structures that are made of fiber-reinforced polymer (FRP) composites. Their excellent mechanical properties, in addition to their low densities, can result in a lightweight structure. However, there are some obstacles that prevent them from being used more widely: high material and manufacturing costs, end of life (EoL), plus optimizing their design and fabrication procedures to be used on a building scale, like they have been used efficiently in the aerospace and automobile industries. The current recycling process for FRP can cause a huge loss in mechanical properties and be costly. The goal of this study is to reuse the entire continuous fiber-reinforced polymer composite with minimal loss in mechanical properties, so the current use of thermosets has to be changed to thermoplastic. The secondary structure of a façade system is intended to replace existing bulk structural systems and scale up the FRP composite to the building scale.

1 INTRODUCTION

1.1 *History of FRPs in industry*

Owens Corning was the first to introduce glass fiber in 1935, kicking off the fiber-reinforced polymer (FRP) industry. Following World War II, the burgeoning petrochemical industry made available glass fiber embedded in polymeric resins; as a result, high-strength, high-stiffness structural fibers were combined with low-cost, light-weight, environmentally resistant polymers to create a composite with better mechanical properties and durability than the constituents alone (Bakis et al., 2002). Moreover, due to the demands of World War II, the FRP industry transitioned from research to manufacturing. Bill Tritt prototyped and tested a totally composite body car built of glass fiber-reinforced polymer composite (GRP) in the 1940s. In the 1950s, manufacturing innovation continued with the developments of pultrusion, vacuum bag molding, and large-scale filament winding. Later, fibers with higher stiffness, strength, and density, such as boron, aramid, and carbon, were used for high-performance applications in space exploration, aerospace, and air travel, as well as the defense industry (Bakis et al., 2002). High-performance fibers were initially too expensive to be employed in other applications; as a result, work began in the 1970s to reduce the cost of high-performance fibers (Bakis et al., 2002). As the cost reduced and the defensive market waned, the use of FRP as a new material in the renewal of infrastructure increased at the end of the 1980s and the beginning of the 1990s. Furthermore, lots of funding opportunities were devoted to industries and governments around the world (Bakis et al., 2002). Figure 1. represents a summary of the history of fiber-reinforced polymers in industry.

1.2 *History of FRPs in architecture and construction*

Fiber-reinforced polymers have been used in architecture since the second half of the twentieth century (Dambrosio et al., 2020). After World War II, a large portion of the polymer output was made available for non-military uses. In 1955, the Radome, an enclosure for a radar station, was mounted in Washington according to Richard Buckminster Fuller’s geodesic dome idea (Knippers et al., 2012). This enclosure had to be a free metal structure, which led to the first assemblies made entirely of synthetic materials. Buckminster Fuller continued to work on polymer geodesic domes, building the “Fly’s Eye Dome” in 1970. The Monsanto Chemical

Company approached MIT in 1954 with the concept of building an entirely polymer-based dwelling. A year later, MIT published “Plastics in Housing,” a study that outlined how the house of the future would look (Knippers et al., 2012). The main motivations for adopting polymers in construction were flexibility for changing families, ease of relocation for increased mobility, and cost-effective housing for the developing middle class. All of these features were to be exhibited in a project that could be easily assembled and modified to fit varied plan layouts and local conditions (Knippers et al., 2012).

Fiber-reinforced polymer structural forms are one of the most common uses in the building and structural industries. The pultrusion method was utilized to create the structural shapes of the fiber-reinforced polymer. Via the pultrusion technique, the fiber-reinforced polymer has been employed in structural, non-structural, and electrical applications. Before the 1970s, the development of small-sized commodities for non-structural and electrical purposes was the main focus (Bakis et al., 2002). Since the 1970s, pultruded structural shapes have been used for primary load-bearing systems. The use of pultruded structural shapes of fiber-reinforced polymer in the design and construction of pedestrian bridges, such as the long cable-stayed Aberfeldy Footbridge in Scotland, is also evident (Bakis et al., 2002).

Figure 1. History of FRPs.

2 MATERIAL INVESTIGATION

2.1 Fiber-reinforced polymer composite (FRP)

FRP composites are high-strength, lightweight, with great fatigue resistance, a high elastic modulus, and low thermal expansion and corrosion resistance (Liu et al., 2015). Besides, they can be ductile (depending on the type of matrix), but they are anisotropic materials (Waimer et al., 2013), which means they present different behaviors in different directions. Since an FRP composite contains a reinforcement (fiber, 60%) embedded in a matrix (polymer, 40%) (Figure 2.) (Liu et al., 2015; Bhargava, 2004), it primarily exhibits the mechanical properties of the fiber in the fiber direction, i.e., relatively high strength and modulus. On the other hand, it exhibits the mechanical properties of the polymer and resin in the direction perpendicular to the fiber axis, i.e., relatively low strength and modulus (Liu et al., 2015).

The matrix of FRP can be a thermoplastic, elastomer, or thermoset. Because of its high mechanical strength, epoxy, a thermoset polymer, is often employed as the matrix material in fiber-reinforced polymer composites (Boon et al., 2021). Although making a thermosetting composite is a simple operation, the long curing cycle of thermosets will increase the manufacturing cost (Boon et al., 2021). On the other hand, fiber-reinforced thermoplastic polymer composites take substantially less time to make because of their fast consolidation cycles; they also offer higher toughness, a longer shelf life, are easier to repair, and can be recycled

(Arhant et al., 2019). The high melt viscosity of thermoplastics can cause non-homogenous impregnation of reinforcement during the infusion process (the process of producing FRTP). The melt flow index must be considered when using thermoplastic polymers. According to the standards ASTM D1238 and ISO 1133, it is defined as a measure of the resistance to flow (viscosity) of the polymer melt at a given temperature under a given force for a predetermined period of time. It has a direct relationship with the flow of thermoplastic and an indirect relationship with viscosity. A thermoplastic epoxy resin (TP-EP) that combines the benefits of thermoset and thermoplastic resins was recently created (Nishida et al., 2018).

Figure 2. Reinforcement/Matrix in FRP composite.

2.2 Market share of FRPs

Fiber-reinforced polymer composites (FRP) have been in use since the 1930s, but they are now gaining popularity in the structure and construction industries (Bakis et al., 2002). FRPs are frequently used in place of metals in construction as well as in the military, energy, transportation, chemical, and electric power industries because of their high strength, light weight, and low maintenance requirements (Xue et al., 2022). Glass fiber-reinforced polymer composites (GFRP) and carbon fiber-reinforced polymer composites (CFRP) as two inorganic synthetic fibers are mostly common in different industries. In 2021, the global market for carbon fiber-reinforced plastic (CFRP), according to Statista, will be worth about 8.2 billion dollars. The size of the global market for carbon fiber-reinforced plastic is anticipated to reach approximately \$13.1 billion in 2027. The market for carbon fiber (CF) is expanding at a fast rate of 10%–12% annually due to the growing use of CF in aerospace, wind turbine blades, and other industrial applications (Xue et al., 2022). Glass fibers (GFs) were in high demand globally in 2019 (5.26 million tons), and it is anticipated that they will continue to lead the composite materials market (Xue et al., 2022). This shows an increased use of these materials in the construction industry. An investigation shows that the market share distribution of fiber-reinforced polymers in the construction industry is about 26 percent (Zyjewski et al., 2017).

While carbon fiber-reinforced plastics (CFRPs) are primarily used in the aerospace, wind power, sporting goods, and automobile manufacturing industries, glass fiber-reinforced plastics (GFRPs) are more commonly used in construction, transportation, industrial applications, electronic products, and other fields (Xue et al., 2022).

2.3 State of the art in recycling and reusing of FRPs

The disposal and burning of FRP will no longer be permitted due to the new regulation (the “green deal”) (Kang et al., 2021). Additionally, recycling has economic and energy advantages; for instance, recycling carbon fibers uses between 80% and 98% less energy than producing virgin fibers (Ghanbari et al., 2021). Consequently, recycling and reusing FRP have become more popular these days. However, due to the combination of two materials in FRP composite, recycling is a challenge (Rybicka et al., 2016). The thermosetting continuous FRP, which is considerably more prevalent than thermoplastic, can be recycled by thermal, chemical, and mechanical processes (Freedden et al., 2022). Thermal and chemical strategies are focusing on the separability of reinforcement and matrix to recover the fibers alone (Freedden et al., 2022). The mechanical strategy for recycling results in a loss of mechanical properties because the continuous FRP is shredded (Freedden et al., 2022). These techniques are extremely expensive, so they are routinely utilized for recovering carbon fiber, and mechanical recycling is mostly used for glass fiber-reinforced polymer (GFRP) composites (Rybicka et al., 2016). Thermal recycling strategy causes approximately 80%

of GFRP strength losses; however, this figure is only about 10% for carbon fiber-reinforced polymer composites (CFRP) (Pender et al., 2019).

There are a few examples and strategies for reusing the entire fiber and thermosetting matrix composite. Bus stops, benches, and children's playgrounds constructed from recycled wind turbine blades are a few isolated examples. The large amounts of End-of-Life (EoL) material cannot be recycled or reused using these methods (Freeden et al., 2022).

Recently, two case studies for reusing and recycling FRP were investigated in the industry. The first is a reuse plan that was designed for the canopy of i-mesh at Expo Dubai. This canopy was designed by Werner Sobek Company and constructed by i-mesh Company by utilizing glass fiber reinforcement and a thermoplastic elastomer matrix. The system contains a set of patterns that are connected to each other and can be separated by certain lines. They plan to take away the canopy after the Expo exhibition and use it as the shading system for the courtyard of a middle-eastern country, which is suffering from the huge amount of light from the sun. Figure 3-Right presents the i-mesh canopy during Expo 2020 Dubai, and Figure 3-Left shows the reuse plan after the exhibition. This reuse potential, though only focusing on the reuse of the panels, can be useful for using the systems again; however, in this case, it is not possible to come back to the level of material filaments, so it can reduce the design potentiality because of these restrictions.

Figure. 3. I-mesh reuse plan.

Cygnat Textkimp's (cygnat-textkimp.com) waste recycling uses superheated steam to gently remove a range of polymers from filters and related production equipment, allowing raw material waste to be reused in your manufacturing process. Using a combination of superheated steam pressure swings or compression and decompression cycles, frozen polymer is removed from contaminated components and assemblies. The process takes place in a controlled environment contained within a custom-designed pressure vessel. The components are enclosed in a pressure vessel, and the pressure is rapidly decreased by opening the blowdown valves. Depending on the polymer type, temperatures above 250 °C will melt or soften the polymer, and a degree of hydrolysis will occur. When under pressure, the steam will penetrate fissures in the polymer, where it condenses as superheated water. On decompression, it boils, instantly cracking the polymer and carrying away broken particles along with the softened, degraded polymer fragments from the outer faces. The pressure swing cycle is then repeated at frequent intervals and controlled automatically with no detrimental effect on the integrity of the filter media or metal structure.

3 EXISTING GAPS AND RESEARCH AIMS

In the previous century, the consumption of building materials has increased dramatically, and the weight of the materials used for the structures is more than half that of the other systems involved. As a result, deconstruction wastes (Ng et al., 2015) and the use of virgin materials (Herrmann et al., 2018) have increased in the construction sector, and their fate cannot be landfill or burning.

The excellent mechanical properties of FRP, in addition to their low densities, can result in a lightweight structure as a result. However, there are some obstacles that prevent them from being used more widely: high material and manufacturing costs, end of life (EoL) in general,

plus optimizing their design and fabrication procedures to be used on a building scale, like they have been used efficiently in the aerospace and automobile industries. Given the size of the market and the anticipated rise in waste generation over the coming years, it is critical that composite products are properly managed when they reach the end of their useful lives.

Besides, current research in the state of the art shows that these materials have been used primarily for temporary lightweight structures (primarily pavilions, shells, and membranes) in recent years. However, the IntCDC and ITKE at the University of Stuttgart presented a possible concept of having fibrous structures on a building scale at the Biennale di Venezia 2021 (Maison Fibre), but there is still a long way to go. Older case studies show the use of these materials at the building scale, but with design, structure, and fabrication processes that are mostly similar to the traditional procedures that have been used for other structural materials like steel (for example, pultruded structural shapes). However, FRP has its own specific mechanical properties and behavior that must be taken into account.

This paper aims to reuse the entire continuous fiber-reinforced polymer composite with minimal loss of mechanical properties, necessitating a switch from thermosets to thermoplastics. A secondary structure for the facade system is designed to take the place of current bulk structural systems and scale up the FRP composite to building scale.

4 RESEARCH METHODOLOGY

According to the standard BS 8887-2:2009, “reusing” is the operation by which a product is put back into use for the same purpose at its end-of-life. In order to reuse the material after the end-of-life of a system, its design must be disassembled and reversible to return to its original situation (Gorgolewski, 2017). In the case of fiber-reinforced polymer composites, disassembly is defined as the separation between the joints that connect the fibrous structure to the context, and reversibility can be defined as the ability to unwind and wind the spool of fiber-reinforced polymer composite without losing any mechanical or physical properties. “Reusing of Fibrous Tectonics” consists of three related but distinct fields: material, computational design, and digital fabrication. Its concept can be summarized in Figure 4.

Figure 4. Research overview.

4.1 Fiber-reinforced thermoplastic polymer composites (FRTPs)

Although thermoset resins are more frequently used in fiber-reinforced polymer composites than thermoplastic resins, this study will use a thermoplastic resin. The pre-impregnated fiber-reinforced thermoplastic polymer composite (FRTP) is used in the research project, and an elastomer thermoplastic matrix has been used to feed the disassembly and reversibility, which are essential for the reusing process. The research project also makes use of the FRTP in the form of roving, which is a bundle of straight strands wound onto spools (Figure 5). However, the aim of this research is only to reuse the materials, but the use of thermoplastic matrix can bring about the possibility of recycling for future development. The unwinding and winding processes are made simpler by the composite’s increased flexibility as a result of the use of elastomer thermoplastic resin. The FRTP spools have already been impregnated and manufactured in the factory. According to the mechanical properties of the FRTP, a design and optimization process is run to reach the final shape of the structure.

Figure 5. Spool of fiber-reinforced thermoplastic polymer composite.

4.2 Form-finding process and fibrous pattern generation

An integral component of this project, which investigated the material’s reusability, was the form-finding procedure. In this study, the form-finding procedure was restricted to the generation of straightforward random patterns. For instance, no two consecutive points could be on the same side of the frame, and each loop had to have four points (mullion or transom). It is significant to note that no load was taken into account when finding the form. Because this is a lab-scale project, the paper’s main emphasis is on reusability. The points were exported in order to be imported for the fabrication part after choosing the fibrous pattern. In Figure 6, the code used to generate the pattern in the Grasshopper can be seen.

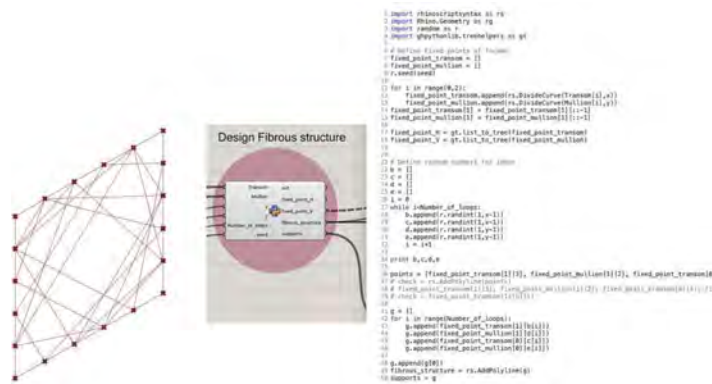

Figure 6. Fibrous pattern generation through grasshopper.

4.3 Lab-scale robotic fabrication system for in-situ fabrication and de-fabrication

The current use of industrial-type robots is primarily suitable for off-site and prefabrication of building components (Dörfler et al., 2019), which can increase the cost of transportation and the total cost in general. However, robotic technology in architecture brings greater freedom, the ability to fabricate intricate shapes and geometries (Dörfler et al., 2019), and improves the sustainability, efficiency, and productivity of building construction. The vertical-robotic system is inspired by the Polargraph drawing robot (<http://www.polargraph.co.uk/>), which includes three different yet connected subgroups. The material subgroups consist of spools of pre-impregnated fiber-reinforced elastomer polymer composite that are flexible enough to unwind and are used to fabricate the secondary structure of the façade system plus the tensioning system. The hardware subgroups, which included two motors, an electronics setup, and an Arduino, moved the end-effector (which is just responsible for fiber placement in this research) to wind the continuous fiber-reinforced thermoplastic polymer (FRTP) composite in the exact place according to the data that came from the design subgroups. The design subgroup is responsible for changing the data coming from the design and optimization process into data that can be read by hardware subgroups. Figure 6 presents the scheme of in-situ robotic fabrication on a façade.

Figure 7. Robotics sub-groups.

During the form-finding process, each loop, which can be a rectangle, is considered a linear connection between four anchor points (two on the mullions and two on the transoms). The final solution of the form-finding process can be summarized in point coordinates, which represent the index of anchor points, respectively. These coordinates will be translated into angles that can be read by the Arduino and implemented by motors. The design subgroup considers any two points in a row as the direction of movement and changes the points' coordinates to the radius that is readable for the stepper motor. No load has been considered in the form-finding process. The difference between the fabrication process and the de-fabrication process is the order of anchor points. In fabrication, the order should be from the point with index 0 to the point with index -1, whereas in de-fabrication, the order should be reversed. Contrary to the de-fabrication process, which uses an additional servo motor to help wind the fiber-reinforced polymer composite back onto the spool, a tensioning system is utilized in the fabrication process since the fiber-reinforced polymer composite has to be pre-tensioned before the filament winding technique. Figure 8 shows the fabrication diagram of one loop of fibrous structure for the facade system. The result of this research has been prototyped at 1:1 scale in the laboratory as an internal secondary structural system for façade to test the reliability and functionality of the methodology exclusively for the fabrication and de-fabrication processes.

Figure 8. Fabrication diagram + final result - * [Index of point, Number of loop].

5 CONCLUSIONS

In order to overcome the difficulties and restrictions associated with using FRP composites in building-scale applications, this paper introduces a novel strategy that involves incorporating a design approach that emphasizes reusability, end-of-life, and environmental impact into the fabrication workflow of a fibrous structure for the secondary structure of a facade. In-situ fabrication is made possible by the suggested robotic system, opening up new avenues for the construction industry. This strategy may help to advance sustainability in the field of fibrous tectonics by using an elastomer thermoplastic matrix for the FRP composite. This study makes a contribution to the field by providing a fresh viewpoint on the use of FRP composites and outlining a potential fix for the environmental problems that currently prevent their use in large-scale construction projects.

This paper is part of a research project conducted at Politecnico di Milano's TextilesHUB laboratory with the collaboration of the i-mesh company, and it focuses primarily on the lab-scale prototyping.

Properties and durability of recycled concrete with mixed granulates: Application for infrastructures

C. Paglia, C. Mosca & E. Giner Cordero

Institute of Materials and Constructions, Mendrisio, Switzerland

ABSTRACT: In the last decades recycled concrete was widely investigated. The reuse of crushed cementitious aggregates allows to close a loop towards a circular economy. In this concern, the cement-based materials are particularly important, because of their worldwide use. The addition of recycled concrete aggregates to produce new concrete is done for many applications in the building sector. Properties such as the compressive strength or the durability issues are attained with an adequate mix proportion and quality of the components. On the other hand, the concrete produced with mixed granulates, such as ceramics, stone and cementitious wastes as main ingredients, still remains an issue to clarify. This work analyzes the main inert components that may be collected in regional recycling centers and preliminary reviews the properties and the durability of recycled concrete that may be produced with a variable content of the components. This allows to better identify the possible uses of such recycled concrete for the infrastructures: embedding, support, basements, or structural.

1 INTRODUCTION

The sustainability is a wide topic that involves numerous building aspects that are linked to the life cycle and the environmental declaration of the products (Norm EN 15804:2021). The re-use of building materials became an important issue in the last decades. The enormous production of inert material waste during construction, such as for instance tunnel break aggregates or excavation as well as the demolition of built infrastructures triggered new finding and possibilities to recycle the mass. This was particularly investigated in the case of lack or reduction of disposal spaces. Many types of inert waste are considered in the building sector, such as recycled concrete aggregates, milled asphalt granulates, excavation or fluvial material, quarry debris, cementitious dusts, various type of ashes (Siddique et al. 2018). Most of the material tends to be re-used as broken coarse aggregates, while fine cementitious aggregates are still a limiting factor, that needs to be further investigated (Norm SIA 2030, 2021). On the other hand, cementitious binder alternatives in partial substitution of Portland cement try to focus on the geographical and geological availability and to reduce the burning temperature down to 800 °C and the CO₂ production, such as for LC3 cements (Scrivener et al. 2018).

In this work, the main focus was given to overview the recycled concrete produced with mixed inert granulates, although a brief indicative application was also treated for recycled concrete with cementitious aggregates. The aim is to further clarify the possible application of such an inhomogeneous material consisting of a mixed granulated recycled concrete, that nowadays is still widely disregarded in relevant engineering infrastructures and brought to disposal. In this concern, clear technical guidelines, compulsory requirements and financial support from the public administration may help to trigger a market for these type of recycled materials (OECD, 2017).

Nonetheless, every step must be followed by appropriate material quality controls.

2 RECYCLED CONCRETE

The recycled concrete aggregates (RCA) are largely used for low grade infrastructures, as a landfilling material or for road bases. This in spite of the fact that, the main mechanical properties, such as a useful compression strength can be easily achieved with an appropriate percentage of addition. This occurs also when the origin of the demolished cementitious material is unknown (Paglia et al. 2021).

The durability performance needed a longer investigation time (ACI Committee 555 2001), and it is still a matter of discussion. This is mainly caused by the microcracks present in the old mortar during the demolition processes and the high porosity (Xiao et al. 2021). The mortar remains the weakest zone for recycled concrete (Etxeberria et al. 2007); (Corinaldesi et al. 2009). At high level of RCA aggregate substitution from 50 to 100 % the durability properties, such as the chloride permeability is questionable [Kou et al. 2013]; (Kanellopoulos et al. 2014). The use of mineral admixture, such as fly ash or silica fume, have a positive effect (Kaur et al. 2021). In this concern, the reduction of the amount of adhered old mortar on the aggregates exhibited an improvement of the performance (Dimitriou et al. 2018). In addition, the CO₂ pre-treatment of waste hydrated cement paste (Mehdizadeh et al. 2022), the carbonation of concrete fines particles (Ho et al. 2021) and the wet carbonation of concrete fines, in order to obtain supplementary cementitious material with high pozzolanicity (Shen et al. 2022), appear to give interesting results. Nonetheless, with known high quality original concrete, that means, by clarifying if it is coming from a building or a bridge and with an appropriate mixing proportion not higher than 50 % of the recycled aggregates, it is possible to prepare a recycled concrete that complies with the main durability requirements (Paglia et al. 2022). By increasing the recycling cycles, the durability properties, such as the freeze/thaw resistance, the chloride ion permeability coefficient and the carbonation depth decreased (Zhu et al. 2019). This also takes place by multi-recycling of coarse aggregate (Ebrau et al. 2018). However, with the appropriate mix design and quality control it appears possible to achieve a 50 years structural concrete live span for each recycling cycle.

3 RECYCLED CONCRETE WITH MIXED GRANULATES

3.1 *The local issue and material source*

The concrete is a common source of recycled cementitious material, that derives from the construction demolition waste. Even more present are unsorted debris mixed materials, that comes from the demolition or from excavation (Figure 1 left). The variation of the components is relatively high. Some material supply to the disposal centers are particularly enriched in ceramic thin tiles (Figure 1 centre-left). This is a result from the demolition of internal part of buildings. In addition, drywall may be present in the debris. This latter component may cause potential expansion issues, when reused in concrete, due to the sulphate that interacts with the aluminate component of the cements. An increase in the ceramic brick and roofing tile elements (centre-right) and crushed fine-grained component (right).

Figure 1. Unsorted mixed debris (left), increase white ceramic tile's component (left-centre), higher brick and roofing tile elements (centre-right) and crushed fine-grained component (right).

tile elements may also be observed (centre-right). The crushing of all the elements to a fine-grained aggregate component < 22 mm (Figure 1 right) may create the conditions for the waste components to be recycled within the cementitious material. It must also be said that, within these mixed materials, wood, plastic and metallic wastes have also to be sorted out in order to get inert inorganic materials.

The geographic location and building culture may also influence the type of mixed materials picked up from the different demolition sites. In spite of the advised selective demolition, that needs to be applied in order to better separate some of the main components, different type of materials enter the actual disposal sites. This is mainly caused by the absence of a market for these type of mixed granulates. Consequently, there is a lack of such materials in the recycling sites and the materials are mainly brought to disposal.

In this concern, a log-term monitoring up to at least one year will be done to identify the type of debris present in the disposal sites. The main components will be identified and an evaluation of the separation possibilities will be investigated.

3.2 *Properties and durability of the concrete*

In order to define a recycled concrete a RC-M type, the content of mixed granulates (M) must be at least 10 % by mass. This percentage derives from a geographic local requirement (Norm SIA 2030:2021). The concrete produced with a mixture of clay stones and carbonate-rich sand debris needed a higher amount of water, because of the higher porosity and water adsorption (Leemann, et al. 1999). A reduction of the modulus of elasticity in structural tests was also found (Olia et al. 2000); (Hoffmann et al. 2006). The density was also lower as compared to natural stone components. The porosity of a mixture with an addition of 60 % by weight mixed granulates exhibited a porosity around 17 %. A little higher as compared to concretes mixed with 90 % recycled concrete aggregates and 30 % recycled concrete with 30 % mixed aggregates. All these latter mixes showed compressive strength on cubes above 45 Mpa after 28 days. On the other hand, the durability, especially the freeze/thaw resistance did not often reach the requirements [Hoffmann, 2006].

3.3 *The ceramic component*

Bricks are among the most used construction materials. Several old buildings in the recent decades were demolished and the availability of such debris increased (Li et al. 2016). Brick waste can be considered an eco-friendly material due to its chemical stability and inert behaviour. It appears that, the use of bricks in form of fine grained dust and added in substitution of cement, exhibits a pozzolanic activity and has a positive effect on strength and durability of concrete when the crushed bricks are added up to 20 % by weight. The pozzolanic activity of bricks derives from its production and chemical composition. Clays are exposed to fire at high temperatures and the main chemical composition indicates a content of SiO_2 , Al_2O_3 and CaO (Wild et al.1997). The crystallinity of the minerals (Walker et al. 2011) and the particle size may inhibit the pozzolanicity (Komnitsas et al. 2015). On the contrary, the use of bricks as coarse aggregate adversely affects the concrete property. This is caused by the porosity contained in the bricks and the addition in concrete should be limited only to contribute to a local environmental improvement (Wong, 2018). Nano brick powder was also added in replacement of cement up to 10 % and the 20 % substitution of sand aggregates improved the mechanical properties (Abbas et al. 2021). While the substitution of maximum 20 % brick aggregates has a similar effect on creep as with conventional concrete with natural aggregates (Gayarre et al. 2019). Bricks have a brittle behaviour and when added in form of aggregates they may increase the fragility of the concrete. This property will be tested in our mixtures. In addition, crushed brick components exhibit a strong angular component. This fact adversely affects the workability of the fresh cementitious blends. The workability and pumpability are reduced. These negative consequences must be faced with adequate chemical additives.

A first characterization of the chemical composition of bricks was done with SEM-EDX device at 15 kV. They exhibit SiO_2 , Al_2O_3 as main components and Na_2O for the solid bricks

(Table 1). The perforated bricks may exhibit CaO contents up to 50 % by weight as already observed (Wild et al. 1997). Occasionally FeO and MgO are also present up to 10 %.

Table 1. Main chemical composition of the solid brick.

Element Number	Element Symbol	Element Name	Atomic Conc.	Weight Conc.	Oxide Symbol	Stoich. Weight Conc.
6	C	Carbon	1.139	0.701		
8	O	Oxygen	68.518	56.156		
11	Na	Sodium	2.804	3.303	Na ₂ O	5.230
13	Al	Aluminum	8.260	11.411	Al ₂ O ₃	25.334
14	Si	Silicon	18.157	26.126	SiO ₂	65.652
16	S	Sulfur	0.000	0.000	SO ₂	0.000
17	Cl	Chlorine	0.000	0.000		
20	Ca	Calcium	1.121	2.302	CaO	3.784

The SEM investigation of the microstructure exhibits more platy phases and less porosity for the solid bricks (Figure 2 left) as compared to the perforated bricks (Figure 2 right). However, the pores are clearly visible in both cases and the microstructure partially assumes a sponge-like morphology. Pores are present in such materials (Wong et al. 2018) and may inhibit the use as coarse aggregates.

Figure 2. Overview of the bricks microstructure in the BSD mode.

In addition, the microstructure of the grinded particles of the solid bricks was investigated. They showed a predominant angular shape, rarely platy or elongated (Figure 3 left). The preliminary study of the particle in contact with water up to 24 hours shows an initial hydration reaction to form a relatively amorphous mass (Figure 3 right), although in this brick type the low CaO content does not allow the pozzolanic activity of the materials (Walker et al. 2011); (Komnitsas et al. 2015) to act and form a stiff gel.

Figure 3. Solid bricks particles prior (left) and after (right) the contact with water up to 24 hours.

Ceramic waste recycled aggregates mainly composed of SiO_2 and Al_2O_3 and derived from sanitary installations are used as fine or coarse substitutions. Generally, the workability is decreased with the addition of such a component, while the mechanical properties and the durability tend to increase if 20 % addition is not exceeded (Magbool et al. 2022). The ceramic waste is used to replace the cement, due to the pozzolanic reactivity and as an aggregate replacement. In both cases, the mechanical performance and the durability was reported to increase also with 40 % substitution degree (Gautam et al. 2021). Durability, in particular chloride ion penetration, appears to be reduced, while the resistance to sulphate attack, resistance to abrasion and the electrical resistivity were reported to increase (Meena et al. 2022). This later parameter may help in reducing the corrosion susceptibility of reinforced concrete, but this fact still needs to be further clarified.

3.4 Application

At the moment, several low grade applications are thought for recycled concrete with cementitious aggregates (Figure 4). The experimental mixtures prepared with mixed granulates or with sorted single components such as brick, tiles or ceramic waste must clarify the possible uses of such concrete RC-M material for the orange parts of the infrastructures. The aim is to identify appropriate mix design that will allow such applications. In this concern and in the case of positive performance of the recycled cementitious RC-M concrete blends, the public sector will impose the use of such material and will create the premise for the development of a local market and the necessity for the recycling companies to collect such mixed waste material and sell it to the concrete producers.

Figure 4. Uses of recycled components for the application in infrastructures.

The unsorted mixed material is actually collected into the disposals is considered not adequate to be reused in concrete. The significant inhomogeneity of the mixed components added to concrete does not allow a reliable production of material with adequate constant behaviour. Its quality would need to be constantly monitored. An unthinkable highly costs for the clients and the producers. On the other hand, more clear specifications or guidelines about the mix design, the mechanical as well as the durability parameters required by the different infrastructural applications may ease the use of a recycled concrete with the partial addition of some type of mixed granulated or single components.

3.5 Prospectives

The recycling of materials is an actual and big concern in the construction industry. At this stage it is necessary to deal with the old way to plan the buildings and the infrastructure. In

the past, often the multiple combination of materials created high performance construction systems from the point of view of the mechanical properties. On the other hand, the durability was mainly considered in the last decades and the reuse and recycling topics only arised in the recent years. This fact suggests another way of thinking when planning the future built environment.

At this stage we still need to deal with the old construction multiple systems. Consequently, during the demolition mixed debris are often present on sites. The demolition waste needs to be separated during the demolition process. If not possible, the separation of some main components is increasingly required in order to recycle high quality materials with known properties. In this regard, the use of some single components or the addition within concrete may be possible. Although further investigations must be done to clarify the influence on the mechanical, physical, chemical, durability and recycling properties of the recycled single components within the concrete. These are some of the aspects that will be clarified in our future work.

4 CONCLUSIONS

Mixed construction demolition debris are widely present in todays building sector. Mixed inert materials, such as excavation and demolition waste must find a better and high technological way to be reused or recycled. The addition of some single components within concrete can be done, while the addition of the mixed granulates has to be questioned. In fact, it is necessary to separate the main components of the mixed debris and better characterize their microstructure and function as a coarse or fine component within cementitious blends. Concrete with the addition of single debris components may be a more reliable way to recycle them. Especially brick or ceramic elements appear to have a change to be added within concrete as a fine pozzolanic addition. In addition, in a further recycle process, it would not be necessary to separate them, because of the similar inorganic nature of the concrete. Furthermore, the higher quality of the recycled material may be used for more technological application and not simply as a filler or protection materials for infrastructure.

ACKNOWLEDGEMENTS

The authors would like to thank the technicians of the Institute of materials and construction SUPSI for sample preparation and testing.

Behavior of bolted shear connectors for demountable and reusable UHPC-formed composite beams

H. Fang

University of Leeds, Leeds, West Yorkshire, UK

ABSTRACT: Steel-concrete composite beams are widely applied in the design and construction of bridges and buildings. Due to the urgent need for the transformation towards sustainability and net-zero, developments of innovative composite systems with improved life-cycle sustainability such as lower embodied carbon and the potential for reuse after the end-of-life stage are required. To address this challenge, this study aims to contribute to the development of the composite beams with the ultra-high performance concrete (UHPC) proven with lower life-cycle embodied carbon than conventional concrete and the high-strength steel (HSS) bolts as the shear connection that facilitates demountability and reuse to reduce the production of new materials and the associated carbon footprint. The behavior of HSS bolts embedded in UHPC slabs is investigated experimentally. The resistance, load-slip responses and failure modes of the HSS bolts are presented and discussed. The suitability of design approaches for shear connection in conventional concrete slab for the HSS bolt shear connection in UHPC slab is also assessed and discussed.

1 INTRODUCTION

Steel and concrete composite structural systems have been widely applied in the construction of various infrastructures owing to the outstanding structural performance compared with the reinforced-concrete or pure steel structures (Johnson 2004; Fang et al. 2023; Wang et al. 2023). Among different types of composite structural systems, steel-concrete composite beams with optimal material efficiency for load bearing are commonly used in medium- and high-rise building and bridges (Johnson 2004; Rehman et al. 2016). With the need to transit towards low-carbon construction and sustainability, reducing the embodied carbon of the structural systems in the life-cycle and eliminating the waste of the structures at the end-of-life stage are required. To realize these goals, research efforts are committed to develop low-carbon and reusable composite systems for their applications in next-generation infrastructures.

The embodied carbon of steel-concrete composite beams is quantified by the CO₂ equivalent emissions generated at different stages in the life cycle including the material production, construction, operation and demolition at the end-of-life stage. To reduce the embodied carbon of structures, alternative and more advanced materials for fabricating low-carbon steel-concrete composite beams are required (Zhao et al. 2021). Besides, accurate design approaches that enable to reduce the design conservatism can also effectively reduce the material consumption associated with the design and subsequent embodied carbon of the composite beams (Uy, 2018; Fang et al. 2021; Chen et al. 2022). Compared with the conventional concrete used to form the composite beams, ultra-high performance concrete developed with much higher strength and improved durability can be applied to form lighter and more durable composite beams. The reduced weight of materials and structures can bring the benefits of reducing energy consumption for the transportation and construction (Uy, 2018; Fang et al. 2023; Liu et al. 2022a). Besides, the outstanding durability of UHPC required much

reduced maintenance compared with the structural components that are formed with conventional concrete and experience gradually structural deterioration (Suwaed & Karavasilis 2017). Thus, the structures formed with UHPC are proven to have lower life-cycle embodied-carbon compared with the conventional concrete counterparts (Dong 2018). Considering these advantages of UHPC for developing low-carbon structural elements, UHPC materials are investigated for its use to form steel-UHPC composite beams to reduce the life-cycle embodied carbon of the structures.

Comprehensive understanding of the structural performance of steel-UHPC composite beams is necessary in order to generate reliable and efficient design of the structures. The structural resistance and stiffness of a composite beam depends on the design of shear connections that connect the steel section with concrete slab and effectively transfer the longitudinal shear forces between the steel and concrete components. Conventional headed stud shear connections are welded permanently to the steel beams, hindering the dis-assembly of structural components for maintenance during the service-life or reuse at the end-of-life stage for sustainability (Suwaed & Karavasilis 2017; Rehman et al. 2016). Demountable shear connection development for steel-UHPC composite beams will maximize the sustainability of the structures and bring the opportunity to dismantle the beams and reuse the components for new infrastructures, facilitating the sustainable future and circular economy of the industry. Therefore, the structural behavior and design of demountable shear connection for steel-UHPC composite beams is the focus of this study.

High strength bolted shear connectors that enable to easily deconstruct the composite beams for sustainable rebuild (Ataei et al. 2019; Moynihan & Allwood 2014) and provides higher strength than stud connectors were investigated experimentally in this study. Experiments were conducted on steel-UHPC composite beam elements with HSS bolted shear connectors to test the behavior of the shear connectors. The ultimate strength, load-slip characteristics and failure modes of the specimens with different parameters related to shear connector arrangements were reported and discussed. Furthermore, the ultimate strengths were also compared with those estimated based on existing standards and the applicability of those methods for predicting the strengths of the HSS bolted shear connectors embedded in UHPC slabs was discussed to provide basis for engineers to implement the design of the structures.

2 EXPERIMENTS

2.1 *Specimens and material properties*

Eight steel-UHPC composite specimens designed with HSS bolted shear connectors were prepared for the experiments. The size and arrangements such as the spacing and height of bolted shear connectors are the main parameters considered in this study to investigate their effects on the behavior of the demountable shear connection embedded in UHPC slab components in order to identify the key parameters for design optimization. The specimens and their parameters are given in Table 1. In the table, the labels of the specimens describe the HSS bolt size, the vertical spacing of the bolt rows and the height of shear connection in the slab. For example, the specimen S1-16-100-h90 refers to the specimen with eight M16 bolts, the embedded height as 90mm in the UHPC slab and the vertical spacing of 100mm between two rows of bolts. The specimens with the 'R' in the label refer to the repeated test specimens to confirm the reliability of the experiments. The geometric properties of a typical specimen, S1-16-100, is shown in Figure 1. For the specimens, the HSS bolts in the grade of 8.8 were used while the 250UB37.3 steel beams were chosen for the specimens. For each specimen, two UHPC slabs with the width of 320mm and the thickness of 120mm and with the embedment of two layers of 12mm reinforcements were cast and connected with the steel beam section via pre-drilled holes by using eight single-nut embedded and pre-tensioned bolts, as shown in Figure 1. During the UHPC placement for the specimens, cylinder UHPC specimens with the standard size of 100×200mm were also prepared for measuring the properties of UHPC.

Table 1. Parameters of the specimens for the experimental investigations.

Specimen	Bolt size	Vertical spacing for bolt rows	Bolt height embedded in UHPC slab (mm)
S-16-100-h90	16	100	90
S-16-100-h90R	16	100	90
S-16-100-h70	16	100	70
S-16-100-h70R	16	100	70
S-16-150-h90	16	150	90
S-16-200-h90	16	200	90
S-20-100-h90	20	100	90
S-20-100-h90R	20	100	90

Figure 1. Dimensions in mm and details of the S-16-100-h90 specimen.

Material properties of the components forming the specimens were measured during the testing period for the steel-UHPC composite structural specimens. Tensile testing of the specimens extracted from the steel beam sections or fabricated from the 12mm reinforcements or HSS bolts were tested following the procedures applied in previous research for steel material property measurements (Liu et al. 2022b&c; Ke et al. 2023). The measurement results including the yield strength and ultimate strength were obtained, as shown in Table 2. The UHPC cylinder specimens were also tested during the days when the steel-UHPC specimens were tested after they were cured for more than 28 days. The resultant cylinder compressive strength (f_c) of the UHPC materials is 125MPa on average.

Table 2. Averaged material properties measurement results for the steel beam, reinforcements and HSS bolts.

Steel specimen	Components or size for each specimen	Yield strength (MPa)	Ultimate strength (MPa)
Steel beam section	flange	345	511
	web	374	519
12mm reinforcement	-	519	684
Grade 8.8 high-strength bolts	M16	790	932
	M20	754	886

2.2 Set-up and procedures of experiments

The steel-UHPC specimens with demountable HSS bolt shear connection were cured at ambient temperature for more than 28 days and subsequently tested using the set-up validated in previous studies (Pavlović and Veljković 2017; Zhang et al. 2019), as shown in Figure 2. The loading was applied to each specimen using a 5000kN loading cell via the displacement control. The displacement rate of 0.15mm/min was adopted to ensure the monotonic loading condition for the experiments and the capture of structural responses with the variation of the loading in the ascending and descending stages. Eight linear variable differential transformers (LVDTs) were located near the bolt connections to measure the slip between the steel and UHPC slabs, as shown in Figure 3.

Figure 2. The set-up of the testing on steel-UHPC composite structural specimen.

Figure 3. Locations of the LVDT placements on one side of the specimen for slip measurements.

2.3 Results of experiments

2.3.1 Failure mode

The failure mode observed for the specimens was the shear fracture failure of the bolts, as shown in Figures 4 and 5 for typical specimens with M16 and M20 bolts respectively. It can be observed in the figures that the fracture of the bolts occurred at the shear plane near the interface of the embedded nut and the steel beam flange, indicating the high stress concentration at the regions. Due to the very high strength of UHPC, minimal damage of the UHPC slab was observed, as shown in Figures 4 and 5.

Figure 4. Failure mode of S-16-150-h90 specimen.

Figure 5. Failure mode of S-20-100-h90 specimen.

2.3.2 Load-slip relationship and ultimate strength

The load versus slip relationship was also obtained from the experimental data and is plotted in Figures 6a and b for specimens with M16 and 20 bolts respectively. As can be seen in the figures, the pattern of the load-slip curves for different specimens is consistent. The variation of load with slip generally demonstrates four stages. At the initial stage, the load increases with quite limited increment of the slip due to the high friction generated at the interfaces of the steel beam and UHPC slab from pre-tensioning the HSS bolts. When the load becomes higher than the friction at the interface, in the second stage, the slip at the interface increases

obviously while the increment of loading is slower than that observed in the initial stage. The slip in the second stage is related to the clearance between the bolts and the pre-drilled holes in the steel beams. At the end of the second stage, the bolt shanks closely contacted the holes of the steel beams and the third stage of the load versus slip relationship started. The loads increased more significantly than that in the second stage since the steel beam and UHPC slab for each specimen transferred more load through the contact between the steel beam and bolted shear connection and that between the bolted shear connection and the UHPC slab. When the loading reached a relatively high level for a specimen, the slip increased gradually with very limited increment of the loading until the bolted shear connection experienced the fracture failure.

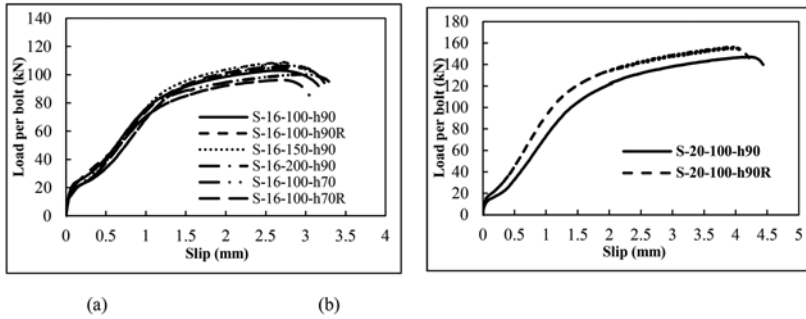

Figure 6. Load-slip curves for typical specimens prepared using (a) M16 bolts and (b) M 20 bolts.

From the load-slip curves, the ultimate strength of the specimens can be obtained and are reported in Table 3 as the resistance ($N_{u,exp}$) per bolt of each specimen. It can be observed in the table that the differences between the $N_{u,exp}$ measured for the specimens designed with the same parameters are minimal. By comparing the $N_{u,exp}$ for the S-16-100-h90 and S-16-100-h90R specimens with those for S-16-100-h70 and S-16-100-h70R, it is evident that the resistance of the high-strength bolted shear connection in UHPC slab is insensitive to the height embedded in the slab. Besides, the effect of vertical spacing between the rows of HSS bolts is also revealed from the results shown in Figure 6 and Table 3. The difference of the $N_{u,exp}$ for S-16-100-h90, S-16-100-h90R, S-16-150-h90 and S-16-200-h90 specimens with different vertical spacing between the rows of shear connection is less than 5%. Thus, the influence of vertical spacing is also limited. Furthermore, the performance of HSS bolt shear connection with larger sizes was also investigated. It is shown that increasing the size of the shear connection from M16 to M20 effectively leads to higher resistance and improved ductility, as observed in Figure 6 and Table 3. On average, the $N_{u,exp}$ for the specimens with M20 HSS bolts is about 46% higher than that for specimens with M16 HSS bolts.

Table 3. Ultimate strength from experiments and those predicted using design approaches.

Specimen	Resistance per bolt from experiments $N_{u,exp}$ (kN)	$N_{u,EC}$ (kN)	$N_{u,AS}$ (kN)
S-16-100-h90	102.9	99.98	119.35
S-16-100-h90R	105.4	99.98	119.35
S-16-100-h70	100.4	99.98	119.35
S-16-100-h70R	96.3	99.98	119.35
S-16-150-h90	108.9	99.98	119.35
S-16-200-h90	106.5	99.98	119.35
S-20-100-h90	147.2	148.4	177.14
S-20-100-h90R	156.4	148.4	177.14

3 EVALUATION OF EXISTING DESIGN APPROACHES

The experimental results for the resistance of HSS bolted shear connection are also used to evaluate the applicability of existing design approaches given for shear connections embedded in conventional concrete slabs. The accuracy of the design approaches in Eurocode 4 and Australian standard is described in the following sections.

3.1 Eurocode 4

Eurocode 4 primarily provides the specifications for estimating the resistance of headed stud shear connection for steel-concrete composite beams. The resistance for each shear connection ($N_{u,EC}$) can be taken as the lesser of the values estimated using Equations (1) and (2). In the equations, d is the diameter of the headed-stud shear connection, f_c is the compressive strength of the concrete slab, γ_v is the partial factor as 1.5 and E_{cm} is the elastic modulus of the concrete slab. In Equation (2), the parameter α is related to the height of shear connection (h_{sc}) embedded in the slab and can be calculated using Equation (3).

$$N_{u,EC} = 0.8 \times f_u \times \pi \times \frac{d^2}{4} / \gamma_v \quad (1)$$

$$N_{u,EC} = 0.29 \times \alpha \times d^2 \sqrt{f_c \times E_{cm}} / \gamma_v \quad (2)$$

$$\alpha = \begin{cases} 0.2 \left(\frac{h_{sc}}{d} + 1 \right) & \text{for } 3 \leq h_{sc}/d \leq 4 \\ 1 & \text{for } h_{sc}/d > 4 \end{cases} \quad (3)$$

These specifications were applied to estimate the resistance of HSS bolted shear connection with the strength predictions shown in Table 3. As can be seen in the table, the $N_{u,EC}$ estimated based on the Eurocode 4 are slightly lower than the $N_{u,exp}$ from experimental results. The mean value of $N_{u,exp}/N_{u,EC}$ ratios equals to 1.03 with the coefficient of variation (CoV) as 0.04, showing the close agreements between the $N_{u,EC}$ and $N_{u,exp}$.

3.2 Australian standard AS 2327

The Australian standard AS 2327 provides the approach for estimating the resistance ($N_{u,AS}$) of HSS bolted shear connection, as the lesser value calculated using Equation (4). The $N_{u,AS}$ estimated for the specimens tested in experiments are presented in Table 3. It can be seen in Table 3 that the resistance of the shear connection was overestimated based on AS 2327. On average, the $N_{u,AS}$ is higher than $N_{u,exp}$ by about 15% with the CoV of 0.04. Comparing the specifications from Eurocode 4 and AS 2327, the Eurocode 4 provides conservative strength predictions for the HSS bolted shear connection embedded in UHPC slab.

$$N_{u,AS} = \begin{cases} 0.5 \times d^2 \times f_u \\ 0.29 \times d^2 \sqrt{f_c \times E_{cm}} \end{cases} \quad (4)$$

4 CONCLUSIONS

The HSS bolted shear connection for steel-UHPC composite beams with demountability for reuse of the structural components were experimentally investigated in this study. Steel-UHPC beam components formed using HSS bolted shear connections with different dimensions, height in the UHPC slab and spacing between the rows of shear connection were prepared and tested in experiments. The experimental results show that the dimensions of the shear connection can significantly influence the resistance while the resistance of the HSS bolted shear connection is

insensitive to the height and spacing. The typical failure mode of the specimens is the shear connection fracture failure since the UHPC slab has quite high compressive strength and experiences ignorable damages. Based on the experimental results, the applicability of approaches in Eurocode 4 and AS 2327 standards for the design of shear connection in conventional steel-concrete composite beams to the HSS bolted shear connection in steel-UHPC composite beams was evaluated. The Eurocode 4 provides quite accurate and slightly conservative predictions for the resistance. However, AS 2327 standard provides unconservative strength predictions. Therefore, the specifications in Eurocode 4 can be considered and used in the design of steel-UHPC composite beams with HSS bolted shear connection.

A monitoring based digital twin for the Filstal bridges

A. Lazoglu & H. Naraniecki

DB Projekt Stuttgart-Ulm GmbH, Stuttgart, Germany

S. Marx
Technical University Dresden, Dresden, Germany

ABSTRACT: Ongoing advances in information technology enable improvements in both the quality and topicality of data-based condition information of physical structures. The digital twin, a sensor-based method to simulate a physical structure, is a promising approach to achieve a preventive and even partly predictive maintenance strategy in the future. This paper provides a digital twin concept for the Filstal railway bridges in Germany. Because of its importance for the transport network, its complex structural components and thus extensive condition monitoring, the Filstal bridges are well suited for the usage of a digital twin. The concept includes the integration, processing and aggregation of data from bridge inspections and analytical structural safety verifications as well as monitoring and diagnostic examinations to continuously display the bridge condition. Although the example at hand will be realized for a railway bridge, the core approach can be used for other bridge structures as well.

1 DIGITAL TWINS FOR FUTURE BRIDGE MAINTENANCE

In 2015, the United Nations unanimously adopted the 2030 Agenda including 17 sustainable development goals. These goals are global aspirations for a sustainable impact on social, economic and ecological developments. Goals number 9 and 13 relate to developments of sustainable, reliable and resource-efficient infrastructure by 2030, considering the Climate Change Program (United Nations 2022).

The German sustainability strategy for road and railway constructions incorporates the above-mentioned objectives and is characterized by the principle of “preservation before new construction” (BMVI 2021). Maintenance management for transport infrastructure in Germany, especially for bridges, is mainly carried out through regular visual inspections and analytical safety verifications. In addition, monitoring or diagnostic examinations of structures may become necessary. The heterogeneous data accumulated over the lifetime of a bridge is often available decentrally from different sources, both digital and analogue, and thus without contextualization.

Technical progress and digitalization are now able to support. High quality sensors, high computing power and complex algorithms for data analysis enable more detailed and higher quality condition acquisition and assessment. Furthermore, the improvement of collaborative work with digital data in BIM as well as the Internet of Things (IoT) offer an excellent basis for creating digital twins, which can positively influence the maintenance strategy of a structure and can therefore result in prolonged operational lifespan. Some initial realizations already show approaches and experience in the creation of digital bridge twins in practice, including (Hagen et. al. 2022), (Pregolato et. al. 2022) and (Wenner et. al. 2021). A comparison of these practical examples illustrates the heterogeneous approaches.

First guidelines such as the smart construction guideline (MEED 2021) or the Gemini principles (Bolton et al. 2018) have already been published internationally. In Germany, an initial guideline for digital twins in operation was developed by the Federal Ministry for Digital and Transport in 2022. With the Filstal bridges, a digital twin is being created for the first time for a railway bridge in Germany.

2 THE FILSTAL BRIDGES

The Filstal bridges are two parallel single-track railway overpasses in southwest Germany and are considered as prestigious due to their special construction method. The bridges went into operation in December 2022. Built as semi-integral structures, with continuous girders over six spans and structure lengths of 472 m and 485 m, the two bridges cross the valley of the Fils at a height of 75 m and are thus the third highest railway bridges in Germany (cf. Figure 1).

Figure 1. 3D scan of the right Filstal bridge.

The extraordinarily slender and deformable pillars are monolithically connected to the superstructure. Above the river, both structures are braced with two V-shaped pillars each, which have the function of frames. The superstructures are designed as longitudinally prestressed box girders. In (Zaidman et. al. 2022) the construction details and special features are discussed in more detail.

Due to exceptions from the common, normatively regulated design of railway bridges, calculation assumptions at neuralgic areas must be monitored and validated. For a better understanding, the most important neuralgic areas are briefly explained below.

- The longitudinal support of each bridge is designed as a special construction consisting of two crossing steel lamellas. The functionality of this longitudinal restraint bearings is relevant for the stability of the structures (cf. Figure 2 left).
- The guide bearings of the superstructures at the abutments limit the lateral displacement of the rail superstructure. The functionality of the bearings is therefore significant for traffic safety (cf. Figure 2 right).
- Large rail deformations can occur above the superstructure transitions. Joint constructions, rail extensions and special rail support points are installed at the transitions. The functionality of these constructions ensures traffic.
- The structures were shifted longitudinally after completion to initiate a compressive stress in the longitudinal restraint bearings. This longitudinal adjustment compensates the shortening of the structure from creepage and shrinkage. A renewed shift was predicted in 12 years after initial shift.
- In the case of superstructure deformation, high bending moments may be seen in the monolithic pillars. The design loads for tensile and compressive stresses of the superstructure may therefore not be exceeded.

One requirement for the operation of the bridge is a data plausibility check which is triggered once monitoring values exceed certain limits. In such a case, a warning message is sent to the person in charge.

Figure 2. Examples of neuralgic components - longitudinal restraint bearing (left) and guide bearing (right).

3 STRUCTURAL HEALTH MONITORING AND ALARM SYSTEM

For condition monitoring of the neuralgic areas of the Filstal bridges, an extensive monitoring system with 192 sensors was installed. Strain gauges on the longitudinal restraint bearings record local stresses and global forces for an evaluation of the functionality. Displacement sensors and inclinometers record relative displacements and relative rotations at the structural joints at the transition to the abutments, whereby bearing clearances can be evaluated. Furthermore, strain gauges and temperature sensors are applied on the reinforcement bars within the filigree pillars to record the pillar strains and compare them with permissible stresses. Temperature sensors at different cross-sections in the structure are used to extract the temperature-induced longitudinal displacements of the structure from the long-term total displacement and thus isolate the remaining creepage and shrinkage components. This is used to calculate the time of the subsequent longitudinal adjustment of the superstructures.

The measurement rate of the sensors is between 100 and 2500 Hz depending on the sensor type. All data are automatically transferred from the on-site measuring system to a cloud storage and form the basis for comprehensive multi-stage processing. The subsequent data processing procedures are modular. A module can contain general or structure-specific algorithms. Through a composition of several modules, an evaluation logic can be generated. Linked modules represent a workflow. The individual modules are technically implemented in the form of microservices. All workflows are managed and monitored by an orchestration framework. Every condition, every interim result and every processing step can be viewed and traced. Workflows can be started using event-based or time-controlled triggers. Figure 3 shows a simplified illustration of the data paths.

Figure 3. Data paths from acquisition to evaluation of the measurement data.

To achieve the highest possible data topicality, high frequency data transfer and data processing is required. This is why the processing steps were automated. The result of the data pre- and postprocessing steps gives quality-assured data as well as an evaluation of structural condition.

Calculations are carried out for the data from the neuralgic structures, which return the current conditions of the structure as a result. Raw data, calculated result data and conditions can be displayed, retrieved and analyzed via a created web platform (cf. Figure 4). The platform is available to those responsible for monitoring and checking the plausibility of the data.

Figure 4. Illustration of the Filstal bridges project in the web platform.

4 CONCEPT OF THE DIGITAL TWIN

4.1 *Connectivity and maturity of digital twins in bridge maintenance*

Depending on the industry sector and scope of the application, digital images of physical objects serve different purposes, leading to different definitions and characterizations (Grieves & Vickers 2017). In the context of bridge maintenance, the following summarizes definitions from the current state of the literature.

Digital twins are digital images of physical components (e.g. abutments), assets (e.g. bridges), systems (e.g. traffic routes), or processes (e.g. traffic management). A characteristic difference is the manual or automated data exchange between the physical object and the digital image. In (Kritzinger et. al. 2018), three degrees of connectivity are distinguished: The digital model (no automated data exchange), the digital shadow (unidirectional automated data exchange from the physical object to the digital images) and the digital twin (bidirectional automated data exchange). In (ARUP 2019), the metric “autonomy” is defined as the degree of independence from human interaction. In addition, the metrics “intelligence”, “learning” and “fidelity” are described. “Intelligence” describes the degree of replication of cognitive processes and fulfilment of tasks, “learning” is the degree of automatic learning for process optimization and “fidelity” is the degree of accuracy or closeness to reality of the available information. The metrics are assigned in five levels from 1-5. In (BuildingSMART 2022), five levels of maturity are also defined for the depth of information within the digital image. The first descriptive maturity level contains as-built data and is, for example, equivalent to a pure BIM model of the physical object. The second maturity level describes an informative representation and additionally uses sensor data, carries out analyses and aggregations and displays the gained information. The third maturity level enables predictivity by predicting future conditions. The prescriptive maturity level furthermore independently develops recommendations for action. In the last, fifth level of maturity, the digital representation acts autonomously. Research shows that realized digital twins in practice currently do not go beyond the third maturity level (ARUP 2019) (MEED 2021).

4.2 *Requirements for the digital twin of the Filstal bridges*

The uniqueness of structures and their varying importance in the traffic infrastructure result in different requirements for the digital image. For the Filstal bridges, one requirement was the automatic integration and aggregation of condition and structural safety information from monitoring data into condition indicators (CI). In addition, damages from regular visual inspections should be located with all the associated information. An existing BIM model is used as the basis for locating the information. Bridge relevant information are aggregated so that the condition and structural safety of the Filstal bridges can be seen based on only a few indicators. In addition, notifications from the alarm system should be integrated. The digital image is intended to provide support for the usual procedure of bridge maintenance.

The unidirectional automated data exchange between the physical and digital object corresponds to a digital shadow. The evaluation and aggregation of bridge data lead to a maturity level of at least 2 (informative representation). Condition predictions from the measurement

Figure 5. Characteristics of the digital image for the Filstal bridges.

data are calculated to some extent, yet sufficient data is not available. This matches analogously to an intelligence level of 2 according to (ARUP 2019). No algorithms for automatic learning (“learning” = level 1) are planned for the digital image, nor is autonomous action (“autonomy” = level 1). The information to be integrated is primarily maintenance-relevant information, which means that only a part of the total structure information is represented. The fidelity of this information can be understood as a reliable representation of some physical components to evaluate the current condition (“fidelity” = level 3). Figure 5 summarizes the different characteristics of the digital image of the Filstal bridges according to the definitions in chapter 4.1. To maintain consistency within this paper the term digital twin will be used.

4.3 3D model of the Filstal bridges

To precisely allocate the various data in the digital twin, a geometric model of the bridge is required. The detailed object information of the BIM model is used as a basis. The objects consist of geometries of different dimensions and associated semantic meta-information (attributes). In the existing BIM model, the bridges are modelled according to a defined bridge hierarchy and all sensors, damages and aggregated condition indicators from sensor data are allocated.

Due to the requirement of an automated, partially real-time, data exchange, the BIM model alone is inadequate. Only by processing and converting the BIM model it is possible to use the geometric model of the Filstal bridges with all semantic information of the components and the sensors as a basis for visualization and location.

4.4 Additional data base for the digital twin

For the automated integration of high-frequency data from the Filstal bridges, a database with a data model is set up in addition to the BIM model.

The designed ontology and the entities defined in it can be used to instantiate specific instance. The entirety of all instances represents the database of the digital twin. Instances can be, for example, bridge parts (e.g. pillar axis 10), damages, sensors or aggregated condition indicators. The transferred semantic information of the BIM model are basically static data that change less frequently over the life cycle. Appropriate technical interfaces and automated processes ensure that the static data of the database are updated immediately when the BIM model is updated.

Further mostly dynamic data is assigned to the individual instances of the digital twin in the database. For example, the condition information from the monitoring of the guide bearings during operation is continuously and automatically integrated into the database for the instance of the guide bearing. Updating is done in ascending order along the relationships of the ontology, so that parent objects always reflect the worst condition of their children.

A linked data approach makes it possible to assign or locate dynamic data in the geometric model in addition to the static data. With a corresponding update rate, current data can thus always be visualized.

4.5 Data aggregation

The intelligence of the digital bridge twin lies in its ability to analyze comprehensive and up-to-date data and convert them into useful information about the structure. Through the

analysis, a recommendation for action can be derived directly from the digital twin. The basis for this is the concept of information aggregation.

Current information about a bridge derives from different sources and is often available as heterogeneous data types, context-free and independent. A distinction must be made between information on assets, conditions and analytical structural safety verifications. The current condition of a bridge structure is recorded by bridge inspectors through regular, usually visual inspections. Damages are assessed about their influence on stability, traffic safety and durability for both road and railway bridges in Germany according to a rating system of grades from 1 to 4. The condition can change over the lifetime of a bridge and thus also the load-bearing capacity. Furthermore, the structural safety depends on the multitude of potential load scenarios and is evaluated by structural engineers within the framework of structural calculations and simulations. The results are analytically determined utilization level.

In the result, the main disciplines “bridge inspection” and “analytical verification” aim at evaluating the safety of the structure. An aggregation of the results is necessary for a comprehensive assessment, as they can influence each other or be mutually dependent. In the example of the Filstal bridges, the actual, variable stresses in the longitudinal restraint bearing are measured with the help of strain gauges and the structural safety is verified via calculated (theoretical) stress capacities and invariable stresses. The regular visual inspections of the bridge condition and the integration of inspection results into the simulations are indispensable, as they constantly update the calculated portion of the load-bearing capacity and indirectly, through the change in the load transfer properties, the calculated portion of the invariable stresses. Aggregation of the results of the disciplines also ensures a more comprehensive, mutual understanding between structural engineers and bridge inspectors.

An automated integration of the visual inspection results into the analytical (measurement-based) verification would currently involve a considerable amount of effort. On the one hand, damage and defects would have to be recorded and documented in sufficient detail. On the other hand, the effect of damage and defects on structural integrity would have to be predefined before integrating this into the computational simulations. For example, a reduction of the cross-sectional area in the case of corrosion damage or a reduction of the bending stiffness in the case of cracking. Because of this difficulty and the requirements for the digital twin of the Filstal bridges the aggregation between structural condition and safety assessment is not automated. Therefore, the condition information from the structural inspection and the structural safety information from the analytical verification are placed as separate information in the digital twin. The consideration of mutual influence is done manually. This concept represents an extension to the concept of the digital twin smartBRIDGE Hamburg in (Herbrand et. al. 2022), among others.

The aggregation of information takes place within the two clusters “bridge condition” and “structural safety”. “Monitoring” and “diagnostics” serve as support within the two clusters by generating additional information. The condition grade, as an indicator of the bridge condition from the visual inspection, and the ratio of the supported to the required track class as an indicator of structural safety are aggregated upwards via the bridge hierarchy.

5 VISUALIZATION AND USAGE OF THE DIGITAL TWIN

In this chapter, the current state of the visualization of the digital twin is shown and an outlook is given on the use cases in which advantages arise from the use of the digital twin.

Figure 6 shows the view for the longitudinal restraint bearing condition indicator within the platform condition control (CC). On the left hand-side the user has access to tabs for asset information, condition and structural safety information, sensor conditions and loading information. In addition, there is a notification tab, where all changes of conditions of all tabs are summarized.

The aggregated structure conditions as well as the structural safety and all other important condition information are summarized separately for each bridge in a structure summary in the top right-hand corner. For the condition and the structural safety calculated from measured data, a rating category is displayed in corresponding colors. In addition an exclamation mark can be assigned to both evaluations as an indicator for potential changes. Since sensor conditions and loading indicators are evaluated using anomaly detection, only exclamation marks can be displayed. The user can see the overall condition of the structures at any time and in any navigation level through the structure summary.

The navigation within the individual tabs takes place according to a defined bridge hierarchy via the selection of the individual bridge, the bridge part and with a final selection of the CI to be viewed. The linking of the CIs to bridge parts and their exact location in the model itself enable the bridge model in the background to be moved according to the navigation and the components and CIs to be highlighted in a user-friendly way. The interactivity between the bridge model and navigation makes the information easy to consume for the user. At the same time, by locating all important information, the digital twin enables a visual representation of neuralgic structure points and allows conclusions to be drawn about possible interactions, so that more detailed and qualitative assessments are possible.

Figure 6. Visualization of the digital twin of the Filstal bridges in condition control.

As soon as a CI is selected by the user, the corresponding information is displayed in a panel (cf. Figure 6). In addition to the name of the CI, the categorization and an evaluation or possible notification, important additional information are displayed. The time diagram shows the result of the measurement-based detection of the last two weeks and compares it with the corresponding limit value. This gives the user a first sufficient insight into the CI's past. For further information on the complete history as well as on the measurement data of the sensors included in the detection, access is provided via the link to a web platform (cf. Figure 4).

The visualization and navigation concept developed together with structural inspectors allows the user a complete and simple overview of the structure's conditions. Information on damage, conditions and structural safety can be displayed and interpreted in parallel. Via the notification tab, the user can view all indicators that exceed limit value and subsequently initiate measures, which allows for a proactive response. The digital twin and the display in the selected form thus serve the bridge inspectors as an auxiliary tool for the operation of the Filstal bridges.

6 CONCLUSIONS

The Filstal bridges successfully went into operation in December 2022. The concept for the digital twin is currently being implemented. In the next steps, the missing components of the concept will be implemented until completion in June 2023, including optimization of the BIM model, setting up the database and development of the front end for visualization. The concept for digital twin was designed to be open and modular, so that further components can be easily connected. For example, it is possible to integrate the condition of mechanical parts on the structure. The contents of individual tabs in the visualization can also be expanded. Due to its modularity, the digital twin can be transferred to different structure types.

BIM was used in the concept as the basis for the visualization and instantiation of the digital twin. The geometric display in combination with the attribution of the structure makes it possible to address specific parts of the structure in the geometric model and accordingly in the visualization of the digital twin. In the future, further possible use cases of BIM in the implementation and operation of the digital twin must be investigated.

To make full use of the digital twin, the visual inspection procedure must be optimized. In perspective damage must be precisely located (geo-referenced). A transition must be made from time consuming manual maintenance documentation to automatic documentation and data processing, e.g. (Bast 2022).

According to the current state of art, the digital twin is only able to show the current state and the current structural safety. In the future, it should be possible to generate predictive conditions and structural safety with sufficient data, but there is still a need for research in this area. Approaches such as those in (Naraniecki et. al. 2022) allow, for example, the prediction of the bridge condition based on bridge and damage data, so that maintenance measures can be planned much more effectively.

The few practical realizations and the great need for optimization make it clear that clearly defined standards and definitions are necessary for establishing the digital twin in operation and maintenance. The digital twin of the Filstal bridges lays another cornerstone. It again demonstrates the added value of digital twins in the operational phase.

An application of drive-by approach on a railway Warren bridge

L. Bernardini, A. Collina & C. Somaschini

Politecnico di Milano, Milan, Italy

K. Matsuoka

Railway Technical Research Institute, Tokyo, Japan

M. Carnevale

Università degli studi di Pavia, Pavia, Italy

ABSTRACT: The present paper illustrates a wavelet-based drive-by methodology to assess bridge health condition, identifying possible damage presence and position. The case study is represented by a single-track, medium span, Warren truss bridge, whose FE model was constructed referring to a real existing structure, and dynamically validated with experimental tests. Vertical bogie accelerations are processed by Continuous Wavelet Transform and the obtained scalogram is sectioned at a specific frequency, associated to the passage of the vehicle over each module of the truss structure. A damage index is then built up starting from the wavelet coefficients referred to this frequency. Therefore, the method exploits the structural conformation of the truss bridge as a tool for detecting damages occurred to its deck. The approach is tested using a 3D train-track-bridge dynamic interaction model: different speeds, track geometrical profiles and damage scenarios are explored to assess the effectiveness of the method and its robustness.

1 INTRODUCTION

Worldwide railway networks are exposed to increasing traffic demands, axle loads and train speeds (Hayward 2011) as well as ageing and deterioration (Fujiu et al. 2022). According to (Dinas et al. 2017), in 2017 it was estimated that in Europe the 75% of steel railway bridges were over 50 years old and almost 35% of them was older than a century. The author in (Lin 2018) reports that, in Japan, the 47% of bridges will be older than 50 years old in 2026. In Australia, considering a sample of 1122 railway bridges, it was reported that the 63% of them were older than 50 years old, while the 8% was older than 100 years old (Aflatooni et al. 2013). In India, in 2019, it was declared that 38,850 bridges were older than 100 years old, while (ASCE 2021) states that in USA the 7.5% of bridges are estimated to be structurally deficient, with the 42% of the total amount of bridges being at least 50 years old. In this context, a great challenge for worldwide infrastructure managers is to ensure operational safety while meeting increasing traffic demands and respecting budget constraints. Traditionally, monitoring of railway bridges is performed by means of visual inspections, that rely on operator skills and experience. Visual inspections, whose periodicity depends on bridge age and type, can be supported by a variety of NDT techniques (Helmerich et al. 2007). Visual inspections are generally featured by high costs, safety and accessibility problems and they are subject to operators' skills (Iacovino et al. 2022). Given these limitations, Structural Health Monitoring (SHM) comes into play to support visual inspections in a transition towards a more efficient condition-based maintenance (CBM) approach.

SHM divides into two main categories: direct approaches which are based on sensors directly deployed on the analyzed structure, and indirect approaches (even called drive-by), that rely instead on the instrumentation installed on vehicles that are used as exciters and mobile sensors (Malekjafarian et al. 2022). Direct approaches are widely spread and adopted (Das et al. 2016), but they have several limitations: costs associated to the measurement set-up and its maintenance,

low flexibility, given their tailored nature. To overcome these limitations and drawbacks, in recent years there has been growing interest in developing drive-by approaches (Malekjafarian et al. 2022). The latter are then divided into two main categories: modal and non-modal indirect approaches, depending on the index that is used as damage sensitive. Compared to conventional approaches (i.e., vibration-based direct technique), drive-by methods have advantages in terms of economy, transportability, and flexibility (Malekjafarian et al. 2022).

The present work proposes a non-modal continuous wavelet-based approach for damage identification and localization. Compared to existing literature which focuses on 2D simply supported beam models, this work deals with a 3D lattice structure, rarely adopted in past works. Moreover, the methodology exploits the modular structural conformation of the Warren truss bridge to identify possible damage occurrence: this new concept which may greatly improve drive-by SHM has not been deeply discussed in literature. The proposed damage index is verified in terms of its effectiveness and robustness inserting, between two consecutive runs, track geometrical irregularity profile and travelling speed modifications. The work is structured as follows: section 2 presents materials and models employed for simulations, and the signal processing technique adopted. Subsequently, section 3 illustrates and describes the obtained results, in terms of damage index effectiveness and robustness to exogenous factors other than the damage. Finally, conclusions are drawn.

2 MATERIALS AND MODELS

2.1 Bridge, track, train models

The bridge FE model presented in this work and shown in Figure 1 is derived from a real existing structure, corresponding to a steel Warren railway bridge, designed in 1946. The geometrical properties of the different elements composing the truss structure were computed by the available technical drawings. The Young Modulus of the adopted steel is assumed to be equal to $2.0 \cdot 10^5$ MPa. Material density is increased by 15% with respect to the nominal value of 7850 Kg/m^3 to take into account the elements of the joints, such as bolts and connecting plates. Moreover, non-structural elements such as track components (e.g., sleepers, steel plates) or handrails are modelled by means of concentrated masses. The ends constraints are assumed to be ideal, therefore, the bridge is considered as a simply supported structure, with a hinge at its entrance and sliding boundary at the exit, in the direction of train transit. Rayleigh damping is assumed: α and β are chosen to obtain a damping ratio in the range of 1% in correspondence of the first bending frequency. The bridge is fitted with a ballast-less track, where the connection between the rails and the girder in the model is represented through viscous-elastic elements, with the purpose to model timber sleepers and fastenings. Outside the bridge span, the track segments correspond to ballasted track.

Figure 1. Railway bridge FE model. H: 7.7 m, L: 60.5 m and W: 5.25 m.

Track geometrical irregularity profiles (i.e., deviations from perfectly rectilinear rails) are obtained from a reference PSD function provided by (OREB176 1989). Two different profiles, plotted in Figure 2a (i.e., line 1 and 2) with their FFTs (see Figure 2b), were adopted in the performed set of simulations, to investigate the effect on method performances played by changes of track profile between consecutive runs. The difference in the two track profiles is limited to the shortest wavelengths, considering that it is associated with differential degradation of timber sleepers. The illustrated FE bridge model was validated from dynamic point of view, showing a maximum difference between first four frequencies all below the 5%, and

a good degree of similarity with experimental mode shapes (i.e., highest difference of 3%), as pointed out by the computation of MAC matrix (see Bernardini et al. 2022).

A three-dimensional multi-body rail vehicle model was used, with primary and secondary suspensions connecting carbody, bogie frames and wheelsets. The motion of each coach is described by 35 degrees of freedom, five for the carbody and each of the two bogies, as well as for each of the four wheelsets. The train adopted in this work is composed of 8 coaches. The end coaches of the convoy are 28% heavier and 5.3% longer, but they share the same bogie centre spacing (17.4 m) and wheelbase (2.85 m).

Figure 2. (a): Track geometrical irregularities. Red solid vertical line defines the entrance of the bridge, while the dashed one identifies bridge exit. (b): Track geometrical irregularities FFTs in double logarithmic scale.

Bridge structure and the rail vehicle represent two dynamical sub-systems coupled through contact forces and congruence at wheel-rail contact patches. Their equations of motion and the procedure for time domain integration are implemented in ADTreS, which is a non-commercial FE (for the structure) and multibody (for the train) simulation tool that has been developed, since three decades ago, by researchers of the Department of Mechanical Engineering of Politecnico di Milano (Bruni et al. 2004).

2.2 Damage scenarios and plan of simulations

In this paper three different damage scenarios were considered: the damage, modelled through a reduction of the 50% of the element elastic modulus, always interests deck cross-girder, in three different positions, as shown in Figure 3. In this way, it was possible to investigate the effect of damage position on the success of its detection by the proposed method.

Figure 3. Damage location across bridge midspan in the three considered damage scenarios (A, B and C).

A group of 10 travelling speeds, ranging from 95 km/h to 104 km/h, was adopted in the simulations, to study the effect, on the performances of the methodology, caused by the deviations of vehicle speed from the reference one. Furthermore, the effect of changes of operational conditions between a run over healthy and damaged structure is of interest. It is important to introduce in the analysis damage hiding sources that can be encountered in real operating scenarios. For instance, assuming an actual implementation of the drive-by methodology, it is reasonable to assume that between one run over the studied structure and the subsequent, even if close in time, some operating conditions may slightly change, such as vehicle speed or track geometrical profile (see Figure 2). These changes consist in real-life noise covering factors, that may undermine the success of the methodology.

2.3 Local bridge deformability

As briefly mentioned before, when considering a diagnostic method relying on a comparison between two different runs, it is of interest to find an index which is as robust as possible to exogenous factors other than the defect. The latter is the target, but its identification can be undermined by a change of different operational factors. Some of them may depend on the vehicle, such as the case of different travelling speeds or coach weight in different runs. Other may depend on other factors, such as environmental agents (e.g., temperature effects) or track geometrical irregularity time evolution, as proposed by (Carnevale et al. 2019) and (Bernardini et al. 2021), but, according to authors best knowledge, generally neglected in literature.

In this work, the idea behind the chosen damage index, which is in the form of wavelet coefficients difference, is to capture structural changes occurred to any of the bridge modules. In fact, given the modular structure of the truss bridge subject of this study, it was noted that this structural configuration is reflected on vehicle response. Figure 4 illustrates the bogie vertical acceleration histories, referred to space, of the leading bogie of the first coach at different travelling speeds (Figure 4a) and their respective spectra (Figure 4b). From the latter it is possible to visualize a main harmonic component, which proportionally increases with speed (Figure 4b). This component is related to the periodicity of module length of the truss bridge, and thus the time necessary to cross it: from now on, the inverse of this time quantity will be referred to as $f_m(v/d)$, where the subscript stands for module. The signal component related to f_m is the starting point of the proposed diagnostic approach, since it may reflect any structural changes occurring to bridge module.

Figure 4. Bogie vertical acceleration at different speeds. (a): low pass filtered ($f_{cut} = 20 \text{ Hz}$) histories referred to space. (b): corresponding FFTs.

2.4 Signal processing and damage index

The proposed signal processing methodology relies on the observation and use of truss bridge local deformability. As shown in the previous section, the bogie vertical acceleration contains a strong harmonic component related to the passage of the bogie over each of the seventh bridge modules. This specific harmonic component may result useful for diagnostic purposes, since it can reflect any structural changes occurring to the module itself. In fact, as a damage occurs to a module of a bridge cross-girder, it is reasonable to expect a local variation of the energy associated to this target harmonic component (i.e., f_m). With the purpose to detect and identify this possible change, a Continuous Wavelet Transform (CWT) is used as a processing tool able to provide information both in time (thus space) and frequency. Equation 1 defines continuous wavelet transform operation:

$$C_{s,\tau} = \frac{1}{\sqrt{s}} \int_{-\infty}^{\infty} x(t) \cdot \psi_{s,\tau} \left(\frac{t-\tau}{s} \right) dt = \langle x, \psi_{s,\tau} \rangle \quad (1)$$

Where $C_{s,\tau}$ are the wavelet coefficients of the time signal $x(t)$, while $\psi_{s,\tau}$ is the wavelet employed (Morlet, in this case): moreover, s represents wavelet scale factor and τ represents the time shift. The adoption of the CWT, instead of the FFT, allows to acquire information that are not only related to frequency but also associated to spatial position across bridge span. While the CWT provides a picture of the energy content associated to each harmonic component of the signal for each time interval (thus position), the FFT provides instead a global overview, stationary in time. Therefore, assuming a damage occurring to one of the seven bridge modules, between healthy and damaged scenario, in correspondence of f_m we may still observe a change of the related FFT harmonic component, but this is reduced being averaged over the other six undamaged modules. It is reasonable to expect that the wavelet coefficients scalogram computed by performing the CWT will better point out the local stiffness variation associated to the damaged element, giving information that are both localized in time and frequency with a specific resolution. As mentioned above, we are specifically interested in the wavelet coefficients corresponding to f_m frequency. The signal processing necessary to the subsequent computation of damage index is shown and summarized in Figure 5.

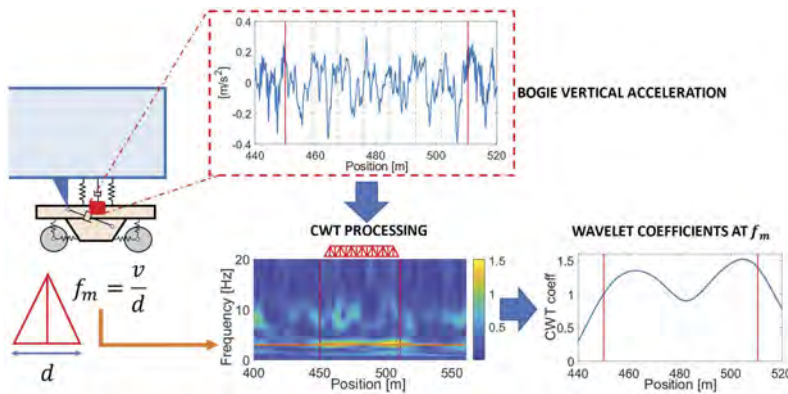

Figure 5. Signal processing procedure, starting from vertical bogie acceleration signal (at $v=100$ km/h) and ending with wavelet coefficients corresponding to the frequency f_m .

The wavelet coefficients associated with f_m are computed for each simulation run, then, the absolute value of their difference between damaged and healthy bridge scenarios is computed and assumed as the damage index (DI). When comparing different speeds, the DI is calculated with the frequency f_m related to each individual speed. The DI is expressed in Equation 2 as a function of f_m and position $\xi (= vt)$:

$$DI(f_m, \xi) = |C_d(f_m, \xi) - C_h(f_m, \xi)| \quad (2)$$

Damage position, if any, is then identified by the maximum value of the damage index DI:

$$\xi_{dam} = \max_{\xi} DI(f_m, \xi) \quad (3)$$

Finally, the positioning error of the damage is defined as follows:

$$e_{pos,d}\% = \frac{|\xi_{dam} - x_d|}{L_b} \cdot 100 \quad (4)$$

Where ξ_{dam} is the identified damage position, while x_d is the actual damage location and L_b is the bridge span length.

3 RESULTS

3.1 Damage index identification performances

Considering the case of a travelling speed of 100 km/h and vertical track irregularity N.1 in Figure 2a, with the assumption of no changes of these parameters between one run and the other, Figure 6 is obtained. In particular, the resulting wavelet coefficients at f_m (3.2 Hz) in case of healthy structure and three different damage locations (see Figure 3) are shown in Figure 6a. Moreover, Figure 6b illustrates the damage index DI as a function of position and damage scenarios: it can be observed the capability of the chosen damage index to identify the damage position, for all the locations considered. In fact, peaks in terms of DI (f_m) are observed in proximity of the defected cross-girder. This means that, in ideal conditions, the position of damage seems not to affect markedly the performances of the method, even if it must be observed that higher accuracy is obtained for scenarios A ($e_{pos,d} = 1.75\%$) and B ($e_{pos,d} = 2.41\%$) compared to scenario C ($e_{pos,d} = 6.41\%$). On the other hand, the latter scenario seems to cause larger discrepancy between damaged condition and the healthy case, leading to higher DI value. In Figure 6c it is possible to observe that in correspondence of damage position and its proximity, DI magnitude increases with higher travelling speed. The difference between DI curves at different speeds is higher at damage location, while far away from it, it generally decreases.

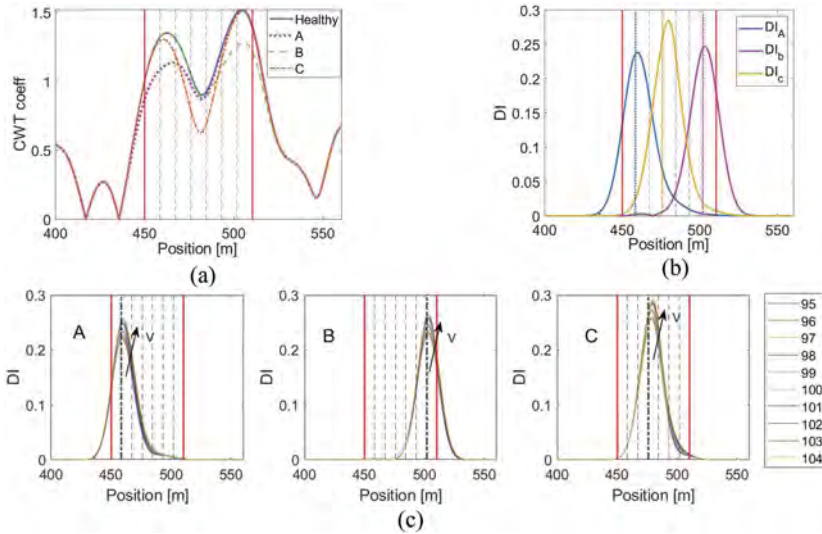

Figure 6. (a): CWT coefficients at f_m in different scenarios: healthy bridge and A, B and C damage locations (as reported in Figure 3). (b): DI as a function of damage location. Train speed 100 km/h, irregularity profile 1 (see Figure 2a). (c): DI as a function of travelling speed, irregularity profile 1 (see Figure 2a).

3.2 Damage index robustness

When dealing with a damage index based on a comparison among parameters computed in case of healthy and damaged structure, it is important to stress that between one train run and the other, several exogenous factors can be source of discrepancy, other than a structural damage. This discrepancy could lead to the identification of false alarms, or, even worse, they could lead to false negatives, since they could hide damage occurrence. That is why, in the present work, a sensitivity analysis is proposed to investigate the robustness of the presented damage index (see Equations 2 and 3) with respect to variations of track geometrical irregularity and travelling speed. As examples, in Figure 7 three distinct cases are presented: the first case regards the computation of DI considering two runs, with same irregularity but different speed (Figure 7a), while the second assumes same speed but different track irregularity (Figure 7b). Finally, the third case (Figure 7c) considers both different speeds and geometrical irregularity, between the two runs. In all the

presented scenarios, once the DI is computed, it is then windowed by means of a Tukey window to isolate and emphasize the region of interest only, in correspondence of the bridge structure.

Figure 7a concerns the robustness of the presented methodology to slight changes of train speed between consecutive runs: the DI peak follows damage position also in case of speed differences of 2 km/h between one run and the other. Better performances were obtained for damage scenarios A ($e_{pos,d}=1.75\%$) and B ($e_{pos,d}=3.41\%$), rather than scenario C ($e_{pos,d}=6.74\%$). It can be pointed out that better damage identification performances are achieved when the speed of the run over the damaged bridge is lower than the speed of the run on the healthy structure.

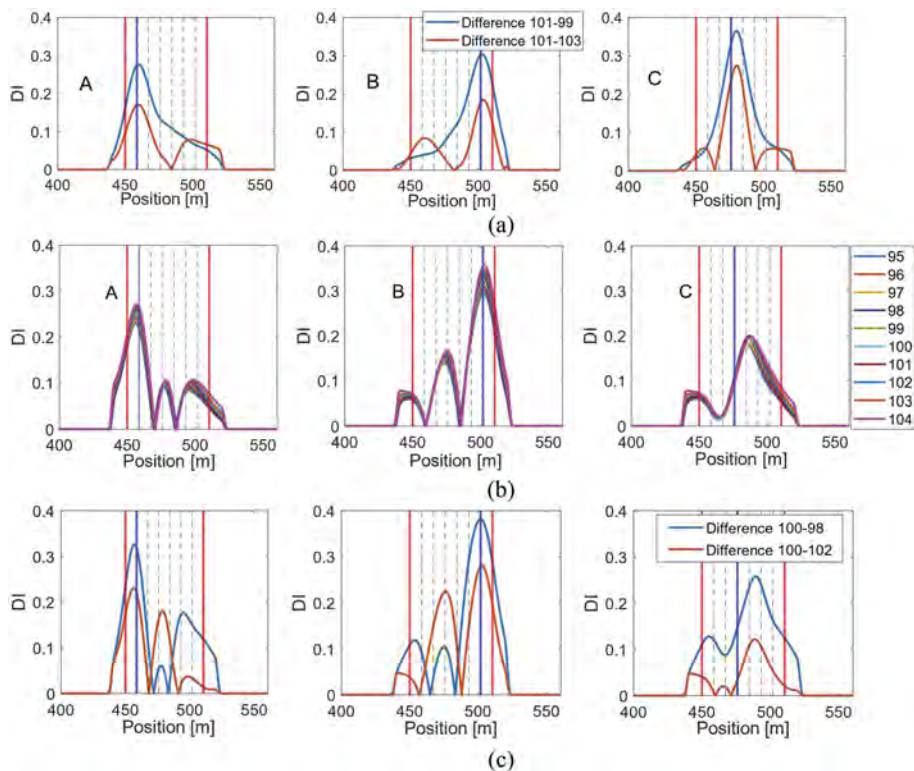

Figure 7. (a): Same track profile (i.e., irregularity 1 in Figure 2a) but different speed. (b): Same speed, but different track profile (1 and 2 in Figure 2a). (c): different speeds and different track profiles.

Moreover, it is possible to highlight that, despite maximum DI is always close to the damaged element, DI differs from zero also in the other regions across bridge span. This outcome is due to that, as shown in Figure 4b, different travelling speeds lead to different magnitudes of the frequency component associated to bridge module crossing on onboard signals.

Figure 7b shows the case in which a change of track irregularity profile (from N.1 to N.2) between the run on the healthy and the damaged bridge is assumed. Travelling speed is kept constant between damaged and healthy scenarios. Larger values in terms of DI peaks are observed for damage A and B, as well as better performances in terms of defect localization compared to scenario C, in which the peak of DI index is localized about one module after its actual position. The method appears to be less robust to a change of track geometrical profile compared to a change of speed between healthy and damaged scenario runs.

Finally, Figure 7c shows the DI when combining a change of train speed and track geometrical irregularity between runs over healthy and damaged bridge. For scenarios A ($e_{pos,d}=3.88\%$) and B ($e_{pos,d}=2.10\%$) the index is still able to identify damage presence with high accuracy, while for case C the identified defect position results to be about one module and half far from the actual location ($e_{pos,d}=21.95\%$). Figure 7c demonstrates that for damages occurring close to bridge ends

good identification performances and robustness to exogenous factors were achieved by the presented method. Conversely, the localization error significantly increases when dealing with a damage scenario closer to bridge midspan.

4 CONCLUSIONS

This paper presented a numerical investigation on the use of a wavelet-based approach for identifying presence and position of damages affecting cross-girders on a Warren Truss bridge deck. The described methodology exploits the local deformability of the structure to assess its health status. Wavelet coefficients associated to the so-called module passing frequency (expressed by the ratio $f_m = v/d$) are used as damage sensitive indexes, revealing good diagnostic performances. The approach has been tested by means of a 3D train-track-bridge dynamic interaction model, considering three different damage scenarios, consisting of a reduction of the 50% of the cross-girder Young modulus. The presented damage index consists of the absolute value of the difference between wavelet coefficients obtained from the run over damaged and healthy structures respectively: in particular, the coefficients of interest are the ones associated to the module crossing frequency (f_m). The adopted damage index shows good performances in terms of damage identification, and promising robustness to exogenous factors, other than the damage. Better damage localization performances were obtained for damages occurring close to the ends of the bridge than towards the midspan.

ABSTRACT: In this paper, the authors investigate energy harvesting on railway bridges. The tuning frequency for the optimal design of cantilever based 3D printed energy harvesters is studied. An analytical model to represent the electromechanical behaviour of the device is presented for the estimation of the energy harvested from train-induced bridge vibrations. A genetic algorithm constrained to geometry and structural integrity is used to solve the optimisation problem. Additive manufacturing by 3D printing of the substructure of the harvester is considered to maximise the design flexibility and energy performance. Optimal device prototypes with PAHT-CF15 substructure are designed for a real bridge in the Madrid-Sevilla High-Speed line. Finally, the performance of energy harvesting is evaluated from in situ experimental data measured by the authors. The results allow quantifying the energy harvested in a time window of three and a half hours and 19 train passages.

1 INTRODUCTION

One of the major limiting factors in the implementation of sensor networks in monitoring applications on railway structures is the lack of a long-term and low-maintenance power supply. Most existing systems require battery changes, and difficulties of access and infrequent maintenance operations can limit their practical implementation. In this sense, piezoelectric energy harvesting is becoming an alternative to the electrical supply of sensors and nodes in remote areas (Wei & Jing 2017, Yildirim et al. 2017). Within the context of this work, many research have focused on the development of energy harvesters based on the piezoelectric effect to transform railway-induced vibrations into electrical energy to be used in small power devices and sensors. The most common typology is that of a bimorph cantilever beam. These systems have the ability to generate energy from environmental vibrations in a frequency range of 3–100 Hz (Sarker et al. 2019). The predominant frequencies of vibrations caused by rail traffic in the infrastructure are within the above range, making it possible to supply low-power devices and sensors. An important problem of energy collection systems is associated with the fact that the performance of the energy production device is limited to a very narrow operating frequency band around its resonance frequency (Erturk & Inman 2011). If the excitation frequency deviates slightly from the resonance condition, the output power is drastically reduced. This unsatisfactory situation is mainly due to the fact that the generator resonant frequency is often not tuned to the vibration frequency. However, compared to some applications, the energy harvesting of railway bridges is less sensitive to frequency effects, because the dynamic behaviour of the structure is mainly determined by the fundamental mode shape (Museros & Alarcon 2005), which is relatively constant. One of the objectives of this work is the estimation of the natural frequency of a bridge and the tuning of harvesting systems in railway bridges.

2 APPROACH

The proposed approach considers that the energy harvester is attached to the bridge in a location defined by the coordinate x_b . This device is subjected to vertical vibration $z_b(x_b, t)$ induced by a train passage that travels at a speed V . The dynamic response of a bridge under the circulation of a rail convoy is complex and is affected by several factors. The most obvious and certain are the bridge properties, the geometric scheme of the train axles, and the speed of circulation V . Furthermore, there are other factors that are much more uncertain in determining the response of the bridge (Rocha et al. 2012), such as structural damping and various interaction mechanisms, the most relevant being vehicle-structure, track-structure, and soil-structure interaction effects. The dynamic response of a railway bridge due to train passage can be described by a stochastic process, assuming that the load has random amplitude described by a Poisson process (Zakęś & Śniady 2018).

The energy harvesting performance is closely related to the dynamic behaviour of the bridge during train passages (Romero et al. 2021), and maximum performance would be obtained when the harvester is tuned to the fundamental mode shape of the bridge. However, the performance of the energy harvester is limited to a narrow frequency bandwidth around the tuning frequency, and therefore the harvested energy is drastically reduced as a result of the detuning effect. Although the harvester device can be tuned to the natural frequency of the fundamental mode shape of the bridge, the uncertainties in the dynamic response affect not only the vibration levels but also the frequency content, making the choice of the tuning frequency more difficult.

In this work, due to the nature of the vibrations caused by rail traffic, the energy collected is processed statistically and represented by a stochastic process following a Gamma distribution $E \sim \Gamma(k, \theta)$ with mean $\mu_E = k\theta$ and variance $\sigma_E^2 = k\theta^2$, where k and θ are the shape and scale parameters, respectively. The mechanical energy is used as an estimate of the efficiency in the conversion of energy from the bridge vibration. A lumped mass model is used to represent the dynamic behaviour of the harvester. The properties of the system are given by the natural frequency ω , the mass m , and the damping coefficient c (Romero et al. 2021). The damping coefficient c is used to represent the energy transfer from the bridge vibration to the harvester system (Stephen 2006).

Then, the instantaneous power corresponds to the power absorbed by the harvester plus the kinetic energy and the mechanical energy in the system during the period T is a function of the velocity of the vibration:

$$E = c \int_0^T |\dot{y}(t)|^2 dt \quad (1)$$

where $y(t)$ denotes the vertical displacement of the lumped mass. The previous equation can be expressed in terms of the Fourier transform of the harvester velocity according to Parseval's theorem (Romero et al. 2021). Then, the displacement of the harvesting device is expressed in terms of the vertical displacement of the bridge and the frequency response function $H(\omega; \bar{\omega})$ of the harvester:

$$y(\bar{\omega}) = m\bar{\omega}^2 H(\omega; \bar{\omega}) z_b(x_b, \bar{\omega}) \quad (2)$$

Thus, the energy collected becomes:

$$E = c \int_{-\infty}^{\infty} |\dot{y}(\bar{\omega})|^2 d\bar{\omega} = c \int_{-\infty}^{\infty} |\iota \bar{\omega} m \bar{\omega}^2 H(\omega; \bar{\omega}) z_b(x_b, \bar{\omega})|^2 d\bar{\omega} \quad (3)$$

where, the imaginary unit number is denoted by the Greek letter ι to prevent confusion with the subscript i used in posterior derivations.

Therefore, the tuning frequency needs to be selected following a statistics procedure. In this work, a stochastic process is proposed to find the tuning frequency.

As an example, Figure 1 shows the frequency content of the acceleration in a railway bridge in three different circulations. The fundamental mode of this bridge corresponds to the first longitudinal bending mode shape with natural frequency $f_{b1} = 6.3$ Hz. More details about the structure can be found in (Galvin et al. 2020). The three circulations are: *i*) Renfe S102 travelling at $V = 290$ km/h (passage #2); *ii*) Renfe S012 at $V = 274$ km/h (passage #11); and *iii*) Renfe S100 at $V = 290$ km/h (passage #17). The passage numbers are in concordance with (Galvin et al. 2020). In all cases, the response presents peaks associated with the load (that is, the ratio of the train speed V to the bogie and axle distances and the corresponding harmonics) and to the lowest natural frequencies of the bridge. The peaks related to the fundamental mode shape were found in 5.16 Hz (passage #2), 5.6 Hz (passage #11) and 6.3 Hz (passage #17), that are in general lower than the natural frequency (marked by a vertical dashed line). Therefore, tuning the harvester is not trivial and the performance will be determined by the dynamic behaviour of the structure in forced vibration, in which the response associated with the fundamental mode shape can occur at frequencies lower than the natural frequency, as shown in Figure 1. A detuning higher than 1% can cause considerable power loss as shown in (Romero et al. 2021).

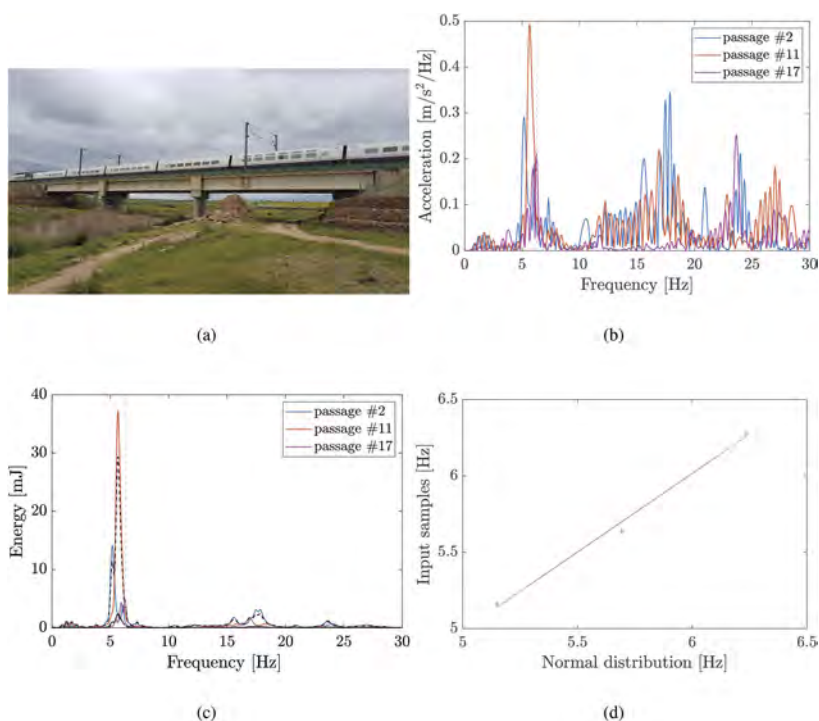

Figure 1. (a) General view of Jabalón HSL bridge. (b) Frequency content of the bridge acceleration at point A7 (see Galvin et al. 2020)) induced by different train circulations. The vertical line represents the first natural frequency of the bridge.

The proposed procedure considers the study of the scattering of the mechanical energy of different harvesters tuned from 1 Hz to 100 Hz to cover a wide range of frequencies, including the most fundamental frequencies of railway bridges. The mechanical energy is computed for each train passage using the experimental records of the bridge accelerations induced by 19 trains over the Tirteafuera bridge.

In order to verify the dispersion of the mechanical energy as a function of the excitation frequency to find the fundamental frequency of the bridge, a statistical analysis is carried out. The dynamic response of the device in the frequency domain is a complex random process in which the real and imaginary parts of the response follow a Gaussian distribution (Lombaert et al. 2014). Therefore, the modulus of the response is the absolute value of a circular bivariate

Gaussian random variable. The probability distribution of the latter follows the so-called Rayleigh distribution or, equivalently, the modulus of the dynamic response contribution, normalised by the squared standard deviation of the real and imaginary parts, follows a chi-square distribution with two degrees of freedom.

The proposed approach considers that the mechanical energy for each tuning frequency and excitation record follows a gamma distribution ($E(\omega_n \sim \Gamma(k, \theta))$), as the chi-square distribution with n degrees of freedom is a special case of the gamma distribution with the shape parameter $k = n/2$ and the scale parameter $\theta = 2$. The confidence intervals, standard deviation, and mean values of the mechanical energy can be derived from the cumulative distribution function, and the shape and scale parameters of the gamma distribution. The mean value of the mechanical energy for all train passages is computed as $\mu = k\theta$ and the standard deviation is $\sigma = \sqrt{k\theta^2}$.

Following, the results of an extensive experimental campaign are presented and the proposed tuning procedure is validated.

3 EXPERIMENTAL VALIDATION

An experimental campaign was carried out to assess the energy harvesting performance in a railway bridge in July-September 2022. The bridge under study belongs to the HSL Madrid-Sevilla. It is a single simply-supported span concrete bridge with three tracks. The deck is composed of a concrete slab of dimension 18m \times 20.6m (length \times width) resting on ten pre-stressed concrete I girders (see Figure 2). The slab carries two ballasted tracks with UIC gauge (1.435m) of high-speed lines separated from one ballasted track with Iberian gauge (1.668m) of a conventional line.

Figure 2. HSL bridge under study (38°43'33.06"N 4°5'20.05"W).

The main experimental campaign was carried out in September 2022 in order to characterise the dynamic properties of the structure along with the dynamic response of the bridge under railway traffic, the analysis of energy harvesting, and the validation of a harvester prototype in a relevant environment.

During the recordings, several RENFE trains (S100, S102, S103, S114, S130, R449, R599, Altaría and freight trains) crossed the bridges. Information that includes the axle schemes, coach distributions, the axle distances and axle loads, as well as more information in this regard, can be found in References (Galvin et al. 2020) and (Renfe).

3.1 Setup

A LAN-XI portable acquisition system from Brüel & Kjaer was used. Endevco model 86 piezoelectric accelerometers with a nominal sensitivity of 10 V/g and a lower frequency limit of approximately 0.1 Hz were used. An Ometron VH-1000-D laser vibrometer with nominal sensitivities 8.0064 V/m/s was used to measure the tip velocity of the harvester. The acquisition system fed the sensors (accelerometers). LAN-XI also performed the Analog/Digital conversion (A/D). The A/D was carried out at a high sampling frequency, which avoided aliasing effects. The acquisition equipment was connected to a laptop for data storage. The acquisition system was configured to avoid sensor overload. The recordings were decimated (to 256 Hz)

to perform data analysis in the frequency range of interest. The response was filtered applying a third-order Chebyshev filter with high-pass frequencies of 1 Hz.

Figure 3. Scheme of the location of the sensors and experimental setup in HSL bridge over Tirteafuera River (38°43'33.06"N 4°5'20.05"W).

3.2 Tuning

In the first instance, vibration levels under operating conditions measured in July 2022 were used to estimate the tuning frequency. The measurement point *A14* located in the girder #4 was chosen. The laser vibrometer was used to avoid the installation of the scaffolding system at this stage. A total of 19 train circulations were recorded between 10.20 and 13.50h. Table 2 summarises the train passages including the type of train, track number according to Figure 3, traffic direction and travelling speed.

The mechanical energy was estimated for harvesters with a damping ratio of 1% tuned in the frequency range 1–30Hz. The confidence intervals, standard deviation, and mean values of the energy were estimated from the shape and scale parameters of the gamma distribution over the frequency range. Figure 4 shows the computed results. It can be observed a predominant frequency around 8 Hz where energy reaches its greatest values. There are also significant values of the energy around 9.3 Hz, which is interesting to note.

Figure 4. Mechanical energy for the bridge over the Tirteafuera River.

The tuning frequency was obtained from the maximum peaks for each circulation around the frequencies 8 Hz and 9.3 Hz. Figure 5 shows the quantile-quantile plot for the energy peak frequencies and a normal distribution with mean the tuning frequency. The results show a great agreement with the normal distribution. The tuning frequencies $f_{t1} = 7.8$ Hz and $f_{t2} = 9.28$ Hz are obtained from the mean value in both cases.

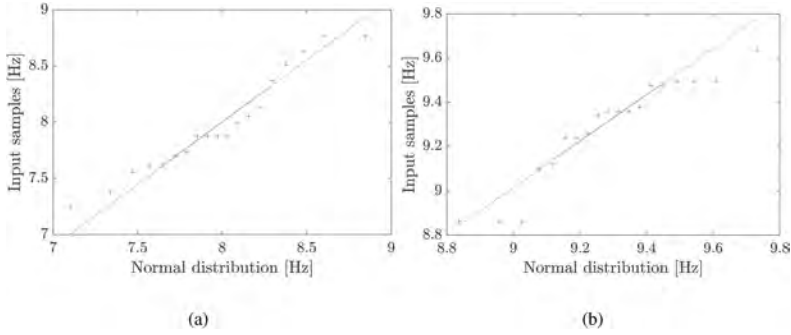

Figure 5. Quantile-quantile plot for tuning frequencies (a) $f_{i1} = 7.8$ Hz and (b) $f_{i2} = 9.28$ Hz.

3.3 Manufacture

An optimal tuning procedure has been performed to adjust the resonant frequency of the harvester to the tuning frequencies. Two energy harvesters tuned to the frequencies identified in the previous section have been manufactured with an optimal design. The piezoelectric patch selected for this application is the commercial DuraAct patch transducer P-876.A12 (Piceramic), composed of a piezoelectric layer covered by copper electrodes. The patch is embedded in a structure mechanically pre-stressed by a polymer surface, making it flexible. Patch dimensions are $L_p = 50$ mm, $b_p = 30$ mm, and $h_p = 0.2$ mm. Additive manufacturing using FDM 3D printing has been selected for the substructure. Among the variety of 3D printing materials, a high temperature polyamide carbon fiber reinforced material (PAHT CF15) is selected. PAHT CF15 is often used to replace metals in some applications due to its high strength.

The material properties of the substructure were experimentally estimated according to the ASTM D638-14 standard (ASTM, 2014). The material properties obtained were: mean Young's modulus $E_s = 7.40$ GPa with a standard deviation of $s_E = 0.33$ GPa; and tensile strength $\sigma_y = 94$ MPa with a standard deviation of $s_\sigma = 9.9$ MPa. A safety factor $\gamma_G = 1.33$ was used to assess structural integrity in the optimisation procedure to account for the standard deviation of the tensile strength.

The design parameters of the harvester are the result of a constrained optimisation problem where the maximum power dissipated by a harvester tuned to the fundamental frequency of the bridge is sought subject to the structural integrity of the system and the imposition of geometry constraints. The constrained optimisation problem is solved using a genetic algorithm and provides optimal values of the design parameters, length (L_s) and thickness (h_s) of the substructure, tip mass (M_t) and optimal load resistance (R_l). Harvesters with a damping ratio of 1% have been considered.

The optimal design parameters for each harvester are collected in Table 1

Table 1. Optimal design parameters for designed prototypes.

Device	L_s [mm]	h_s [mm]	M_t [kg]	R_l [k Ω]
Tirteafuera f_{i1}	106.7	0.94	0.09	664
Tirteafuera f_{i2}	90.9	0.73	0.076	552

3.4 Modal identification

The modal parameters of the bridge were identified from the ambient vibration data through an operational modal analysis using the Enhanced Frequency Domain Decomposition (EFDD) (Brincker et al. 2001). The EFDD technique is based on the decomposition of the power spectral density of the measured acceleration using singular value decomposition (SVD) (Tadeu et al. 2022). The natural frequencies of the structure are identified from the peaks of the singular

value curves of the accelerations of ambient vibrations (Figure 6). The fundamental mode corresponds to the first longitudinal bending mode with natural frequency $f_{b1} = 8.14$ Hz and modal damping $\zeta_{b1} = 1.72\%$. It is interesting to note that there is some decoupling between high-speed and conventional tracks due to the difference in mass of both areas, since the frequency of the fundamental mode is associated with the first bending mode of the bridge in the high-speed track area and there is another frequency associated with the first bending mode of the bridge in the conventional track area at $f_{b2} = 8.65$ Hz with $\zeta_{b2} = 1.42\%$. In addition, an important peak is observed at $f_{b3} = 9.54$ Hz corresponding to the first transverse bending mode with modal damping $\zeta_{b3} = 0.5\%$, and a peak at $f_{b4} = 11.51$ Hz of the first torsional mode with modal damping $\zeta_{b4} = 0.78\%$. These frequencies are higher than the tuning frequencies obtained previously due to effect of the crossing train in the dynamic response of the bridge.

Figure 6. Singular Value Decomposition from ambient vibration.

Table 2 summarises the estimated energy collected with harvesters tuned to the tuning frequencies obtained with the proposed approach and harvesters tuned to the natural frequencies of the bridge. The results show that the energy generated in the case of harvesters tuned to the tuning frequency is much larger.

Table 2. Simulated Energy harvesting [mJ] in train passages recorded at Tirteafuera HSL Bridge (July 2022).

4 CONCLUSIONS

The research presented here falls within the framework of the development of autonomous monitoring systems. A statistical procedure to estimate the tuning frequency of energy harvesters placed on railway bridges has been presented. A simplified lumped analytical model for the analysis of bimorph cantilever beams and an optimal tuning procedure have been followed. The analytical model allows us to study harvesters tuned to different frequencies with different lengths of substructure and PZT patches, which allows greater flexibility in the design. The performance of harvesters for a real bridge on the Madrid-Sevilla High-Speed line has been analysed. The energy collected by harvesters tuned to the frequencies obtained from the statistical process has been estimated, obtaining higher power levels than those tuned to the natural frequencies of the bridge.

ABSTRACT: This paper presents a long-term monitoring campaign for safety assessment of an over 100 years old steel railway bridge in Vänersborg in the southwest of Sweden. Due to its age, the bridge is affected by severe corrosion, and cracks have been detected during inspection. In anticipation of a large-scale repair of the bridge, a comprehensive monitoring system has been installed. The monitoring system consists of 5 accelerometers, 16 strain gauges, 1 inclinometer and 3 weather measurement sensors (temperature, wind speed and wind direction). Data is collected continuously with high sampling frequency, transmitted to a structured IoT database in the cloud, and used for further processing and visualization. This paper describes the safety assessment processes, the underlying ideas behind them, the challenges encountered, and the developed monitoring dashboard for visualization of results. It also discusses the increased capabilities of the system after an entire year of monitoring.

1 INTRODUCTION

Today's modern transportation infrastructure relies, to a large extent, on structures that were built during the 20th century. A substantial number of bridges have reached their expected service life, and the number is rising. It is inevitable that some bridges will fail to comply with the safety requirements in the present regulations and should, formally, be strengthened or replaced. However, budget limitations will enforce a need to keep unfit bridges in service until remedial actions are possible.

A specific example is the railway bridge in Vänersborg in Sweden, shown in Figure 1. Since 1914, the bridge has carried commuter and freight trains over the Trollhätte channel. The bridge is opened several times per day to allow for boat traffic. The peculiar design of the counterweight mechanism causes bending of the truss members, and cracks have emerged in the riveted connections adjoining the concrete volume. Other parts are severely affected by corrosion, e.g., the upper chord of the leaf truss. Keeping the bridge's safety at an acceptable level requires recurrent inspections and maintenance actions.

Kühn et al. (2008) have suggested a stepwise assessment procedure for cases when standard measures fail to prove sufficient safety. The last phase (IV) in the approach includes intensified monitoring as a remedial action to reduce uncertainties in load effect estimations, combined with sophisticated assessment methods. A similar incremental assessment procedure is suggested by ISO (2010) with monitoring as a final intervention to provide sufficient safety.

Relating to the Vänersborg Bridge, a sensor system and a cloud-based data analysis framework were installed during autumn 2021 to facilitate continuous monitoring of the present state. This paper presents the bridge, the monitoring system and the analysis routines implemented. Some selected results from one year of monitoring are also presented.

Figure 1. A photo of the Vänernsberg Bridge.

2 THE VÄNERSBERG BRIDGE

The movable bridge can be attributed to a type described by y Koglin (2003) as a Single Leaf Heel Trunnion Bascule Bridge, sometimes called a Strauss Bascule Bridge. The design allows a low elevation above the water, without the need to build a watertight chamber for the counterweight.

It was constructed 1914-1916 and is built up by riveted steel members. As shown in Figure 1, the leaf is designed as a truss, acting as simply supported in its resting position. The single track has wooden sleepers attached directly to the open steel grid constituting the bridge deck. The axle loads are distributed through the system of sleepers – stringer beams – crossbeams to the main load-bearing truss. The lower and upper chords of the main truss and some of the diagonals have box-like sections. The other main members have I shaped cross-sections. Secondary bracings have typically L or T shaped sections.

The leaf is lifted by an operating link with rack attached to a trunnion at the upper joint of the main truss. The counterweight is attached by a link to the same joint assisting the lifting of the leaf. The counterweight is built up by its own truss but moves together with the leaf. The members consist of riveted plates and L profiles in box or I shape. The material in the members is steel classified as St37 with yield stress of 240MPa.

2.1 Instrumentation and data acquisition system

The data monitoring system consists of a HBM-Quantum data acquisition unit CX22B-W connected to one HBM-Quantum 16-channel measurement amplifier MX1615B (for strain gauges) and one 8 channel measurement amplifier MX840B (for accelerometers and inclinometer). The system is connected with a 4G-router for data transmittal to the cloud server. In addition, a Vaisala WXT530 weather station is installed to gather data on wind speed, wind direction and outside air temperature.

The selected logging procedure provides sampling of all sensors continuously at 200 Hz with a low pass filter at 50 Hz, with the exception of the weather data which is sampled at 4 Hz. At the end of each 10 minutes sampling period, the raw data for all sensors is stored in a file having a file name that identifies the date and time period when the data was recorded. The raw data files are backed up on-site on an external disk, and also continuously transmitted to the cloud server for real-time analyses and visualization in the dashboard (see Section 4).

The instrumentation is composed of:

- 16 strain gauges of type HBM weldable 350 ohms, LS31HT-6/350VE (Figure 2(a)).
- 5 piezoelectric accelerometers of type PCB type 393A03 with measurement range 0.5-2000 Hz and sensitivity 1 V/g (Figure 2(b)).
- 1 inclinometer of type Vigor Technology SST141 with measuring range $\pm 90^\circ$ (Figure 2(c)).
- 4G-router with antenna.

Figure 3 shows the sensor locations.

3 DATA PROCESSING AND ANALYSES IN THE CLOUD

3.1 Data flow and processing

To enable a wide range of applications and to maximize the usability of the collected data, the raw measurement data files have to be transformed into a structured and interoperable data model. The data files are continuously sent from the edge gateway on the bridge to a backend cloud. There the files are parsed, filtered, cleaned and transformed for storage in a database. The database provides the basis for different decision support tools and is divided into two parts. One part is dedicated to handling the incoming IoT datastreams from the various sensors and supporting aggregation and visualization as well as exporting data to external data consumers such as smartphones and web browsers. The system implements the OGC SensorThings (OGC, 2021) standard for exchanging IoT data.

The second part of the database is dedicated to the analysis of data, for instance, to apply machine learning to detect a change in the behaviour of the bridge or extract sequences from the sensor data streams. PostgreSQL was selected as the storage engine because of its support for handling streamed IoT data as well as structured relational data. Figure 4 shows the overall software architecture and data flow of the bridge monitoring system.

3.2 Fatigue analysis

The strain gauges were placed to measure nominal strains, free from local stress concentrations caused by sharp geometry changes and rivets. The measurements provide time series for train passages and bridge openings. These are recalculated to stresses by Hooke's law and an elastic modulus of 210 GPa. By the standardized rainflow cycle counting routine (ASTM, 2017), stress range spectra are calculated for the loading events, describing the number of

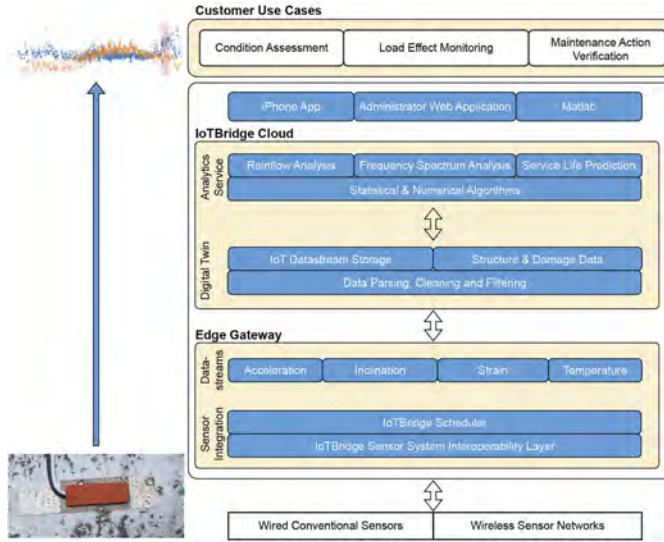

Figure 4. Software architecture and data flow in the bridge monitoring system.

cycles n in the associated stress range $\Delta\sigma$. By implementing the Palmgren-Miner rule (Palmgren, 1924; Miner, 1945), a fatigue limit state equation can be formulated as

$$G = D - \frac{(\gamma_{Mf}\gamma_{Ff})^3}{K_1} \sum_i n_i \Delta\sigma_i^3 - \frac{(\gamma_{Mf}\gamma_{Ff})^5}{K_2} \sum_j n_j \Delta\sigma_j^5 \quad (1)$$

where D is the limit value for the accumulated damage typically assigned to unity, γ_{Mf} and γ_{Ff} are partial safety factors. The indices i and j counts the stress ranges above and below the constant amplitude fatigue limit, respectively. The constants K_1 and K_2 represent the fatigue strength and are associated to the detail category $\Delta\sigma_c$ as

$$K_1 = 2 \cdot 10^6 \Delta\sigma_c^3, \quad K_2 = 5 \cdot 10^6 \Delta\sigma_D^5 \quad (2)$$

The variables $\Delta\sigma_c$ and $\Delta\sigma_D$ are defined in the Eurocode (CEN, 2008) together with the bilinear fatigue endurance curve implemented in (1). A limit state equal to or less than zero ($G \leq 0$) defines an exhausted service life.

For riveted bridge members, Kühn et al. (2008) suggest a detail category of $\Delta\sigma_c = 71$ MPa. The associated values are assigned to $\Delta\sigma_D = 52$ MPa and $\gamma_{Mf} \gamma_{Ff} = 1.35$. Moreover, a fatigue limit is considered with the value $\Delta\sigma_L = 29$ MPa which leads to exclusion of all stress ranges smaller than $\Delta\sigma_L/1.35 = 21$ MPa. The linear relation between the limit state and the number of cycles enables an estimation of the remaining service life by extrapolation.

3.3 Machine learning algorithms

The machine learning and damage detection process is composed of several sequential steps.

1. Event extraction. To compare the state of the bridge over time, some unit of comparison has to be selected. These are here denoted as events, where each event is a time series of measurements. Several different events are extracted and analyzed separately: trains of different type passing, the different phases of bridge openings and rest-sequences, i.e. sequences of measurements where there is little external influence occurring. The trains are divided into groups based

Figure 5. Comparing a number of events in the time domain for a strain gauge sensor before (in blue) and after (in red) a certain time point. In 5(a), the synchronized sensor measurements are shown. In 5(b), the same data is shown but with the trend subtracted. In this instance, there is no considerable change visible.

on the number of “peaks” found in the strain gauge measurements and the direction of the passing train. Each peak represents two adjacent bogies in two wagons or a bogie between two wagons.

2. Synchronization and preprocessing. The median is removed from all events. Thereafter, train passages are synchronized using the procedure presented in Lee et al. (2022) to put all trains on the same x-axis of “relative location”. It is calculated by first subtracting an absolute point (the first peak) from the time of each measurement to obtain a relative time for each measurement. Thereafter, the relative time is multiplied by velocity to obtain a location relative to the absolute point for each measurement. Bridge openings and rest-sequences are more easily synchronized using relative time. After the synchronization, a trend can be extracted from each event type independently by discretizing the x-axis and then calculating a mean for each point for a number of events. This trend can then be subtracted from each event to transform the time series to become more stationary. Subsequent steps process both sequences with and without trend. Examples of synchronized train passages, with and without trend, can be seen in Figure 5.
3. Feature extraction. After events have been categorized, synchronized and preprocessed, feature extraction can take place. Here time domain features, frequencies, cross-correlations and autoregressive model coefficients are extracted to be used as input for the next step.
4. Change detection. Finally, the features are fed into a change detection process to detect abnormal activity. Here only features of the same type of event are processed together and compared. The process uses Mahalanobis distance to fuse different subsets of features and then performs univariate change detection on the generated damage indices to detect changes. In most damage detection processes, changes are detected in single observations, but by using change detection, anomalies involving multiple points are instead detected. This can be advantageous in circumstances where outliers are common. Additionally, since subsets of features are used, the results become more interpretable. That is, if all features are involved in a found change, it is difficult to interpret what the change was caused by, but with few features it becomes easier.

4 MONITORING AND ANALYTICS DASHBOARD

To provide support for several different use cases such as condition assessment, load effect monitoring and maintenance action verification, a graphical dashboard has been implemented to assist bridge engineers and inspectors. The dashboard has multiple functions. One function is to provide a general overview of the bridge, e.g. are the sensors working, where are they located, how many train passages and bridge openings have there been, when did the last event occur, etc. An example of such information is shown in Figure 6.

The second function is to report analytical information relevant to maintenance planning or further theoretical analyses. Here, fatigue analysis is important, since it provides valuable information about the estimated accumulated damage and enables a prediction of remaining service life.

Figure 6. Dashboard overview.

Finally, the third function is a set of tools to analyze detected changes on the bridge to be able to make a decision if an inspection is necessary. To do this, features can be visualized, and synchronized events can be compared before and after the change in the time and frequency domain. An example of this functionality is shown in Figure 5 for a strain gauge sensor for a certain type of train passing with four peaks, where events before the change are colored in blue, and events after the change are colored in red. In Figure 5(a), the raw synchronized events are shown and in Figure 5(b) the same data is shown but with the trend subtracted. Subtracting the trend makes it easier to detect smaller deviations. In this case, there is no obvious difference before and after the change. There is also the option of clicking on individual discretized points in the time domain to visualize how they have changed over time.

5 RESULTS

From the start of December 2021 until December 2022, the bridge has been continuously monitored, with more than 25000 train passages and 2300 bridge openings having been registered. Examples of results from the monitoring and analyses are presented in the following sections.

5.1 Accumulated fatigue damage

An example of fatigue damage calculated for the measured strains in gauge SG9 is shown in Figure 7. The solid blue line is based on the recorded strains during the monitoring period. A forecast simulation for 365 days for the same sensor is shown as red lines starting in November 2022. The used forecast procedure has during the year been rudimentary, simply simulating similar traffic events and intensity, projecting past measurements into the future repeatedly for a number of iterations (in the figure 100). After a year or more of collected data, a more accurate model can be developed taking seasonal effects into account.

After about one year of collected data an accumulated fatigue damage of $D = 0.01$ is shown in Figure 7 for gauge SG9, which is the gauge giving the highest value so far. The forecast estimates the same amount of damage during the coming year. With this progress, the total service life can be estimated to be 100 years.

5.2 Sensor faults

Within the first few months of monitoring, four strain gauge sensors showed abnormal activity and a closer inspection revealed that it was caused by sensor faults. The current approach

for damage detection is more robust to these types of errors since it can still detect other changes from other subsets of features where sensor faults are not present. Furthermore, if a change is determined to be a sensor fault, a classifier can be generated using a simple threshold to eliminate these observations from the detection process.

Figure 7. Accumulated fatigue damage and forecast simulation for strain gauge SG9.

5.3 Detected changes

As is generally known, it is often necessary to have collected the entire environmental cycle of variability before being able to more accurately anticipate and discriminate environmental change from structural change. Thus, this initial monitoring period can be seen as a more exploratory stage to oversee what kind of changes the bridge is subjected to. This is especially important in a country such as Sweden with diverse seasons and below-zero temperatures.

One of the more prominent patterns that was observed was the often non-linear changes that occurred during larger temperature changes when transitioning from spring to summer and from autumn to winter. One such example is shown in Figure 8 for a feature (blue), plotted together with temperature (orange) on a normalized y-scale. As can be seen, the change in trend for this feature across most of the year has a smaller impact than the variability between nearby observations. Yet, at the end of the year a large temperature change downwards caused an abrupt non-linear change. In Figure 9, the logged frequency spectrum is compared before (in blue) and after (in red) the change using the dashboard. As can be seen, the spectrum looks very different above 60 Hz before and after the time of change.

After a year has passed, it will be possible to control for environmental variability, and in particular temperature, more accurately.

Figure 8. A detected change shown for a feature (blue) with temperature (orange) on a normalized y-scale. The detected change is shaded in red.

6 CONCLUSION

There are many challenges present in continuous real-world monitoring of bridges that are rarely taken into account in the academic sphere. Such as sensor faults, standardized procedures to simplify decision-making, system maintenance, etc. To handle these issues, practical and iterative improvements have been valuable to create a system that is more robust and effective. At the same time, observing and investigating within year data has been beneficial to understand the bridge and its behavior.

The most difficult issue, as discussed in section 5.3, is understanding what caused deviations to manifest in the data, and while tools for further visualization have been developed, it is still not always easy to make a decision. For this reason, in the future, incorporating more theoretical validation procedures, such as the finite element method, could be interesting to include another source of information into the system. Another option would be to include other sensors, such as cameras to connect data to tangible phenomena.

Figure 9. The logged frequency spectrum before (blue) and after (red) the timepoint of a change for a number of events. The change corresponds to the one shown in Figure 8.

Regarding the safety of the bridge, a yearly accumulated fatigue damage of about 0.01 is calculated for recordings at strain gauge SG9. This gives an estimation of the remaining fatigue life of 100 years which is about the same as the age of the bridge.

A Bayesian bridge model update with complex uncertainty under high-speed train passages

K. Matsuoka

Railway Technical Research Institute, Tokyo, Japan

D. Mizutani

Tohoku University, Sendai, Japan

C. Somaschini, L. Bernardini & A. Collina

Politecnico di Milano, Milan, Italy

ABSTRACT: Bayesian structural model updating is an important technique to achieve digital twin with uncertainty. However, complexly distorted tails of the joint posterior probability density function (PDF) are not easy to estimate when a correlation exists between model parameters. Estimating the lower confidence bound of the joint posterior PDF requires several samples at the tails of the PDF. However, this task is difficult to achieve because the Markov chain Monte Carlo (MCMC) method concentrates on the samples near the expected value. Thus, to estimate the distorted tails of the joint posterior, the authors develop a new methodology called dual sampling, comprising two-step MCMCs. The second step sampling complements the samples around the tail of the joint posterior PDF, which are insufficient in the first step conventional MCMC method. The proposed method is applied to the maximum acceleration data of an Italian high-speed railway bridge.

1 INTRODUCTION

To manage a large number of structures, the development and practical application of structure monitoring methods have been promoted. Structural model update estimates the existing performance of a real structure by updating the parameters of the numerical model based on the measurement data obtained by monitoring. Especially since the pioneering work of Beck and Au (2002), a large body of research on Bayesian structural model updating has progressed (Simone et al. 2015).

Recently, attempts have been made to detect and evaluate damage by estimating structural models (parameters) that best fit measurement data and focusing on their uncertainty (Nishio et al. 2012; Kitahara et al. 2022). Additionally, a reliability design method for reinforcement considering uncertainties of updated model parameters has been developed (Matsuoka et al. 2020a).

Existing performance evaluations in Bayesian structural model updating often fail to assume independence between the estimated parameter uncertainties (Nishio et al. 2012). For example, in a bridge, multiple structural parameters (e.g., bending stiffness, support stiffness, and modal damping ratio) are estimated. However, the maximum displacement and acceleration at the mid-span, which are representative performance indicators, are due to a combination of these effects. In this case, each parameter cannot be evaluated independently because of the correlation of the uncertainties of each parameter (i.e., the spread of each parameter distribution). Therefore, evaluation of the tail space of the joint posterior probability density function (PDF), which considers the correlation between parameters, is required in the

uncertainty evaluation in the Bayesian structural model update. However, because samples around the tail of the joint posterior PDF are difficult to generate using the Markov chain Monte Carlo (MCMC) method (a typical Bayesian estimation method), another method for tail evaluation is required (Matsuoka et al. 2020b).

The authors in this study propose a new approach that uses a two-step MCMC method (Figure 1). Using the lower confidence bound (LCB) of the likelihood obtained using the MCMC method in the normal Bayesian structural model update, authors re-estimate the vicinity of the likelihood LCB, which represents the uncertainty, using another search method. Hence, the tail of the joint posterior PDF, which is complicatedly distorted, can be estimated. Figure 1 illustrates the case of two parameters as a conceptual diagram. However, as the number of parameters increases, the tail space to be estimated in the second step expands rapidly. The second step is spatial estimation instead of optimal value estimation. Therefore, the authors adopt the replica exchange MCMC (Lin et al. 2022), which is a numerical search method for objective functions with multiple peaks. This new approach is called the dual MCMC because it uses a two-step MCMC. After explaining the dual MCMC method, the proposed method is applied to the measured acceleration data of the Sesia bridge (Matsuoka et al. 2019).

Figure 1. Concept of the dual MCMC, which is a method for estimating tails of joint posterior PDF when a correlation exists between parameters.

2 DUAL MCMC METHOD

2.1 Forward computation model

The target is a bridge where trains pass. For the forward calculation, the elastically supported beam at both ends and the moving load model presented in Figure 2 are used. In this study, the physical parameters (i.e., bending stiffness, support stiffness, and modal damping ratio) of the beam model illustrated in Figure 2(a) are updated using MCMC based on the maximum acceleration data of the bridge when trains pass. The unit length mass is assumed here to be known. The train was modeled as a moving load train with the same axle arrangement and axle load. Specifically, application to the more detailed finite element model presented by Matsuoka et al. (2019) is a future topic. The physical parameters of the bridge are updated using the MCMC method so that the maximum acceleration when a train passes by this model matches the measured value. Additionally, the tail of the joint posterior PDF, which represents the uncertainty that is lacking in the first step, is supplemented by the replica exchange MCMC in the second step.

Figure 2. (a) Elastically supported beam at both ends and (b) moving load model.

2.2 First step: MCMC

The parameters of the beam model in Figure 2(a) are estimated using the MCMC method based on the bridge maximum acceleration. The response of the model shown in Figure 2 can be calculated from the theoretical solution of the equation of motion. Here the process of obtaining the maximum acceleration $a_M(v)$ at the bridge mid-span by giving the train speed v and other unknown parameters EI , k_0 , and ξ is expressed as a function F . Here, $\theta = [EI, k_0, \xi]$ is the unknown parameter vector.

$$a_M(v) = F(\theta, v) \quad (1)$$

Let $\mathbf{D} = (\tilde{y}_1, \tilde{y}_2, \dots, \tilde{y}_{S_n})$ be the measured data set of maximum acceleration when trains pass and $\mathbf{V} = (\tilde{v}_1, \tilde{v}_2, \dots, \tilde{v}_{S_n})$ be the train speed measured data. Note that S_n is the amount of data. From Bayes theorem, the occurrence probability of parameter vector θ given the measurement data set \mathbf{D} is given by Equation (2).

$$P(\theta|\mathbf{D}) \propto \mathcal{L}(\mathbf{D}|\theta)P(\theta), \quad (2)$$

where $\mathcal{L}(\mathbf{D}|\theta)$ is the likelihood function; $P(\theta)$ and $P(\theta|\mathbf{D})$ are the prior and posterior PDFs, respectively; \propto represents a proportional relation; and posterior PDF $P(\theta|\mathbf{D})$ is the distribution of parameter θ that represents the existing performance updated by the measured data set \mathbf{D} . Likelihood function $\mathcal{L}(\mathbf{D}|\theta)$ is defined as in Equation (3) in this paper. Furthermore, σ_1^2 is the variance of the normal distribution.

$$\mathcal{L}(\mathbf{D}|\theta) = \prod_{sn=1}^{S_n} N(\tilde{y}_{sn} - F(\theta, \tilde{v}_{sn}), \sigma_1^2) \quad (3)$$

Prior PDFs are set to be almost unconditional as in that of Mastuoka et al. (2020a). Equation (4), obtained by substituting the likelihood function and prior PDFs into Equation (2), is estimated using random walk Metropolis–Hastings (RW-MH), which is one of the MCMC methods.

$$P(\theta|\mathbf{D}) \propto P(k_0)P(EI)P(\xi) \prod_{sn=1}^{S_n} N(\tilde{y}_{sn} - F(\theta, \tilde{v}_{sn}), \sigma_1^2) \quad (4)$$

RW-MH is a method of obtaining samples from a PDF that cannot be sampled directly by generating random numbers. To obtain the p ($p = 2, \dots, \bar{p}$) sample $\theta^{(p)}$ of the model parameter θ using RW-MH, sample $\theta^{(p-1)}$ is added with a random number ϵ_p following a normal distribution with mean 0 and variance ν^2 to generate the p th sample candidate θ' .

$$\theta' = \theta^{(p-1)} + \epsilon_p, \quad \epsilon_p \sim N(0, \nu^2) \quad (5)$$

Because candidate θ' is generated according to a distribution different from the target distribution $P(\theta|\mathbf{D})$, it is corrected to match the distribution $P(\theta|\mathbf{D})$. In RW-MH, if the candidate follows the distribution $P(\theta|\mathbf{D})$, it is adopted, and if the probability of following is small, it is rejected with the probability. Specifically, the p th sample candidate is accepted with the probability expressed in Equation (6).

$$\alpha(\theta'|\theta^{(p-1)}) = \text{Min} \left[\frac{L(\mathbf{D}|\theta')}{L(\mathbf{D}|\theta^{(p-1)})}, 1 \right] \quad (6)$$

Practically, sampling is performed along with the Gibbs sampling method. With enough $p = \underline{p}$ iterations, $\theta^{(p)}$ converges to a random number generated from the distribution $P(\theta|\mathbf{D})$. The expected value and LCB of $P(\theta|\mathbf{D})$ can be calculated as statistics of $\theta = [\theta^{(\underline{p})}, \dots, \theta^{(\bar{p})}]$. However, the number of samples that correspond to the $P(\theta|\mathbf{D})$ tail is insufficient for evaluating

the uncertainty. Therefore, the likelihood \mathcal{L}_α that corresponds to the α LCB in the obtained $\mathcal{L}(\mathbf{D}|\boldsymbol{\theta})$ is used to estimate the tail space of the joint posterior PDF in the second step.

2.3 Second step: Replica exchange MCMC

The replica exchange MCMC is a type of extended ensemble method. It generates sample sequences using multiple MCMCs and exchanges the samples between sequences on the way. This exchange allows the movement between the peaks of the likelihood function via different sequences (Figure 3). Consequently, multimodal distributions and spatial estimations are possible.

Figure 3. Mechanism of the movement between peaks by exchanging replica distributions.

Now, the generation probability of tail space Θ_α of the desired posterior PDF is defined as in Equation (7) by the joint distribution of S different replica distributions.

$$P(\Theta_\alpha) = P(\theta_1, \theta_2, \dots, \theta_S) = \prod_{s=1}^S P(\theta_s | \mathbf{D}, T_s) \quad (7)$$

However, because this is the estimation of the parameter space corresponding to α LCB (and not the estimation for best fitting to the data), the likelihood function is defined again. The new likelihood \mathcal{L}' in the second step spatial estimation problem is expressed as in Equation (8).

$$\mathcal{L}'(\mathbf{D}|\boldsymbol{\theta}_s, T_s) = N(\mathcal{L}(\mathbf{D}|\boldsymbol{\theta}_s) - \mathcal{L}_\alpha, \sigma^2) \quad (8)$$

Here, $N(\mathcal{L}(\mathbf{D}|\boldsymbol{\theta}_s) - \mathcal{L}_\alpha, \sigma^2)$ is the normal distribution with the expected value $\mathcal{L}(\mathbf{D}|\boldsymbol{\theta}_s) - \mathcal{L}_\alpha$ and variance σ^2 . Hence, $P(\theta_s | \mathbf{D}, T_s)$ is given by Equation (9).

$$P(\theta_s | \mathbf{D}, T_s) = \exp\left(\frac{-T_s \mathcal{L}'(\mathbf{D}|\boldsymbol{\theta}_s)}{Z(T_s)}\right) \quad (9)$$

Samples according to each replica distribution of Equation (9) are generated using the RW-MH, and the sample exchange between replica distributions is repeated with the exchange probability r according to Equation (10).

$$r = \exp[(T_{s+1} - T_s) \cdot (\mathcal{L}'(\mathbf{D}|\boldsymbol{\theta}_{s+1}) - \mathcal{L}'(\mathbf{D}|\boldsymbol{\theta}_s))] \quad (10)$$

Sample generation of each replica distribution in the replica exchange MCMC method can be calculated simultaneously through parallel computing. In this study, the method was implemented in Matlab.

3 APPLICATION TO SESIA VIADUCT

3.1 Test bridge and data

Dual MCMC presented in Chapter 2 is applied to the Sesia bridge (Matsuoka et al. 2019), an Italian high-speed railway bridge. The Sesia bridge is a steel–concrete composite bridge and has a span length of 45.2 m. Here, the maximum acceleration at the mid-span during the running of two types of trains (i.e., ETR500Y1 and ETR1000) obtained on the Sesia bridge (Figure 4) is used. As shown by Matsuoka et al. (2019), the maximum accelerations with 15 Hz LPF were used, where the primary bending mode of the bridge is dominant. Dual MCMC using a forward calculation model estimates the bridge bending stiffness, support stiffness, modal damping ratio, and their uncertainties. The numbers of target trains are six ETR500Y1 and 15 ETR1000. In MCMC at the first step, $\bar{p} = 1,000$ until burn-in, and $p = 20,000$ from burn-in to the end of the calculation. In the second step, replica exchange MCMC, the authors estimated the parameter space with a 5% LCB of the likelihood distribution obtained in the first step. The number of replica distributions is 4, and sampling was performed 20,000 times (a total of 80,000 samples) for each replica distribution.

Figure 4. Measured values and calculation results of the expected value model of the posterior distribution obtained in the first step of MCMC.

3.2 Results of the first step MCMC method

Figure 5 shows each posterior distribution and joint posterior PDFs estimated using the MCMC method. Additionally, the black dots in the figure are the samples obtained in the second step of the replica exchange MCMC method, and the red line shows the 5% upper and lower confidential bands of the posterior distribution of each parameter. The estimated support stiffness is almost independent of other parameters. Meanwhile, a correlation exists in the joint posterior PDFs between the bending stiffness and modal damping ratio. Samples near the tail of the joint posterior PDF of the bending stiffness–modal damping ratio are outside the 5% LCB of each parameter because of this correlation. Therefore, the LCB parameter combination should be evaluated considering the correlation. Note that no problem exists in independently evaluating the expected value for each parameter. Figure 4 shows the evaluation results of the model with the expected values of the parameters obtained using the MCMC method in the first step. In the case of any train, it roughly agrees with the tendency of the sample.

3.3 Results of the second step MCMC

The tail space of the joint posterior PDF, which cannot be evaluated using the first step MCMC, was estimated using the replica exchange MCMC method. Figure 5 (black plots) illustrates the joint posterior PDF of the obtained sample. Evidently, the distorted tail space samples in the joint posterior PDF of the bending stiffness and modal damping ratio are heavily supplemented. Additionally, some correlation can be confirmed in the tail space of the joint posterior distribution of the support stiffness and bending stiffness. Figure 6 shows the

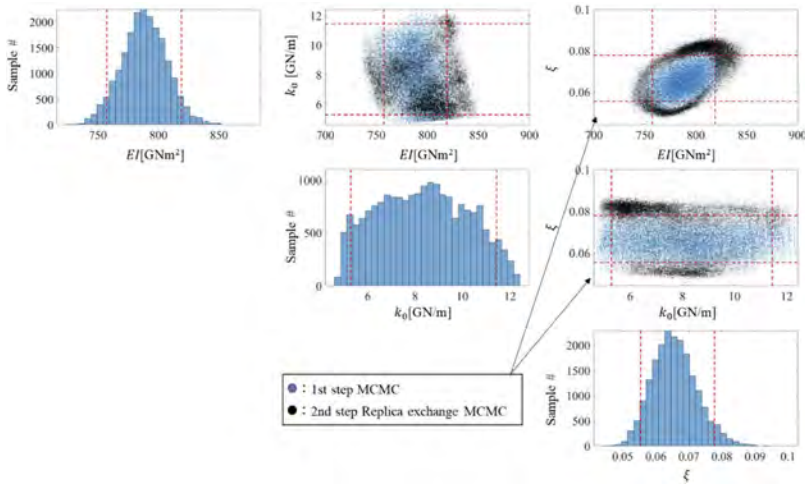

Figure 5. Posterior distributions of each parameter obtained using MCMC in the first step (black dots are the results of the second step).

estimated tail space (with a cylindrical shape) in the parameter space. These models represent the 5% LCB of the likelihood, and countless combinations of parameters exist that evaluate the maximum acceleration higher or lower than the measured data.

Figure 6. Tail space of the joint posterior distribution obtained using the replica exchange MCMC.

Therefore, selecting and using the most important model from the tail space are necessary. Generally, a model that evaluates values that are on the safe side is used. However, in the joint posterior distribution of the modal damping ratio and bending stiffness, a tail space with a lower limit of 5% outside the 5% LCB red line for each parameter exists. Therefore, the estimation of the tail space using the proposed method is clearly important for robust evaluation.

4 CONCLUSIONS

This study investigated the estimation of uncertainty when a correlation exists between parameters in the Bayesian structural model update. When a correlation exists between the parameters of the structural model, the tail of the joint posterior PDF is complexly distorted. Thus,

uncertainties cannot be evaluated by assuming that each parameter is independent. To estimate such a distorted tail space, the authors proposed a dual MCMC that uses two-step MCMCs. The expected value and likelihood distribution of each parameter were evaluated in the first step MCMC. Then, focusing on the LCB of the likelihood distribution obtained at the first step, the tail space of the joint posterior PDF, which cannot be evaluated using the first step because of insufficient samples, was largely compensated by the second step replica exchange MCMC.

The proposed method was applied to the maximum acceleration data of the Sesia bridge on the Italian high-speed railway. A correlation was found between the modal damping ratio and bending stiffness in the joint posterior PDF obtained using the MCMC method. Furthermore, the results of the second step replica exchange MCMC clarify that the tail space of the joint posterior PDF, which corresponds to 5% LCB of the likelihood, is a space with a cylindrical shape. Additionally, estimating the tail space considering the correlation is necessary because the model of 5% LCB when each distribution is assumed to be independent does not match the model considering the correlation.

ABSTRACT: Bridges are a sensitive part of railway infrastructure and are subject to deterioration of their materials and support conditions during their life cycle. Regular use and the effects of time can affect the behavior of a structure. Therefore, the condition assessment of these assets is one of the most critical issues for infrastructure operators, aiding bridge integrity management. The present paper aims to study the dynamic structural responses and the soil-structure interaction of a reinforced concrete (RC) railway bridge. For this study, a six-span reinforced concrete bridge with 180 meters in total length, built in the 80s and rehabilitated in 2017, was employed as a case study. The bridge superstructure contains longitudinal beams with rectangular cross-sections, transverse beams, and a concrete deck with variable cross-sections. The infrastructure is composed of caissons supported by a rock layer. A numerical model was developed using the finite element method considering the soil-structure interaction process from Winkler springs calibrated adequately according to soil characteristics and foundation type. The springs, applied on the foundations and bearing devices, were positioned according to design and construction information, which provided physical and mechanical characteristics necessary to develop the computational modeling. Results regarding natural frequencies of vibration, deformations, displacements, accelerations, and velocities in the deck, beams, and pile caps of the railway bridge were analyzed and compared with monitoring results, assessing the bridge's structural response when subjected to dynamic loads. The numerical results adhered to those found in the monitoring campaign, thus validating the modeling methodology strategy employed in the bridge study. The results can be used to evaluate the structural condition and assess the bridge's behavior during its life cycle. Therefore, it can support the development of models to predict failures and even be incorporated into a digital twin that can be employed for bridge integrity management.

1 INTRODUCTION

Several studies have been directed toward improving damage detection and structural performance evaluation knowledge in recent years. These studies were motivated by the demands that emerged due to the increase in loading conditions, material deterioration, new conditions of use, or even exceptional events such as hurricanes, explosions, and earthquakes.

Inspection and monitoring strategies provide reliable data regarding the bridge condition and support activities of maintenance, strengthening, and retrofitting. In this sense, manual inspections are an essential source of information for structural integrity assessment. However, this activity can be time-consuming, laborious, expensive, unsafe, and highly subjective, depending on the inspector's experience (Spencer et al. 2019). Therefore, computer vision-based techniques are presented as innovative data resources to automate civil infrastructure

inspection, mainly when associated with Unmanned Aerial Vehicles (UAVs) for image acquisition (Yeum 2015, Catbas et al. 2018).

Parallel to the existing inspection activities for condition assessment, Structural Health Monitoring (SHM) stands out as a process to provide accurate and in-time information regarding bridge structural condition and performance. The strategy seeks to detect, locate, and quantify structural damages through data acquisition from field measurements. The obtained information can be used to plan and design maintenance activities, increase safety, verify design hypotheses, reduce uncertainties and, in general, increase our knowledge about the monitored structure (Glisic & Inaudi 2007). For example, using accelerometers and strain gauge sensors allows an analysis of the bridge's structural behavior, static and dynamic, under service conditions (Brownjohn 2007).

Integrating inspection and monitoring data to Finite Element Modeling (FEM) strategies enables the assessment of current deterioration or damage of a structural asset. Furthermore, it can assess future bridge behavior by adjusting the input parameters and load conditions in the numeric model. As stated by Brownjohn (2007), computational simulation via FEM exposes the integration between the structural elements, allowing a verification of the system's global behavior, whose validation is dependent on the values obtained in situ when using instrumentation techniques. Additionally, FEM models can help monitoring campaigns by identifying critical positions to assign the monitoring sensors.

Several studies have been carried out to investigate the influence of considering the soil-structure interaction (SSI) on the response of bridges to loads of a dynamic nature. SSI analysis evaluates the combined effects of soil, foundation, and structure bridge system structural responses, enabling a more complete computational representation of the asset condition. For example, Wu & Qiu (2020) studied the dynamic analyses of pile-supported bridges, including soil-structure interaction, under stochastic ice loads. For this case, nonlinear spring models were employed to represent the soil-foundation interface. The authors verified that structures supported by soft soils present higher displacements and lower natural frequencies than fixed supports.

Once implemented, numerical models must be calibrated appropriately. Thus, using experimental data collected from structural health monitoring systems is a common way to verify the efficiency of a model. For instance, Zangeneh et al. (2020) compared the modal characteristics of a high-speed railway bridge to its numerical models to propose a reliable simplified model adequate for design practices. In addition to finite element modeling, analytical formulations can provide essential insights into the influence of foundations on the overall stiffness of bridges, as done by Zangeneh et al. (2019). The authors proposed a simplified discrete model for calculating modal parameters of the fundamental vertical mode of a simply-supported beam on viscoelastic supports. It was observed that an important parameter to evaluate the soil-structure interaction relevance is the ratio between the superstructure stiffness and the soil-foundation system stiffness. A large value for this ratio implies a greater capacity of the soil to dissipate energy by radiation, making such a consideration beneficial for the system's structural performance.

In this context, including soil-structure interaction during the numerical modeling of bridges becomes essential for dynamic analysis, such as for evaluating the structure and foundation seismic performance (Raheem 2022). Studies in this regard have verified some of the following aspects: the influence of considering SSI and wave passage effects for the seismic vulnerability of continuous bridges (Ramadan et al. 2020); bridge failure probability estimation from uncertainties parameters on SSI modeling (Xie & Desroches 2019); quantification of the impact of considering soil-structure interaction for the development of bridge-specific fragility curves (Stefanidou & Kappos 2017); performance evaluation of a group of piles under seismic action considering soil-fluid-structure interaction (Zhan et al. 2020). Several other studies are being developed to expand the use and capabilities of SSI strategies.

The present work aims to apply the methodological aspects used in primary studies in the field of structural analysis for bridges considering soil-structure interaction to produce reliable computational results to evaluate the dynamic behavior of a reinforced concrete railway bridge. The developed numerical model, validated by monitoring campaigns, will provide subsidies to assess the structural condition and the bridge behavior during its life cycle.

2 RAILWAY BRIDGE CASE STUDY

2.1 Asset description

For this paper, a six-span reinforced concrete railway bridge with 180 meters in total length, built in the 80s and rehabilitated in 2017, was employed as a case study. The asset is in the northern region of Brazil. The bridge comprises two continuous sections: the first section includes two 25 meters spans, and the second has four 25 meters spans. Each section ends with abutments (Figure 1a), and there is a 5 cm joint between the two continuous sections at the intermediate supports. The bridge superstructure consists of two longitudinal beams with rectangular cross-sections, transverse beams, and a concrete deck with variable cross-sections. The superstructure is supported on the pile caps by neoprene bridge bearings. The infrastructure comprises pile caps and caissons supported by a rock layer (Figure 1b).

Figure 1. Case study railway bridge details: (a) abutment details, (b) detail of caissons and pile caps.

Due to an act of vandalism (Figure 2a), the continuous section with two spans of the bridge had to be recovered and reinforced in 2017 (Figure 2b). The longitudinal girders near one of the bridge abutments were repaired and strengthened, the transverse beams were

Figure 2. Bridge rehabilitation process: (a) damage caused by an act of vandalism in 2017, (b) process for bridge rehabilitation and strengthening.

reconstructed, and the damaged pile cap was repaired and reinforced. At the time, a comprehensive study had to be developed to define and design the retrofit activities. If a previous thorough condition assessment of the asset by inspection and/or monitoring campaigns and a validated computational model were available, the cost and time employed to determine the necessary interventions could have been minimized.

In order to create a 3D geometric model of the bridge, a parameterized model of the asset was developed using the environment Rhino/Grasshopper. The modeling strategy focused on obtaining a model with a reliable representation of the bridge geometry and the interaction between the parts. For the process, data from design and construction was employed, as well as “as-is” information provided by previous inspections. The railway bridge was modeled in two different arrangements: the bridge in its original configuration (before the vandalism act of 2017, Figure 3a) and the bridge configuration after the retrofit activities (Figure 3b).

Figure 3. Modeling arrangements: (a) bridge in its original configuration, (b) bridge after the rehabilitation and strengthening process (strengthening elements in dark gray).

2.2 Asset instrumentation

The asset was instrumented in 2020 to assess the condition of the strengthened region by a third-party company contracted by the bridge owner. The bridge modal parameters, such as natural frequencies, vibration modes, and damping ratio, were determined by ARTEMIS Modal Pro 6.1 software. The software uses two techniques for modal identification: one in the frequency domain (FDD – Frequency Domain Decomposition) and the other in the time domain (Stochastic Subspace Identification). In general, accelerations over time were converted to the frequency domain using mathematical and stochastic models. The final graph provided by the software presents the singular values obtained from the decomposition of the spectral density matrices. For each vibration mode, the natural frequency and its associated damping ratio can be obtained. Thus, from the monitoring responses, it is possible to locate the accelerometers according to the peaks provided in the graph and prepare the instrumentation plans to obtain the vibration modes in the field. Table 1 summarizes the natural frequencies for each vibration mode and their respective damping ratio.

The data obtained by the structural health monitoring campaign was employed to properly calibrate the computational models presented in this paper. A well-validated model can reduce model uncertainties and improve its accuracy in predicting the system’s structural responses.

Table 1. Experimental natural frequencies.

Mode	Frequency (Hz)	Damping ratio (%)
I	1.8	3.6
II	3.0	2.5
III	7.7	1.0
IV	9.6	0.2

2.3 Asset computational model

Springs were used along the caissons to simulate the soil-structure behavior. Details about the methodology employed can be found in Morrison (1993). It was decided to simulate the pipes in shell finite elements since the results found through discretization in bar elements proved to be incompatible with the instrumentation performed on the asset.

Using an adequately calibrated Winkler spring model to describe the behavior of a structure-foundation-soil system is one of the most commonly adopted methods to portray the combined effects of this type of system and its material properties. Thus, springs were employed along the caissons to simulate the soil-structure interaction behavior. The methodology adopted for this paper can be found in further detail in Morrison (1993). The bridge components were represented numerically by shell finite elements since this modeling approach provided more relevant results than a simplified modeling strategy with bar elements to describe the asset actual behavior verified on the field. In order to describe the soil-structure springs' stiffness, a soil Poisson's coefficient of 0.30 was adopted for the first 1.0 *m* layer of soil and 0.40 for the subsequent layers. Therefore, Table 2 displays the horizontal spring stiffness coefficients assumed according to the caisson's diameter (1.40 m) and the depth of the element.

Table 2. Soil-structure horizontal spring stiffness.

Depth (m)	Stiffness (<i>tflm</i>)
0.70	2352
7.00	11956

Springs with equivalent vertical stiffness were employed to represent the as-built steel support frames adopted for the bridge strengthening process, as detailed in Figure 2b. For this, a vertical spring stiffness of 170 *tflm* was assumed for the numerical model. The neoprene bearing pads were represented according to the technical procedures proposed by Guerreiro (2003). Table 3 presents the vertical spring stiffness adopted for the bridge bearing pads, considering a shear modulus of 1 *MPa* for the components.

Table 3. Neoprene bearing pads vertical stiffness.

Bridge axis	Stiffness (<i>tflm</i>)
E4	7.8
E5	3.3

Figure 4 illustrates the computational model with isoparametric shell elements with three nodes (linear interpolation) developed in CSiBridge 21 for the bridge after rehabilitation. The numerical model has about 52,000 nodes and 110,000 shell elements. The railway bridge foundations were assumed as fixed supports at the bedrock region.

The shell thickness element was calibrated in agreement with the asset modal frequencies obtained experimentally to evaluate the structural responses. The experimental damping rates have been used in the computational model according to modal patterns (Table 1).

A modal FEM free vibration analysis has been carried out using concrete strength and Young modulus applied in each asset region as established by Table 4. The experimental values for the damping ratio introduced in Table 1 were used to feed the computational model. The shell element thickness was calibrated in agreement with the modal frequencies obtained experimentally during the bridge condition assessment.

Infrastructure	15	21797

3 COMPUTATIONAL RESULTS

The natural frequencies of the bridge after rehabilitation were compared with the bridge's original configuration to verify the increase in stiffness provided by the adopted strengthening strategies. Likewise, the natural frequencies rehabilitated bridge were compared with those extracted from the monitoring campaign performed by a third-party company in 2020 to validate the modeling approach developed in this paper. Figure 5 displays natural frequencies obtained by the modal analysis for Mode I and Mode II.

Table 5 presents a comparison between the natural frequencies obtained experimentally with the proposed computational model. A good convergence can be seen between the obtained results, which allows for validating the numerical model produced. It should also be noted that the modeling strategy adopted in this paper, which includes the soil-structure interaction, displayed better results when compared with the model produced by the third-party company. Thus, the use of a more detailed model, using shell elements instead of bar elements, in addition to the use of an SSI approach, provided satisfactory improvements to attain the bridge structural responses.

The deviation between the experimental results to the natural frequencies obtained by the numerical model proposed in this work was close to 5%. On the other hand, the computational model established by the third-party company displayed a 10% deviation from field measurements, demonstrating the improvements provided by the technique adopted for this paper.

The strengthening elements ensured a stiffness increase of 10% for the bridge compared to the original project when measured by the frequency in Mode I (longitudinal bending) and a stiffness increment of 11% for Mode II (torsion). Furthermore, the bridge strengthening caused an order of 10% approximately increase in stiffness for free vibration in Mode I and Mode II.

Figure 5. Modal analysis results.

Table 5. Comparison between computational and experimental natural frequencies.

Modal shape	Proposed Model	Third-party company model	Experimental
Mode I	1.89	2.00	1.80
Mode II	2.84	3.30	3.00

4 CONCLUSIONS

Based on the results obtained in this paper, it can be concluded that:

- SSI models provide satisfactory improvements in the numerical responses;
- The soil-structure model proposed by Morrison (1993) provided an adequate representation of the soil stiffness around the caissons;
- The approach described by Guerreiro (2003) proved to be compatible with the level of stiffness and damping in the neoprene bearing pads;
- The modeling strategy with shell elements proposed in this paper proved to be more efficient in representing the railway bridge actual behavior when compared to a modeling strategy considering beam finite elements;
- The strengthening process produces an increase of 10% in the bridge stiffness for bending and torsional behavior;
- The calibrated computational model represents the real-life asset, enabling the bridge condition assessment;
- A chain of analysis considering material degradation and different load case scenarios can be conducted using the validated model to predict the bridge behavior and support repair or strengthening measures for the structure;

- The validated modeling strategy will enable the performance assessment of the railway bridge throughout its life cycle and support the development of new research activities related to the management of this type of infrastructure.

ABSTRACT: In this paper, a drive-by damage detection methodology for high-speed railway (HSR) bridges is addressed to appraise the application of Mel-frequency cepstral coefficients (MFCC) to extract the Damage Index (DI). A finite element 2D vehicle-track-bridge (VTBI) model that incorporates the train, ballasted track and bridge is presented. The formulation includes track irregularities and a damaged condition induced in a structure region. The feasibility of applying cepstrum analysis components to the indirect damage detection in HSR by on-board sensors is evaluated by numerical simulations. Different damage scenarios were simulated, as well as external excitations such as measurement noises and different levels of track irregularities. The results show that MFCC-based DI are highly sensitive regarding damage detection and robust to the noise. Bridge's stiffness can be recognized satisfactorily at high speeds and under different levels of track irregularities. Moreover, the magnitude of DI extract-ed from MFCC is related to the relative severity of the damage.

1 INTRODUCTION

With the continual development of new HSR lines around the world, bridges represent a significant component of these infrastructures; consequently, the demand for condition evaluation of such a vast number of bridges is rapidly rising (Wang *et al.*, 2021). Vibration-based Structural Health Monitoring (SHM) has been intensively researched as one of the most prevalent assessment techniques in the past few decades. In direct SHM, the dynamic responses of structures are often examined utilizing on-bridge sensors. However, deploying sensors and equipment for these sorts of monitoring is time-consuming and labor-intensive (Zhan *et al.*, 2021).

For this reason, indirect approaches for SHM of bridges have received significant interest. The most common method employed is a drive-by estimation of passing railway bridges based on the on-board measured data of a train in service traveling on the designated routes (Yang *et al.*, 2019). As a relevant application of the drive-by bridge inspection method (Micu *et al.*, 2022), the structural damage of the bridge under different conditions can be detected based on the identified modal parameters (OBrien, Malekjafarian and González, 2017).

Cepstrum-based operational modal analysis has been studied recently (Morgantini, Betti and Balsamo, 2021). Cepstrum analysis may detect slight spectrum variations from the vibration

signal as a function of quefreny. Initial cepstrum-based analytical studies show considerable potential for SHM applications (Randall, 2009). Despite the fact that this study topic has lately sparked interest in the SHM field, there are currently a limited number of works applying MFCC to indirect health monitoring for damage detection.

This study addresses a drive-by damage detection methodology for HSR bridges to evaluate the application of MFCC to extract bridge-damage-related features. The article’s organization is as follows: First, the train cars comprise four-axle vehicles, the track is treated as a beam resting on evenly distributed spring-mass systems, and the bridge deck of the high-speed rail has been described as a simply supported Bernoulli-Euler beam. The formulation covers track irregularities and induced damage circumstances in a particular structure section. Second, a demonstration of the suggested drive-by damage detection strategy and a discussion of the damage index extraction from the MFCC method are provided. After that, the feasibility of using cepstrum analysis components for indirect damage detection in HSR by on-board sensors is investigated using numerical simulations in which dynamic analyses are carried out using MATLAB® code. The final section summarizes the key results, and some prospects are highlighted.

2 METHODOLOGY

2.1 Vehicle-track-bridge dynamic interaction system

This section describes the 2-dimensional VTBI model used in the present study to numerically simulate a high-speed train response to a bridge crossing event. Plane VTBI systems can satisfactorily predict vertical dynamic response (Quirke *et al.*, 2017). As to ballasted railways tracks consisting of rails, pads, sleepers, ballast, and sub-ballast, it is possible to depict the track with varying degrees of complexity, which may be roughly categorized by the number of sprung layers taken into account (Cantero *et al.*, 2016).

2.1.1 Vehicle model

Figure 1a shows the multi-rigid-body vehicle model considered in this paper. The rigid bodies corresponding to the carbody and bogie frames have concentrated masses m_c and m_b , and rotational inertias J_c and J_b (about the transverse horizontal axes through its centers of gravity). The wheelsets were considered as lumped masses m_w coupled to the bogie frames by spring-dashpot sets constituting the primary suspension with spring stiffness k_{1y} , and damping coefficient c_{1y} . Spring-dashpot sets, constituting the secondary suspension system, couple bogie frames to the carbody (spring stiffness k_{2y} , and damping coefficient c_{2y}). Each car of the vehicle model contains ten independent degrees of freedom (DOFs): seven vertical displacements for the masses ($y_c, y_{b1}, y_{b2}, y_{w1}, y_{w2}, y_{w3}$, and y_{w4}) and three rigid bar pitching rotations (ϕ_c, ϕ_{b1} , and ϕ_{b2}). The train crosses the bridge at constant speed v with N_c independent vehicles.

2.1.2 Track model

Figure 1b depicts the track model as a beam laying on uniformly distributed spring-mass systems. Finite Element (FE) discretization models the rail as a 2D Euler–Bernoulli beam with four parameters: Young’s modulus E_r , sectional area A_r , moment of inertia about the transverse axis I_r , and mass per unit length m_r . The sleepers are represented as masses M_s within a regular spacing L_s and coupled to the rail by a spring-dashpot system (stiffness K_p and viscous damping C_p) representing the pad. A spring-dashpot layer with stiffness K_{ba} and damping coefficient C_{ba} connects the sleeper to the ballast bodies (lumped masses M_{ba}). The su-ballast’s dynamic qualities are considere as an extra spring-dashpot layer (stiffness K_{sb} and viscous damping C_{sb}). Random irregularity profile functions on the rail surface account for the x-coordinate rail irregularities $r(x)$, which are measured relative to the beam’s vertical static equilibrium locations (mean horizontal axle).

2.1.3 Bridge model

The HSR bridge deck is modeled as a simply supported Bernoulli-Euler beam (Figure 1c) utilizing FEM formulation with 2D beam elements, whose properties are mass per unit length of \bar{m}_b , Young’s modulus E_b , sectional area A_b , and moment of inertia I_b . In order to simulate the

structure's damage to be identified and localized indirectly by the passing vehicle, a beam region has its bending stiffness affected by a coefficient f_{sr} (reduction stiffness ratio).

Figure 1. 2-D vehicle-track-bridge dynamic interaction system: (a) vehicle model, (b) track model, and (c) bridge model.

2.1.4 Equations of motion for the VTBI system

The subsystems aforementioned are integrated into a single VTBI model. A set of equations of motion describes each subsystem. These second-order differential equations can be represented in a general matrix form utilizing the time-dependent mass, damping, and stiffness global matrices \mathbf{M} , \mathbf{C} and \mathbf{K} , along with the vector of external forces \mathbf{F} , and solved for the vector \mathbf{X} of the global displacements (DOFs). The coupled equations of motion for the entire model can be represented as

$$\begin{bmatrix} \mathbf{M}_V & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{M}_T & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{M}_B \end{bmatrix} \begin{Bmatrix} \ddot{\mathbf{X}}_V \\ \ddot{\mathbf{X}}_T \\ \ddot{\mathbf{X}}_B \end{Bmatrix} + \begin{bmatrix} \mathbf{C}_V & \mathbf{C}_{VT} & \mathbf{0} \\ \mathbf{C}_{TV} & \mathbf{C}_T & \mathbf{C}_{TB} \\ \mathbf{0} & \mathbf{C}_{BT} & \mathbf{C}_B \end{bmatrix} \begin{Bmatrix} \dot{\mathbf{X}}_V \\ \dot{\mathbf{X}}_T \\ \dot{\mathbf{X}}_B \end{Bmatrix} + \begin{bmatrix} \mathbf{K}_V & \mathbf{K}_{VT} & \mathbf{0} \\ \mathbf{K}_{TV} & \mathbf{K}_T & \mathbf{K}_{TB} \\ \mathbf{0} & \mathbf{K}_{BT} & \mathbf{K}_B \end{bmatrix} \begin{Bmatrix} \mathbf{X}_V \\ \mathbf{X}_T \\ \mathbf{X}_B \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}_V \\ \mathbf{F}_T \\ \mathbf{F}_B \end{Bmatrix} \quad (1)$$

where the subscripts V , T and B represent, respectively, the vehicle, track, and bridge subsystems.

The connectivity of the subsystems is theoretically defined by additional off-diagonal block matrices in equation (1). The beam element's form function and the mechanical parameters of the system determine these coupling terms.

2.2 MFCC-based drive-by damage detection

The primary objective of feature extraction is to transform the unprocessed input signal into a representation with minimal variables that contains the most discriminating information, which can effectively reduce the input's dimensionality and eliminate redundant or irrelevant information to generate a series of feature vectors. In this regard, cepstral analysis is widely employed to extract MFCC characteristics from raw data (Babajanian Bisheh *et al.*, 2021). The MFCC depicts the short-term power spectrum of a signal with a linear cosine transform of a log power spectrum on a nonlinear Mel frequency scale (Lee *et al.*, 2016). Figure 2 depicts a flowchart that summarizes the methodology developed in this paper for drive-by damage detection of HSR bridges using MFCC to extract features.

2.2.1 Vehicle's acceleration segmentation short-term spectra, adapted Mel-frequency scale and frequency warping

The Short-time Fourier Transform (STFT) analyzes the vehicle's acceleration signal's frequency content over time. Thus, sliding a window function over the vehicle's vertical acceleration time histories discretizes them into j segments. After segmentation and windowing, the STFT takes all segments' Discrete Fourier Transform (DFT) to calculate the vehicle's short-term spectra for each frame.

After the STFT has been evaluated, the frequency spectrum of each frame, in a procedure known as frequency warping, is undertaken to emphasize the signal's Mel-frequency characteristics. Considering that lower frequency of bridges is always more important, an adapted formula proposed by Mei *et al.* (2019) for the correspondence between Hertz f and Mel frequency m scales was applied and is as follows.

$$m = 5 \ln(1 + f/5) \quad (2)$$

The DFT values are weighed using a series of N triangular filters, known as a filter bank, to achieve frequency warping. This approach minimizes the amount of information that is corrupted in the spectrum (or Mel-spectra, or cepstrum) of the vehicle's reactions at frequencies higher than the bridge's relevant frequencies.

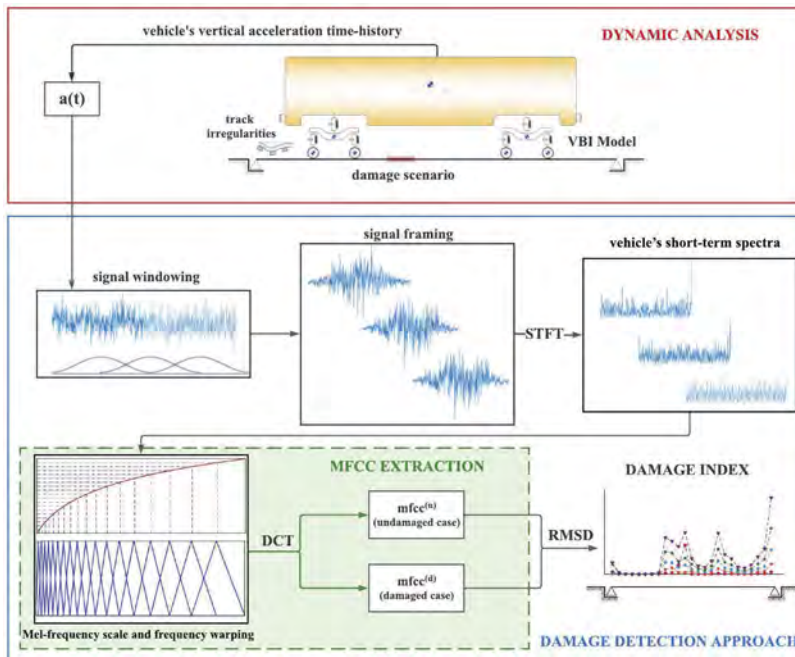

Figure 2. Flowchart of the drive-by damage detection approach using MFCC.

2.2.2 Mel-frequency cepstral coefficients (MFCC) and extracted Damage Index

The next step is obtaining the list of MFCC associated with the short-term spectra. The Inverse Discrete Cosine Transform (DCT) is employed, and then the \mathbf{mfcc}_j discrete vector related to the j th short-term cepstrum $X_j(f)$ becomes

$$\mathbf{mfcc}_j = \left\{ \mathbf{mfcc}_k^j \right\}^T, \quad k = 1, 2, \dots, N_f - 2 \quad (3)$$

with the k th component \mathbf{mfcc}_k given by

$$m fcc_k^j = \sum_{n=2}^{N_f-1} \text{Log}X_n \cos\left(\frac{\pi}{N-2}\left(n-\frac{3}{2}\right)k\right) \quad (4)$$

In Equations 3 and 4, N_f is the number of filters in the filter bank, and $\text{Log}X_n$ denotes the n th filter log-energy output, which can be written as

$$\text{Log}X_n = \log\left(\sum_{l=1}^{L_n} TF_n(f) \times |X_j(f)|^2\right) \quad (5)$$

in which TF_n is the n th triangular filter that is applied over the j th short-term power spectrum $|X_i(f)|^2$, in its $l = 1, 2, \dots, L$ samples.

In the last stage of the procedure, MFCC are used to calculate the damage indices (DI), from which the HSR bridge damage prognosis is performed. Thus, by comparing the aforementioned vectors \mathbf{mfcc}_i^u , extracted from the recorded vehicle's responses when it crosses the undamaged bridge, to the \mathbf{mfcc}_i^d ones, provided by the vehicle passing over the bridge under the presence of damage; the along bridge span DI are taken by the Root Mean Square Deviation described as

$$DI_j = \sqrt{\frac{\sum_{k=1}^{N-2} (m fcc_k^{j(u)} - m fcc_k^{j(d)})^2}{\sum_{k=1}^{N-2} (m fcc_k^{j(u)})^2}} \quad (6)$$

3 RESULTS AND DISCUSSION

The VBI model and the drive-by damage detection procedure have been implemented in MATLAB®, and the feasibility of using damage features extracted from MFCC in indirect SHM of HSR infrastructure is numerically evaluated in this section for two different levels of track disturbance: low disturbance (LD) and high disturbance (HD), in addition to the case where no irregularity is considered. To test the method's sensitivity to the severity of the damage, five damage scenarios were simulated in the bridge, assuming bending stiffness decreases of $f_{sr} = 5\%$, 10% , 15% , 20% and 25% in a portion of the Euler-Bernoulli beam with a length of 1.2m (the bridge span is $L=45$ m). In order to verify the sensitivity of MFCC-based DI to the position of the damage, these damage scenarios were investigated in different cases where these regions were located around the midspan cross-section and at $1/4$ of the span from the left support.

Table 1. Properties of the bridge model.

Properties		Notation	Value	Unit
Deck	Reinforced concrete density	ρ_c	2500	kg/m ³
	Reinforced concrete area	A_c	6.0191	m ²
Ballast (Zhai, 2020)	Ballast density	ρ_b	1750	kg/m ³
	Ballast area	A_b	3.6315	m ²
Sleeper (Zhai, 2020)	Sleeper mass (half)	m_s	170	kg
	Sleeper spacing (half)	l_s	0.60	m
Rail (Zhai, 2020)	Rail mass per unit length (per rail seat)	\bar{m}_r	60.64	kg/m
<i>Euler-Bernoulli beam:</i>				
Mass per unit length			13350	kg/m
Modulus of elasticity		E	39	GPa
Cross-section moment of inertia		I	2.60	m ⁴
Span length		L	45	m

Figure 3. Idealized cross-section of the bridge numerical model.

Table 1 provides a summary of the bridge parameters, which were derived using an idealized cross-section with a reinforced concrete deck and ballasted track (Figure 3). A smooth rail profile was anticipated, and a 40-meter track length was considered before the bridge. The VTBI model was discretized with a bridge mesh size of 0.6 m and a rail mesh size of 0.2 m. The Rayleigh damping coefficients for the first and second bridge modes are adjusted to attain a damping ratio of 0.5%. Table 2 lists the assumed vehicle parameters for the ICE3 Velaro (Quirke *et al.*, 2017).

Table 2. Mechanical, geometrical, and suspension properties of the 2D vehicle model (ICE3 Velaro) (Quirke *et al.*, 2017).

Properties		Notation	Value	Unit
Concentrated masses	Carbody	m_c	47800	Kg

Distance between bogie centers from adjacent cars		L_{ac}	7.40	M

Figure 4. DI values under different damage conditions at the midspan, for the vehicle running at $v = 144$ km/h, and under different levels of track irregularities: (a) NC, (b) LD, and (c) HD.

3.1 Performance of the proposed drive-by damage detection using MFCC

The performance of MFCC in providing DI that can determine whether the system has structural damage is now under discussion. Figures 4 and 5 depict the DI values obtained for the train running speeds of $v = 144 \text{ km/h}$ $v = 288 \text{ km/h}$. The DI values obtained from MFCC gave robust information regarding the location of the damage. In addition, it can be observed that the sensitivity of the proposed DI to the degree of damage and its placement is unaffected. Figure 6 demonstrates that the DI values for scenarios with multiple damage.

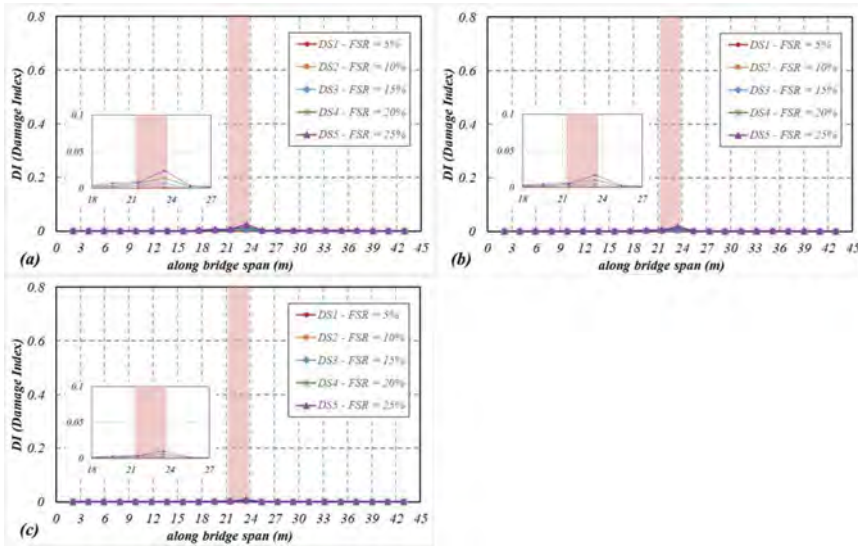

Figure 5. DI values under different damage conditions at the midspan, for the vehicle running at $v = 288 \text{ km/h}$, and under different levels of track irregularities: (a) NC, (b) LD, and (c) HD.

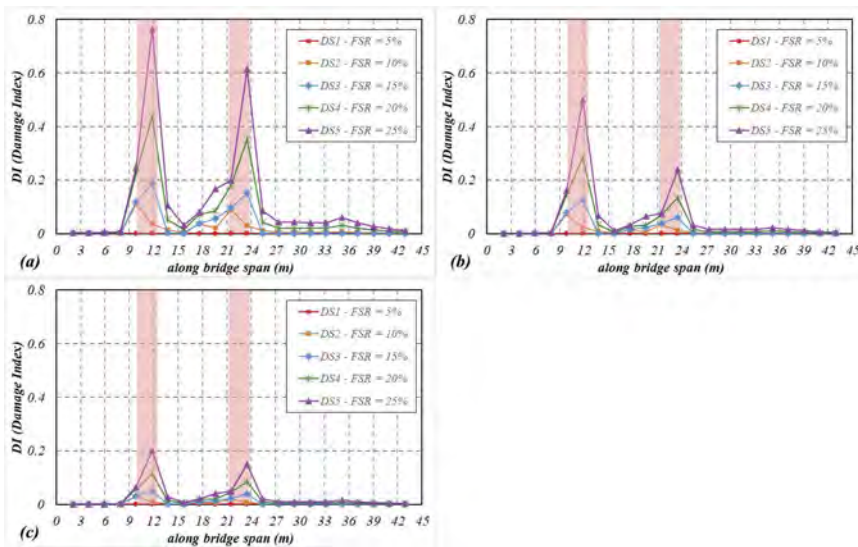

Figure 6. DI values under different damage conditions at the 1/4 of the span and at the midspan, for the vehicle running at $v = 144 \text{ km/h}$, and under different levels of track irregularities: (a) NC, (b) LD, and (c) HD.

4 CONCLUSIONS

This study evaluates the applicability of MFCC to a drive-by approach for HSR bridge deterioration detection. The proposed framework is implemented in MATLAB, and through numerical simulations, damage indices (DI) are extracted from the Root Mean Square Deviation of the MFCC calculated using the recorded vehicle responses when it crosses an undamaged bridge and those obtained when it passes over the structure under induced damage scenarios. Our investigation has led us to the following key findings:

- The MFCC-obtained DI values provided reliable information regarding the location of the damage. Under all conditions, the DI values could reliably indicate the location and severity of the damage.
- The magnitude of the feature generated from MFCC correlates with the speed of the vehicle over the bridge and the degree of track imperfections. The DI values are more sensitive to excitation sources resulting from track imperfections than to those resulting from damage.
- The results reveal that the distribution patterns of DI vary depending on the site of the damage, with a propensity to exhibit peaks close to the damaged zones.

ABSTRACT: The main mechanism of deterioration of reinforced concrete structures is the corrosion of steel reinforcement, and the maintenance and repair of corroded reinforced concrete structures costs billions of dollars per year. Several studies have been proposed with the aim of modeling the behavior of corroded reinforced concrete structures, highlighting the importance of evaluate the uncertainty of the corrosion phenomenon, and the corrosion initiation time and the corrosion rate have a significant impact on the reliability of these structures over time. Corrosion of reinforcements is usually expansive, subjecting the surrounding concrete to tensile stresses that can cause cracking and even spalling of the concrete. Although concrete cracking has an impact on both initiation and propagation of corrosion, few articles consider this effect in corrosion modeling. This article presents a reliability-based evaluation of corroded reinforced concrete structures. In the proposed model, analysis of concrete cracking due to reinforcement corrosion (expansion of steel bars) is carried out in order to update the corrosion propagation model. In the corrosion propagation phase, it is proposed different corrosion rates and compressive resistance of concrete cover, depending on the cracking state of the element. The proposed framework is illustrated on a reinforced concrete railway bridge.

1 INTRODUCTION

The rail network constitutes an important part of the transport infrastructure, and therefore the railway bridges must be maintained in order to guarantee the safety of their operation. The main mechanism of deterioration of reinforced concrete structures is the corrosion of steel reinforcement, and the maintenance and repair of corroded reinforced concrete structures costs billions of dollars per year.

The phenomenon of reinforcement corrosion in RC structures has several uncertainties, being intrinsic to the phenomenon, or contained in the measurement and quantification errors of factors that affect corrosion, as well as in the simulation of the structural behavior (Vatteri et al. 2016). In this way, probabilistic approaches are justified, since deterministic approach can lead to conservative structural responses in order to guarantee structural safety, but end up increasing maintenance costs (Pugliese & Sarno 2022). Furthermore, through probabilistic approach is possible to estimate the probability of failures mode, which is important in asset management.

Corrosion of reinforcements is usually expansive, subjecting the surrounding concrete to tensile stresses that can cause cracking and even spalling of the concrete. The corrosion rate is governed by the availability of water and oxygen at the steel surface (Vu & Stewart 2000) and

the phenomenon of concrete cracking can accelerate the entry of these components through the concrete cover. According to Zhang et al. (2019), the cracking of concrete cover can change the levels of corrosion in the reinforcements, which justifies the study and appropriate consideration of the corrosion rate after concrete cracking.

This article presents a reliability-based evaluation of corroded reinforced concrete structures. In the proposed model, analysis of concrete cracking due to reinforcement corrosion (expansion of steel bars) is carried out in order to update the corrosion propagation model. In the corrosion propagation phase, it is used accelerated corrosion rates and compressive resistance of concrete cover, depending on the cracking state of the element. The proposed framework is illustrated on a reinforced concrete railway bridge.

2 CORROSION MODELING

Corrosion is usually divided into two phases: initiation and propagation of corrosion. In some cases, as in this work, the concrete cracking period is also considered, due to the impact on the corrosion process.

The main effects considered in modeling structures under corrosion are: reduction of the steel area of the longitudinal bars and stirrups; changes in strength, stiffness and ductility of steel bars; changes in the strength and ductility of concrete under compression, due to cracking induced by the expansion of steel bars; deterioration of bond between steel bars and concrete; reduction of concrete confinement by stirrup corrosion.

This article presents the modelling of corroded RC structures through reduction of the steel area of the longitudinal bars, changes in the strength and ductility of concrete under compression, due to cracking induced by the expansion of steel bars, besides considering the acceleration of corrosion rate after concrete cracking.

2.1 Corrosion initiation

The main chemical protection against reinforcement corrosion is due to the high alkalinity of the concrete's interstitial water, due to the presence of calcium hydroxide ($\text{Ca}(\text{OH})_2$), released in cement hydration reactions. In this highly alkaline environment ($\text{pH} > 12.5$), a passivating film, consisting of a thin film of iron oxide (Fe_2O_3), is formed around the steel reinforcement, providing protection against corrosion. This protection is called passivation. The corrosion initiation corresponds to the period of time until the depassivation of the reinforcement.

The two main phenomena that can destabilize this protective film are concrete carbonation and chloride contamination. In this study, the bridge analyzed is located in a region where contamination by chlorides is not important, and the initiation mechanism being analyzed is the carbonation of the concrete.

In concrete carbonation, carbon dioxide presents in the atmosphere, when penetrating the concrete, reacts with hydrated cement compounds, transforming them into carbonates, thus reducing the alkalinity of the concrete.

Yang et al. (2014) presented a model to predict the depth of carbonation in concrete that is used in herein. The depth of carbonation progress (x) is given by:

$$x = \sqrt{\frac{2D_{\text{CO}_2}(t)\text{CO}_2}{a_{\text{CO}_2}} \cdot t} \quad (1)$$

where D_{CO_2} = diffusion coefficient (m^2/s); a_{CO_2} = amount of carbonatable constituents per volume of concrete; CO_2 = concentration of carbon dioxide in kg/m^3 .

The diffusion coefficient (D_{CO_2}) is:

$$D_{\text{CO}_2}(t) = \frac{136.6 \cdot 10^{-4}}{86400} \beta_s \beta_f \beta_h \left(\frac{a}{C}\right)^{0.1} [\varepsilon_p(t)]^2 \quad (2)$$

where β_s is a correction factor for SCMs, β_f is a coefficient related to the finishing materials; β_h is coefficient depending on relative humidity; $\varepsilon_p(t)$ = total porosity of cement; a = aggregate content in concrete (kg/m^3);

2.2 Concrete cracking initiation

Most corrosion products have a volume greater than intact steel reinforcement, that is, as corrosion occurs, due to expansion, the bars exert an internal pressure on the concrete cover, resulting in tensile stresses in the concrete, which can generate cracking of the concrete and even spalling of the concrete cover. In order to analyze the cracking limit state of concrete, and even modify the propagation of concrete after cracking, it is necessary to estimate the time between the onset of corrosion and cracking of the concrete.

El Maaddawy & Soudki (2006) developed a mathematical model in order to estimate the time from the corrosion initiation to concrete cracking, taking into account the internal pressure caused by the expansion of corrosion products. The concrete around corroded reinforcement is modeled as a thick-walled cylinder. The model is validated with experimental results available in the literature and is adopted herein. The expression to evaluate the time from corrosion initiation to concrete cracking (t_{cr}) is given:

$$t_{cr} = \left[\frac{7117.5(D + 2\delta_0)(1 + \nu + \psi)}{iE_{ef}} \right] \left[\frac{2Cf_{ct}}{D} + \frac{2\delta_0 E_{ef}}{(1 + \nu + \psi)(D + 2\delta_0)} \right] \quad (3)$$

where D = diameter of steel reinforcing bar (mm); δ_0 = thickness of porous zone; C = clear concrete cover (mm); ψ = factor depends on D , C and δ_0 ; f_{ct} = tensile strength of concrete; ν = Poisson's ratio of concrete (adopted 0.18); i = current density; E_{ef} = effective elastic modulus of concrete.

2.3 Corrosion propagation

It is possible to quantitatively assess the intensity of corrosion by measuring the flow of electrons or ions, that is, the density of the corrosion current, or just the corrosion current (i_{corr}). In this study, as carbonation corrosion is adopted, the corrosion considered will be uniform. For this purpose, based on the numerical corrosion propagation model proposed by Ghods et al. (2007), Ghods et al. (2008) developed a simplified model for determining the corrosion current that has more easily measurable input parameters, with experimental validation of the results obtained, that is adopted herein, which is given by the following expression:

$$i_{corr} = -3,7 \cdot 10^{-3} + \frac{5,06}{\rho} + \left(\frac{0,333}{\rho} - 3,83 \cdot 10^{-4} \right) \ln \left(\frac{D_{O_2} CsO_2}{c} \right) \quad (4)$$

where i_{corr} = corrosion current density (A/m^2), ρ is concrete resistivity ($\Omega.m$); c is the concrete cover (m); D_{O_2} is the oxygen diffusion coefficient (m^2/s); CsO_2 = dissolved oxygen concentration in pore water at the concrete surface (kg/m^3).

In order to estimate the resistivity of concrete (ρ), the mathematical model proposed by Zhang et al. (2021) is adopted herein

As the corrosion current varies after concrete cracking, the diameter of the steel bar $D(t)$, for the uniform corrosion model, is given (in mm), at time t , depending on the different time intervals as:

$$D(t) = \begin{cases} D_0 - 0,0232 \int_0^{t_{dep}+t} i_{corr}(t) dt, & \text{if } t_{dep} \leq t \leq t_{cr} \\ D_0 - 0,0232 \int_0^{t_{dep}} i_{corr}(t) dt - 0,0232 \int_{t_{dep}}^t k_{ac} i_{corr}(t) dt, & \text{if } t \geq t_{cr} \end{cases} \quad (5)$$

where D_0 is the initial diameter of the steel bar (mm); and i_{corr} is the current of corrosion ($\mu A/cm^2$), t_{dep} = time until depassivation or time to corrosion initiation, t_{cr} = time between corrosion initiation and concrete cracking; k_{ac} = acceleration corrosion coefficient after concrete cracking.

According to Ma et al. (2015), the corrosion rate increases as concrete cracking increases, however the quantification of the impact on corrosion is difficult, with epistemic uncertainty

in the acceleration coefficient (k_{ac}). Thus, the coefficient of acceleration is considered a random variable, with a normal distribution of mean 2.0 and coefficient of variation 0.25.

2.4 Effect of corrosion on concrete compressive strength

The concrete cracking or even the delamination of the concrete cover, in addition to facilitating the ingress of water and oxygen, which can accelerate the corrosion process of the reinforcements, can reduce the resistance of concrete cover, thus also reducing the resistance capacity of the structural element. In this study, this effect is considered through the model proposed by Coronelli & Gambarova (2004), who proposed the reduction of the cover concrete to compression, dependent on the magnitude of the average tensile strain in the transverse direction, based on modified compressive field theory of Vecchio & Collins (1986). The reduced concrete strength ($f_{c,red}$) proposed is adopted in this study and the equation is shown below:

$$f_{c,red} = \frac{f_c}{1 + K \frac{\varepsilon_1}{\varepsilon_{c0}}} \quad (6)$$

where K = coefficient related to bar roughness; ε_{c0} = strain at the peak compressive stress; f_c = concrete strength of intact concrete; ε_1 = average smeared tensile strain in the cracked concrete at right angles to the direction of the applied compression.

3 RELIABILITY ASSESSMENT

In structural reliability analysis, the safety and functionality of the structure can be evaluated by the probability of violation of ultimate and service limit states of a given structural element or of the entire structure, during its period of use. This type of analysis can be used for designing new structures or even for assessing the state of deterioration of existing structures.

3.1 Limits states

The limit states, or even the failure modes and loss of functionality of structures and structural elements can be quantified through equations called limit state equations. For each limit state of the structure, a limit state equation, $g(\mathbf{X})$, is written as a function of the random variables (\mathbf{X}):

$$g(\mathbf{X}) = g(\mathbf{X}_R, \mathbf{X}_S) = 0 \quad (7)$$

where \mathbf{X}_R and \mathbf{X}_S = vectors that describe the random variables associated with resistance and loading, respectively.

In this study, the functionality and safety of the bridge are analyzed by evaluating the main girder of the bridge. The service condition of the bridge is assessed in terms of cracking of the concrete and the safety condition is obtained from the flexural capacity of the beam, which is usually the critical limit state.

In determining the flexural capacity of the beam, the theory of Euler-Bernoulli is considered. The calculation of the resistant moment is obtained by continuously increasing the curvature of the section until crushing of the concrete or excessive deformation of the steel. The Fiber Method is adopted to compute the resulting forces across the section. The stress-strain ratio of the concrete used was that of the Brazilian standard NBR 6118 (2014), ignoring the contribution of concrete in tension. Steel was modeled as perfect elasto-plastic.

3.2 Monte Carlo simulation

The determination of the probability of failure and the reliability index can be obtained through simulation methods where the most used is the Monte Carlo simulation method, however its computational cost is high. In the Monte Carlo method, a finitely high number of simulations is performed, where in each simulation the model variables assume certain values, which are obtained using the probability distributions of the random variables.

In this study, the random variables are determined with Latin Hypercube Sampling. At each simulation, a set of random variables is obtained, which is then used to calculate each limit state. The time dependency is handled by discretizing the lifetime of the structure year by year.

3.3 Traffic loading

As the case study of this article refers to a railway bridge, and the structural element analyzed is the main beam of the bridge, a methodology for determining the maximum annual bending moment must be obtained. The monitoring of the train crossing over the bridge was carried out by measuring the wheel load, during different intervals over the course of a year.

Thus, from the data set obtained, statistics for wheel load were adjusted. From the wheel load statistics and the number of trains passes over a year, it was possible to numerically obtain the maximum annual bending moment and adjust a distribution of extreme values, which was then adopted in this study. The maximum annual bending moment due to train's passage was adjusted by a Gumbel distribution with $\mu_n = 2380$ kNm and $\beta = 1.02e-04$.

4 CASE STUDY

In order to apply the presented methodology, a railway bridge, designed in 1972, was used as a case study. The railway bridge has three simply supported spans of 18.67 m each, with a cross section of two beams. This bridge is mainly responsible for transporting iron ore.

Figure 1. Geometry of girder transversal section, units in cm.

The following table presents the random variables and their respective adopted probability distributions. In order to determine the variables related to environmental conditions, data were obtained from the meteorological station near the bridge in question, available at INMET (2022).

The other statistics related to the geometry of the bridge and the materials used were obtained through the structural design of the bridge and recommendations available in the literature (Beck 2019, Santiago 2019, Morales 2017, Rocha et al. 2015, JCSS 2001).

Table 1. Distribution of random variables.

Variable	Distribution	Parameters
Concrete strength (f_c)	Normal	$\mu = 23.4$ MPa, $\sigma = 4.68$ MPa
Steel yield strength (f_y)	Normal	$\mu = 610$ MPa, $\sigma = 24.4$ MPa
Concrete specific mass	Normal	$\mu = 2500$ kg/m ³ , $\sigma = 125$ kg/m ³
Nominal cover (c)	Lognormal	$\mu = 3$ cm, $\sigma = 1$ cm
Relative humidity (RH)	Normal	$\mu = 72.64\%$, $\sigma = 4.68\%$
Temperature (T)	Normal	$\mu = 24.11$ °C, $\sigma = 0.81$ °C
CO ₂ concentration (CO ₂)	Normal	$\mu = 0.82$ g/m ³ , $\sigma = 0.1$ g/m ³
Resistance model error	Lognormal	$\mu = 1.2$, $\sigma = 0.18$
Load model error	Lognormal	$\mu = 1.0$, $\sigma = 0.1$

The number of simulations in Monte Carlo Simulation was adopted 200000. The high number of simulations was adopted due to the complexity of the analysis of the resistance to bending, in order to guarantee the adequate convergence of the method.

Figures 2 and 3 below show the histogram of the depassivation time and corrosion current, which directly impact the period of initiation and propagation of corrosion, respectively.

As for the depassivation time, it is possible to notice that the number of simulations grows gradually until the depassivation time is close to 30 years, after which it starts to fall. This information shows the importance of considering corrosion for evaluating the bridge in question.

Regarding the intensity of the corrosion current, it is noted that most of the simulations present values close to 1, however, higher values can be found, and this should contribute to the probability of failure. It is important to point out that these corrosion current values do not yet consider the possibility of corrosion acceleration over time, depending on the cracking of the concrete.

Figure 2. Depassivation time histogram (time in years).

Figure 3. Corrosion rate histogram (corrosion current in $\mu\text{A}/\text{cm}^2$).

The following figure shows the reliability index over time for the service limit state of concrete cracking, due to expansion of the bars by corrosion. In analysis regarding the cracking service limit state of concrete, low reliability index results were obtained, being approximately equal to 2.0 in 10 years and equal to zero (failure probability equal to 50%), in less than 80 years. The explanation for the rapid deterioration of the concrete cover can be explained by the reduced cover used in the structural design.

It is also worth noting that although some authors consider only depassivation or concrete cracking as a limit state, the resistance capacity of structural elements, in general, is much higher than the service limit and the determination of the ultimate limit state can introduce relevant information to inspection, monitoring and intervention.

Figure 4. Reliability index for concrete cracking (service limit state).

Thus, Figure 5 presents the reliability index over time for the limit state related to the flexural capacity of the bridge's main girder.

In order to analyze the effect of cracking on the resistance capacity of the beam, due to the increase in corrosion and the reduction in the strength of the covering concrete after cracking, four models were built, with and without such effects. In model 1, the element strength was analyzed without increasing the corrosion rate and without loss of compressive strength of the cover concrete. In model 2, with an increase in the corrosion rate and without loss of compressive strength of the covering concrete. In model 3, without an increase in the corrosion rate and with loss of compressive strength of the covering concrete. Finally, in model 4, an increase in the corrosion rate and loss of compressive strength of the cover concrete was considered simultaneously.

Figure 5. Reliability index for flexural capacity (safety limit state).

From the results of the reliability index related to bending, it is possible to analyze the impact of the effect of the acceleration of corrosion and reduction of the compressive strength of the cover after cracking.

In the analyzed example, the acceleration of corrosion had a significant impact, noting the different response in relation to models 1 and 2. However, the reduction of the compressive strength of the cover concrete did not present a significant difference, noting a small difference of response between models 1 and 3 and between models 2 and 4. This small difference can be explained by the slenderness of the cross-section (30x195 cm) and the small cover of the example in question, which corresponds to approximately only 1.5% of the total height. It can also be emphasized that this

difference is within the margin of error of the fiber method and the Monte Carlo method itself, which even with a relatively high number of simulations, still presented convergence difficulties.

5 CONCLUSIONS

The evaluation methodology of a reinforced concrete bridge subjected to reinforcement corrosion and concrete cracking was presented and applied in a real example, and can also be applied in other types of structures.

Concrete carbonation as a phenomenon of reinforcement depassivation was considered in the proposed methodology, although concrete cracking due to service loads was not considered, which could further accelerate the initiation process and consequently the deterioration of the structure by corrosion.

Through the analysis carried out, it was possible to notice that the impact of corrosion acceleration due to concrete cracking on the structural element's resistance capacity can be relevant and studies regarding the measurement of this acceleration coefficient are still quite scarce.

Although in the analyzed example the impact of reducing the compressive strength of the concrete cover was very small, it cannot be concluded that this effect can be neglected in all cases. Other examples, such as columns or beams with greater width, should be studied in order to understand the impact of this phenomenon on different corroded reinforced concrete structures.

ABSTRACT: High-speed railways (HSR) are considered a reliable and efficient means of transportation which, combined with the capability of on-schedule attendance, emerges as a very competitive transportation system. These advantages have led to the rapid expansion of highway networks and the growing demand for higher operational speeds. In the design and operation context, HSR bridge dynamic analysis is thought to be a crucial element and, in most applications, the moving load method has been utilized for this purpose. However, for short and medium-span bridges, this method tends to be over-conservative, and the interaction between train and bridge considerably influences the accuracy of the bridge responses. Although several efforts have been dedicated to developing enhanced methodologies for the proper modeling of vehicle-bridge interaction (VBI), only a few studies have considered the uncertainties in material properties, geometry, and loading conditions. The acknowledgment of such uncertainties as an integrating part of the dynamic analysis may enhance the response prediction of the bridge, which enables the understanding of the probability of adverse outcomes due to excessive vertical accelerations of the deck. Loss of interlock among ballast grains, which degrades the rail stability, and the loss of wheel-rail contact, are examples of problematic performances of the bridge in such circumstances. In this study, the dynamic responses of a simply supported bridge are evaluated utilizing a 2-D VBI model, accounting for the influence of the passage of a high-speed train.

1 INTRODUCTION

High-speed railways (HSR) are considered a reliable and efficient means of transportation, which combined with the capability of on-schedule attendance, results in a very competitive transportation system. These advantages have led to the rapid expansion of highway networks and the growing demand for higher operational speeds (Rocha et al. 2014). Thus, as the construction of new high-speed lines and the retrofit of conventional ones for high-speed purposes have increased in recent years, the dynamic behavior of railway bridges has been subject of many research works (Johansson et al. 2014, Lu et al. 2012, Mellat et al. 2014, Moliner et al. 2012, Zeng et al., 2016).

In particular, the demand for bridges and viaducts along a high-speed railway is significantly greater relative to conventional railways, due to the inherent strict design criteria, resultant of large radii curves, and fully closed operation requisites. In France, the total bridge length of the lines of TGV Southeast Line from Paris to Lyon, TGV Northern Line from Paris to Lille, and TGV South-East Extension Line from Lyon to Valence hold the percentage of 6%, 21.5% and 32.2% of the railway extension, respectively (Guo et al. 2012).

In this context, the bridge's dynamic response is a design aspect that is not only related to the bridge's structural safety but overall railway line functionality. The moving loads

originated from the passing trains over the bridge induce a periodical excitation due to the regular axle spacing. Depending on the train velocity, the periodical load frequency may coincide with the structure's natural frequencies, causing a resonance phenomenon, with the amplification of the dynamic responses of the bridge. In this regard, the most critical configurations are the simply supported short-to-medium-span bridges (Moliner et al. 2012). In most design and operation applications, the moving load method has been utilized for assessing the HSR bridge dynamics. However, for short and medium-span bridges, this method tends to be over-conservative, and the interaction between train and bridge has a considerable influence on the accuracy of the bridge responses, thus justifying the recent efforts in the development of vehicle-bridge interaction (VBI) models (Rocha et al. 2014).

The amplification of the dynamic responses leads to high levels of deck's vertical acceleration which can cause adverse consequences concerning the train running safety and serviceability, such as ballast destabilization, loss of wheel-rail contact, increased fatigue-related damage, passenger discomfort, and higher risk of derailment due to the loss of the rail stability (Bebiano et al. 2017, Galvín et al. 2018, Rocha et al. 2012). The European Standard Eurocode (2003) limits the vertical acceleration of the deck at 3.5 m/s^2 for ballasted tracks and 5.0 m/s^2 for ballastless tracks. In the circumstances where the limit is reached, the deck must be stiffened or replaced.

Although the existence of uncertainties in the system is well acknowledged, most studies have conducted the dynamic analysis in a deterministic manner, disregarding all randomness involved with the parameters of both the structural system and vehicle. Nevertheless, uncertainties are intrinsic to the entire system, due to track irregularities, random material properties, and geometry in various manufacturing conditions, as well as load characteristics. Therefore, it is sensible to address the uncertainties of the parameters by employing a probabilistic approach (Liu et al. 2020, Mao et al. 2016, Rakoczy & Nowak 2014). Rocha et al. (2012), studied the safety of a filler beam railway bridge subjected to the passage of a deterministic TGV double high-speed train considering the uncertainties in the structure parameters. The variability of the bridge, track, and train was accounted for by Rocha et al. (2014), as well as track irregularities. Different methods for the safety assessment of railway bridges for high-speed trains were compared by Rocha et al. (2015), including the Monte Carlo Simulation and Latin Hypercube Sampling combined with a tail modeling method and an enhanced simulation procedure. In a similar context, laboratory tests were used by Matos et al. (2019) to update the structure model and compute the structural reliability. An application of robust design optimization of Tuned-Mass-Dampers and Multiple-Tuned-Mass-Dampers to vehicle-bridge coupled vibration problems was presented by Miguel et al. (2016). Parameters of bridge materials, environmental factors, and prestressing were considered by Liu et al. (2019). Both train and structure uncertainties were considered by Liu et al. (2020) and Mao et al. (2016) in a train-bridge coupled system analysis; and Gaussian random processes for the bridge and load characteristics were utilized by Wu and Law (2010).

This work aims to demonstrate the utilization of a VBI model in a structural reliability analysis of a simply supported bridge subjected to the passage of a Siemens ICE3 Velaro high-speed train, regarding the levels of vertical acceleration of the deck and considering uncertainties of both structure and vehicle.

2 VEHICLE-BRIDGE DYNAMIC INTERACTION SYSTEM

Vibrations caused by the passing trains can seriously impair the functionality of the track and bridge structures. In turn, the track and bridge's dynamic behaviors can influence the trains' dynamic performance. Therefore, in a comprehensive analysis, the train, track, and bridge must all be taken into account as a coupled system and analyzed simultaneously, thus enabling to identify the dynamic performance and service life of the train-track-bridge system (Zhai et al. 2019).

In general, in train-bridge dynamic interaction models, the bridge subsystem modeling utilizes Finite Element Method (FEM) or continuous beam theories, whereas the theory of multi-body system dynamics is adopted to establish the moving vehicle subsystem (Iwnicki et al. 2019, Zhai et al. 2013). This section describes the 2-dimensional VBI model used in the present

study to numerically simulate a high-speed train response to a bridge crossing event, which is regarded as an entire dynamic system in the derived dynamic governing equilibrium equations of motion. Despite the simplifications, plane VBI systems can satisfactorily predict the vertical dynamic response (Nguyen et al. 2014, Quirke et al. 2017), and the vehicle model presented as follows is widely used in the literature (Azimi 2011, Azimi et al. 2013, Ferrara 2013, Koç 2021, König et al. 2021, de Miguel et al. 2019, Youcef et al. 2013, Yu et al. 2018).

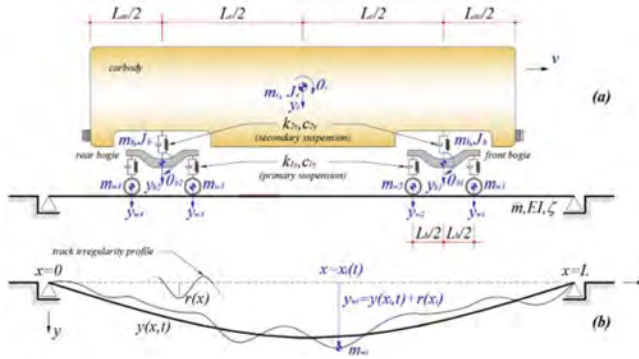

Figure 1. 2-D vehicle-bridge dynamic interaction system: (a) vehicle model and (b) bridge model.

2.1 Vehicle model

The multi-rigid-body vehicle model utilized for analysis is schematically described in Figure 1.a). It is considered a train constituted of N_c independent vehicles that crosses the bridge at a constant speed v . As the focus lies in evaluating the effect of resonance due to the periodical excitation induced by the train passage, each locomotive or wagon consists of a carbody, two bogies, four wheelsets, and the spring and damping connections between the components. The carbody and bogie frames were modeled as rigid bodies with concentrated masses given respectively by m_c and m_b , and rotary inertias J_c and J_b , taken about the transverse horizontal axis through its center of gravity. The wheelsets were represented as lumped masses m_w connected to the bogie frames by means of spring-dashpot sets representing the primary suspension with spring stiffness k_{1y} , and damping coefficient c_{1y} . Bogie frames are coupled to the carbody by spring-dashpot sets with spring stiffness k_{2y} , and damping coefficient c_{2y} , representing the secondary suspension system.

2.2 Bridge model

The bridge deck of the HSR has been modeled as a simply supported Bernoulli-Euler beam (Figure 1.b) with a mass per unit length of \bar{m} , Young's modulus E , moment of inertia I , and equivalent damping coefficient c . It was assumed that the downward deflection of the beam $y(x,t)$ is positive, as well as the rail irregularities $r(x)$ at the x -coordinate, taken into account by introducing random irregularity profile functions on the beam surface. Both deflection of the beam and track irregularities are measured relative to the beam's vertical static equilibrium locations (mean horizontal axle). The vertical deflection $y(x,t)$ of the beam is given by

$$y(x,t) = \sum_{i=1}^n A_i(t) \sin(i\pi x/L), \quad (1)$$

in which $A_i(t)$ is the amplitude of the i th shape mode at the instant t , i is the number of half-waves in which the beam is partitioned, n is the total number of modes, and L is the beam length.

2.3 Kinematic restrictions

Altogether, the vehicle model has 10 degrees of freedom (DOFs). However, it was imposed that each train's axle is kinematically constrained to the bridge deck to establish the dynamic

interaction on the VBI model (Lou & Zeng 2007) – the reaction forces of the structure are transmitted to the vehicle’s axles and vice versa (Quirke et al. 2017). Thus, the vehicle’s motion can be described by six independent DOFs (y_c , y_{b1} , y_{b2} , θ_c , θ_{b1} , and θ_{b2}), once the wheelset’s vertical displacements are constrained by the bridge displacements at the contact point between them (Figure 1.b) by the constraint equations

$$y_{wk}(x_k, t) = y(x_k, t) + r(x_k), \quad k = 1, \dots, 4. \quad (2)$$

For the numerical simulations, the vertical track profiles along the bridge’s length with random vertical irregularities were generated using a random function $r(x)$ of zero expectance and constant variance presented by Podworna (2015) and expressed by a trigonometry series as

$$r(x) = 2 \sum_{j=1}^N \sqrt{S(\Omega_j) \Delta\Omega} \cos(\Omega_j x + \phi_j), \quad (3)$$

where ϕ_j is a random phase with uniform distribution in $[0, 2\pi \text{ rad}]$, $S(\Omega_j)$ is the power spectral density (PSD) function evaluated in the j th spatial frequency Ω_j (rad/m) of the discrete domain $\Omega_j = \Omega_l + (j - 1/2)\Delta\Omega$, with $j = 1, 2, \dots, N$, and whose frequency band $\Delta\Omega = (\Omega_c - \Omega_r)/N$ is defined by the lower and upper limits spatial frequencies, respectively $\Omega_l = 2\pi L_{r,max}$ and $\Omega_u = 2\pi L_{r,min}$, and by the wavelength range $[L_{r,min}, L_{r,max}]$ in which the PSD function is included. The German PSD function has been used, which is written by

$$S_V(\Omega) = \frac{A_V \Omega_c^2}{(\Omega^2 + \Omega_r^2)(\Omega^2 + \Omega_c^2)}, \quad (4)$$

where $\Omega_c = 0.8246$ rad/m and $\Omega_r = 0.0206$ rad/m are the cut-off frequencies and A_V is the roughness constant (Zhai 2020).

2.4 Equations of motion for the VBI system

By using the Lagrange’s equation, the equations of motion for the VBI system have been derived and written in matrix form as

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{C}\dot{\mathbf{u}} + \mathbf{K}\mathbf{u} = \mathbf{F}, \quad (5)$$

where \mathbf{M} , \mathbf{C} , and \mathbf{K} are the mass, damping, and stiffness time-dependent global matrices, and $\ddot{\mathbf{u}}$, $\dot{\mathbf{u}}$, \mathbf{u} , and \mathbf{F} are the acceleration, velocity, displacement, and load global vectors, respectively.

3 STRUCTURE RELIABILITY ANALYSIS

The probability of failure of a structure can be understood as the susceptibility of the violation of a limit state. On the other hand, the structural reliability expresses the level of confidence that the requisites concerning the performance of a structure will be kept, while the service life and design conditions are respected (Beck 2019). Usually, the structure behavior can be described by a limit state, which can be written as a function $g(\mathbf{X})$ of the random variables including the ones associated with the geometry and material properties, resistance, and actions:

$$g(\mathbf{X}) = g(X_1, X_2, \dots, X_n). \quad (6)$$

The equation $g(\mathbf{X}) = 0$ establishes the threshold between the failure domain $\Omega_f = \{\mathbf{x} | g(\mathbf{x}) \leq 0\}$ and the safety domain, and the failure probability can be expressed as

$$p_f = P[\{g(\mathbf{X}) \leq 0\}] = \Phi(-\beta) = \int_{\Omega_f} f_X(\mathbf{x}) d\mathbf{x}, \quad (7)$$

where $f_X(\mathbf{x})$ is the probability density function of the random variables in $g(\mathbf{X})$. The reliability index β is taken as a quantitative measure of the reliability of a structure (Šomodíková et al. 2016).

4 METHODOLOGY

The idealized structure under study is a ballasted prestressed voided slab bridge, constituted of a single simply supported span of 27m. The bridge characteristics are summarized in Table 1, as well as Figure 2. To elaborate the cross-section properties, the dimensions as in Aparicio (2009) were taken as reference.

Vehicle properties were assumed for the Siemens ICE3 Velaro High-Speed Train (Quirke et al. 2017) and are listed in Table 2, according to the uncertainties suggested by Salcher et al. (2016), except for the occupancy rate, adjusted to the statistics made available by the International Union of Rails (2020). The track irregularities with random roughness constant are considered in the path traveled by the train along the bridge's length.

Table 1. Variables for the bridge model.

Variable	Type	Distribution	Value/ parameters	Ref.
Cross-section area	Deterministic	-	5.5799 m ²	-
Inertia	Deterministic	-	2.2767 m ⁴	-
Concrete specific weight	Random	Gaussian	$\mu = 2625 \text{ kgf/m}^3$, $\sigma = 262.5 \text{ kgf/m}^3$	(Morales 2017)
Ballast specific weight	Random	Uniform	$a = 1500 \text{ kgf/m}^3$, $b = 2000 \text{ kgf/m}^3$	(Rocha et al. 2015)
Concrete compressive strength	Random	Gaussian	$\mu = 44.8 \text{ MPa}$, $\sigma = 4.48 \text{ MPa}$	(Santiago & Beck 2017)
Damping ratio	Random	Gaussian	$\mu = 2\%$, $\sigma = 0.3\%$	(Rocha et al. 2015)
Roughness constant	Random	Uniform	$a = 0.592 \times 10^{-6}$ rad m $b = 1.009 \times 10^{-6} \text{ rad m}$	(Salcher et al. 2016)

Figure 2. Typical cross-section dimensions for analysis.

Table 2. Vehicle properties.

Variable	Distribution	Value
Carbody mass	Gaussian	$\mu = 47800 \text{ kg}$, $\sigma = 478 \text{ kg}$
Bogie mass	Gaussian	$\mu = 3500 \text{ kg}$, $\sigma = 35 \text{ kg}$
Wheelset mass	Gaussian	$\mu = 1800 \text{ kg}$, $\sigma = 18 \text{ kg}$
Carbody rotary inertia	Gaussian	$\mu = 1.96 \times 10^6 \text{ kg m}^2$, $\sigma = 1.96 \times 10^4 \text{ kg m}^2$
Bogie rotary inertia	Gaussian	$\mu = 1715 \text{ kg m}^2$, $\sigma = 17.15 \text{ kg m}^2$
Primary suspension stiffness	Gaussian	$\mu = 2.40 \times 10^6 \text{ N/m}$, $\sigma = 2.40 \times 10^5 \text{ N/m}$
Secondary suspension stiffness	Gaussian	$\mu = 7.00 \times 10^5 \text{ N/m}$, $\sigma = 7.00 \times 10^4 \text{ N/m}$
Primary suspension damping	Gaussian	$\mu = 2.00 \times 10^4 \text{ N.s/m}$, $\sigma = 2.00 \times 10^3 \text{ N.s/m}$
Secondary suspension damping	Gaussian	$\mu = 4.00 \times 10^4 \text{ N.s/m}$, $\sigma = 4.00 \times 10^3 \text{ N.s/m}$
Occupancy rate	Beta	$\mu = 0.627$ $\sigma = 0.07$

The reliability analysis has been conducted through simulation using Latin Hypercube Sampling. The safety criterion adopted herein is controlled by the levels of vertical acceleration of the bridge's deck. Above the level of 7 m/s^2 the ballast layer may experience the loss of interlock between ballast grains, thus leading to the loss of lateral resistance of the sleepers, and thus characterizing the failure of the structure (Zacher & Baeßler 2009).

5 RESULTS

The adopted model proved suitable for simulations since the continuous beam model reduced the number of DOFs to be evaluated in each dynamic analysis, resulting in a significant reduction in overall computing time when compared to finite element models.

The histograms for the deck's vertical acceleration according to the train speed can be observed in Figure 3.a) for 290 km/h, 320 km/h, and 350 km/h.

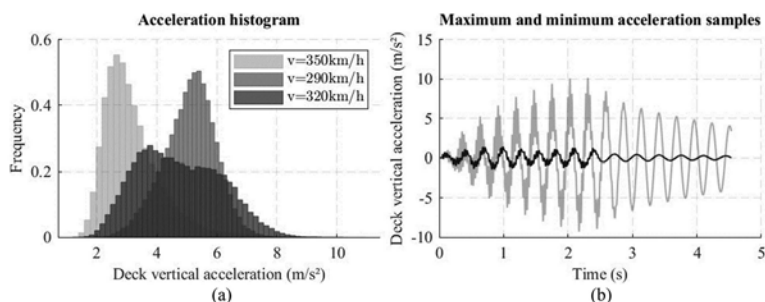

Figure 3. (a) Deck's vertical acceleration histograms; (b) Maximum (grey) and minimum (black) acceleration samples for the train speed of 320km/h.

Figure 3.b) compares two distinct samples for the vertical accelerations at deck's mid-span for a fixed train speed of 320 km/h. This result shows that the dynamic responses are susceptible to changes when the uncertainties are addressed and may deviate considerably from a deterministic analysis. The vertical accelerations of the deck proved to be equally sensitive to the train speed changes, once the train speed interval of 10 km/h induced visible impacts on the response values.

In Figure 4.a), the failure probabilities for all evaluated cases are described. The dynamic responses evaluated at the mean value of the random parameters are also presented in Figure 4.b) for comparative purposes. It is observed that the introduction of uncertainties in the dynamic analysis can cause a shift in the maximum resonant response, as for the proposed example the maximum response evaluated at mean values was registered for the speed of 300 km/h, which does not correspond to the train speed associated with the minimum reliability index (320 km/h).

Figure 4. (a) Failure probabilities according to train speed; (b) Reliability index and acceleration at parameters' mean values according to train speed.

6 CONCLUSIONS

This paper aimed at evaluating the structural reliability of the dynamic response of a simply supported bridge subjected to the passage of a high-speed train. For this purpose, a VBI model along with simulation through Latin Hypercube Sampling was implemented.

The model proved to be efficient for the proposed evaluation, although with more refined evaluations and to smaller failure probabilities the number of required simulations may become computationally expensive.

The results showed that the dynamic responses are directly influenced by the presence of uncertainties, and that the failure probabilities can exhibit significant variation within the examined range of velocities. In addition, the inclusion of uncertainties in the analysis led to a change in the train speed at which the maximum resonant response occurred, when compared to the same dynamic evaluation performed at the mean values of the random variables.

Resilience and the use of life-cycle cost analysis in civil engineering in the US

T. Neimeyer, B. Parsons & L. Champion

American Society of Civil Engineers, Reston, VA, USA

A. Kane

Institute for Sustainable Infrastructure, Washington, DC, USA

L. Orsenigo

ICMQ, Milan, Italy

ABSTRACT: This presentation will combine the efforts of the American Society of Civil Engineers (ASCE) and the Institute for Sustainable Infrastructure (ISI) to promote resilience and the use of life-cycle Cost Analysis in Civil Engineering in the US. ASCE's Committee on Sustainability (COS) is working on a US Standard (ASCE 73-xx) or Manual of Practice for sustainable infrastructure and the Standard or Manual has many references and ties to resilience and life-cycle cost analysis. Additionally, ASCE's Structural Engineering Institute has been working on sustainability through their SE 2050 initiative. ASCE's Grand Challenge for the Society is to reduce the life cycle cost of infrastructure projects by 50% by 2025 and steps taken to achieve this will be described.

ISI's Envision infrastructure rating tool has many ties to life-cycle cost analysis and resilience that would help a project achieve Verified, Silver, Gold, or Platinum awards. Three example projects in the US will be highlighted. Within the Envision tool, credit is given in several of its sections, and specifically, Credit LD3.3-Conduct a Life-Cycle Economic Evaluation as well as six (6) sections on resilience. ISI partnered with ICMQ to establish Envision in Italy and now has over 6 Envision awarded projects and over 300 people who have achieved ENV SP status in Italy. Two (2) example projects in Italy will be highlighted with a connection to resilience and life-cycle civil engineering.

1 INTRODUCTION

Two national societies based in the United States have taken on the challenge of pushing life cycle cost analysis, resiliency and sustainability for civil engineering infrastructure projects. They are the American Society of Civil Engineers (ASCE) and the Institute for Sustainable Infrastructure (ISI). This paper will describe their efforts and will give example projects that demonstrate resilience and sustainability. In addition, ISI has expanded its growth internationally and Italy will be hi-lighted for its efforts in using the Envision infrastructure rating tool.

2 ASCE

ASCE is the oldest of all American engineering societies having been founded in 1852. It has a robust membership of approximately 151,000 with locations all around the world. Within ASCE, there are nine technical Institutes, and we will be using the Structural Engineers Institute (SEI) to show what efforts are being made on Life Cycle Cost Analysis and sustainability as it relates to reduction of embodied carbon. Also, ASCE has many Committees that further their

efforts. Three committees specifically work on resiliency and sustainability. They are the Committee on Sustainability (COS), Infrastructure Resiliency Division (IRD) and the Committee on Adapting to Climate Change (CACC). To show ASCE's commitment to sustainability and resilience, you can look directly to their newly adopted code of ethics updated on October 26, 2020. Within the code of ethics, under the Natural and Built Environment, it is specifically stated that "Engineers adhere to the principles of sustainable development" as well as "Engineers mitigate adverse societal, environmental, and economic effects". These statements in the code of ethics demonstrate that ASCE is committed to sustainability and resilience.

In October of 2022, ASCE adopted a new strategic plan that will guide the Society's efforts over the next five (5) years. Within the Plan's strategic shifts section, it is clearly stated that "Innovate. Drive creative development and renewal of future-ready, safe, sustainable, equitable, robust, and resilient infrastructure". This guiding document empowers the Institutes and Committees of ASCE to develop sustainable and resilient infrastructure within their programs. The Committee on Sustainability has gone as far as proposing a performance-based Standard or Manual of Practice for Sustainable Infrastructure that is currently in the review and appeals process.

3 ASCE INDUSTRY LEADERS COUNCIL

ASCE has an advisory council to the ASCE Executive Director, and the Board of Direction known as the Industry Leaders Council (ILC). In July 2014, the ILC proposed that ASCE undertake a grand challenge of reducing the life cycle cost of infrastructure by 50% by 2025 and fostering the optimization of infrastructure investments for society. Within this grand challenge, there were four pillars of execution: 1. Life Cycle Cost Analysis, 2. Resilience, 3. Innovation and 4. Performance Based Standards for Design. The ASCE Board approved the grand challenge for incorporation throughout the Society. ASCE then commissioned the ENO Center for Transportation to publish a report on Maximizing the Value of Investments using Life Cycle Cost Analysis (LCCA). What the report noted was that the concept of life cycle cost analysis has many interpretations which make reporting and analyzing on LCCA progress from a national perspective almost impossible. Additionally, the report noted that while nearly all respondents to a survey on LCCA agreed that LCCA should be a part of the decision-making process, only 59% said they currently employ some form of it. Though the Grand Challenge held promise, the idea of measuring it on a national level did not. Nonetheless, the idea of increasing the use of LCCA began to take hold. One major infrastructure owner, the Port Authority of New York and New Jersey, requires LCCA to be used on most projects more than \$2.5 million in construction costs and has even developed a 12-page guide detailing how to apply LCCA while recognizing that its use was too costly on smaller projects. Other case studies in the ENO report included infrastructure owners from the US Army Corps of Engineers, the North Carolina and Pennsylvania Departments of Transportation, Denver's Regional Transit District, and the Metropolitan Transportation Commission for the San Francisco Bay Area.

While LCCA makes sense from a value viewpoint, many infrastructure owners have constrained budgets and are subject to four-year political election cycles. Though a project may have lower life cycle costs when including operations, maintenance and de-commissioning, the initial capital cost may be higher. If you only have limited budgets, you may make a less than optimal decision to take a lower up-front initial cost in order to do more projects. In doing so, you please the political stakeholders with more ribbon cuttings, while saddling future stakeholders with higher life cycle costs.

In 2015, ASCE engaged Lehigh University to undertake a survey of its membership entitled "Utilization of Life-Cycle Cost Analysis (LCCA) and Performance Based Design (PBD) for New and Existing Infrastructure". The conclusion stated "Overall, this report serves as baseline documentation describing the current use of LCCA and PBD strategies in the civil infrastructure sectors based upon the responses received from 67 survey participants. Several infrastructure sectors were polled in this study. Among the participants in the survey, most are focused on highways, buildings, and bridges; however, other infrastructure sectors such as the pipeline, fresh and wastewater systems, ports and waterways, transit, and rail industries are also represented among the responses. The most common professions polled were

professors, structural engineers, design engineers, project managers, and consultants. Accordingly, survey participants work for universities, engineering consultants, and government organizations. A majority of respondents work in the private sector and of those who work in the public sector, a majority indicated that their organization functions at the federal and state levels. Based on the survey results, it is concluded that life-cycle cost analysis is held in high regard and is of vital importance to most infrastructure sectors. A small percentage indicated that no official guidelines are employed, and that life-cycle analysis and management processes are only cost driven. More professionals use LCCA to evaluate different life-cycle management alternatives and design systems than those who do not, and among those who use LCCA methodologies, most indicated they use LCCA in the design and planning phase for new structures. Regarding the implementation of LCCA with respect to newly designed structures/systems, most said that there are no official guidelines (e.g., codes, standards, regulatory requirements) in their infrastructure sector. Furthermore, besides official guidelines, a majority of the time, engineering judgement is utilized to conduct LCCA regarding newly designed systems and O&M of existing systems.

Many survey participants believe that LCCA practices are neither consistent nor standardized. Additionally, there is a lack of versatile, accessible, and affordable software applications to help facilitate LCCA. In general, LCCA is not required in most sectors, and it is often not adopted because of the lack of a developed framework for analyzing all relevant costs. It is recommended that risk concepts be included within the life-cycle assessment of infrastructure systems. Additionally, the lack of awareness, standardization across infrastructure sectors, and political conflicts prevent the efficient implementation of LCCA. Many professionals agree that LCCA should be compulsory within their infrastructure sector and that publishing standards and/or guidance documents is the best way to promote the implementation of LCCA.”

One could conclude that this survey confirmed that most practitioners were familiar with LCCA and lauded its use, however the lack of standards/frameworks or official guidelines were an impediment to its use.

4 ASCE POLICIES

Within ASCE, there are over 200 policies that are approved by the Board of Direction. These policies are started at the Committee or Institute level and undergo reviews every three years. These policies guide ASCE as to positions on various issues from climate change to professional licensing. Several of these policies have relevancy to resilience and life cycle cost analysis as detailed below.

Perhaps the most relevant policy on resilience is Policy Statement 500-Resilient infrastructure initiatives adopted by the Board of Direction on July 11, 2020. The policy statement says, “The American Society of Civil Engineers (ASCE) supports initiatives that increase resilience of infrastructure against man-made and natural hazards through education, research, planning, design, construction, operation and maintenance. Development of performance criteria and uniform national standards that address interdependencies and establish minimum performance goals for infrastructure is imperative. Furthermore, an all-hazard, comprehensive risk assessment that considers event likelihood and consequence, encourages mitigation strategies, monitors outcomes, and addresses recovery and return to service should be routinely included in the planning/design process for infrastructure at all government levels.”

This policy statement was first approved in 2003 and has been revised and reapproved several times since.

ASCE’s Infrastructure Resilience Division (IRD) is a division/committee in the Committee on Technical Advancement established in 2014. The IRD’s purpose is to serve the civil engineering profession in advancing civil infrastructure and lifeline systems for local, regional, and national resilience against all hazards. Unified definitions for critical infrastructure and resilience can be found in ASCE’s Policy Statement 518. This Policy Statement defines critical infrastructure to include systems, facilities, and assets so vital that their destruction or incapacitation would have a debilitating impact on national security, the economy or public health, safety, and welfare. In this policy, resilience is the ability to plan, prepare for, mitigate, and

adapt to changing conditions from hazards to enable rapid recovery of physical, social, economic, and ecological infrastructure.

More relevant to Life-cycle cost analysis is ASCE Policy statement 451. In this policy statement, ASCE recommends the appropriate use of Life-Cycle Cost Analysis principles in planning and design processes to evaluate the total cost of projects. There can be no clearer statement on LCCA and ASCE's 2021 Report Card for America's infrastructure calls for smart investing by, among other methods, planning the cost of building, operating, and maintaining the infrastructure for its entire lifespan.

Other relevant ASCE policies include:

Policy 360-Climate Change

Policy 418-The role of the civil engineer in sustainable development

Policy 488-Greenhouse gases

Policy 517-United Nations sustainable development goals

Policy 556-Owners' commitment to sustainability

In Policy 418-The role of the civil engineer in sustainable development, it is clearly stated that ASCE supports performing Life Cycle Assessment on projects from planning to reuse. Lastly, in Policy 517-United Nations' Sustainable Development Goals, ASCE supports implementation of the civil engineering aspects of the UN Sustainable Development Goals (SDGs).

As can be seen by these Policy Statements, ASCE is very supportive of resilience and sustainability and the use of LCCA on civil engineering infrastructure projects.

5 ASCE STRUCTURAL ENGINEERS INSTITUTE (SEI) 2050

At ASCE, there are nine (9) Institutes. With 30,000 members, SEI is one of the largest and has a mission to advance and serve the structural engineering profession. ASCE's Structural Engineering Institute is at the forefront of a new program aimed at reducing embodied carbon in the structural engineering industry. The SEI Structural Engineers 2050 Commitment Program provides structural engineers with the tools and resources necessary to contribute and track projects toward the vision of net-zero embodied carbon structures by 2050. The program was developed in response to the SE 2050 Challenge, put forth by the Carbon Leadership Forum (CLF), that states "All structural engineers shall understand, reduce, and ultimately eliminate embodied carbon in their projects by 2050." In response to the CLF challenge, the SEI Sustainability Committee has been developing the first national program focused on structural engineering firm commitments to achieve net-zero embodied carbon structures by the year 2050. The SE 2050 Commitment Program is broken down into three strategies: plan, implement, and share. After a structural firm formally signs onto the commitment, it creates an embodied carbon action plan, centered on four main topics: an embodied carbon education plan, a reporting plan, reduction strategies, and advocacy. Firms will then implement their action plan with the support of educational resources and tools. Structural firms will input projects' embodied carbon measurements into the SE 2050 database. After an adequate amount of embodied carbon data has been collected for different regions and building types, embodied carbon benchmarks and reduction targets will be developed.

6 INSTITUTE FOR SUSTAINABLE INFRASTRUCTURE (ISI)

Based in Washington, DC, ISI is an education and research nonprofit (a 501c3) that was established in 2010 by the American Public Works Association (APWA), the American Society of Civil Engineers (ASCE), and the American Council of Engineering Companies (ACEC). ISI collaborated with the Zofnass Program for Sustainable Infrastructure at the Harvard University Graduate School of Design to develop Envision, an infrastructure rating tool for sustainability. Note how Envision has "isi" within its name.

The Envision rating system is utilized across the United States, Canada, and Italy. To date, over 135 projects have completed the third-party verification process representing over USD

\$130 billion in development. In addition, there are over 6,500 active credentialed professionals trained in the use of Envision—Envision Sustainability Professionals (ENV SPs).

Within the Envision framework there are several credits that address project life-cycle cost analysis (LCCA) and resilience. LCCA is directly addressed in credit LD3.3 Conduct a Life-Cycle Economic Evaluation. The levels of achievement within this credit begin with a standard LCCA of the proposed project. As they advance to higher levels of achievement Envision users then use LCCA to compare alternatives to inform better decision making. At the highest levels of performance Envision requires a sustainability cost-benefit analysis that monetizes the social, environmental, and financial costs and benefits of the project. This cost-benefit analysis must also demonstrate a net positive present value for the project.

Envision has six credits that work synergistically within its Resilience subcategory. These include CR.1 Avoid Unsuitable Development, CR 2.2 Assess Climate Change Vulnerability, CR 2.3 Evaluate Risk and Resilience, CR2.4 Establish Resilience Goals and Strategies, CR2.5 Resilience and CR2.6 Improve Infrastructure Integration. In order to be resilient, infrastructure must be informed, resourceful, robust, redundant, flexible, integrated, and inclusive. Resilience includes the ability to withstand short-term risks, such as flooding or fires, and the ability to adapt to changing long-term conditions, such as changes in weather patterns, sea-level rise, or changes in climate. Understanding the types of risks and probability of risks allows the project team to deliver an informed project design that anticipates and withstands these risks, minimizing its overall vulnerability. Maximizing resilience ensures a longer useful life and primes the project to more fully meet the future needs of the community.

These credits represent a mitigation hierarchy for resilience beginning with CR2.1 which encourages avoiding site-related risks whenever possible. In CR2.2 Envision users specifically identify vulnerabilities due to climate change and in CR2.2 they assess wider ranging risks to project performance (e.g., environmental hazards, changing demographics, and economic stressors). In CR2.4 project teams take the important step of embedding sustainability and resilience goals within the project delivery process in order to mitigate identified risks. CR2.5 requires project teams to implement monitoring and response systems to ensure resilience goals are met and maintained. In CR2.6 the project leverages other infrastructure systems to increase resilience through greater diversity, redundancy, or efficiency and to reduce the likelihood of systemic or cascading failures.

Throughout the Envision resilience credits higher levels of achievement are reached by expanding the scope of the resilience planning from the project level to the infrastructure network, and ultimately to the community. Below are two (2) case studies. In 2019 the Huntington Levee project received an Envision Bronze award. This 2,800-foot-long levee was designed to protect 160 homes in the floodplain from 100-year flood events. The community had previously been impacted three times by flooding since 2002. The project was completed in June 2019 and in July of 2019 a significant storm event brought waters close to the top of the new levee. The payback from this project was almost immediate in protecting the community.

Figure 1. Huntington Levee project in Fairfax County, Virginia.

In 2012 New York City was devastated by Superstorm Sandy. While the region suffered total damages of nearly \$50 billion, New York City alone experienced and estimated \$19 billion in damages. In 2022 the New York City East Side Coastal Resilience project received an Envision Gold award. The 2.4-mile-long \$1.45 billion USD flexible flood barrier protects over 110,000 residents from coastal flooding. In addition to providing flood protection the project improves open spaces, playgrounds, parks, and provides greater accessibility to coastal areas for the community.

Figure 2. The East Side Coastal Resiliency project uses a series of berms, flood walls, flood gates and raised parklands to create a continuous 2.4-mile barrier to protect 110,000 residents of the Lower East Side in Manhattan from future coastal and tidal flooding.

7 ISI IN ITALY

As ISI was increasing its presence in the US, an opportunity was presented in Italy. ISI partnered with ICMQ to establish Envision in Italy and now has 6 Envision awarded projects as well as three (3) in the pipeline and over 300 people who have achieved ENV SP status. Twenty-five (25) projects have done a preliminary assessment and three (3) guidelines have been published for the application of the Envision protocol to the Italian Railway Infrastructure, Transmission Electric Power Lines of Terna and Eolic Wind Farms. Below are two (2) case studies from Italy:

8 THE BOLOGNA BYPASS PROJECT

Serving as a vital transportation node for Italy and providing a strategic artery for a leading national manufacturer, the Bologna highway system is closely tied to the country’s economic prosperity.

The Bologna Bypass project is the first highway infrastructure project in Europe to receive the Platinum award — the highest attainable rating level with Envision®. At a cost of €1.5 billion, the bypass will strengthen the urban section of the A14 expressway linking Bologna, Bari, and Taranto with an extension of approximately 13 kilometers. While retaining connections with the A1 expressway linking Milan and Naples, and the A13 (Bologna-Padua) expressway, the bypass speeds up access to Bologna via the city’s ring road system. Vehicles will spend approximately 4.5 million fewer hours on the road per year as a result of the project. This will significantly enhance the quality of life in local communities and reduce CO2 emissions in metropolitan Bologna substantially (1,350 tons per year).

A significant feature of this project was that the design addressed not only the needs of vehicular traffic, but also the necessity of connecting the A14 highway with other

transportation modes, all informed by a strong network logic. The purpose was to integrate the bypass with key urban junctions and existing local infrastructure in a way that would generate socioeconomic value, maximize benefits and promote sustainability.

A public-private partnership (PPP) project, the Bologna bypass also benefited from the strong work of an interdisciplinary project team emphasizing transparency and broad stakeholder involvement throughout the design process. With this foundation, a transformative project took shape focusing on the environment, innovation, and mobility.

This project provided an historic opportunity to redevelop the bypass area on a regional scale while recognizing and protecting its environmental value; not least, by systematically reducing noise and air pollution.

The new system's interconnections are made of enclosures and protections, in contrast to the existing road network infrastructure — revolutionizing the traditional image of road facilities.

Specific consideration was given to how this new infrastructure would be integrated into the urban and landscape context. To cite one innovative example, the San Donnino sound tunnel adds significant green space and pedestrian urban spaces and includes the installation of photovoltaic panels capable of delivering 2.3 megawatts of power. Other examples include the use of overpasses and the design of acoustic barriers extending through the highway system for more than 20 km.

The bypass includes the establishment of a well-structured network of landscape-friendly infrastructure assets along the entire highway corridor. Some 20 kilometers of cycle-pedestrian paths will be constructed, urban underpasses will be improved, more than 130 hectares of “softscape” will be reclaimed, over 30,000 new trees will be planted, urban and rural parks will be reinforced and enlarged, and over 50 hectares of abandoned land will be returned to the region.

Aspects of the project that were selected for verification using the Envision framework included quality of life and economic impacts; the safeguarding of water resources and soil conservation; sustainable use of resources during construction; and climate resiliency. As well, the opportunity to strengthen the requirements governing contractors and the supply chain towards sustainability, in the invitations to tender, was identified by the project team. Finally, the importance of formulating policies for the correct identification and allocation of the resources needed to fulfill the project vision was also addressed through the Envision verification process.

The principles that guided the design for the Bologna Bypass, aligned with national and international directives, have truly changed the “design paradigm” for highway projects in Italy towards a holistic approach. That approach has also been adopted by Autostrade per l'ItaliaGroup, the company responsible for the project, as it pursues more effective design solutions supporting sustainability on future projects.

The new paradigm, at its core, is about the implementation of methodologies to realize an integrated design that makes it possible to monitor the full life-cycle of a project, and to advance projects in a collaborative environment with broad stakeholder involvement. This supports transparency around infrastructure project standards and outcomes that are geared towards sustainability.

9 PARCO EOLICO ALTO VASTESE

Two e2i Energie Speciali's Wind Farms, consisting of the full repowering of the previous plants located in Castiglione Messer Marino and Roccaspinalveti in the Abruzzo Region in Italy, have been recently awarded by Envision the Platinum certificate for sustainable infrastructure.

E2i Energie Speciali (E2i) is one of the leading companies in the Italian renewable energy market with a total installed capacity of approximately 724 MW, through 40 wind farms and 3 PV plants.

Castiglione Messer Marino e Roccaspinalveti wind farms' full repowering (i.e. a comprehensive entire reconstruction) are part of a Repowering plan which E2i, first in Italy, has been carrying out with the aim to increase its green energy production whilst minimizing

the impact on the territory by reducing the number of installed turbines and strengthening the relationship with local Communities.

In the Abruzzo Region, e2i installed 188 wind turbines in the early 2000s for a total capacity of 114 MW. A first phase of Repowering projects was concluded in 2019 resulting with an overall power output of 131 MW. A second phase involved the wind plants mentioned above which allowed to reach a new total power output of 145 MW.

In these repowering projects, the activities were focused in the Municipality of Castiglione Messer Marino, where 24 old wind turbine generators (WTGs) were replaced by 4 new VESTAS V114 wind turbines for a total installed capacity of 2MW and in the Municipality of Roccaspinaveti, where 23 old WTGs were replaced by 9 new VESTAS V114 wind turbines for a total installed capacity of 7 MW.

Compared to the previous plants now dismantled, such repowering project allowed to obtain the following positive environmental objectives: a 72% reduction of installed WTGs numerosity and approximately 1.5x increase of the power output, with a nearly 2.0x total energy production. The project layout considered the geological nature of the land, its altimetric profile as well as E2i's internal goal to re-utilize as much as possible existing roads and existing infrastructures, in order to minimize the environment impact. The expected annual energy production of these two new plants will be double the energy output of the previous plants at approx. 114 GWh/year, corresponding to the energy needs of approx. 42.000 residential customers in the Italian market and avoiding the emission of 32.000 tons of CO₂ equivalent. The recognition of the Platinum level confirms the high level of sustainability recognized to repowering projects which manage to take care of both social, environmental, and economic issues for local Communities and underlines how E2i pays significant attention to the entire life cycle of its plants, from the development and design phase to the construction, the operation, and the dismantling phases.

10 CONCLUSIONS

This document has outlined the importance and application of resilience, sustainability, and life cycle cost analysis in civil engineering projects. Many “forward thinking” infrastructure owners in the US use Life-Cycle Cost Analysis to help make decisions on their projects. But many do not. The same can be said for resilience and sustainability. Two US based Societies (ASCE and ISI) have made it an imperative that to do the “Right” project, you must consider resilience and sustainability and LCCA as a tool to be used to optimize decision making. Several surveys have shown that owners in the US may acknowledge the benefit of resilience and LCCA, however, they do not implement them on their projects. There needs to be considerably more progress and ASCE and ISI are helping to further this effort.

The Envision rating tool from ISI has many benefits. One of the better ones is having rating criteria that favor life cycle cost analysis and resilience. If implemented at the planning phase of a project, Envision will help the planner/engineer design a more resilient and sustainable project.

ASCE will continue to push its policies, Institutes, and committees to publish standards, and manuals on Engineering Practice to further the use of LCCA and designing resilience into projects. It is imperative that public and private sector infrastructure owners hear the “call” of both ASCE and ISI to make LCCA and resilience a part of larger infrastructure projects.

The value of multi-criteria decision analysis for asset management

J. Bödefeld

Federal Waterways Engineering and Research Institute, Karlsruhe, Germany

F. Marsili

Helmut Schmidt University/University of the Federal Armed Forces Hamburg, Germany

ABSTRACT: Ageing and neglected maintenance are the main reasons for an inadequate condition of waterway infrastructure in Germany. Available maintenance resources are limited, which is why prioritising maintenance measures is becoming increasingly important. In this paper, three different approaches to the maintenance prioritisation based on the Multi-Criteria Decision Analysis are presented for different constellations of infrastructure. First, the risk of neglecting the maintenance of ship locks is assessed with the help of the Multi-Attribute Utility Theory. Then, a concept based on the Simple Multi-Attribute Rating Technique is developed for the risk-based maintenance planning of a system of culverts. Lastly, an approach to vulnerability assessment of a levee system based on the Weighted Influence Non-linear Gauge System is formulated to derive weights for vulnerability indicators that also consider their interdependencies and permit the aggregation of the related information. The results show that the Multi-Criteria Decision Analysis supports the strategic prioritization of maintenance actions for waterways infrastructure and any infrastructure system with similar characteristics.

1 INTRODUCTION

Infrastructure is the backbone of a healthy economy and its management is a complex discipline that therefore plays an essential role in modern societies. Ageing of civil infrastructure adversely affects its performance. Due to limited resources in recent decades, an immense backlog of outstanding maintenance has built up (Ralph, 2015).

This is also true of the infrastructure of federal waterways in Germany. These waterways include more than 300 locks, 300 weirs and 240 culverts. All in all, there are around 2,000 engineering structures that require a corresponding amount of maintenance. The condition of locks detailed in Figure 1 is a direct consequence of this maintenance backlog. A quarter of the structures are in a non-sufficient condition and well over half of the structures that are currently in a sufficient condition will require action in the near future. As well as resolving the issue of infrastructures in a non-sufficient condition, proper maintenance management also needs to prevent structures that are in a sufficient condition from deteriorating into a non-sufficient condition.

In order to tackle the backlog with the limited resources available, the relevant maintenance measures must be prioritized. Prioritizing infrastructure management measures is a major challenge. Deciding which measures are suitable for each specific structure is a predominantly technical issue. Engineers have experience in identifying optimum solutions. However, a wider range of criteria must be taken into account when prioritizing measures for a large portfolio of assets. Finite resources will lead to assets and thus infrastructure being abandoned. This makes it all the more important to prioritize measures in an objective, transparent and fact-based way that balances interests. However, engineers have little experience in structuring decision-making processes that take decisions to another level.

Figure 1. Condition of locks in Germany (BAW 2022).

In response to this challenge, risk-based maintenance strategies have been developed for identifying those system elements that are linked to higher probabilities of failure, and the magnitude of the consequences of failure, e. g. Arunraj & Maiti (2007). The risk arises in these cases from neglected maintenance. However, the problem of evaluating risk for infrastructure systems is not trivial.

Multi-criteria decision-making methods can be useful in solving this problem. These methods are introduced briefly in section 2. Section 3 considers use-cases for different waterway infrastructures and it demonstrates the possibilities of the method. The paper ends with a conclusion in section 4.

2 MULTI-CRITERIA DECISION ANALYSIS METHODS IN THE MAINTENANCE OF CIVIL INFRASTRUCTURE

It is possible to design a framework with stakeholder participation that can solve a given prioritization task using a combination of existing data and expert knowledge. In such a framework the discussion is steered away from the individual structure towards the target and the criteria, resulting in a transparent and comprehensible decision-making process.

The first step is to analyse the problem. Criteria such as the level of consideration (e.g. component, structure, network), the target (e.g. increasing availability or reliability) and the form of the result (e.g. classification, ranking) must be clarified. AI methods can promote understanding or reduce the dimension the given problem (Marsili & Bödefeld 2021b). Available and suitable attributes and their characteristics (e.g. qualitative, quantitative) must be set. Costly data collection can be avoided if it is possible to resort to existing data. The potential of secondary data, that is, data not explicitly collected for infrastructure management, should also be considered and exploited at this stage.

Then, a suitable method to combine the data with expert knowledge is selected. On the one hand, experts support the analysis of the problem and the definition of the target. On the other hand, they help to evaluate and weigh the importance of the various criteria and attributes. Finally, they evaluate the plausibility of the result.

As a rule, the criteria and the attributes describe the vulnerability or criticality of the alternatives, i.e. of the assets under consideration. A risk-oriented view results, even if risk has not been considered explicitly. The decision process identifies those structures for which a maintenance measure will have the greatest utility. These are the structures that are currently linked with the greatest risk of deferred maintenance.

3 USE-CASES FOR WATERWAY INFRASTRUCTURE

3.1 The Multi-Attribute Utility Theory (MAUT) for locks

In the first case study considered in this paper, the analysis focuses on a group of 18 locks located in a network of artificial canals and characterized by one, two or three chambers. The oldest lock chambers are about 100 years old, the youngest about 15 years. The locks have

very different characteristics. The construction of the chambers ranges from heavyweight walls to sheet piling to modern reinforced concrete. The type of lock gates varies e. g. from miter gates to sliding gates to lifting gates.

The aim of this approach is to increase the reliability, availability and maintainability of the locks. The locks that have a low reliability, availability or maintainability must therefore be identified because these are thus predestined for prioritized repair. Repair measures are planned at the level of the lock chambers, as these usually have to be closed for this purpose. Consequently, the approach described here also focuses on ranking the lock chambers according to the risk of a deferred maintenance; as there are 28 lock chambers with different designs, 28 different alternatives need to be evaluated. Prioritizing the repair of these objects is expected to significantly reduce the overall risk of the system. The attributes describing the alternatives have been aggregated with the Multi-Attribute Utility Theory (MAUT), in which preferences over attribute values are expressed by the definition of utility functions.

A strict, self-imposed constraint of the approach requires the use of existing data. The purpose of this was to avoid time-consuming data research so that results could be produced in a timely manner. All data were taken from existing databases explicitly developed for infrastructure management, and from databases which were not necessarily developed for this purpose (secondary database). The following six attributes were finally used for an evaluation of the alternatives; the first three attributes address the reliability of the lock, the second three attributes address the consequences of damage:

- the number of serious damages of the lock gates,
- the number of serious damages of the construction of the chamber,
- the number of unscheduled inspections,
- the number of unplanned service interruptions,
- the criticality of the lock service interruptions,
- the transport volume affected by the lock service interruption.

A major advantage of MAUT is that it enables quantitative and qualitative information to be combined. In particular, qualitative expert knowledge is integrated via the definition of the utility functions and the definition of the criteria or attributes weights. For the problem described, an exponential function was chosen to describe the utility, since all attributes show an increasing risk and thus an increasing benefit of a repair as the value increases.

The aim of the work was to demonstrate the potential of multi-criteria decision making in a civil-engineering world that is not used to its application. Although higher level approaches to identifying the utility function or determining the CE exist (Makhoul 2019), simple, pragmatic approaches were used to keep the structure of the analysis simple. Building on a basic acceptance of the procedure, corresponding improvements are conceivable for determining the parameters and for taking into account the individual assessment of the experts or stakeholders.

The choice of a parametric family for the utility function has the advantage that the definition of the parameters is based on the definition of a single quantity, called certainty equivalent (CE), which corresponds to a value of the utility of 0.5. The experts determine the CE, taking into account the minimum and maximum value of each attribute. Being increasing values of attributes linked to higher risk, the CE corresponds to the value of the attribute that is still acceptable for the experts. E.g. for the attribute “number of serious damages”, the experts have set a maximum permissible number of 1, and thus the value of the CE corresponds 1. This results in the utility function shown in Figure 2. Due to the increased benefit compared to a linear increase, a risk aversion of the experts becomes visible.

Thus, the benefit of a repair can be determined for each lock chamber depending on the characteristic of the attribute. In order to determine the total benefit, the attributes still have to be weighted. A direct rating method was chosen to find adequate weights: the experts were asked to determine them. These vary from 0.3 (criticality of lock service interruption) and 0.2 (unplanned service interruption and unscheduled inspection) to 0.15 (serious damages of the lock gate), 0.1 (serious damages of the construction) and 0.05 (transport volume). In the experts’ opinion the consequences of failures (service interruption and unscheduled inspection) contribute more to the risk than the probability of failure (serious damages) as they got higher weights.

Figure 2. Utility function for the attribute “number of serious damages”.

Finally, a ranking for the repair of the lock chambers can be determined by identifying the aggregated utility. The result was visualized in a GIS map, with the benefit graded between 0 and 1 on a colour scale from green (0) to red (1), see Figure 3.

A detailed description of the approach is given in Marsili & Bödefeld (2021a). For the recording of individual expert opinions, reference is made to an extensive basic literature from the psychological field (Kahnemann 2012). Of course, other approaches are possible to elicit expert opinion. However, it is necessary to consider that multi-criteria analysis methods are still uncommon in the field of civil engineering. In choosing simple techniques, it is intended to promote a basic acceptance of the procedure, based on which the method can be further developed and more refined information elicitation techniques can be used.

Figure 3. Aggregated utility (risk) for the 28 lock chambers.

3.2 The Simple Multi-Attribute Rating Technique (SMART) for a system of culverts

In the second case study, attention is put on an asset of 48 culverts characterized by different dimension, material, construction typology. The culverts encroach on a system of levees, built to retain water in an artificial canal system. Again, the goal is to identify those objects that are related to a higher risk of deferred maintenance, and therefore on which repair actions can have the greatest effect in terms of improving reliability and availability. Five attributes characterizing the culverts were extracted from an existing construction database:

- Encroachment on a levee (yes/no),
- Encroachment on a sealed canal (yes/no),
- Presence of a rake (yes/no),
- Presence of a sand trap (yes/no),
- Size of the drainage basin [m²].

Using a clustering approach based on k-medoids algorithm (Kaufmann & Rousseeuw 1990), the 48 alternatives were reduced to 15 representative objects corresponding to the cluster medoids. The optimal number of clusters was found using the silhouette approach by Rousseeuw (1987). In particular, the medoid is the point where the average dissimilarity between the medoid and all other cluster members is the lowest; it thus corresponds to the most central point in the cluster.

During a discussion among experts, four significant failure processes were identified: “collapse of the barrel/headwall”, “leakage out of the culvert”, “piping inside the culvert” and “afflux”. As the first three processes might lead to damage to the canal and further on to flooding due to levee breach, the last process may cause cross catchment flooding due to afflux of the culvert.

It can be seen that the influence of an attribute depends on the failure scenario. For example, a sand trap and a rake protect the culvert from structural damages, but can trigger the afflux scenario if not cleaned properly. Some attributes increase the probability of failure and the severity of the consequences. E.g. a big drainage basin might, on the one hand, transport debris and particles and thus increase the probability of failure. On the other hand, this results in greater cross catchment flooding.

The key steps of the Simple Multi-Attribute Rating Technique (SMARTS) are the definition of single-attribute utility functions and swing weighting. The definition of the single attribute utility functions is trivial for binary attributes as such attributes can only take two values corresponding to the maximum and minimum utility. For the single continuous attribute “drainage basin”, a linear function can be assumed, as it does not matter whether small improvements in the value of the attribute fall near the minimum, in the middle or near the maximum.

An intra failure scenario risk assessment is performed first by considering each failure scenario separately. The swing weights are determined in two steps. In the first step, the ranking of the weights is determined by ranking the attributes that contribute most to the risk. To do this, their values are varied from worst to best (swing). In the second step, the weights themselves are determined. Assuming that the swing from the worst to the best value of the first ranked attribute is worth a full 100 points, the deviation in the other attributes is evaluated in relation to this value by direct expert rating. The weights are then determined by dividing the assigned points by their total sum, as shown in Table 1.

Table 1. Swing weighting of the failure scenario “collapse of the barrel/headwalls”.

Attribute	Swing	Levee	Sealed Canal	Rake	Sand Trap	Drainage Basin	Rank	Score	Weight
Benchmark	No	No	No	Yes	Yes	0.04	0		
Levee	Yes	Yes	No	Yes	Yes	0.04	1	100	0.385
Sealed Canal	No	No	Yes	Yes	Yes	0.04	5	10	0.269
Rake	No	No	No	No	Yes	0.04	2	70	0.192
Sand Trap	No	No	No	Yes	No	0.04	3	50	0.115
Drainage Basin	No	No	No	Yes	Yes	72.70	4	30	0.038
							Total	260	1

The scenario-dependent utility can now be determined for each alternative. To determine the total utility of an alternative, the failure scenarios have to be weighted and the total benefit is summed up using the weighted sum method. This represents the inter failure scenario risk assessment. Three factors were considered to define the weights: the length of the cause-effect chain, the recognizability of the failure scenarios and the extent of the long-term consequences. The highest weight of 0.33 is given to the scenario “collapse of the barrel/headwalls”, followed by the scenarios “leakage out of the culvert” and “piping inside the culvert”, each with a weight of 0.25. The last scenario, “afflux”, receives a weight of 0.17.

The approach is aimed at promoting data-driven decisions, simplifying the structure of the decision problem and improving the interpretation of the results. The results show that 15

clusters are clearly identified within the set of 48 culverts. The prototypes can be considered as the alternatives of the decision problem. Four clusters containing 14 culverts can be recognized as dominant alternatives by means of the visual assessment of the attribute profiles characterizing each cluster.

Detailed notes on the approach can be taken from Marsili & Bödefeld (2021b).

3.3 *The Weighted Influence Non-linear Gauge System (WINGS) for dams*

Levees usually ensure a water level above the adjacent terrain. The dams presented in the study area are parts of artificial canals and therefore permanently exposed to water. Levee failure leads to serious damage, as the escaping water can cause devastating flooding of the surrounding area. Levee failure is often triggered by erosion, scouring and slippage, which subsequently cause part of the levee to collapse, visible through a loss of the levee crest or a hole in the levee.

When considering levees, the presence of penetrating structures implies special attention. On the one hand, encroaching structures imply a point of discontinuity in the levee body, which higher the vulnerability of the levee to the above-mentioned degradation processes. On the other hand, the condition of the levee influences the condition of a penetrating structure, e.g. instability of the levee provokes settlements to the penetrating structure. But the condition of the penetrating structure also influences the condition of the levee, e.g. in the case of leakage. A levee must therefore be considered as a system of systems (SoS) in which the interaction and interdependencies among subsystems is also taken into account. A new approach based on such consideration is proposed, according to which the Weighted Influence Non-linear Gauges System (WINGS) is applied to derive weights for vulnerability indicators that also consider their mutual casual interactions. Expert judgements are often fraught with uncertainty. To take this into account, the approach is combined with interval arithmetic. The final objectives are to identify the most important vulnerability factors and to develop an aggregated vulnerability index.

Two experts were recruited whose knowledge was discussed and visualized with the help of cognitive maps. The use of cognitive maps for the structured elicitation of expert opinions and stakeholder analyses has already been successfully applied in various contexts (Ferreri 2016). While one expert has a lot of experience in the study area, the experience of the second expert is derived from basic studies on levees. Additional information to support the analysis is derived from existing literature on canal levees and databases of historical earthen dam failures (TU Delft 2016).

In this way the binary vulnerability factors shown in Table 2 were identified. By simplifying, it is assumed that the factors take only two possible values: yes/no, fulfilled/not fulfilled, good/bad. These can be considered as binary parameters having two possible values, on/off, where “on” corresponds to “the vulnerability factor is enabled” and “off” corresponds to “the vulnerability factor is disabled”.

The experts indicate the strength of all vulnerability factors and the level of mutual influence using a direct rating system. It is thus possible to examine the structure of the relationships between the factors, to define the weight the factors according to their involvement in the system, and to classify them as “influencing” and “influenced”. In case of uncertainty, an interval evaluation is given. Following the WINGS methodology (Michnik 2013) and considering Alefeld et al. (2000) for interval arithmetic the bounds for the position and especially the total involvement value associated with each factor were obtained, from which the bounds for the vulnerability index will be derived.

It can be stated that

- the stability of the levee (St) and erosion (Er) have, as expected, the greatest influence;
- influencing factors with medium influence are culvert condition (CC), pipeline condition (PC) and vegetation (V);
- influenced factors with medium influence are internal seal (IS), seal (S), embankment walls (E) and drainage (D);
- all other factors are influenced to a small degree.

Table 2. Binary values assumed by the vulnerability factors.

Vulnerability factors	Disabled (off)	Enabled (on)
Pipeline encroachment (P)	No	Yes
Pipeline condition (PC)	Good	Bad
Culvert encroachment (C)	No	Yes
Culvert condition (CC)	Good	Bad
Other objects (O)	No	Yes
Stability of the levee (St)	Fulfilled	Not fulfilled
Soil erosion (Er)	Fulfilled	Not fulfilled
Burrowing animals (B)	No	Yes
Vegetation (V)	No	Yes
Change of the geometry (G)	No	Yes
Seal (S)	No	Yes
Internal seal (IS)	No	Yes
Drainage (D)	No	Yes
Embankment walls (E)	No	Yes
Inspection devices (I)	Yes	No
Levees water level (LH)	<3 m	≥3 m

To assess its vulnerability, the levee has to be divided into homogeneous segments, which are characterized by different lengths: from several hundred to a few meters (i.e. in case of object encroachment). For each segment, an interval vulnerability index is computed considering the upper and lower bound of the total involvement value which characterizes each vulnerability factor.

Figure 4. GIS maps showing a portion of the study area with the upper vulnerability index.

The visualization of the vulnerability assessment on GIS maps facilitates communication with third parties and other stakeholders affected by the vulnerability of the dams. The result can contribute to determining which objects should have priority for maintenance measures or at least require more in-depth consideration as a matter of priority. For further detailed information on the approach see Marsili et al. (2021c).

4 CONCLUSIONS

The task of infrastructure management requires tailored approaches to prioritizing the use of increasingly limited resources. The paper analysed three different elements of the waterway infrastructure with suitable applications of the multi-criteria decision-making method. An initial prioritization was made based on existing data.

AI methods, such as the cluster analysis used, are able to reduce the dimensionality of the problem and increase its understanding.

Although no explicit risk assessment was carried out, it was necessary to consider failure scenarios. The attributes considered in the MCDA can be assigned to vulnerability (probability of occurrence) and criticality (consequences). Thus, an implicit risk assessment was carried out for the lock chambers and culverts, and a vulnerability assessment was carried out for the dams without considering consequences.

The analysis already significantly promotes the understanding of the problem. All methods allow the combination of expert knowledge and existing data, which made it possible to achieve results quickly. Vagueness inherent in expert knowledge can be countered with interval arithmetic methods.

Suitable forms of visualization facilitate the presentation of the results and promote the necessary communication. The potential of the methods could thus be proven. Results may be improved by more detailed data, broader expert discussions and needs-oriented in-depth investigations.

ACKNOWLEDGMENT

This study has been developed within the research project PREVIEW, funded by the German Ministry of Education and Research, whose aim is to increase the resilience of German waterways infrastructures.

Toward enhancing community resilience: Life-cycle resilience of structural health monitoring systems

N. Makhoul

Politecnico di Milano, Milan, Italy

R. Kromanis

Universiteit Twente, Enschede, The Netherlands

ABSTRACT: Resilience is becoming a vital quality, particularly as our built environment faces increasing risks due to the aging of our infrastructure and climate change. Moreover, the built environment is relying largely on information technology and becoming digitalized. Consequently, it is crucial to ensure in addition to the resilience of structures and infrastructure, the resilience of the structural health monitoring SHM systems which provide information and help sustain and monitor the functionality of the built environment. The process involved in securing resilience throughout the life cycle of monitoring systems includes 1) planning and preparation before acute shock events and daily stressors, 2) absorption of shock events and 3) recovery and adaption afterward, as well as a continuous adaption for the daily stressors. Furthermore, enhancing the resilience of SHM systems contributes to, as well as improves, the resilience of structures and infrastructures. In this article, the life cycle resilience of SHM systems is discussed including community participation in SHM via crowdsensing. Comparisons between the resilience of SHM systems are presented. Results are discussed, and recommendations are offered.

1 INTRODUCTION

Hazards are becoming increasingly frequent, (i.e., due to increased urbanization, climate change, etc.) and infrastructure, societies, and the environment are suffering more severe consequences. Thus, it is vital to preserve the functionality of the critical infrastructure and community during and after hazard events, to minimize the losses and mitigate the risks of disasters. To mitigate the consequences of external chronic stresses and acute shocks, resilience-thinking is developed introduced lately for designing and assessing infrastructure as well as for urban planning. Resilience-based engineering aims to foresee and get ready and prepare for changing conditions (shocks and stresses), to adapt and recover rapidly from them, in addition to classical risk mitigation procedures (i.e., risk-based engineering). The focus of disaster mitigation strategies has shifted from disaster response to preparedness and prevention (Makhoul & Argyroudis 2018), (Makhoul & Argyroudis 2019), (Ayyub 2014), and (Ayyub 2015).

Resilience engineering is considered for all levels (i.e., materials, components, structures, networks, infrastructure, systems, the systems of systems, city levels, country, etc.), and aims to study multiple levels and hazard interdependencies. Community resilience includes all the above-mentioned and additionally encompasses social-technical-environmental interactions. The study aims to present accurately community resilience and to improve the decision-making procedure that it follows ((Folke et al. 2002),(Maguire & Hagan 2007), (Cutter et al. 2008)). Nevertheless, metrics and tools for the resilience quantification of socio-technical systems are still not soundly established, and procedures and standards are yet to arise (Lloyd's Register Foundation 2015). In (Koliou et al. 2020) a detailed state of the art of community resilience was offered and it was followed by the development of a community model (Roohi et al. 2021).

In the last decades, digitalization is playing a crucial role in everyday life and the built environment is relying predominantly on information technology and is becoming digitalized. The built environment is relying increasingly on structural health monitoring (SHM) and its data and information for

hazards, losses, and performance prediction modeling. Therefore, it is crucial to ensure the resilience of the SHM systems which provide information and help sustain and monitor the functionality of the built environment. Moreover, the community is gradually participating in the monitoring such as through crowdsourcing. However, until now, nothing was achieved on the topic of the resilience of the monitoring system and even less on the case of the involvement of society in monitoring. In (Makhoul et al. 2023a), a first study was done to address this issue by discussing the resilience of computer vision-based monitoring systems (CV-based systems) and their measurement. In (Makhoul et al. 2023b), adaptive pathways using emerging technologies (such as SHM systems, artificial intelligence (AI), and Machine Learning (ML)), the method was applied for critical transportation infrastructure and discussed as well resilience of CV-based systems, and AI and ML resilience and adaptation characteristics. Moreover, (Makhoul 2022), (Makhoul 2023b), and (Makhoul 2023a) discussed the data quality of SHM and related adequate decision-making processes.

In this article, we focus on the life cycle resilience of SHM systems. To this purpose, Section 1 discusses the resilience of SHM systems: Section 2.1 introduces resilience engineering and its methods and quantifications, Section 2.2 discusses the SHM systems and their types, then Section 2.3 presents the resilience of some examples of SHM systems. Section 3 offers the life cycle resilience of monitoring systems and life cycle costs. Finally, Section 4 concludes the main findings presented in this article.

2 RESILIENCE OF SHM SYSTEMS

2.1 *Resilience engineering*

The resilience importance takes source from the aptitudes of structures, assets, infrastructures, etc. to properly accommodate during its lifetime abrupt events and chronic stressors (e.g., earthquakes, hurricanes, storms, climate change, etc.). Those aptitudes or abilities are: 1) preparing and planning before an event/stressor, 2) absorbing the hazard (i.e., shocks and stresses) event consequences; 3) efficaciously responding to the hazard event disturbance by using the available resources efficiently (i.e., equipment, manpower, resources for operations, etc.); 4) recovering quickly and restoring the infrastructure/system functionality; 5) adapting to the changes of the situation and retaining improvement lessons for the future.

2.1.1 *Methods and quantifications*

Numerous resilience assessment procedures were suggested in the last decades (i.e., quantitative, qualitative assessment, deterministic and probabilistic techniques, 3) components, systems, networks, infrastructure, and system of systems levels) to face extreme and natural hazards. Among the several proposed methods, the attribute-based method (Fisher & Norman 2010) and (Pettit et al. 2010) analyze the system resilience properties (i.e., robustness, resourcefulness, adaptivity, and recoverability). It assesses the resilience semi-quantitatively or qualitatively by answering what makes it resilient and checking to what extent the properties are available). Performance-based approach quantifies the resilience of infrastructure, assets, systems, etc. (Bruneau et al. 2003), (Rose 2007), and (Alderson et al. 2015). It facilitates thus comparative analyses, cost-benefit, and planning analyses. The two procedures are complementary, and when combined provide the stakeholders with a comprehensive understanding of infrastructure resilience.

Moreover, numerous resilience assessment procedures are available such as the resilience-triangle method (Bruneau et al. 2003), the availability-based resilience approach (Ayyub 2014), and the simplified model (Ayyub 2015). This quantification increases in complexity conditional on needs and scales (i.e., single facility or system, systems, the system of systems, infrastructure networks, and community). Additionally, a variety of other resilience methods exist for instance the agent-based that considers complex systems, networks, users, control, and approximate reasoning comprising machine learning fuzzy logic. However, resilience assessment procedures need to be followed by adequate decision-making processes. Therefore, the adaptive pathways would be a suitable solution to consider the flexible aspect of the decision-making procedure and are very suitable for social and environmental applications and considerations such as the climate change adaptation process.

Several resilience metrics were offered such as in (Bruneau & Reinhorn 2007); (Reed et al. 2009); (Cimellaro et al. 2010); (Ouyang & Dueñas-Osorio 2014), (Nan & Sansavini 2017), (Capacci et al. 2020), and (Capacci & Biondini 2020).

The basic initial metric was formulated by the following Equation (1) for a single event:

$$R = \int_{t_0}^{t_h} Q(t) / (t_h - t_0) dt \quad (1)$$

where the functionality $Q(t)$ is a function ranging from 0% (i.e., loss of total performance) to 100% (i.e., no performance reduction).

The time t ranges from t_0 (i.e., the initial time of occurrence of the considered extreme event), t_i (i.e., the time of recovery work initiation), t_r (i.e., the recovery time from the event E), and t_h (i.e., the time of investigated horizon). T_{oh} , the total recovery time is formulated by $T_{oh} = t_h - t_0$.

The functionality of the system, infrastructure, structure, asset, etc. is subject to the losses induced by the disastrous event (E) occurring at t_0 . At E occurrence the functionality drops and is articulated by a loss function through fragility functions among others. The recovery function represents the functionality formulation in the aftermath of catastrophic event E and resulting losses. It is represented by a variety of shapes depending on the society's recovery capabilities and preparedness (Cimellaro et al. 2010) and (Bocchini et al. 2012). Figure 1 depicts the resilience metric and characteristics.

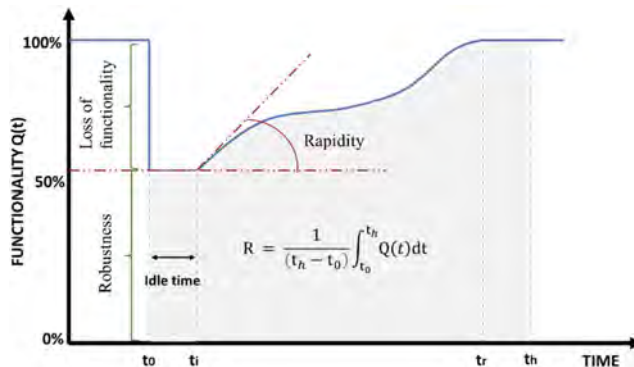

Figure 1. Resilience metric.

2.2 SHM SYSTEMS

With the advent of technologies, a wide range of SHM systems (sensors and sensing technologies) are commercially available. Sensors refer to physical devices that are designed specifically for collecting certain types of measurements. Sensing technologies can be attributed to approaches that are used to analyze data collected by devices that are not specifically designed for SHM purposes, for example, analyzing video-capturing bridge vibrations for the estimation of vibration parameters. SHM systems enable measuring physical (e.g., strain, displacement), environmental (e.g., temperature, humidity), and chemical (e.g., carbonation, corrosion) parameters. In this article types of SHM systems are defined by their intended use:

- 1) *Contact sensors* are either attached to the surface of a structure or inserted/integrated into elements of a structure (e.g., cast in concrete). Examples are (i) vibrating wire strain gauges installed on the surface of a concrete bridge (Barr et al. 2012), and (ii) wireless (strain gauge) sensor network for the instrumentation of prestressed concrete bridge (Hu et al. 2013).
- 2) *Non-contact (also remote) sensing* allows collecting measurements using either vision- or laser-based technologies without coming to a touching distance of the structure. Examples are (i) applications of modified GoPro action cameras for measuring vibration parameters of a suspension bridge (Kromanis & Elias 2023) and (ii) analysis of radar satellite data for the detection of unexpected bridge displacements (Cusson et al. 2021).

Table 1. Characteristics of the contact sensors, non-contact sensing, and crowdsensing.

Sensor or sensing technology	Type*	Pros	Cons	Failure	Repair	Time to repair
Vibrating wire strain gauge, sensor install on a steel bridge	C	High precision; high measurement collection frequency; reliable	Requires special attachment; usually, wired connection; expensive	Mechanical or electrical failure; detachment	replace or repair	days
Global position satellite, receivers installed on a bridge deck	C	Measures displacements in three axes;	Limited measurement resolution (approx. 1 cm); at least two receivers needed; expensive	Mechanical or electrical failure of a receiver; vandalism.	Replace or repair	days
Camera, a camera with a zoom lens installed away from the bridge	NC	No need to access the structure; low-costs; easy to use; distributed sensing	Limited measurement resolution (to the field of view and image processing algorithm); deluge of data	Mechanical or electronic; out of focus; vandalism	replace	In periodic monitoring (no failure), in continuously monitoring (hours/days)
Satellite imaging, Periodically collected and analyzed satellite images for bridge displacements	NC	Distributed measurement; no need to install sensors on the bridge	Satellite images are collected infrequently (days); images are expensive; difficult to analyze data	None expected	No repair needed	No failure expected
Smartphones, citizens provide smartphone sensor (accelerometer and gyroscope) data when crossing bridges	CS	No direct costs for sensors from asset owners; large volumes of data enable rather accurate estimates	Issues related to data privacy and ethics; limited measurement resolution; the need for a large amount of data	None	None	No failure

*C – contact, NC – non-contact, CS – crowdsensing

Figure 2. Functionality and resilience metric for infrastructure system and contact sensors, non-contact sensing, and crowdsensing.

3) *Crowdsensing* (also crowdsourcing) is a technique in which the deluge of data collected by citizens using smartphones is analyzed to assess the performance of a structure. Data can be collected from pedestrians and vehicle drivers ((Ozer & Feng 2017) and (Matarazzo et al. 2022)). This technique is very promising as it requires no investment in sensors and

sensing technologies. However, there are challenges related to data privacy that needs to be addressed before crowdsourcing become a ubiquitous sensing technology.

2.3 Examples of resilience of SHM systems

The recovery of functionality of infrastructure and monitoring systems depends on (i) the repair actions and their costs, (ii) the availability of manpower, their expertise, and costs, (iii) and the involvement of the society in the recovery work. In Table 1, some characteristics of the contact sensors, non-contact sensing, and crowdsensing are presented. The table details how these monitoring systems might fail and what needs repairing, the time needed to repair, and their limitations and advantages. Moreover, to ensure the redundancy of the monitoring systems in case of deterioration of contact monitoring systems, some non-contact monitoring systems (such as computer vision-based systems (e.g., cameras) and satellites imaging), as well as crowdsensing should be envisioned (even, today, though the accuracy of the latter is less than the former).

3 LIFE CYCLE RESILIENCE OF SHM SYSTEMS AND LIFE CYCLE COSTS

For ensuring the resilience of an infrastructure (or asset), it is necessary to consider the life cycle resilient assessment of the infrastructure system and the SHM system that it benefits from. Moreover, the life cycle maintenance costs for infrastructure systems and their relative SHM systems need to be considered. Figure 3 depicts the functionality, resilience metrics, and recovery of the considered infrastructure system lifetime and their related SHM systems (i.e., contact sensors, non-contact sensing, and crowdsensing). It shows two likely hazard events occurring at t_{01} and t_{02} , and their respective investigated time horizons t_{h1} and t_{h2} .

Figure 3. Functionality and resilience metric infrastructure system lifetime and the related contact sensors, non-contact sensing, and crowdsensing.

Life cycle maintenance costs were discussed by many researchers ((Messore et al. 2021), (Frangopol et al. 1997), (Liu & Frangopol 2005), and (Kong & Frangopol 2004)), where they introduced to compute the simple formulation of the present value of cumulative life-cycle maintenance cost (C_{PV}) due to all maintenance interventions. Maintenance interventions are allocated monetary expenses covering direct and indirect costs. The time effect is accounted for by a discount rate converting future cost into the value at the present time:

$$C_{PV} = \sum_{k=1}^N \frac{C_{t_k}}{(1 + \nu)^{t_k}} \quad (2)$$

where C_{t_k} is the cost of maintenance interventions applied at time t_k , and ν is the discount rate.

The cost in this article considers not only the cost of maintenance interventions for the infrastructure but as well the costs of the maintenance interventions for the SHM systems (contact sensors, non-contact sensing). Thus, the total cost of maintenance (C_{Total}) is given by Equation 3 along with the costs of the SHM systems in Equations 4 to 7.

$$C_{Total} = C_{Infrastructure} + C_{SHM\ System} \quad (3)$$

$$C_{SHM\ System} = C_{Contact} + C_{NonContact} \quad (4)$$

$$C_{Infrastructure} = \sum_{k=1}^n C_{0k} = \sum_{k=1}^n \frac{C_k}{(1 + \nu)^{t_k}} \quad (5)$$

$$C_{Contact} = \sum_{k_c=1}^n C_{0k_c} = \sum_{k_c=1}^n \frac{C_{k_c}}{(1 + \nu)^{t_{k_c}}} \quad (6)$$

$$C_{NonContact} = \sum_{k_{nc}=1}^n C_{0k_{nc}} = \sum_{k_{nc}=1}^n \frac{C_{k_{nc}}}{(1 + \nu)^{t_{k_{nc}}}} \quad (7)$$

where C_{tkc} and C_{tknc} are the cost of maintenance interventions applied at time t_{kc} and t_{knc} for the contact sensors, and non-contact sensing respectively. The cost of crowdsourcing is independent of the cost of the investment allocated to the infrastructure. Similarly, no additional cost is required for the usage of the satellite by the global position satellite receivers, while some costs are expected for satellite imaging. However, in both cases, no maintenance costs are expected. Finally, we note that Equations (2) to (7) can benefit from failure probabilities considerations such as in (Frangopol & Liu 2007), (Han et al. 2021), (Frangopol et al. 1997).

Figure 4. Life cycle costs for an infrastructure system and its SHM systems.

4 CONCLUSIONS

The built environment is relying largely on information technology and is becoming digitalized. In parallel resilience is a vital quality in this era. Therefore, in this article, the resilience of SHM systems and the effects on the life cycle infrastructure systems are discussed. Resilience engineering is briefly introduced and the types of SHM Systems and their characteristics are, mainly contact sensors, non-contact sensing, and crowdsensing. It is concluded that: 1) the loss functionality and recovery of contact sensors, in contrast to non-contact sensors, are tightly linked to the infrastructure system. Therefore, non-contact sensors can be replaced more easily than contact sensors. And their recovery time is minimal. 2) Non-contact sensors

and crowdsensing are more advantageous than contact sensors. They support and ensure the robustness and reliability of SHM systems and their measurements than contact sensors. 3) Satellite imaging can be used to enhance the resiliency of the measurements, as it is a source of backup for SHM with less probable disruptions.

ACKNOWLEDGEMENT

We thank Politecnico di Milano for funding this research through the Seal of Excellence project. The authors received financial support for this article from the Designing Systems for Informed Resilience Engineering (DeSIRE) Programme supported by the Centre for Resilience Engineering of the four universities of technology in the Netherlands (4TU).

ABSTRACT: Life-cycle concepts are used broadly in decision-making, such as the structural performance of buildings and lifeline systems and their management. However, life-cycle concepts are not yet explicitly incorporated into the community recovery modeling process, and nor do they typically consider socio-economics beyond a typical benefit-cost style analysis. This study incorporates life cycle concepts into community resilience analysis for physical-social interdependent networks following tornado hazards. More specifically, this study examines the preparedness, response, and recovery of buildings and households and explores the impacts of policy decisions on the life cycle phases across temporal and spatial domains using a fully interacting community resilience model. In order to achieve this goal, the methodology integrates a series of existing community resilience models across engineering and social science disciplines. This work can further expand and provide community decision-making support for physical-social interdependent networks impacted by more policy decisions and generic natural hazards.

1 INTRODUCTION

Life Cycle Assessment (LCA) has been traditionally considered a systematic procedure for compiling and examining the use of materials and energy and the associated environmental impacts resulting from the operation of a product or service system throughout its life cycle stages. The life cycle stages of a product or service system can last from the material extraction to the final disposal (ISO 14040). Over the last decade, life-cycle concepts have been broadly incorporated into structural engineering from various perspectives for decision-making and structure asset management. For example, Life Cycle Engineering (LCE) within civil engineering can assess a structure's long-term condition, safety, and serviceability, considering the effects of loading and environment as well as maintenance in conjunction with their economic impacts. The scope of the assessment is usually the whole life cycle of a structural system consisting of design, construction, use phase, and end of life (Dong 2016). In addition, life cycle concepts can help describe the entire process for an experimental study which included the construction, testing of buildings with retrofits (e.g., steel special moment frame, wood structural panels, viscous damping), collapse testing, and recycling and disposal (e.g. Bahmani et al. 2016).

However, life-cycle concepts are not yet explicitly incorporated into the community-level resilience modeling process, and nor do they typically consider socio-economics beyond a typical benefit-cost style analysis. In order to model a community as a life cycle problem, analysts and researchers should include true *interdisciplinarity* in community-level models and

can include *temporal* aspects of community recovery (van de Lindt 2021). From this perspective, this study incorporates life cycle concepts into community resilience analysis for physical-social interdependent networks following tornado hazards. More specifically, this study proposes a physical-social interdependent resilience methodology and examines the preparedness, response, and recovery of buildings and people and explores the impacts of policy decisions (e.g., mitigation retrofitting) on the life cycle phases across temporal and spatial domains using a fully interacting community resilience model.

2 PHYSICAL-SOCIAL INTERDEPENDENT RESILIENCE METHODOLOGY

Figure 1 shows the physical-social interdependent resilience methodology impacted by tornado hazards applied in this study. The methodology integrates a series of existing community resilience models across engineering and social science disciplines, including a household allocation model (Rosenheim et al. 2021), building damage model (Memari et al. 2018, Masoomi and van de Lindt 2016, Masoomi et al. 2018, Koliou et al. 2017), population dislocation model (Peacock et al. 2012, Rosenheim et al. 2021), residential building recovery model (Wang and van de Lindt 2021), and household housing recovery model (Sutley and Hamideh 2020).

The prerequisite step for the following physical-social resilience assessment is to assign building archetypes and their corresponding fragility functions to each building over the community and allocate housing unit information to a household level based on census-block socio-demographic data. The entire process starts with the building damage prediction. Subsequently, households may need to stay in emergency shelters/housing for approximately two weeks or more, temporarily moving out of their towns and dislocating. Over time following an event, residential buildings are repaired, new buildings are constructed, and ultimately households relocate to their permanent housing. Within each chained model mentioned earlier, Monte Carlo simulation (MCS) is widely applied to ensure uncertainty propagation.

This study uses a wind-induced residential building retrofit strategy as a typical policy decision to improve community resilience and examine how the policy decision impacts the preparedness, response, and recovery of buildings and people over the community, reflected in the physical-social interdependent resilience metrics. The typical resilience metrics for the physical-social interdependent networks following tornado hazards in this study include the number of non-functional buildings, the number of dislocated households, time needed for damaged residential buildings to be fully repaired, and the time needed for dislocated households to relocate to permanent housing.

3 ILLUSTRATIVE EXAMPLE USING JOPLIN MISSOURI TESTBED

Joplin is a typical small to medium size community and is located in Southwest Missouri in the United States. On May 22nd, 2011, an Enhanced Fujita 5 (EF5) tornado hit the city of Joplin, resulting in 161 fatalities and 1,150 injuries. The 2011 Joplin tornado is the costliest single tornado event in United States history, associated with a \$2.8 billion loss. Since then, the city of Joplin was increasingly selected by researchers as a testbed to perform multi-disciplinary community resilience assessments impacted by tornado hazards (e.g., Prevatt et al. 2012, Houston et al. 2017, Wang et al. 2021, Wang et al. 2022, Wang and van de Lindt 2022). In this illustrative example, a series of EF3 idealized tornado scenarios (Standohar-Alfano and van de Lindt 2015) created based on the historical events from 1973 to 2011 was developed as a stressor to strike the Joplin testbed at different locations. Figure 2 shows the overlay of the Joplin built environment and 30 horizontal EF3 idealized tornado scenarios, whose impacts will be averaged in this study.

Table 1 presents the original and retrofit designs for residential buildings applied to the community resilience assessment in this study. This illustrative example assumes the residential buildings were originally designed with the combination of wood shingles, wood sheathing panels nailed on center in 304.8 mm (12 inches) and at the edge in 152.4 mm (6 inches), and

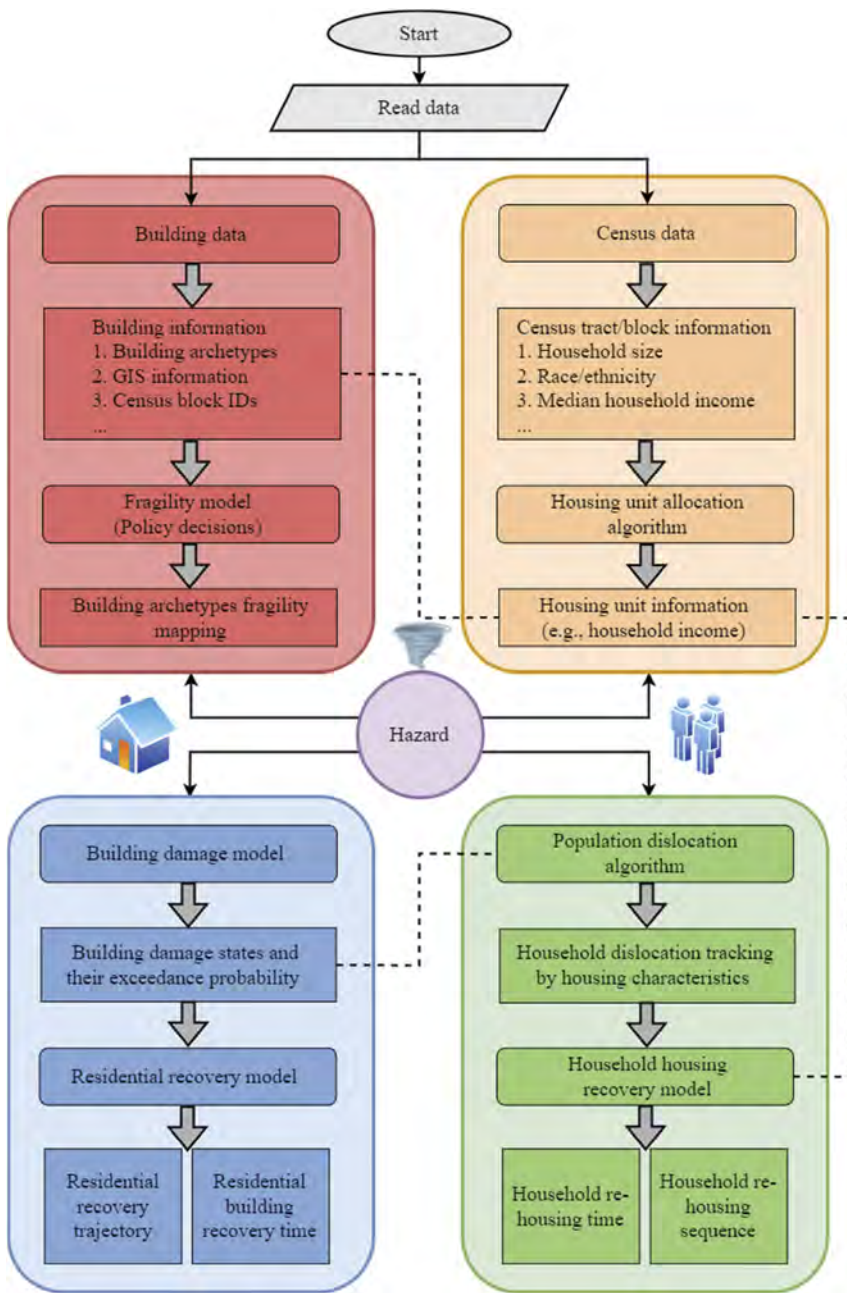

Figure 1. Physical-social interdependent resilience methodology flowchart.

two toenails for roof-to-wall connections. The retrofit designs for the residential buildings have improved asphalt shingles, wood sheathing panels nailed at all the locations in 152.4 mm (6 inches), and two hurricane clips for roof-to-wall connections. Please refer to the detailed fragility functions in different damage states in Wang et al. (2022) for original designs and retrofit designs of residential buildings. In general, this illustrative example assumes the buildings are non-functional when they are predicted with the probability of being in or exceeding moderate damage greater than 0.5 over the MCS realizations.

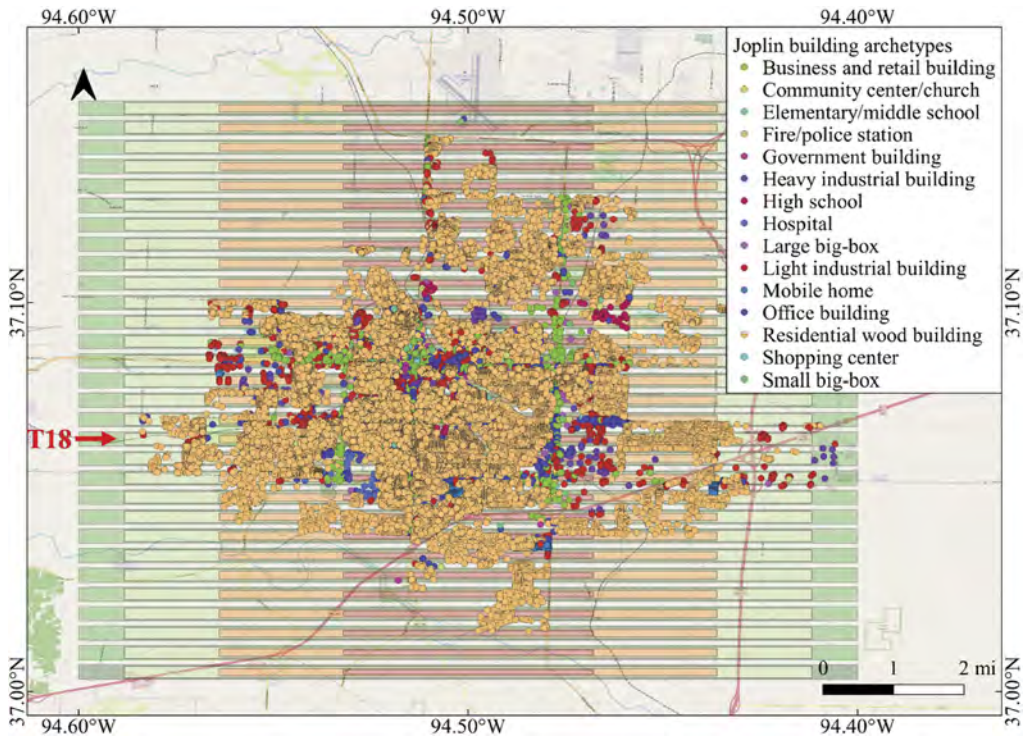

Figure 2. Joplin built environment and idealized tornado scenarios.

Table 1. Original designs and retrofit designs for residential buildings.

Structural elements	Selections	Original design	Retrofit design
Roof covering	Wood shingles	X	-
	Asphalt shingles	-	X
Roof sheathing nailing pattern	8d C6/12	X	-
	8d C6/6	-	X
Roof-to-wall connection type	Two 16d toenails	X	-
	Two H2.5 clips	-	X

If incorporating life-cycle concepts into the community resilience modeling, it is essential to use an interdisciplinary resilience assessment approach to model the community's life cycle phases, such as preparedness, response, and recovery, as mentioned earlier. In this illustrative example, the metrics of building damage and household dislocation, which are intended to represent maintaining of the physical service stability and population stability following tornado hazards, are used to describe the physical-social disruption response, as shown in Table 2. With the improvement of residential building performance, presumably increasing numbers of households would be able to stay at home and not dislocate; therefore, the physical-social network in the community is always interdependent. Table 2 presents the total number of buildings and households located within the tornado paths and the number of non-functional buildings and dislocated households with/without the improvement of retrofit designs impacted by a typical EF3 tornado scenarios and the average of all the simulated EF3 tornado scenarios. T18 is the tornado scenario striking the most buildings and households in the simulations. On average, when applying the retrofit designs to all the residential buildings within the tornado path, the percentage of non-functional buildings can be reduced from 84.8% to 57.4%, and the percentage of dislocated households can be reduced from 70.4% to 50.7%. The dislocated

households can be tracked by different household characteristics, such as tenure status, race/ethnicity, and household income, which are not elaborated herein for brevity.

Table 2. Building damage and household dislocation improved by retrofit designs of a typical MCS.

Tornado scenarios	Total number of buildings	Total number of households	Un-retrofitted		Retrofitted	
			Non-functional buildings	Dislocated households	Non-functional buildings	Dislocated households
T18	1,653 (100%)	2,027 (100%)	1,438 (87.0%)	1,404 (69.3%)	993 (60.1%)	988 (48.7%)
Mean	408 (100%)	570 (100%)	346 (84.8%)	401 (70.4%)	234 (57.4%)	289 (50.7%)
SD	473	659	404	463	275	330

Residential building recovery is essential for dislocated households to consider the relocation back to their pre-disaster community during the physical-social interdependent recovery process. The residential building recovery approach predicts the time required for residential buildings damaged in any damage state to fully recovered in this illustrative example (Wang and van de Lindt 2021). Figure 3 shows histograms of the recovery time of a typical residential building falling in the EF2 region of the T18 tornado scenario, where the recovery time of all residential buildings within a typical MCS realization fits a lognormal distribution. The average time for this residential building recovery before and after retrofits is 90.9 weeks and 54.9 weeks, respectively; meaning the recovery time can be shortened by 40%. Table 3 provides the percentage of residential buildings fully recovered in each time step within different (i.e., short-term, intermediate, long-term) recovery stages. The residential building recovery model applied in this illustrative example is a damage-driven recovery model considering the household capability to assess financial resources such as insurance, loans, and personal savings. The percentages of residential buildings fully recovered falling within the simulated tornado scenarios on average and those within the T18 tornado scenario have a slight difference due to different household characteristics at different census blocks. Without building retrofits, the percentages of residential buildings fully recovered in six months, one year, and two years are 9.2%, 23.1%, and 79.3%, on average for the 30 tornado scenarios. The percentages can be increased to 25.2%, 63.8%, and 93.1% for the same tornadoes when residential buildings were modeled as retrofitted.

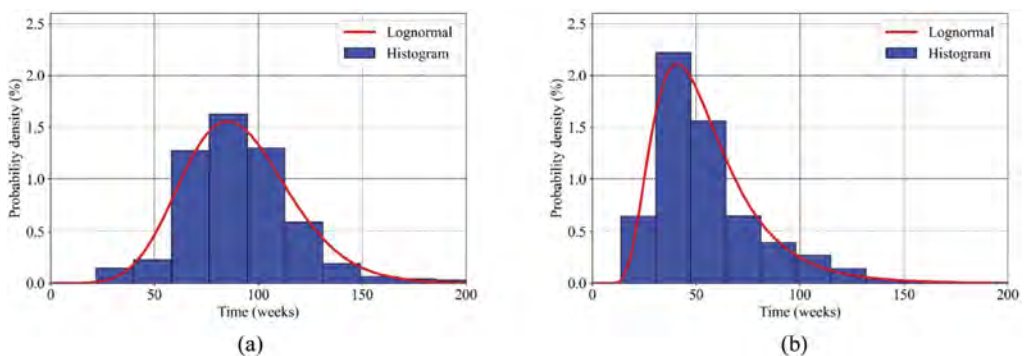

Figure 3. Histogram of a typical residential building recovery time in the EF2 region of the T18 tornado scenario: (a) without building retrofits; (2) with building retrofits.

The household housing recovery prediction in this illustrative example describes a complex long-term process for re-sheltering households after being disrupted by tornado hazards and consists of four stages: emergency shelter, temporary shelter, temporary housing, and permanent

housing (Bolin and Stanford 1998, Badeaux 2018). Sutley and Hamideh (2020) comprehensively detailed the four stages above to model household housing recovery as stages 1 to 4 and proposed a re-housing failure as a fifth possible stage. This illustrative example herein modified this model slightly and implemented it to predict the household housing recovery process. Figure 4 shows the household housing recovery sequence of a typical household residing in a residential building with and without retrofits where the residential building falls within the T18 tornado scenario. It is important to note that the household housing recovery model used herein is directly related to household social-vulnerability characteristics rather than residential building designs. However, improving residential building design can significantly reduce the severity of building damage and resulting household dislocation. Only dislocated households are predicted to have a household re-housing sequence, and non-dislocated households are assumed to stay in permanent housing. In reality, improving residential building design can also reduce the sequence’s duration and increase the number of households re-locate back to the community.

Table 3. The percentage of residential buildings fully recovered improved by retrofit designs (mean values).

Tornado scenarios	Residential buildings	Design hazard performance								
		Phase 1: Short-term			Phase 2: Intermediate			Phase 3: Long-term		
		Days			Weeks			Months		
		0	1-3	3-7	1-6	6-12	12-24	6-12	12-24	24+
T18 (an example)	Un-retrofitted	0%	0%	0%	0%	1.0%	7.7%	20.2%	78.1%	100%
	Retrofitted	0%	0%	0%	0%	2.8%	22.3%	61.0%	92.5%	100%
Average of all tornado scenarios	Un-retrofitted	0%	0%	0%	0%	1.3%	9.2%	23.1%	79.3%	100%
	Retrofitted	0%	0%	0%	0%	3.6%	25.2%	63.8%	93.1%	100%

Figure 4. Household housing recovery sequence of a typical household residing in a residential building with/without retrofits.

Household housing recovery time is defined as whenever the household moves to permanent housing (Stage 4). Figure 5 illustrates the histograms of household housing recovery time of all households not experiencing household re-housing failure but residing in the residential buildings located in the T18 tornado scenario within a single MCS realization. Overall, the average recovery time for households moving back to permanent housing is reduced from 22.6 weeks to 19.8 weeks for all the tornado scenarios when applying mitigation retrofits to

their residential buildings. Note that the residential building recovery model is a physical model driven by building damage, and the household housing recovery model is a process-based model controlled by the household's social vulnerability. The integration and comparison between these two models need further investigation. However, it is clear from this initial analysis and comparison of these two models that households are likely to be ready for permanent housing before their previous residential building is fully repaired. This underscores the complexities of combining process-based and data-driven models in community resilience modeling, but it is noted here that it is still needed.

Figure 5. Histogram of household housing recovery time of most households residing in the residential buildings located in the T18 tornado scenario: (a) without building retrofits; (2) with building retrofits.

4 CONCLUSIONS

This study incorporates life cycle concepts into community resilience analysis, uses wind-induced residential building retrofit strategy as a typical policy decision to improve community resilience, and examines how the policy decision impacts the preparedness, response, and recovery of buildings and households within a community, reflected in the physical-social interdependent resilience metrics. On average, when applying residential building mitigation retrofitting subjected to EF3 tornado events, the percentage of non-functional buildings can be reduced from 85% to 57%, and dislocated households can be reduced from 70.4% to 50.7%. Considering the life cycle phases of physical-social interdependent networks on a temporal scale, the average residential building recovery time can be shortened by 40%. The household housing recovery model shows the average recovery time for households moving back to permanent housing is reduced from 22.6 weeks to 19.8 weeks with retrofitting of residential building, a less impactful result. The integration and comparison between residential building recovery and household housing recovery needs further exploration and, in particular, synthesizing the assumptions embedded in each model type. This work can further expand and provide community decision-making support for physical-social interdependent networks impacted by more policy decisions such as recovery financing and generic natural hazards such as earthquakes and floods.

Impact of modeling uncertainty on seismic life-cycle cost analysis of RC building under mainshock-aftershock sequences

S.P. Rayjada, J. Ghosh & M. Raghunandan

Indian Institute of Technology Bombay, Mumbai, Maharashtra, India

ABSTRACT: Aftershocks can increase financial losses by causing further damage to buildings whose seismic capacity is already impaired in mainshock. To anticipate such losses, seismic life cycle cost analysis under mainshock-aftershock sequences is gaining interest from decision-makers in the past decade. Although, the state-of-the-art framework for aftershock loss assessment accounts for the uncertainty in state of the structure due to damage accumulation, time-dependent nature of seismic hazard and variability in the ground motion characteristics, one of the major uncertainties associated with variability in analytical building modeling parameters called “modeling” uncertainty is not accounted in the existing framework. Therefore, this study proposes a framework to assess the variability of expected seismic life cycle cost mainshock-aftershock sequences considering modeling uncertainty. Application of the framework is demonstrated using a case study example of four-story modern ductile reinforced concrete (RC) building and results reveal the criticality of considering the modeling uncertainty.

1 INTRODUCTION

Earthquake-induced losses place a significant financial burden on the stakeholders. Hence, modern construction practice must accurately evaluate such losses for efficient channeling of monetary resources. In this regard, seismic life cycle cost analysis (SLCCA) has proven to be a robust approach for decision-making that estimates the expected lifetime economic losses incurred due to seismic events in present-day value. SLCCA constitutes a probabilistic approach incorporating site-specific seismic hazard characteristics and vulnerability details of the structure of interest. Over the years, various methodologies have been developed and implemented for design optimization, retrofit prioritization and structural performance assessment, among others (Ellingwood & Wen 2005; Padgett et al. 2010; Wen & Kang 2001).

The traditional SLCCA framework deals with significant earthquake events with a long return period that provides sufficient time for the structure recovery. However, the major seismic event is often followed by a cluster of subsequent earthquakes within a short period, referred to as “aftershocks,” that pose additional risk to already damaged structures leading to a substantial additional financial burden to society. Hence, recent research efforts aim to account for the additional losses imparted due to aftershocks in the SLCCA framework (Shokrabadi & Burton 2018a; Yeo & Cornell 2009b). For instance, Yeo & Cornell (2009b) proposed the Markov process-based approach to estimate direct and indirect losses under mainshock-aftershock sequences. This approach is further extended by Shokrabadi & Burton (2018a) with reduced complexity and its application is demonstrated using a case study example. Furthermore, the study provided detailed insights into structural and non-structural losses in pre-mainshock and post-mainshock environments. Yin & Li (2011) and Song et al. (2016) utilized a sampling-based approach to estimate the lifetime loss under the mainshock-aftershock sequences for wood and steel building, respectively.

For the reliable implementation of these frameworks, it is essential to account for various sources of uncertainty during structural response assessment. Uncertainties may be considered to

stem from variability in ground motion characteristics termed “record-to-record” uncertainty (RTR) and uncertainty in analytical building modeling parameters called “modeling” uncertainty. Although studies in the past decade have highlighted the criticality of considering modeling uncertainty in seismic risk and life cycle assessment (Gokkaya et al. 2016; Liel et al. 2009; O’Reilly & Sullivan 2018), existing aftershock loss assessment frameworks do not incorporate the effect of modeling uncertainty. Therefore, this study proposes a framework to assess the impact of modeling uncertainty on seismic life cycle cost under mainshock-aftershock sequences.

At the onset, a brief overview of the SLCCA framework considering aftershocks is provided, followed by a framework to account for modeling uncertainty. In the proposed approach, the contribution of modeling uncertainty is derived from the mainshock analysis and aftershock fragility curves are adjusted accordingly. Thereafter, the application of the proposed framework is illustrated using a case study example of a four-story RC building. The paper ends with conclusions highlighting the key findings.

2 SEISMIC LIFE CYCLE COST CONSIDERING AFTERSHOCKS

The expected seismic life cycle cost during service life under a mainshock environment ($E[SLCC]_{MS}$) can be effectively calculated using analytical framework proposed by Ellingwood & Wen (2005) incorporating three essential components, namely site-specific hazard curve, seismic fragility and cost related to each damage state.

$$E[SLCC]_{MS} = \frac{1 - e^{-\alpha T}}{\alpha T} \sum_{i=1}^n [\ln(1 - P_{T,i}) - \ln(1 - P_{T,i+1})] C_{ds}^i \quad (1)$$

where, T is service life of the structure and α is an inflation-adjusted discount ratio. Consequently, n represents the total number of damage states while C_{ds}^i is the damage state-related cost. $P_{T,i}$ is T -year probability of exceeding damage state i that can be estimated as:

$$P_{T,i} = 1 - (1 - P_{Al,i})^T \quad (2)$$

In the above equation, $P_{Al,i}$ is an annual probability of exceeding each damage state determined by convolving site-specific hazard curve and seismic fragility.

$$P_{Al,i} = \int P_i[EDP > edp_i | IM] \left| \frac{dH(im)}{dim} \right| dim \quad (3)$$

where, $H(im)$ is seismic hazard curve representing an annual probability of exceeding the specified level of intensity measure $IM = im$. $P_i[EDP > edp_i | IM]$ is the probability of exceeding i^{th} damage state at a specified earthquake intensity $IM = im$ and can be obtained from a seismic fragility curve. EDP is an engineering demand parameter that characterizes the structural damage, and edp_i represents the threshold EDP for damage state i . The additional losses incurred due to aftershocks are calculated separately and added to the existing framework, as shown below.

$$E[SLCC]_{MSAS} = \frac{1 - e^{-\alpha T}}{\alpha T} \sum_{i=1}^n [\ln(1 - P_{T,i}) - \ln(1 - P_{T,i+1})] [C_{ds}^i + E[C_{AS}^i]] \quad (4)$$

where, $E[C_{AS}^i]$ represents the expected value of loss due to a series of aftershocks when the structure has already experienced damage state i under mainshock. This study utilizes the methodology proposed by Shokrabadi & Burton (2018a) to estimate $E[C_{AS}^i]$. It is important to note that the abovementioned SLCCA formulation under mainshock environment assumes that the structure will return to its pre-damaged state before next earthquake occurs. This assumption is valid for mainshock events as a time interval between successive major mainshock events is long enough to restore the building to its pre-mainshock state. However, a

series of aftershocks following a mainshock does not allow time to restore the building and the damage state of the building before each event is unknown. Hence, structural performance assessment under mainshock-aftershock sequences requires an explicit consideration of uncertainty in determining the state of the structure through Markov process-based formulation (Shokrabadi & Burton 2018a; Yeo & Cornell 2009b). Furthermore, it is computationally challenging to consider all possible events as multiple aftershock events likely follow the mainshock. To address this issue, Shokrabadi & Burton (2018a) proposed an efficient approach in which the time range of evaluation (time after mainshock during which aftershock is assumed to occur) is discretized into small unit-time intervals $[t_0, t_1]$ such that more than one earthquake cannot occur during the interval. For a given time interval, transition probability matrix representing uncertainty in the state of the structure can be estimated as:

$$\mathbf{P}(t_0, t_1) = \begin{bmatrix} P_{11}(t_0, t_1) & P_{12}(t_0, t_1) & \cdots & P_{1n}(t_0, t_1) \\ 0 & P_{22}(t_0, t_1) & \cdots & P_{2n}(t_0, t_1) \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 1 \end{bmatrix} \quad (5)$$

Here, $P_{ij}(t_0, t_1)$ terms represent the probability that the structure transitions to damage state j under the seismic event, given that it has already experienced damage state i under the previous event. $P_{ij}(t_0, t_1)$ can be calculated based on aftershock fragility curve as described below.

$$P_{ij}(t_0, t_1) = \mu(t_0, t_1) \int (P_{i,j}[EDP > edp_j | IM] - P_{i,j+1}[EDP > edp_{j+1} | IM]) f_{IM}(im) dim \quad (6)$$

where, $P_{i,j}[EDP > edp_j | IM]$ is the probability that a structure with an initial state i state exceeds the state j that can be obtained through aftershock fragility curves conditioned on initial state i . $f_{IM}(im)$ is the probability density function of intensity measure while $\mu(t_0, t_1)$ is aftershock occurrence rate for a given time interval. It is worthwhile to note that the rate of aftershock occurrence decay over time as the aftershocks are most likely immediately after mainshock and the temporal decay of aftershock rate is described by the nonhomogeneous Poisson process characterized by Omori's law (Yeo & Cornell 2009a). At time t_m after the mainshock (m time units), a transition probability matrix can be obtained as:

$$\mathbf{P}^m = \prod_{r=1}^m \mathbf{P}(t_{r-1}, t_r) \quad (7)$$

The aftershock loss at time t_m after mainshock is estimated using the transition probability matrix and structural damage loss matrix (\mathbf{E}_C) as shown in Equation (8). The elements of the damage loss matrix- E_{Cij} represent the difference of loss associated with two damage states i and j .

$$E[C_{AS}]^m = e^{-at_m} [\mathbf{P}^m \circ \mathbf{E}_C] \quad (8)$$

The aftershock losses corresponding to each damage state - $E[C_{AS}^i]$ (Equation (4)) are estimated by taking the sum of each row of $E[C_{AS}]^m$ matrix.

3 FRAMEWORK TO INCORPORATE MODELING UNCERTAINTY

While the previous section provides a brief introduction to SLCCA methodology considering aftershocks, this section aims to propose the framework to incorporate the effect of modeling uncertainty. Fundamentally, this study assesses the contribution of modeling uncertainty from mainshock analysis using a Monte Carlo simulation-based approach and aftershock fragility curves are adjusted accordingly. At the onset, the building is designed as per modern seismic design codes followed by numerical modeling in a finite element platform. The modeling uncertainty corresponds to the randomness associated with predicting finite element model

parameters. For example, if a building is modeled using lumped plasticity model by providing an inelastic spring at the ends of beam-column members as shown in Figure 1, uncertainty associated with predicting inelastic spring properties represents modeling uncertainty. As depicted in Figure 1, modeling uncertainty is captured by generating a sufficiently large number (N_{MC}) of nominally identical but statistically different building models. On the other hand, RTR uncertainty is incorporated by selecting a set of ground motions with varying attributes.

Incremental dynamic analysis (IDA) is performed by randomly pairing ground motion and building samples, followed by estimation of the median (med) and dispersion (β) of the fragility curve (Vamvatsikos & Cornell 2002). The fragility dispersion obtained for this case corresponds to the total uncertainty ($\beta = \beta_{TOT}$) that captures both the record-to-record variability and the modeling uncertainty. Thereafter, a building model developed with the mean estimate of model parameters termed as *Mean Model*, is subjected to a suite of ground motions for incremental dynamic analysis. In this case, corresponding fragility curve parameters represent only record-to-record uncertainty ($\beta = \beta_{RTR}$). As commonly adopted in literature, the modeling uncertainty contribution to the dispersion ($\beta = \beta_{MOD}$) can be conveniently extracted from the total uncertainty using square root of sum of squares (SRSS) technique for all damage states.

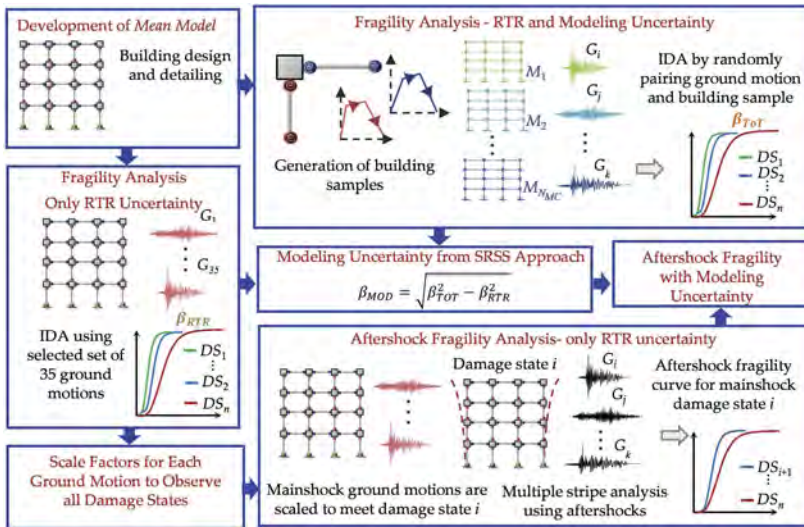

Figure 1. Framework to develop aftershock fragility curves considering modeling uncertainty.

For aftershock fragility assessment, *Mean Model* is first subjected to mainshocks scaled to a level that pushes the structure to a desired damage state i followed by multiple stripe analysis using aftershock ground motions as per the recommendation of Shokrabadi & Burton (2018b). This exercise is repeated for all mainshock damage states and corresponding aftershock fragility curves are obtained. The contribution of modeling uncertainty estimated earlier from mainshock analysis is added to the aftershock fragility curve parameters using SRSS approach.

4 CASE STUDY EXAMPLE

A four-story, three-bay commercial building in Los Angeles, USA is selected as a case study building to assess the impact of modeling uncertainty. The building is designed as a special moment resisting frame (SMRF) to withstand gravity and earthquake loads in accordance with modern seismic design standards in the USA (Raghunandan et al. 2015). The nonlinear finite element model of the building is developed as a 2-D moment resisting frame in the finite element platform OpenSEES (McKenna et al. 2012). The beams and columns are modeled as

lumped plasticity beam-column elements wherein the inelastic flexural springs are provided at the ends of elastic elements. These springs have nonlinear hysteretic properties that can capture complex structural behavior and the hysteresis model proposed by Ibarra et al. (2005) is used to characterize spring's cyclic behavior. The hysteresis model parameters include a monotonic backbone curve and a cyclic degradation parameter as depicted in Figure 2 determined based on Gaussian process regression (GPR) models recently proposed by Rayjada et al. (2023). These models are fitted to the experimental column test results with varying design and details and one potential advantage of GPR models lies in the pointwise estimates of prediction uncertainty based on the location of a data point within the sample space that leads to a more comprehensive estimation of modeling uncertainty (Rayjada et al. 2023).

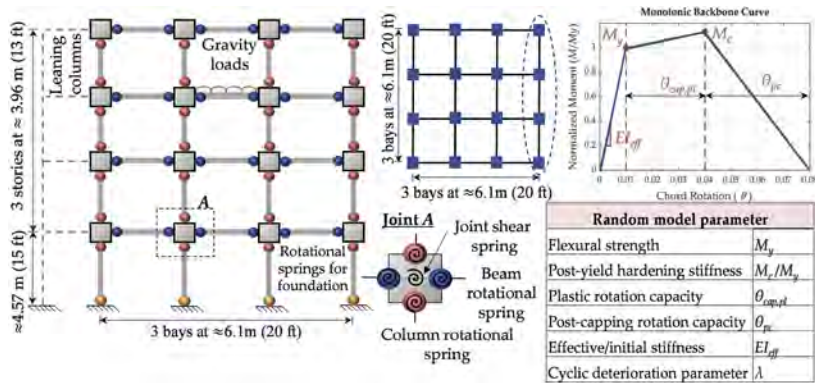

Figure 2. Graphical representation of analytical building model and random model parameters.

For the hysteresis model adopted here, six parameters, as depicted in Figure 2 are assumed to be random. A total of 3500 samples (N_{MC} in Figure 1) are generated to reflect modeling uncertainty based on GPR model. In this process, the correlation between parameters of the same element (beam or column) is considered as per Rayjada et al. (2023) while full correlation is assumed between parameters of beams (beam-to-beam) and columns (column-to-column). Furthermore, zero correlation is considered between beams and columns (beam-to-column).

4.1 Seismic fragility assessment

For developing fragility curves under mainshock environment, this study utilizes a set of 35 far-field crustal ground motions from FEMA P-695 (FEMA 2009) for IDA. To characterize ground motion intensity, elastic spectral acceleration for the fundamental time period of *Mean Model* - 0.75s ($Sa[T = 0.75 \text{ s}]$) at 5% damping is selected as *IM*. At the same time, maximum interstory drift ratio (ISD_{max}) is used as the *EDP* to describe the structural response. The damage states for fragility assessment are defined as per previous studies (Padgett & Li 2016) and presented in Table 1. As per the methodology proposed in Figure 1, IDA is performed for *Mean Model* and building samples to estimate fragility curve parameters as reported in Table 1. Furthermore, the contribution of modeling uncertainty to total uncertainty is calculated using SRSS approach and the reduction in median fragility is also estimated.

Aftershock fragility curves are developed for all mainshock damage levels as depicted in Figure 3 using multiple stripe analysis of the *Mean Model* (Shokrabadi & Burton 2018b). Here, the selected set of 35 ground motions is used as aftershocks for simplicity and structural performance assessment using recorded mainshock-aftershock sequences will be taken up in the future. Aftershock fragility curves are adjusted to account for modeling uncertainty by reducing the median as per Table 1 and increasing dispersion with β_{MOD} using SRSS approach. Aftershock fragility curves considering modeling uncertainty are presented in Figure 3 with dashed lines.

Table 1. Seismic fragility results.

Damage State	Description	Threshold ISD_{max}	Fragility Parameters RTR		Fragility Parameters TOT		Median Reduction	β_{MOD}
			med	β	med	β		
Slight	Light damage to structural components and finishes	1%	0.68	0.23	0.64	0.26	5%	0.12
Moderate	Moderate strength deterioration and unreparable damage	2%	1.31	0.33	1.23	0.33	6%	0.00
Extensive	Severe structural damage up to the point of incipient collapse	4%	2.14	0.39	1.95	0.40	9%	0.11
Complete	Collapse is imminent for a major portion	7.5%	3.01	0.45	2.60	0.48	14%	0.17

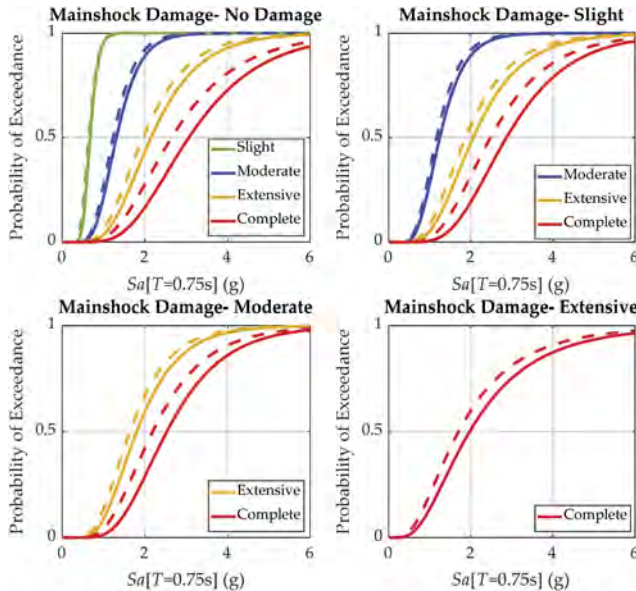

Figure 3. Aftershock fragility curves for all mainshock damage states. Fragility curves considering modeling uncertainty are presented with dashed lines.

4.2 Seismic hazard assessment and estimation of damage state transition probability

The seismic hazard curve for Los Angeles is obtained from Unified Hazard Tool developed by the United States Geological Survey (USGS 2014) for mainshock environment. To estimate the aftershock seismic hazard at a site, this study adopts the aftershock probabilistic seismic hazard analysis results by Yeo & Cornell (2009a). As per their simplified approach, aftershock seismic hazard curve is assumed to be 50 times the given mainshock hazard curve. Furthermore, Omori's law parameters proposed in previous literature for the California region are used to estimate the mean number of aftershocks $\mu(t_0, t_1)$ as mentioned in Equation (6) (Reasenbergs & Jones. 1989; Yeo & Cornell 2009a). It is assumed that the aftershocks can occur 30 days after a mainshock, and transition probability is evaluated (Equation (7)) with an increment of 0.01 days. The transition probability matrix at the end of 30 days is presented in Table 2. It is observed that the transition probability increases substantially by incorporating modeling uncertainty highlighting its criticality in SLCCA.

4.3 Damage state-related cost

Cost related to each damage state (C_{ds}^i in Equation (1)) typically includes various direct and indirect losses. However, only direct cost due to damage/repair is considered for simplicity in this study. Damage/repair costs corresponding to each damage state are represented as the percentage of replacement value, also referred to as the damage index. The damage index for slight, moderate, extensive, and complete damage states is assumed to be 5%, 20%, 40% and 100%, respectively as recommended by Ellingwood & Wen (2005). It is worthwhile to note that Ellingwood & Wen (2005) considered a 90% damage index for the complete damage state. However, the owner prefers to replace the building if damage/repair cost exceeds 60% of the replacement value (FEMA 2018). Therefore, 100% damage index is adopted for the complete damage. Replacement cost per sq. ft. (\$ 203) is obtained by converting FEMA-227 (FEMA 1992) estimates to present-day value. The damage loss matrix (\mathbf{E}_C in Equation (8)) is estimated for after-shock SLCCA based on the difference of cost associated with damage states.

Table 2. Damage state transition probability matrix at the end of 30 days.

	Without Modeling Uncertainty					With Modeling Uncertainty

* Mod. – Moderate, Ext.-Extensive, Comp. – Complete

4.4 Expected seismic life cycle cost

The expected seismic life cycle cost is estimated by incorporating modeling uncertainty for 50-year service life and 4% discount ratio according to the formulation illustrated earlier. The results for the mainshock environment and mainshock-aftershock sequences are depicted in Figure 4 (a). Overall, the expected seismic life cycle cost ($E[SLCC]$) has increased by 44% considering the effect of modeling uncertainty and mainshock-aftershock sequences revealing a severe underestimation of expected losses in the mainshock environment. Additionally, a 25% and 27% hike is observed after incorporating modeling uncertainty for mainshock environment and mainshock-aftershock sequences, respectively. Figure 4 (b) shows the effect of modeling uncertainty on aftershock losses related to each damage state - $E[C_{AS}^i]$ normalized with respect to replacement cost. Due to modeling uncertainty, an increase from 7.2% to 9.5% is observed in total aftershock losses. Furthermore, losses corresponding to intact and slight damage states are increased by 24% and 29%, respectively, while a 40% rise is observed for moderate and extensive damage states.

Figure 4. (a) Effect of modeling uncertainty (MU) on $E[SLCC]$ under mainshock environment (MS) and mainshock-aftershock (MS-AS) sequences (b) Aftershock losses related to each damage state $E[C_{AS}^i]$.

5 CONCLUSIONS

This study proposes a framework to incorporate the effect of modeling uncertainty for seismic life cycle cost assessment under mainshock-aftershock sequences and augments the existing literature that only accounts for naturally occurring ground motion variability. The framework includes a two-fold approach in which modeling uncertainty in beam-column parameters is characterized first using a novel Gaussian Process Regression approach. Subsequently, its impact on mainshock fragility curves is assessed by performing the incremental dynamic analysis of a large number of building samples. Based on the results, the aftershock fragility curves are adjusted to account for modeling uncertainty. The application of the framework is demonstrated using a case study example of a four-story commercial RC building. It is observed that the total aftershock losses increased by 32% and the expected seismic life cycle cost increased by 27 % after incorporating modeling uncertainty. As the characterization of detrimental effects of aftershocks is getting increasing attention from policymakers and stakeholders, this study recommends the adequate quantification and propagation of modeling uncertainty for reliable estimation of the expected seismic life cycle cost.

Sensitivity analysis on resilience components throughout the lifecycle of an asset

N.K. Stamataki

Laboratory of Reinforced Concrete & Seismic Design of Structures, Democritus University of Thrace, Xanthi, Greece

D.V. Achillopoulou

James Watt School of Engineering, University of Glasgow, Glasgow, UK

ABSTRACT: Sustainability of Critical Transport Infrastructures (CTIs) is split in three pillars economy, society and environment and can be estimated indirectly by quantifying resilience. The future provisions have led to the next generation of Eurocodes accounting for the climate change effects, severe increase of service loads, carbon emissions and invested capital. A novel methodology is introduced to quantify the resilience and sustainability level of CTIs, with a special focus on bridges. The different resilience components and distinct periods of the bridge's lifecycle are expressed by Key Performance and Performance Indicators. The components are factored through a Sensitivity Analysis to identify the crucial one. A case-study bridge is examined, exploiting data from its lifecycle to inform owners and stakeholders about the condition, functionality, and operation as well as the resilience and sustainability level. Based on the indicators, decision-making is assisted for a rapid and reliable data-driven asset's management and adaptation analysis.

1 INTRODUCTION

In the last decades, climate resilience and adaptation strategies for Critical Transport Infrastructures (CTIs), such as highway bridges, are of high strategic socioeconomic importance under the prism of sustainable design and maintenance solutions. CTIs have a crucial socioeconomic impact and are essential to withstand extreme hazard events caused by climate change and at the same time meeting the targeted levels of safety and functionality (Asian Development Bank 2021); (Capacci et al. 2022); (Panda & Ramos 2020). Especially, vulnerable high-way Reinforced Concrete (RC) bridges that are close to complete their lifecycle are facing long-term consequences, such as damages and/or disruption resulting in extensive losses. One third of the USA. bridges are characterized as structurally obsolete increasing the risk of losses. The investment to avoid losses of structurally deficient bridges, according to the American Road and Transportation Builders Association is over \$58 billion for their replacement or re-pair (Black 2022). What is more, according to the EU Joint Research Centre the annual expected damages caused to infrastructures are considered to reach €0.8 billion by the end of the century in Europe (Panda & Ramos 2020).

Recent climate projections underpin the increasing urgency of action by considering also global economic risks (Panda & Ramos 2020); (Drzik 2019); (Asian Development Bank 2021). In light of this, resilient and sustainable solutions, including adequate climate change mitigation and adaptation measures have a key role in the allocation of capital for CTIs. Resilience and sustainability are both drivers used to assist in the decision-making process of assets throughout their lifecycle expressed by various indicators (Frangopol et al. 2017); (Asian Development Bank 2021). The indicators that exceed thresholds can trigger pathways for

adjustment of the CTIs. The main objectives of this research are to introduce a novel methodology for the quantification of the resilience and sustainability levels of bridges and identify the criticality of the resilience components in each period. Through a Sensitivity Analysis (*SensAn*) the participation factors for the structural and functional components of resilience are weighted. The methodology is applied to the case-study bridge in the Netherlands and results in a reliable data-driven asset approach that correlates functional and structural performance to define the lifecycle analysis of the bridge.

2 METHODOLOGY

This proposed methodology of Achillopoulou et al. (2022) quantifies resilience and sustainability level of a bridge throughout its life cycle by using Resilience and Sustainability Indices (RIs and SIs), briefly illustrated in Figure 1. The estimation of the indices derives by considering: i) Key Performance Indicators (KPIs) that represent the distinct periods of the asset’s life-cycle (e.g. initial state, recovery period), each one of them contributes at a different level to the final estimation of SIs with the use of weight factors (Wf); ii) different components of resilience that express the structural integrity and the functionality level of the asset, each one also, contributes at a different level to the estimation of RIs by using participations factors (β_c) and iii) a number (n) of Performance Indicators (PIs) to define each one of the resilience components.

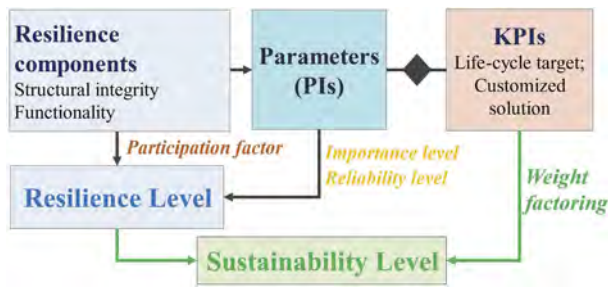

Figure 1. Schematic representation of the methodology.

Resilience quantification is a data-driven process based on the reliability (L_i) and importance (γ_i) level of the PIs as well as the criticality of the resilience components at the different periods of the bridge lifecycle as Equation 1 presents. The reliability level of each PI is taken into account with the use of a reducing factor (Achillopoulou et al. 2022); (Makhoul et al., in press). The factor’s value is crucial and depends on the damage type as well as the available monitoring or artificial data (Achillopoulou et al. 2020); (Argyroudis et al. 2022). The importance level for each PI ranges from 1 to 4, with 1 corresponding to a low importance level meaning that the parameter is not the most crucial to base upon decisions (Achillopoulou et al. 2022); (Makhoul et al., in press). Also, the participation factors of the components result from a Sensitivity Analysis (*SensAn*) based on the targeted resilience levels as described in the next section.

$$RI(t) = \beta_c(t) \cdot \frac{1}{n} \cdot \sum_i^c \gamma_i(t) \cdot L_i(t) \quad (1)$$

The sustainability’s pillars (society, environment, and economy) are considered indirectly in this methodology by the defined PIs that express the impact of an extreme event’s occurrence (e.g., extreme hazard due to climate change, traffic and/or population increase) on the asset’s structural integrity and functionality, the limitations of resources and the environmental legislation for the bridge mitigation measures. Sustainability level is defined by the SIs that scale from 1 to 4, with 4 corresponding to a high level of sustainability (Achillopoulou et al. 2022);

(Makhoul et al., in press). The SIs are estimated by utilizing the calculated RIs and the weighted KPIs using the metric in Equation 2.

$$SI(t) = \sum_1^m W_f(t) \cdot RI(t) \quad (2)$$

where m is the total number of the distinct periods of the asset's life cycle (KPIs).

3 CASE-STUDY

The oldest prestressed highway bridge of Flevopolder in the Netherlands, “Hollandse Bridge” is chosen as the case study due to the various mitigation measures taken over time as well as the fact that has been the main link between the Randstad and the province of Flevoland, including its two largest cities Almere and Lelystad. The bridge is operating since June of 1969 and from the very start, the traffic load increased radically resulting in functionality problems (Achillopollou et al. 2022). The development of the near town city, Almere, augmented the traffic flow further up to overloaded in the 1980s. During the 90s (from 1993 to 1999) various mitigation measures had been taken such as the widening of the bridge's deck. In 2007, the Dutch Organization for Applied Scientific Research decided that the bridge was unsafe to carry traffic loads over 12 tons and applied traffic restrictions. The decision led to tremendous economic losses for the county that busted the renovation of the bridge one year later (2008) and the installation of a Structural Health Monitoring (SHM) system. However, the continuous increase in the traffic load from 2011 to 2014 resulted in further actions that include the reconstruction of the existing bridge and the construction of a new one next to it. The bridge's timeline from 1699 to 2015 is illustrated in Figure 2.

Figure 2. Timeline of Hollandse bridge from 1969 to 2015.

4 SENSITIVITY ANALYSIS

Sensitivity analysis (*SensAn*) in linear programming is used to manage problems and answer hypothetical questions with precise estimates of the coefficients. The changes in the objective function's optimal solution are examined while coefficients varying within certain limits (Borogovo et al. 2018). In this study a *SensAn* is performed for the participation factors (β_c) of the resilience components to i) identify the criticality of the components per period and ii) evaluate the RIs of the case-study bridge based on the initial estimation (Achillopollou et al. 2022). The thresholds and the correlation of the RIs are defined based on the already calculated resilience curve as Table 1 concludes. Once the RIs thresholds are defined, the initial limits of the structural integrity (β_s) and functionality (β_f) participation factors are defined. The β_c are considered complementary and thus, only the initial values of the β_s are defined in Table 1.

Table 1. Resilience indices correlation and the initial limits of the participation factors components.

Period (m)	RI _m	RIs correlation	β_s initial limits
Initial state	RI _I	RI _I ≥ RI _E	$\beta_{s,I} \geq 0.30$
Absorption (exposure)	RI _E	RI _E ≥ RI _{ID1} & RI _E = RI _{cr}	$\beta_{s,E} \geq 0.20$
Idle-time 1 st	RI _{ID1}	RI _{ID1} ≤ RI _E & RI _{ID1} ≤ RI _{ID2/REC1}	$\beta_{s,ID1} \geq 0.30$
Idle-time 2 nd /Recovery 1 st	RI _{ID2/REC1}	RI _{ID2/REC1} ≥ RI _{ID1} & RI _{ID2/REC1} > RI _{cr}	$\beta_{s,ID2/REC1} \geq 0.16$
Recovery 2 nd	RI _{REC2}	RI _{REC2} ≥ RI _{ID2/REC1} & RI _{REC2} > RI _{cr}	$\beta_{s,REC2} \geq 0.16$
Recovery 3 rd	RI _{REC3}	RI _{REC3} ≥ RI _{REC2} & RI _{REC3} > RI _{cr}	$\beta_{s,REC3} \geq 0.45$
Adaptation 1 st	RI _{IAD1}	RI _{IAD1} ≥ RI _{REC3}	$\beta_{s,AD1} \geq 0.40$
Adaptation 2 nd	RI _{AD2}	RI _{AD2} ≥ RI _{IAD1}	$\beta_{s,AD2} \geq 0.40$

For example, the resilience index threshold at the initial state (RI_I) is presented in Figure 3a. The change of the RIs values while β_s ranges within the permissible limits (from 0 to 1) for the initial state and exposure are illustrated with the linear functions. The RI_{tot} values are higher for the initial state and lower for exposure as expected. In cases that RI_{tot} falls under the critical value equal to 40% of the initial index (RI_I), the structural component is less significant and there is a shift of the higher and lower values of the RI_{tot} between exposure and initial state. This practically means, that in order to realistically illustrate the resilience level of exposure lower than that of the initial state, the β_s factor should be at least 0.30.

To use further β_s for predicting the RIs in hypothetic scenarios, the distribution type and function of the factor are defined. This helps to reduce uncertainties and optimize the 1st estimation of the β_s which was based on experts' judgments. The histograms and Probability Density Functions (PDF) of the β_s have been used per period and the violin diagram of β_s has been plotted for the initial period as shown Figure 3b. The β_s distribution function followed is the t-distribution with n-1 degrees of freedom and the highest probability of β_s value is considered to be the median which is equal to 0.65. The distribution was divided in five percentiles (5%,35%,50%,75% and 95%) and the confidence interval taken into account was 95% present. With the defined values of the β_s factor, the resilience curve where redesigned.

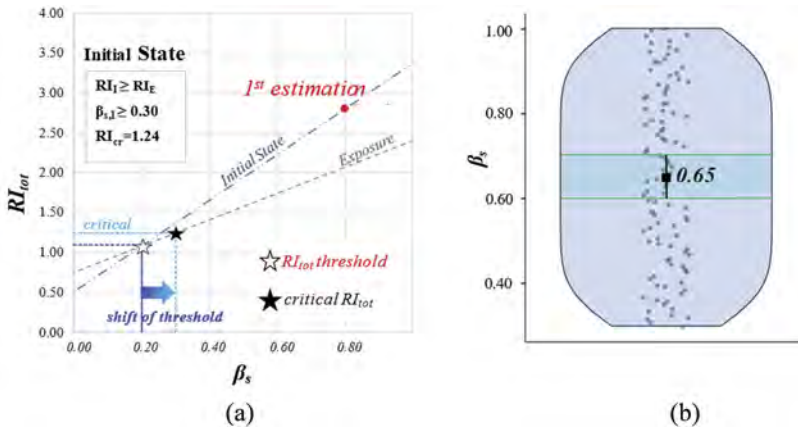

Figure 3. (a) Range of β_s values considering resilience thresholds in initial and exposure state and (b) β_s data distribution-violin diagram at initial state.

5 RESULTS

Table 2 lists β_s factor for each period of the asset. It includes also, the objective β_s prediction ($\beta_{s,mean}$), the range of the values between 25% and 95% percentiles as well as the bottom and upper limit of the confidence interval. The 1st estimation of the factor is proven to be among

the ranges except for the adaptation period in which the structural component's contribution is highly underestimated. Considering the goal values (95% confidence interval) for the adaptation period the error of the 1st estimation reaches up 46%. Whereas, for the recovery periods the 1st estimation of the structural component is most realistically considered, noting the smallest error. It is worth noticing that the highest error of the structural contribution to resilience derives for the exposure period. This means that it is underestimated and therefore higher losses are predicted.

Table 2. Predictions of structural resilience component factor (β_s) per period.

Period	Criteria KPIs	Objective $\beta_{s,mean}$	β_s limits			Goal (95% confidence interval)		1 st estimation $\beta_{s,1st\ estimation}$	1 st estimation error

Based on the β_s predictions, the resilience curves are recalculated as illustrated in Figure 4a and are plotted versus the 1st estimation. The fundamental difference of the 1st estimation and the 95% confidence interval values (dark green shaded area) is that losses are considered higher and present abrupt decrease especially for the adaptation period. Whereas the predictions present a more balanced distribution of losses between the different periods. Figure 4b presents a Pearson correlation analysis of the KPIs considering the average importance values of all the PIs for each period of the asset towards the RIs derived for the predictions of β_s . This analysis advocates that the $RI_{tot,max95\%}$ is much better correlated with the importance level attribute to each PI per period. The reliability analysis confirms the methodology and the PIs adopted.

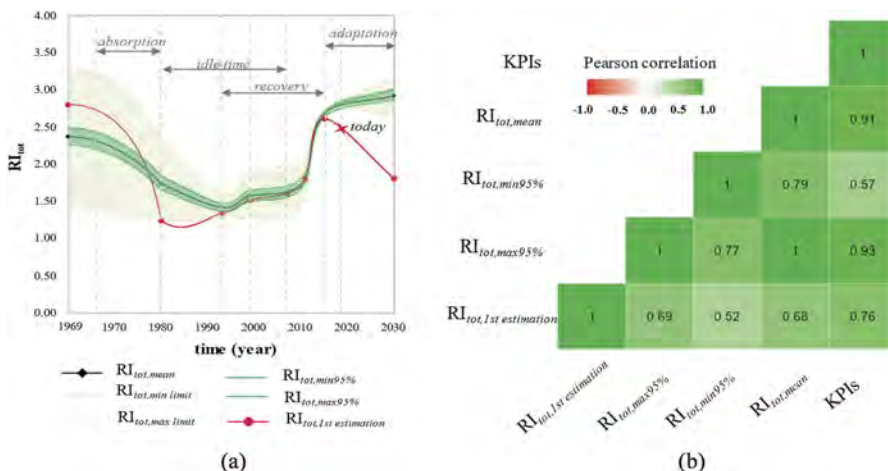

Figure 4. (a) Resilience based on predictions and (b) Pearson correlation of the KPIs and RI_{tot} .

6 CONCLUSIONS

The main conclusions of this study are outlined to the following:

- KPIs that are crucial for a balanced lifecycle of the asset is exposure and adaptation.
- Structural resilience component participation factor (β_s) is proven to follow a t-distribution with $n-1$ degrees of freedom for this case-study and the reliable values optimize the 1st estimation of the factor.
- The methodology is confirmed to be reliable for the importance level it gives to each one of the criteria and PIs chosen throughout the lifecycle of the asset.
- Further research is needed including other case-studies and make prediction of the s factor based on the bridge type.
- Future research aims in expanding the methodology including the investment capital component as well as unpredicted events.

A Markovian framework to model life-cycle consequences of infrastructure systems in a multi-hazard environment

Kenneth Otárola

University College London, London, UK

ABSTRACT: Existing frameworks for multi-hazard life-cycle consequence (LCCon) analysis typically disregard the interactions between multiple hazards and obtain the total LCCon as the sum of the consequences caused by the individual hazards modelled independently. This practice leads to inaccurate life-cycle consequence estimates and ineffective risk-informed decision-making for disaster-mitigation strategies and/or resilience-enhancing policies. In addition, most available LCCon formulations fail to accurately incorporate the damage-accumulation effects due to incomplete (or absent) repairs between different hazard events. To address these challenges, this paper introduces a Markovian framework for efficient multi-hazard LCCon analysis of deteriorating structural systems, appropriately accounting for complex interactions between hazards and their effects on a system's performance. The changes in the system's performance level (e.g., damage or functionality state) are quantified with transition probability matrices following the Markovian assumption and the expected LCCon estimates are obtained by combining the performance level distribution with suitable system-level consequence models, which can include direct asset losses as well as socio-economic consequences. To showcase the framework applicability, a simple road network with a single case-study ordinary reinforced concrete bridge subject to earthquake-induced ground motions and environmentally-induced corrosion deterioration is investigated, estimating consequences in terms of community welfare loss.

1 INTRODUCTION

Many existing risk modelling frameworks independently analyse and aggregate the expected consequences due to multiple hazards (e.g., Dong & Frangopol, 2016). However, it has been demonstrated that multiple, often interacting, hazards can lead to consequences greater than the sum of those related to individual hazards (e.g., De Angeli et al., 2022). As such, it is imperative to account for hazard interactions when quantifying the potential impacts of the events on the performance of critical assets and the communities they serve for risk-informed decision-making on future disaster-mitigation strategies and resilience-enhancing policies. The frameworks for multi-hazard life-cycle consequence (LCCon) analysis that have gained considerable attention over past years neglect such interactions. In addition, they assume that systems sustaining structural/non-structural damage are either instantaneously repaired or do not receive any repair actions after an event (e.g., Fereshtehnejad & Shafieezadeh, 2018). Hence, dynamic changes in the performance of the systems during their service life are not adequately tackled, preventing the accurate quantification of the associated LCCon estimates.

To enable the optimal life-cycle management of structural systems (e.g., buildings or bridges) subject to multiple (and often interacting) hazard events, and of the infrastructure systems that rely on them (e.g., road networks), this paper proposes a Markovian framework for multi-hazard LCCon analysis, which explicitly accounts for the interacting consequences of the hazard events. Using the Markovian assumption (e.g., Bonamente, 2017), the framework can adequately

model damage accumulation and, therefore, performance deterioration (i.e., reduction) while being computationally efficient (e.g., Iervolino et al., 2016). Markov processes have been extensively used for LCCon analysis of utility networks (e.g., Bocchini et al., 2013). They have also recently been used for life-cycle analysis of buildings, mainly in mainshock-aftershock-related applications (e.g., Shokrabadi & Burton, 2018). A comprehensive integration of the different types of hazard interactions is currently lacking in these formulations.

As such, the framework proposed in this paper advances the current knowledge by including the lifetime adverse impact of multiple hazard events and their interactions on the LCCon analysis of structural systems and associated infrastructure systems. It can also be integrated with suitable system-level consequence models to quantify the expected LCCon in terms of direct asset losses and socio-economic consequences. As an example, the proposed framework is applied to the LCCon analysis of a simplified transportation network with a single bridge subject to earthquake events and deterioration effects. Consequences are quantified in terms of welfare losses directly related to the increased travel time due to the actions taken on the bridge.

2 GENERAL FRAMEWORK

The proposed Markovian framework for multi-hazard LCCon analysis efficiently computes expected LCCon estimates of a structural system subject to multiple hazard events causing state changes. The performance of the system is modelled as a discrete-time, discrete-space Markovian process (i.e., treating the state of the process as a discrete variable; e.g., Iervolino et al., 2016). Namely, the system's performance domain is partitioned into mutually exclusive and collectively exhaustive performance states/levels. Such states should be represented using a single harmonised scale valid for different hazard types since specific hazards can cause different types of performance impairment to a system. Thus, for instance, a valid (hazard-agnostic) scale could be defined in terms of the system's functionality. For example, the adopted functionality states (FSs) for a bridge could be defined as: 1) no restrictions; 2) weight restrictions; 3) one lane open only; 4) emergency access only; 5) closure (e.g., Capacci et al., 2020). If the considered hazards can cause similar damage mechanisms to a system (i.e., a consistent damage scale can be used), the performance can also be defined directly in terms of damage states (DSs).

The transition probabilities between FSs (i.e., the probabilities that after one event, the system is in the m -th FS given that it was in the n -th FS before the event) are derived employing state-dependent functionality models (defining the probability of exceeding a FS given a hazard intensity and the FS achieved during a prior event; e.g., fragility relationships) and hazard models (defining the probability of exceeding a hazard intensity measure –IM– given the hazard characteristics; e.g., hazard curves). The transition matrices (i.e., the stochastic square matrices used to describe the FS transitions) are assembled by collecting each (n,m) transition probabilities between FSs, also characterising the system's performance deterioration. The resulting expected consequences are obtained from suitable system-level consequence models (i.e., linking the FSs to a consequence metric of interest).

In the following section, an analytical formulation is presented to compute the expected LCCon estimates. This formulation is based on classical hypotheses for performance-based engineering and is divided into two modelling stages (Zaghi et al., 2016). The first stage, hazard modelling, considers Level I interactions that are independent of the presence of a physical system (e.g., a landslide triggered by an earthquake event). The second stage, consequence modelling, considers Level II interactions resulting from the impact of hazards on a physical system, such as functional impairment due to the accumulation of damage during a seismic sequence.

For modelling purposes, the Level I interactions can be subclassified in (Iannacone et al., 2023): 1) *non-interacting*: hazards whose co-occurrence is purely coincidental (e.g., earthquakes and hurricanes); 2) *concurrent*: hazards that co-occur or have a significant joint probability of occurrence in a period of time (e.g., storm surge, sea waves, and strong wind that co-occur during a hurricane); 3) *successive*: hazards with a causal relationship. Two broad categories can be identified within successive hazards based on their causal relationship: *Type A* (i.e., when a secondary hazard is triggered by the occurrence of a primary hazard) and *Type B* (i.e., the rate of occurrence of a secondary hazard increases following the occurrence of a primary hazard).

Level II interactions are related exclusively to the impairment of a physical system's performance, described by damage or functionality states, given the occurrence of hazard events. In general, the system's performance deterioration can be caused by shock deterioration processes associated with hazard events occurring at a point in time (e.g., an earthquake-induced ground motion) or gradual deterioration processes associated with ageing and/or deteriorating mechanisms (e.g., steel rebars corrosion). System performance can also be recovered (i.e., improved) due to potential repair actions executed in between hazard events. However, such actions are typically intended to recover from shock deterioration processes rather than those due to gradual deterioration.

3 ANALYTICAL FORMULATION

The total expected LCC on estimates associated with a structural system subject to multiple hazard events can be obtained by summing the expected hazard-induced consequences during its service life, obtained as in Equation (1).

$$E[C] = \sum_{i=1}^{\infty} P(i, t_{LC}) \sum_{j=1}^i \mathbf{F}_{S_j} E[\mathbf{C}_{F_{S_j}}]^T \quad (1)$$

In Equation (1), \mathbf{F}_{S_j} is the $1 \times N_{F_S}$ probability mass function (PMF) of the system's FSs after the j -th hazard event, $E[\mathbf{C}_{F_{S_j}}]$ is the consequence model (i.e., a $1 \times N_{F_S}$ vector with the expected consequences associated with each FS), N_{F_S} is the total number of FSs, and $P(i, t_{LC})$ is the probability of having i hazard events during the service life (t_{LC}), obtained as in Equation (2).

$$P(i, t_{LC}) = \frac{(v_T t_{LC})^i e^{-(v_T t_{LC})}}{i!} \quad (2)$$

In Equation (2), v_T is the total rate of occurrence (in a selected time unit) of N_h hazards, regardless of their type and event characteristics. It is assumed that hazard events of the same type (h) occur according to a homogeneous Poisson process with a rate of occurrence equals v_h ($h = 1, \dots, N_h$). Therefore, v_T can be computed as in Equation (3).

$$v_T = \sum_{h=1}^{N_h} v_h \quad (3)$$

It is worth noting that $P(i, t_{LC})$ can also be obtained through a simulation-based approach (e.g., Iannacone et al., 2023). The PMF of the system's FSs after the j -th hazard event only depends on the current PMF of the system's FSs and can be estimated as in Equation (4).

$$\mathbf{F}_{S_j} = \mathbf{F}_{S_{j-1}} \mathbf{T}_{F_S} \quad (4)$$

In equation (4), $\mathbf{F}_{S_{j-1}}$ is the $1 \times N_{F_S}$ PMF of the system's FSs after the $(j-1)$ -th hazard event, and \mathbf{T}_{F_S} is the $N_{F_S} \times N_{F_S}$ transition matrix quantifying the probability of transitioning between the FSs given an event, obtained as in Equation (5).

$$\mathbf{T}_{F_S} = \sum_{t_j=0}^{t_{LC}} \sum_{t_{j-1}=0}^{t_j} f(t_{j-1}, t_j | i, t_{lc}) \mathbf{T}_S \mathbf{T}_{G, \Delta t_j} \mathbf{T}_{R, \Delta t_j} \quad (5)$$

In Equation (5), \mathbf{T}_{F_S} accounts for possible repair actions and gradual deterioration in the time between the occurrence of the $(j-1)$ -th hazard event and the j -th hazard event (i.e., interarrival-time), denoted as Δt_j . The quantity $f(t_{j-1}, t_j | i, t_{lc})$ is the PDF of two hazard events occurring at a time t_{j-1} and t_j , conditioned on the occurrence of i hazard events during the nominal lifetime of the system (details on how to obtain this PDF are shown in Fereshtehnejad & Shafieezadeh, 2018), \mathbf{T}_S is the

$N_{F_S} \times N_{F_S}$ transition matrix associated with a shock deterioration process accounting for the possible hazard events (e.g., earthquake- and flood-related events), $\mathbf{T}_{G,\Delta t_j}$ is the $N_{F_S} \times N_{F_S}$ transition matrix associated with a gradual deterioration process occurring in Δt_j (e.g., deteriorating mechanisms), and $\mathbf{T}_{R,\Delta t_j}$ is the $N_{F_S} \times N_{F_S}$ transition matrix associated with the repair actions occurring in Δt_j . The matrix \mathbf{T}_S can be obtained combining the $N_{F_S} \times N_{F_S}$ transition matrices for individual, non-interacting, hazard types \mathbf{T}_{S_h} , as in Equation (6).

$$\mathbf{T}_S = \sum_{h=1}^{N_h} \frac{v_h}{v_T} \mathbf{T}_{S_h} \quad (6)$$

A significant challenge in using Equation (1) is linked to the high computational cost of integrating all the possible outcomes for the occurrence of the hazard events and the total number of hazard events during the selected time horizon. Such a drawback is exacerbated by $\mathbf{T}_{G,\Delta t_j}$ and $\mathbf{T}_{R,\Delta t_j}$ being a function of Δt_j . Nonetheless, Equation (1) can be significantly simplified by modelling the expected LCCon estimates as the sum of the expected consequences in N_t fixed time intervals of length Δt , where $N_t = \lfloor t_{LC}/\Delta t \rfloor$. Selecting a sufficiently small Δt such that only one (primary) hazard event is likely within each interval, the expected LCCon estimates can be computed with Equation (7).

$$E[C] = \sum_{m=1}^{N_t} \mathbf{F}_{S_{t+m\Delta t}} E[\mathbf{C}_{F_S}]^T \quad (7)$$

In Equation (7), $\mathbf{F}_{S_{t+m\Delta t}}$ is the $1 \times N_{F_S}$ PMF of the system's FSs at time $t + m\Delta t$, computed as in Equation (8). \mathbf{F}_{S_t} is the $1 \times N_{F_S}$ PMF of the system's FSs at time t .

$$\mathbf{F}_{S_{t+m\Delta t}} = \mathbf{F}_{S_t} \prod_{i=1}^m [\nu_T \mathbf{T}_S \mathbf{T}_G + (1 - \nu_T) \mathbf{T}_R \mathbf{T}_G] \quad (8)$$

In equation (8), \mathbf{T}_S is the transition probability due to the gradual deterioration in the time interval Δt , \mathbf{T}_R is the transition probability due to the recovery actions in the time interval Δt , $\nu_T \mathbf{T}_S \mathbf{T}_G$ corresponds to the transition probability due to shock and gradual deterioration, multiplied by the probability of observing a shock-type hazard event in a selected Δt (equal to the rate ν_T under the small-interval assumption). $(1-\nu_T) \mathbf{T}_R \mathbf{T}_G$ corresponds to the transition probability due to repair actions and gradual deterioration, multiplied by the probability of not observing a shock-type hazard event in a selected Δt (equal to $1-\nu_T$ under the small-interval assumption). It is assumed that only a transition due to a hazard event or a repair action occurs in a unit of time since, commonly, repair actions will be interrupted after a significant event. Nonetheless, such an assumption can be relaxed. In this case, $\nu_T \mathbf{T}_S \mathbf{T}_G$ can be written as $\nu_T \mathbf{T}_S \mathbf{T}_R \mathbf{T}_G$. The following subsections describe the derivation of the described transition matrices.

3.1 Shock deterioration transition matrix

The shock-type deterioration transition matrix \mathbf{T}_S only has diagonal and upper-triangular entries corresponding to the probabilities of transitioning from a given FS to a higher FS (i.e., a transition between progressively worse FSs) or staying at the same FS after a hazard event. It is obtained from the transition matrix of the individual hazard types \mathbf{T}_{S_h} using Equation (6). Otáróla et al. (2023) detail how to assemble each \mathbf{T}_{S_h} accounting for Level I and II interactions in the four following cases: 1) hazard type h does not interact with other hazards; 2) hazard type h induces the simultaneous occurrence of other multiple concurrent hazards; 3) hazard type h is the primary hazard of a successive Type A interaction; 4) hazard type h is the primary hazard of a successive Type B interaction.

3.2 Gradual deterioration transition matrix

Before the gradual deterioration initiation time (t_i), there is no transition between FSs. Thus, the gradual-type deterioration transition matrix (i.e., \mathbf{T}_G) is numerically equal to the identity matrix ($\mathbf{T}_G = \mathbf{I}$). After t_i , the system starts transitioning from a given FS to a higher FS (i.e., a transition between progressively worse FSs) or staying at the same FS, and \mathbf{T}_G becomes an upper-triangular matrix whose entries correspond to the probability of transitioning in Δt , as in Equation (9) (which is valid for $t > t_i$). Several probabilistic models can be used to model the system's gradual deterioration (e.g., Duracrete, 2000, Iannacone & Gardoni 2019) and, thus, to obtain the (n,m) entry of the matrix \mathbf{T}_G . In the described procedure, gradual deterioration is treated for modelling purposes as the impact of non-monitored, yet frequent, small shocks.

$$\mathbf{T}_G(n, m) = \begin{cases} P(FS_m|FS_n, \Delta t) & \text{if } n < m \\ 1 - \sum_{i=1}^{N_{FS}} \mathbf{T}_G(n, i) & \text{if } n = m \\ 0 & \text{if } n > m \end{cases} \quad (9)$$

3.3 Repair actions transition matrix

The repair-type recovering transition matrix (i.e., \mathbf{T}_R) only has diagonal and lower-triangular entries relating to the probabilities of transitioning from a given FS to a lower FS (i.e., a transition between progressively better FSs) or staying in the same FS as the structural system recovers with time. The repair actions are modelled through a Poisson process. The daily rate of occurrence of an event where the system is recovered from a worse FS to a better FS is assumed as the inverse of the difference between the repair times of each FS ($T_{n,m}$). This time difference does not necessarily correspond to the repair times associated with each state-dependent FSs; however, this is the simplest approximation to a potential recovery path between the FSs. The values of $T_{n,m}$ are defined if $n > m$, and can be found in the literature (e.g., HAZUS, 2003). The (n,m) entry of the matrix \mathbf{T}_R is obtained as in Equation (10). The Δt should be expressed in the same units than $T_{n,m}$.

$$\mathbf{T}_R(n, m) = \begin{cases} \left(\frac{1}{T_{n,m}} \Delta t\right) e^{-\left(\frac{1}{T_{n,m}} \Delta t\right)} & \text{if } n > m \\ 1 - \sum_{i=1}^{N_{FS}} \mathbf{T}_R(n, i) & \text{if } n = m \\ 0 & \text{if } n < m \end{cases} \quad (10)$$

4 ILLUSTRATIVE APPLICATION

The proposed framework is demonstrated using a simplified case-study road network with a single symmetric double-span box-girder seat-type bridge (Figure 1a). Such a bridge represents a typical bridge vulnerability class in Southern California and is located in downtown Los Angeles (Lat: 34.052, Lon: -118.257). The bridge is characterised by: deck width: 23 m; number of spans: 2; span lengths: 45.7 m; number of columns: 2; columns radius: 0.85 m; columns height: 6.70 m. It comprises seat-type abutments (which include an arrangement of nonlinear springs for shear keys, elastomeric bearing pads, soil backfill, and abutment piles), column bents (which include nonlinear fibre sectional models for columns and column foundational springs), and an elastic superstructure representing the box-girder deck, designed and detailed according to Caltrans Seismic Design Criteria 2.0 (Caltrans, 2019). The bridge is assumed to undergo earthquake-induced ground motions while experiencing environmentally-induced corrosion deterioration in a marine splash exposure. DSs are used as performance states (so FS = DS in the previous equations) since a unique shock-type hazard is investigated, as in common performance-based engineering practice. The time- and state-dependent fragility relationships developed in Otárola et al. (2022) are used to assemble \mathbf{T}_S and HAZUS repair times are used to assemble \mathbf{T}_R (HAZUS, 2003). Table 1 to 3 presents the

transition matrices for the case-study bridge. In total, four DSs are adopted, corresponding to slight (DS1), moderate (DS2), extensive (DS3), and complete (DS4) structural damage. Although the entries for T_S and T_R are obtained from fragility and recovery models, respectively, values for T_G are ideal and are used for illustrative purposes, estimating its non-diagonal entries as those corresponding to T_S divided by 100 for $a\Delta t = 1$ month.

The expected LCCon is estimated in terms of expected welfare loss ($E[\Delta W]$; i.e., a measure of the impact of road network disruption on the commuters' well-being, Silva-Lopez et al., 2022) and considering 80 years as the bridge's service life. A welfare-loss consequence model is developed, associating each DS to a restrictive action that causes an increase in the travel time of the members of the community, namely: 1) DS0: no restrictions; 2) DS1: speed restrictions; 3) DS2: one lane open only; 4) DS3: one lane open only and speed restrictions; 5) DS4: closure. The consequence estimates are obtained from analysing the road network performance given a restrictive action. The outcome of such analyses is the aggregated travel time of the commuters, T , from where the difference in the travel time is obtained as $\Delta T = T - T_0$, where T_0 is the travel time in the "no restrictions" case. To compute ΔT , a graph-based approach based on the shortest-path algorithm is implemented (Dijkstra, 2022). In this regard, the road network is idealised as a directed graph (the travels are assumed to be directed to a unique destination, i.e., node 4 in this application) where nodes represent the locations of interest and edges represent the links between these locations. A demand of 500, 500, and 1000 vehicles/h is assumed to originate from nodes 1, 2, and 3, respectively. The links are assumed to be at full capacity with no congestion in the "no restriction" case (i.e., vehicles move at the free flow speed); the free flow speed is assumed as 40, 80, 40, and 80 km/h for the two-lane links 1-2, 1-3, 2-4, and 3-4, respectively. A speed restriction is assumed to reduce the free flow speed to 75% of the original value. A lane closure is assumed to reduce the capacity of the link to the value C^* , causing a congestion and changing the aggregated travel time associated with the link to

$$T^* = \frac{C^*}{D} T_0 \quad (11)$$

In this case study, $C^* = C_0/2$ is assumed, where C_0 is the capacity of the link in the “no restriction” case. No reduction in the demand is assumed between cases.

The ΔT metric is then used to estimate the welfare loss (ΔW) as in Equation (12), using the same parameters presented in Silva-Lopez et al. (2022), where y is the commuter’s wage rate, assumed to be 17.8 USD/h. Thereby, the consequence model $E[C_{FS}] = [0, 52.26, 156.79, 261.32, 522.63]$ is proposed in utils/h units.

$$\Delta W = \frac{1}{2y^{0.26}} \Delta T \quad (12)$$

Figure 1b Shows the expected life-cycle welfare loss for the case-study road network for the bridge starting in pristine conditions ($F_{s_0} = [1, 0, 0, 0, 0]$) as obtained by employing the proposed framework. Additionally, the expected life-cycle welfare loss of a structural upgraded bridge at $t = 0$ years (yr) is presented. Such an upgrade is assumed to ideally increase the median fragility values by 20% (i.e., to increase the lateral-resisting system structural capacity). As expected, an enhancement in the bridge’s seismic lateral resisting system can significantly reduce its LCC estimates, as also observed in Figure 1b. Given the flexibility and efficiency of the proposed framework, such improvements can be analysed at any point in time and utilised to showcase the value and/or significance of risk management and adaptation pathways.

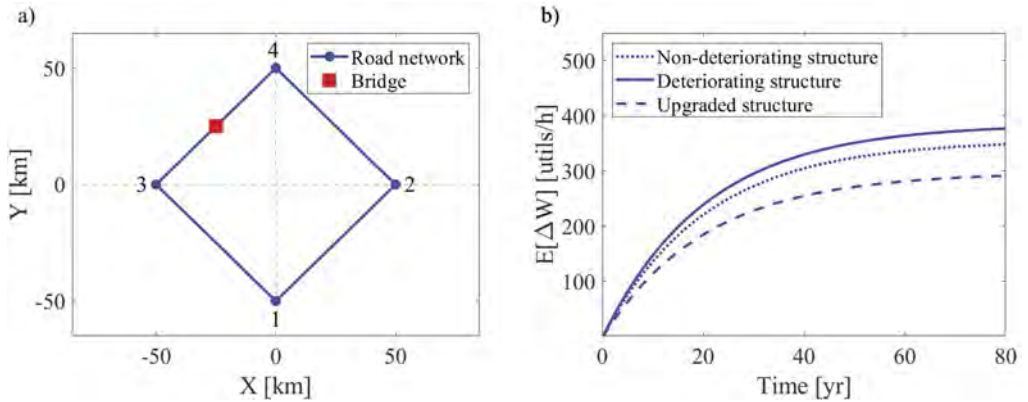

Figure 1. a) Case-study road network and b) expected life-cycle welfare loss.

5 CONCLUSIONS

The paper presented a Markovian framework for multi-hazard life-cycle consequence analysis of deteriorating structural systems. Transition matrices for shock deterioration, gradual deterioration, and repair actions were established to model the performance state change accounting for the possible interactions among hazards. Different unitary consequences (in terms of repair costs) were assigned to different performance states, allowing to obtain the expected Life Cycle Consequences of the system. The framework can be used to model the time- and state-dependent deterioration and recovery processes with significantly low computational demand. The proposed framework was applied for a simplified road network with a double-span box-girder seat-type bridge subject to earthquake-induced ground motions and corrosion-induced deterioration. The results showcase how the formulation can be implemented in actual risk modelling practice to adequately assess the life-cycle consequences of structural systems due to multiple hazards.

Integrating life-cycle analysis into civil infrastructure resilience decision making: Illustrative application to seismic resilience modeling of US communities

Milad Roohi

University of Nebraska-Lincoln, Omaha, NE, USA

Jiate Li & John W. van de Lindt

Colorado State University, Fort Collins, CO, USA

ABSTRACT: This paper aims to integrate life-cycle analysis into civil infrastructure resilience modeling and decision-making in seismic-prone communities. To achieve this aim, the authors present a methodology for modeling seismic life-cycle resilience of interdependent buildings and lifeline systems and subsequently informing resilience decisions directly related to the maintenance and retrofit of interdependent infrastructure to enhance a community's physical, social, and economic systems. The methodology consists of 1) community data collection, 2) seismic hazard analysis, 3) physical damage analysis, and 4) system-level functionality and restoration analysis, 5) socio-economic impact analysis, 6) life-cycle optimization and retrofit decision-making. The methodology begins by developing geospatial datasets to characterize a community's interdependent civil infrastructure. Subsequently, ground motion prediction models are employed to simulate scenario earthquakes and obtain spatial intensity measures within the community. A fragility-based computational model of the networked infrastructure is then developed using graph theory to perform physical damage analysis using Monte Carlo simulations by accounting for structural aging and degradation. The damage estimates are used as input to an input-output model to perform functionality and restoration analysis by accounting for infrastructure networks' cascading failure and interdependency. An illustrative case study is presented to demonstrate the implication of the methodology to perform seismic life-cycle resilience in US communities, including Shelby County, TN. The methodology will assist engineers and urban planners in assessing the vulnerability of critical buildings and lifeline systems and developing life-cycle resilience-informed mitigation strategies to improve the seismic resilience of communities.

1 INTRODUCTION

Infrastructure systems are highly interconnected and interdependent, making them susceptible to disruptions caused by natural disasters and aging. The losses incurred due to these disruptions, the impact of climate change, and regulatory mandates have underscored the need for governments, private sectors, and communities worldwide to undertake a more thorough assessment of their portfolio exposure and risk. In the past decades, advanced catastrophe risk models have been developed to characterize the performance of the built environment and the direct and indirect impacts of natural hazards through data and analytics to develop risk management solutions and policies. More recently, extensive research has been conducted to develop advanced multiscale multidisciplinary community resilience modeling frameworks and computational tools to quantify multidisciplinary resilience metrics and compare alternative policies or strategies for mitigation and post-hazard recovery planning (Roohi et al. 2021, Deierlein et al. 2020, Cremen et al. 2023). These computational models adopt a system of

systems modeling approach to account for interdependency between networked infrastructure and socio-economic systems. Depending on data availability, the scale and hazard of interest, and computational resources, community resilience models can be developed with various levels of resolution and uncertainty. The community resilience models are computationally complex in which data availability, model assumptions, parameters, and inputs can play a crucial role in the accuracy and robustness of estimated resilience metrics. These resilience metrics are, by and large, primarily based on social science and economics; however, most civil engineering studies consider only damage and direct losses without the ability to accurately model indirect losses, e.g., those impacting the economic sectors that interact within a community.

Despite the advancements in resilience modeling and the capability of the models to distinguish the vulnerability of structures based on their characteristics (e.g., construction type, occupational type, seismic design code, and building height), other characteristics such as service age and environment of the structure are needed to be considered to improve the accuracy in evaluating the performance of the infrastructure. Several studies (Akiyama et al. 2011; Zheng et al. 2021) have demonstrated that deterioration and aging will significantly impact the service lifetime, seismic vulnerability, and seismic life-cycle performance of infrastructure systems. To account for these impacts, life-cycle analysis (LCA) is an essential tool that can be integrated into resilience modeling by assessing the performance of a structure throughout its lifespan to obtain a more comprehensive understanding of the impacts of the environment on infrastructure systems and how these systems can be made more sustainable and resilient. This analysis involves a detailed investigation of various elements of a system, including its design, construction, maintenance, and retrofitting. The analysis begins with a hazard assessment, which involves identifying potential damage due to a hazardous event. Engineers can determine the required design criteria for a structure based on this assessment. During the design phase, engineers use various design methods to ensure the structure can withstand the expected forces. The design process also involves selecting appropriate construction materials and techniques that can enhance the seismic resistance of the structure. Once the structure is constructed, it undergoes regular maintenance and inspection to identify any signs of damage or deterioration. If necessary, retrofitting measures can be implemented to improve the structure's performance. LCA can help owners and engineers to identify potential risks and to develop appropriate mitigation strategies. This analysis can also help to reduce the risk of structural damage and loss of life. This is particularly important as buildings built in the 1970s and earlier are still being utilized today, both in developing and developed regions of the world. However, these structures were not designed to adhere to the 1976 Uniform Building Code, which introduced design standards for ductile behavior during seismic activity (Bai et al. 2003). Consequently, these structures are vulnerable to damaging earthquakes, thereby presenting a potential danger. Thus, officials must provide various policy options to implement performance evaluation and retrofit plans for the most vulnerable (i.e., non-code and low-code compliant) and critical buildings.

The previous exposition highlights the need to develop integrated life cycle resilience modeling approaches capable of accounting for i) cascading impacts of the failure in components of infrastructure in the functionality of the networked system, ii) accounting for structural aging, strength degradation, and retrofit, which can significantly impact the seismic performance of infrastructure systems. This paper addresses this need by integrating LCA into civil infrastructure resilience modeling and decision-making in seismic-prone communities. To achieve this aim, the authors present a methodology for modeling seismic life-cycle resilience of interdependent buildings and lifeline systems and subsequently informing resilience decisions directly related to the maintenance and retrofit of interdependent infrastructure to enhance the community's physical, social, and economic systems. An illustrative case study is presented to demonstrate the implication of the methodology to perform seismic life-cycle resilience in US communities, including Shelby County, TN. The methodology will assist engineers and urban planners in assessing the vulnerability of critical buildings and lifeline systems and developing mitigation strategies to improve the seismic resilience of communities.

2 PROPOSED METHODOLOGY

The methodology consists of 1) community data collection, 2) seismic hazard analysis, 3) physical damage analysis, and 4) system-level functionality and restoration analysis, 5) socio-economic impact analysis, 6) life-cycle optimization and retrofit decision-making. The methodology begins by developing geospatial datasets to characterize a community's civil infrastructure and interdependency. Subsequently, ground motion prediction models are employed to simulate scenario earthquakes and obtain spatial intensity measures within the community. A fragility-based computational model of the networked infrastructure is then developed using graph theory to perform physical damage analysis using Monte Carlo simulations. The damage estimates are used as input to an input-output model to perform functionality and restoration analysis by accounting for infrastructure networks' cascading failure and interdependency.

2.1 Data and information of physical infrastructure

The initial phase of the process involves the creation of geospatial datasets (in the form of shapefiles) that describe the buildings and lifelines system of the community. This step also involves the development of an interdependency matrix for the physical infrastructure network. The interdependency is modeled by estimating the service areas of each network infrastructure and performing geospatial analysis to identify the buildings within each service area (refer to Linger and Wolioskx 2001 and Roohi et al. 2022 for further information). This information is critical to understanding the relationships between different infrastructure components and the potential cascading impact of a seismic event.

2.2 Spatial seismic hazard analysis

In the second step, a spatial multi-hazard analysis is conducted to generate a spatial distribution of hazard intensity measures to measure the effects of seismic wave propagation, liquefaction, and landslide as the main phenomena affecting the integrity of distributed networked infrastructure (see Farahani et al. for further details). The seismic event scenarios are generated using various ground motion prediction equations (GMPEs) developed for spatial hazard modeling. The GMPEs consider different characteristics, such as earthquake magnitude, the distance between source and site, local soil conditions, and fault mechanism. The intensity measures are selected based on the seismic vulnerability of the component or system of interest, including peak ground acceleration, spectral acceleration, peak ground velocity, or peak ground displacement.

2.3 Infrastructure systems model development

The third step in the process is to develop a fragility-based computational model of the networked infrastructure using the fundamental graph theory. This involves creating a directed graph model of the community, represented by an $n \times n$ adjacency matrix $M(\mathcal{G}) = [m_{ij}]$, and mapping fragility functions to individual components based on their structural attributes. These fragility functions relate a given hazard intensity measure to the conditional probability of exceeding a particular damage state, such as insignificant, moderate, extensive, or complete. Fragility functions are often described using a lognormal cumulative distribution function given by

$$F_R[IM = im] = \Phi \left[\frac{1}{\beta_k} \cdot \ln \left(\frac{im}{\lambda_k} \right) \right] \quad (1)$$

in which Φ is the standard cumulative probability function, λ_k median capacity and $\beta_k = \sigma(\ln R)$ or logarithmic standard deviation associate with d_{s_k} . In addition to the basic parameters of construction type, occupational type, and seismic design code, other parameters such as service age and environment of the structure are considered to better capture the life-cycle of the infrastructure. Structural aging and strength degradation can significantly impact the fragility parameters of

structures, particularly the median fragility, which is most affected. The loss of section caused by corrosion and deterioration can cause the median fragility to decrease, but the decrease may not be linearly related to the fragility, which takes into account the dynamic response and nonlinear behavior of the structural component. Therefore, a 20% loss in section may not correspond to a 20% decrease in median fragility. Due to uncertainties in the degradation mechanisms, aging also affects the variability and uncertainty (characterized by β). As a result of aging, these variabilities tend to increase. Structural fragility parameters can be modified to take aging into account, and this can be done using a Bayesian procedure to update the fragility models used in the risk assessment (Ellingwood and Song 1996). To illustrate the outcome of this update, Figure 1 presents the fragility curves of an arbitrary building structure under different service ages.

Figure 1. Illustrative fragility curves for an arbitrary building structure with different service age.

2.4 Physical damage and functionality analysis

The fourth step is to estimate each infrastructure component's damage and functionality states, given the hazard intensity measure. The damage estimate is obtained using the fragility functions given by Equation 2 to estimate potential damage to the physical infrastructure component. Given the fragility function F_R of an infrastructure component and hazard intensity measure IM , the conditional probability of damage measure is given by

$$P_f[DS \geq DS_k | IM = im] = \int_0^{im} \frac{1}{\sqrt{2\pi}\beta_k s} \exp\left[-\frac{1}{2} \left\{ \frac{\ln(s) - \lambda_k}{\beta_k} \right\}^2\right] ds \quad (2)$$

where $p_f(\cdot)$ denotes the probability of being at or exceeding a particular damage state, DS_k , for a given intensity measure, IM . Then, Monte Carlo simulations (MCS) are performed to estimate the physical damage to each infrastructure component. Subsequently, HAZUS restoration curves are used to estimate the functionality of each component immediately and days after a seismic event. Finally, the functionality estimates are used as input to an input-output (I-O) model to simulate the functionality of components by accounting for the interdependency between networked infrastructure. An I-O model uses a perturbation vector, given by u , to capture the inoperability of the components of a disrupted interconnected system due to cascading effects.

$$q = M(\mathcal{G})q + u \quad (3)$$

where $u = [u_1, u_2, \dots, u_n]^T$; $u_i \in [0, 1] \subset \mathbb{R}$ is the perturbation vector obtained from non-functionality of individual network components subject to seismic hazard and $q = [q_1, q_2, \dots, q_n]^T$; $q_i \in [0, \infty) \subset \mathbb{R}$ is the resulting non-functionality vector due to their

connections to the perturbed infrastructure components and their cascading failure. The non-functionally vector q can be calculated as follows:

$$q = \left(I - M(G)^T \right)^{-1} u \quad (4)$$

2.5 Life-cycle optimization and retrofit decision-making

Let R_i be the retrofit cost of a system of interest i ; T the (random) time of occurrence of the earthquake that may affect it, and L_i is the loss associated with earthquake loss for system i ; including damage and failure consequences, as well as repair and maintenance actions. L_i can be obtained by converting the DSs into monetary values. For buildings, repair costs are estimated by multiplying the square footage of each building type within that occupancy by the probability of that building type being in the given damage state and the repair costs per square foot for the given damage state (relative to the replacement cost). The structural loss for each structural system can be quantified as follows

$$L_i = CS_{occ} = BRC_{occ} \sum_{DV=IO}^c CS_{PL,i} = BRC_{occ} \sum_{DV=IO}^c p[DS = ds] RCS_{PL,occ} \quad (5)$$

Figure 2. Buildings (left) and lifeline (right) systems of the MMSA. The figures show the directed graph for each networked lifeline system and their interdependent model.

Figure 3. The number of buildings with various construction types (left) and most probable damage state subject to $M_w 7.1$ earthquake scenario (right).

where $CS_{PL,occ}$ is the cost of structural damage (repair costs) associated with damage state ds , and occupancy class occ , BRC_{occ} is the building replacement cost of occupancy class occ , as described in the HAZUS Inventory Technical Manual. $R_{CS_{PL,occ}}$ is the structural repair cost ratio (in % of building replacement cost) for occupancy class, i , in damage state, ds (refer to Table 112 of HAZUS Technical Manual). Then, the following objective function must be minimized to determine the optimal life-cycle-optimized community-level retrofit action:

$$U = \sum_{i=1}^N (R_i + E[L_i^{-qT}]) \quad (6)$$

where $E[\cdot]$ stands for expected value, and q is an adequate discount rate.

2.6 Case study: Memphis metropolitan statistical area (Mmsa), TN, US

This methodology is demonstrated through the case study of MMSA. The buildings, EPN, WDS, and boundary shapefiles were created using an extensive MMSA testbed database, including 306,003 buildings of various construction types and occupancy uses, collected by the Mid-America Earthquake Center. The community model was created with the Interdependent Networked Community Resilience Modeling Environment (IN-CORE), as shown in Figure 2. Fragility functions were assigned to each component based on their structural attributes. The Boore and Atkinson (2008) GMPE was used to generate two different scenario events with magnitudes $M_w 6.5$ and $M_w 7.1$ to study the effect of hazard intensity. Damage to all buildings and lifeline systems within the MMSA was evaluated using the mapped fragility curves and IMs. Component-level damage estimates were used to perform functionality and restoration analysis of buildings and networks, considering the interdependency between systems and the cascading failure of each network component using the I-O model.

Figure 4. Most probable damage state subject to $M_w 7.1$ earthquake scenario.

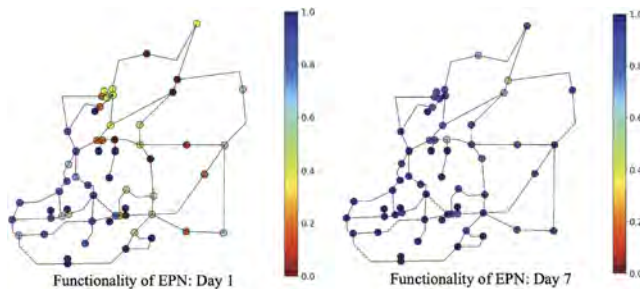

Figure 5. Functionality analysis of EPN substations by accounting for the interdependency between EPN and WDS subject to $M_w 7.1$ scenario earthquake.

2.7 Results and discussion

Figure 3 presents the number of buildings with various construction types. As can be seen, most of the buildings are wood construction. As a representative result, Figures 3 and 4 also present the statistics of the most probable damage state of buildings subject to $M_w 7.1$ scenario earthquake. Figure 4 presents example results obtained from functionality and restoration

Table 1. Building functionality estimates days following seismic events obtained by accounting for infrastructure interdependency.

Seismic Event	Functionality	1 day	3 days	7 days	30 days	90 days
M_w 6.5	Functional	30.2%	53.6%	98.6%	98.6%	98.6%
	Non-Functional	69.8%	46.5%	1.4%	1.4%	1.4%
M_w 7.1	Functional	16.8%	28.5%	86.5%	86.5%	86.5%
	Non-Functional	83.3%	71.5%	13.5%	13.5%	13.5%

analysis of EPN substations under M_w 7.1 scenario earthquake by considering the interdependency between EPN and WDS and the cascading failure of each network component using an I-O model (Haimes et al. 2005). Table 1 summarizes building functionality estimates by accounting for the interdependency between buildings, EPN, and WDS subject to M_w 6.5 and M_w 7.1 scenario earthquakes. Comparing the results for these two seismic events shows that high-intensity earthquake causes more significant impacts in terms of the number of buildings that do not operate normally to provide their regular and reliable pre-event services. The outcomes of the proposed methodology could be readily used as input to life-cycle optimization presented in the methodology section to investigate various community-level retrofit strategies and make informed decision-making. The results of this analysis can be used as input to social and economic models to quantify resilience metrics such as impacts of employment, household income, and population dislocation, as demonstrated in Roohi et al. 2021. This case study illustrates the capability of the proposed methodology to assist engineers and decision-makers in evaluating the vulnerability of critical buildings and lifeline systems and developing mitigation strategies to improve the seismic resilience of communities.

3 CONCLUSIONS

This paper presents a methodology for integrating life-cycle analysis into civil infrastructure resilience modeling and decision-making in seismic-prone communities. This integration allows assessing the performance of a structure throughout its lifespan to obtain a more comprehensive understanding of the impacts of the environment on infrastructure systems and how these systems can be made more sustainable and resilient. The proposed methodology is designed to model seismic life-cycle resilience of interdependent buildings and lifeline systems and inform resilience decisions directly related to the maintenance and retrofit of interdependent infrastructure to enhance community resilience. The methodology consists of community data collection, seismic hazard analysis, physical damage analysis, system-level functionality and restoration analysis, life-cycle optimization and retrofit decision-making. An illustrative case study is presented to demonstrate the implication of the methodology to perform seismic life-cycle resilience in US communities, including Shelby County, TN. The methodology will assist engineers and urban planners in assessing the vulnerability of critical buildings and lifeline systems and developing mitigation strategies to improve the seismic resilience of communities. The paper concludes by highlighting the need for integrated life cycle resilience modeling approaches capable of accounting for cascading impacts of the failure in components of infrastructure in the functionality of the networked system, accounting for structural aging, strength degradation, and retrofit, which can significantly impact the seismic performance of infrastructure systems.

Smart resilience: Capturing dynamic, uncertain and evolving lifecycle conditions

R. Rincon & J.E. Padgett

Rice University, Houston, TX, USA

ABSTRACT: Modern cities are becoming increasingly smart and interconnected, with the capacity to gather unprecedented amounts of information. However, available methods for resilience quantification lack agility to cope with the ever-changing conditions and data that underpin disaster resilience and lifecycle performance analysis. In this paper, we discuss the limitations in the models themselves, i.e. even though frameworks predict uncertain and temporally evolving system performance, they are unable to learn from new data. To address these limitations, we pose a ‘smart resilience modeling concept’ which presents the ability to update model estimations and to efficiently estimate the lifecycle resilience as new data emerges. Hypothetical examples on community infrastructure affected by deterioration effects and punctuated events are presented. This conceptualization is expected to lay a foundation for smart resilience models capable of capturing the dynamic, uncertain, and evolving characteristics of future environmental demands, societal characteristics, and infrastructure conditions.

1 INTRODUCTION

The exposure of the built infrastructure to disruptive events demands a comprehensive way to measure its resilience. The importance of its quantification lies in the need of communities to set a baseline, define resilience goals and actions, quantify progress, and to estimate the social benefits and losses of resilience-related decisions (Committee on Increasing National Resilience to Hazards and Disasters *et al.* 2012). Modeling techniques are needed to establish such measurement in a prospective way; we need to predict communities and systems’ capacity to withstand, adapt to and progressively recover after a disruption (Bruneau *et al.* 2003, Cimellaro *et al.* 2010). This requires interdisciplinary work and, although it has been a field of active research in the past decade, gaps and questions about measuring resilience still exist.

In the engineering community, there are difficulties in measuring resilience because of its multidimensional nature, the lack of evidentiary data and the uncertain and evolving conditions that underpin disaster resilience (National Academies of Sciences, Engineering, and Medicine 2019). Different efforts have been made to improve resilience estimation; for example, considering time-affected conditions of the engineering systems (Ghosh and Padgett 2010, Rokneddin *et al.* 2014, Jia and Gardoni 2019, Capacci *et al.* 2020); acknowledging the absorptive capacity of the system to accommodate or reduce the events’ impacts (Ouyang and Dueñas-Osorio 2012, Decò *et al.* 2013); take account of the availability of resources needed for recovery processes (González *et al.* 2016); the multi-hazards conditions and cascading effects (Hernandez-Fajardo and Dueñas-Osorio 2013); the varying demand-supply of infrastructure services after events (Ouyang and Dueñas-Osorio 2012, Blagojević *et al.* 2022), among others. However, existing resilience modeling paradigms are designed with constrained inputs and model settings, and therefore easily become outdated over time.

To solve this limitation, we pose the idea of a ‘smart resilience modeling approach’. We consider the infrastructure systems’ resilience as a dynamic and uncertain quantity that evolves as

data and new modeling approaches emerge. A ‘smart’ resilience model should be able to continuously learn from new data gathered, cope with shifts in environmental demands, consider variations in social needs and infrastructure uses, handle new monitoring parameters from emerging technologies, and others, adapting to the dynamic conditions of the systems. This paper presents the needs of such a framework using hypothetical examples. It is shown that lacking flexibility for coping with the emerging sources mentioned above may hinder the community spatial resilience, reduce their ability to identify and adaptively learn from varying threats and diminish the ability to understand the community progress towards resilience goals, with probable worse impacts within the most vulnerable populations.

2 LIFECYCLE RESILIENCE MODELING

Infrastructure lifecycle and resilience assessments are commonly separate analyses given the differences in their temporal scale. Lifecycle analyses typically evaluate the system time-dependent performance in which progressive and punctuated events can affect the infrastructure during decades of service (Sanchez-Silva *et al.* 2011). On the other hand, resilience assessments are usually related to the recovery phase after a punctuated disturbance occurred, often framed in a scale from days to years (see Figure 1). Recent emphasis has been given to the joint evaluation of lifecycle and resilience aiming to capture the increased vulnerability in aging infrastructure, shifts in user-demands over time and the adaptation of communities after shock-based events. However, lifecycle resilience modeling paradigms still lack flexibility to include these variations as new knowledge about the system becomes available at any point at time. This makes the lifecycle resilience modeling challenging to be repeatable, generalizable and, sometimes, impractical to be applied (National Academies of Sciences, Engineering, and Medicine 2019).

Figure 1. Lifecycle resilience analysis and resilience assessment time scales.

2.1 Smart resilience modeling

“Smart resilience” has appeared recently as a concept to depict the use of emerging technologies and intelligent practices (e.g. models, algorithms or tools) to enhance the system’s capacity to handle, absorb, react and recover from any disturbance (DesRoches and Taylor 2018, Kumar *et al.* 2019, Padgett *et al.* 2022). Different examples in the literature demonstrate these smart technologies has permeated the resilience lifecycle assessment, including real-time health monitoring, physical and social sensors, IoT, and digital twins (Li and Pozzi 2019, Fan *et al.* 2021, Panakkal and Padgett 2022, Yabe *et al.* 2022). Also the evaluation of the benefits obtained from introducing these smart technologies for infrastructure monitoring purposes and the adaptability gained by the possibility of on-time decision-making have seen a tremendous increase of interest from researchers (Rabiei and Modarres 2013, Malings and Pozzi 2016, Zuluaga and Sánchez-Silva 2020). However, most of the recent contributions tend to focus on specific and individual portions of the infrastructure resilience lifecycle, i.e. they concentrate on introducing data acquisition techniques for characterization of exposed inventory, definition of system parameters to be monitored, or estimation of system performance during the post-disaster response phase.

To address the measurement and estimation of infrastructure resilience we pose a ‘smart modeling paradigm’. We focus on the modeling paradigm itself to tackle the dynamic, uncertain and

evolving lifecycle conditions over time. Smart resilience modeling refers to algorithms able to infuse existing modeling techniques with the ever-changing conditions measured or observed on the systems' dynamics (social, environmental, physical, and others). Hence, these must be flexible algorithms able to evolve as new knowledge and innovative approaches arise in the infrastructure lifetime horizon (see Figure 2).

Figure 2 depicts, conceptually, the system resilience estimations influenced by potential sources of data such as periodic or continuous observations (red stars and lines, respectively). For example, with the vast advances in smart technologies, shifts in the functionality of the system could be suddenly observed. On the other hand, performance estimates of the system are predicted by means of existing algorithms, which may include the effect of degradation stressors (blue lines) or the estimation of recovery trajectories after a shock event (green line). One key goal of the smart resilience concept is to continuously fuse these different knowledge sources to inform future resilience models. The outcomes of such approaches result in mean estimates of the system performance with bounds that show the varying uncertainty and its relationship with data collection efforts (black solid and dashed lines). Such a modeling paradigm requires intelligent algorithms to estimate, efficiently and confidently, the actual resilience of the system as time evolves. Recursive Bayesian algorithms, active learning, and transfer learning techniques, among others, are envisioned for this purpose. Such methods can help to limit the resources required for computation and data gathering, overcome data limitations and introduce the heterogeneous gathered knowledge into the assessment of future systems' resilience.

Figure 2. Resilience modeling of infrastructure performance over time and potential to leverage different data sources in a smart resilience framework.

3 ILLUSTRATIVE EXAMPLE

3.1 Problem definition

A rather simple transportation network is selected to explain the smart resilience approach (Figure 3). It consists of seven cities connected through 10 roads which condition depends on bridges' availability. Multi-span simply supported concrete bridges (assumed as representative of the bridges in the network) are affected by deterioration processes related to chloride ingress (Ghosh and Padgett 2010). The bridges' capacity to sustain service loads (i.e. live loads) and extreme loads (represented by seismic events) are affected. The live loads crossing the bridges are represented probabilistically by a three parameter Weibull distribution following Chowdhury *et al.* (2013), and seismic loads by a point of fault rupture that generates events whose magnitude follows a truncated Gutenberg-Richter model ($M_{w,min} = 5$, $M_{w,max} = 8$, $b = 1$). The loads and magnitude probability distributions are considered fixed in this study.

Bridges in this network are the only components considered susceptible to failure producing a complete road closure. Failure events related to live loads occur when a live load exceeds the bridge's moment capacity or the reliability index (β) reaches a value of $\beta = 2.6$ (Vishnu 2019). Besides, when a seismic event occurs leading to extensive damage is also considered as bridge failure (or if $\beta = 1.5$). It is assumed that a failure condition always requires a complete bridge closure for intervention purposes.

Inspection campaigns, information about failure events and data collected during repair activities are documented in Table 1. Bridge deterioration affected components are examined (using intrusive approaches) every 5 years. Deck or total bridge replacements are reported if the moment capacity has been exceeded on the bridge's deck or a seismic event damaged structures within the network. Finally, field observations of the progress and used times are collected during bridge interventions. These sources of information are used to update model inputs, model parameters or to infuse authoritative data within the predicted model estimations.

Figure 3. Hypothetical transportation network.

Table 1. Timeline of data collected and event occurrence.

Year	Event type	Data gathered	Unit
0	Exposed assets	Bridges ages: 45, 24, 26, 12, 47, 37, 19, 37	years
5	Bridge inspection	Deterioration affected parameters*	cm
15	Bridge inspection	Deterioration affected parameters*	cm
17	Seismic event, $M_w=5.7$	Damaged condition	0,0,0,0,1,0,1,0
25	Bridge inspection	Deterioration affected parameters*	cm
35	Bridge inspection	Deterioration affected parameters*	cm
36	Exceeded moment capacity on a bridge	Damaged condition	0,0,0,0,0,1,0,0
38	Seismic event, $M_w=7.8$	Damaged condition	0,1,0,1,0,1,0,1
40	Bridge inspection	Deterioration affected parameters*	cm

* Deterioration affected parameters correspond to rebars' diameter measured on columns, deck and elastomeric bearing dowels (data not shown here for brevity).

3.2 Lifetime reliability and resilience assessment

Given the small size of the network, the system failure evaluation is performed through matrix-based approaches (Kang *et al.* 2008). This method enumerates the m possible 'network states' into a matrix of system events \mathbf{C} ; i.e. the entire sample space of mutually exclusive and collectively exhausting (MECE) bridge states combinations or 'network states'. The probability of occurrence of each MECE events, arranged in vector $\mathbf{P}(\mathbf{t})$, is obtained using individual bridges' failure probabilities; these are time-dependent functions conditioned on seismic intensities im or live loads w , $p_S(im, t)$ and $p_L(w, t)$ respectively. Finally, the probability of disconnection $Pr(\mathbb{D}|t)$ of any source-terminal pair can be obtained using this method combined with network science algorithms (see details in Kang *et al.* 2008). In the present study, the probability of losing connection between any city and City 7 is defined as a network-level reliability metric of interest.

Additionally, the method has been extended to obtain the probability of network disconnection $N_{\mathbb{D}}$; a vector \mathbf{D} is created using the indicator function over the connectivity of the system for the MECE events (0 if the network is connected, and 1 otherwise). Then, $N_{\mathbb{D}}$ is computed as:

$$Pr(N_{\mathbb{D}}|t) = \mathbf{D}^T \mathbf{P}(\mathbf{t}) \quad (1)$$

For seismic events, the bridge's failure probability $p_S(im)$ is computed from the bridge fragility functions proposed by (Rokneddin *et al.* 2014) and the intensity measure obtained from the (Atkinson and Boore 1995) ground motion model. Hence, the network states probability vector \mathbf{P} is also conditioned on the magnitude of the event. The analysis of the unconditional failure probability of the system $P_{sys,s}$ requires the integration of the network failure events over the joint probability density function of the event magnitudes (Kang *et al.* 2008). In this study, $P_{sys,s}$ is computed for each time t of analysis obtaining a lifetime metric useful for decision making.

The system failure probability for extreme live loads depends on $p_L(w,t)$, which is obtained from the surrogate model presented by Vishnu (2019) for exceeding the allowable moment in a bridge deck. To consider the uncertainty on the bridge structural parameters and in live loads w (inputs required of the surrogate model), p_L is computed using 10,000 Monte Carlo (MC) simulations. Mean failure probability p_L for each year t is obtained by updating the deck reinforcement bar diameter on the MC analysis; then, p_L is used for the lifetime network reliability analysis.

In addition to reliability metrics, average network resilience is computed from the network states. Each network state, represented by one MECE event, indicates a unique network condition, thus MC analysis is used to simulate the bridge recovery processes. The recovery simulation of each damaged bridge follows the approach proposed by Decò *et al.* (2013) and simultaneous repairs are assumed to occur if the number of available crews (n_{crews}) is larger than one. The simulated repair schedule defines the time at which functionality at the road level is recovered, resulting in a stepwise network recovery profile. The 'network functionality' η is assumed to be equivalent to the 'global network efficiency' (weighted version) often used in network science (LiYing Cui *et al.* 2010). The time-dependent efficiency computed during the repair phase is normalized by the unperturbed network functionality η_0 , canceling out the normalization factor:

$$Q(t_r) = \frac{\eta(t_r)}{\eta(t_{r0})} = \frac{n(n-1) \sum_{j \neq i} \frac{1}{d_{ij}(t_r)}}{n(n-1) \sum_{j \neq i} \frac{1}{d_{ij}(t_{r0})}} \quad (2)$$

where $d_{ij}(t_r)$ refers to the distance between ij pairs considering all the available roads at recovery time t_r . The resilience metric is computed using Equation 3, with $Q(t)$ as the functionality metric, T_R assumed as the total time required to finish repair activities within the network, and a target functionality TQ, commonly assumed as 100% (Ouyang and Dueñas-Osorio 2012). This proposed metric depicts the evolution of the global system functionality (in terms of distance traveled by the users), between the nodes of the network, relative to the original system state.

$$R(t_r) = \frac{\int_0^{T_R} Q(t_r) dt_r}{\int_0^{T_R} TQ(t_r) dt_r} \quad (3)$$

The average network resilience obtained for each MECE event is arranged in vector \mathbf{U} . It is used to obtain the time-dependent mean network resilience N_R :

$$N_R(t) = \mathbf{U}^T \mathbf{P}(t) \quad (4)$$

4 RESULTS: SMART TIME-DEPENDENT RESILIENCE ASSESSMENT

New knowledge that emerges at a certain time t are denominated here as 'learning events'. If a certain learning event occurs during time t , the subsequent step should consider the knowledge acquired through a fusion process. For example, bridge mean failure probabilities for extreme live loads are initially predicted using a deterioration model without introducing any observation (see Figure 4a). These, translated into reliability indexes β , can help to define the expected year when bridge deck replacement must take place. Following a recursive Bayesian estimation approach, specifically the Kalman filter algorithm (Kalman 1960), lifetime predictions are updated by infusing the knowledge obtained from the inspection cycles defined in Table 1. The first inspection is clearly depicted by a large shift on the predicted values for β towards the "true performance" (i.e. when complete knowledge is available); beyond that point the recursive Bayesian approach improves the

model predictions, increasing its accuracy with every new observation. If after each updating process large computational efforts are needed, then smart algorithms can also be used to reduce the burden. For example, active learning reliability estimation methods, e.g. using gaussian process regression and MC analysis (Echard *et al.* 2011), are possible solutions for recomputing the large MC analysis. In addition to enhancing individual performance indicators, infusing the knowledge from observations clearly influences the computed mean network total restoration time T_R (i.e. the estimated performance) as depicted in Figure 4b. Annual expected T_R is relatively small considering that the failure associated to live loads, for this particular example, presents a low failure probability.

Observations about bridge deterioration on column and elastomeric bearing dowel rebars affect the expected seismic response of bridges. The model for parameterized seismic fragility functions (Rokneddin *et al.* 2014) is suitable for time-dependent analysis and it is easily updated as new information about the components' conditions is collected. However, although directly measured, data gathered is only representative of the real (yet uncertain) structural state. The probability of extensive damage predicted by the fragility functions is also updated indirectly as new information from the rebar condition is considered in the recursive Bayesian estimation. Figure 5a depicts the evolution of approximate seismic reliability index and the impact of new data introduced to the model. The implications of the observations on the bridge's conditions are propagated to the network reliability N_R as observed in Figure 5b. After some sequential observations the model greatly improves its guesses about the future resilience, reducing the error between the predicted and the 'true' system performance indicators.

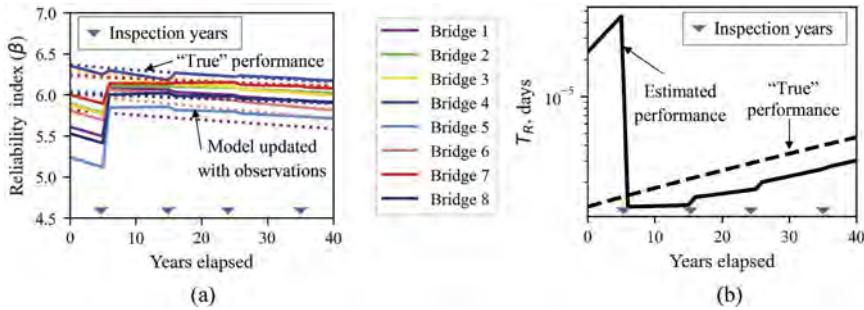

Figure 4. Model estimations and updated predictions for a) bridge-level reliability index and b) time-dependent mean network downtime for extreme live loads.

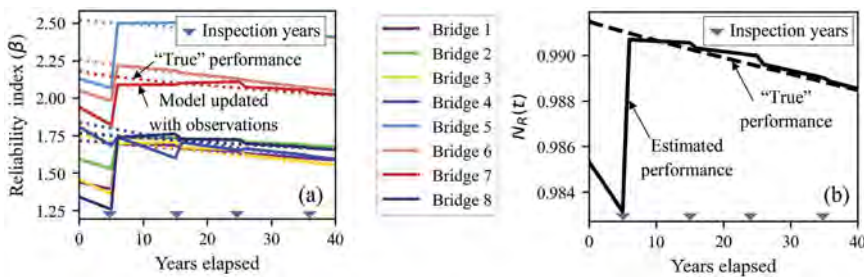

Figure 5. Model estimations and updated predictions for a) bridge-level reliability index for an event of Mw=6 and b) time-dependent mean network resilience for seismic events.

Finally, the occurrence of seismic events in years 17 and 38, and the failure of bridge N° 6 in year 36 require the total replacement of some bridges. Once these replacements are done, the recursive Bayesian estimation must be initiated again on those bridges using the information of the new conditions (e.g. new column rebar area). The introduction of renewed conditions is depicted as an abrupt positive modification on the mean network downtime and mean network resilience (see Figure 6). Note that this change influences both the 'true' and estimated performance; it occurs considering that the 'true' network vulnerability is also diminished with newer bridges. Repair

times measured during the intervention efforts could also be used to additionally improve the distributions of the model inputs (not included for brevity). This illustrative example shows that the model predictions sequentially updated with observations tend to represent more accurately the performance metrics at the component (bridge) and system (network) level.

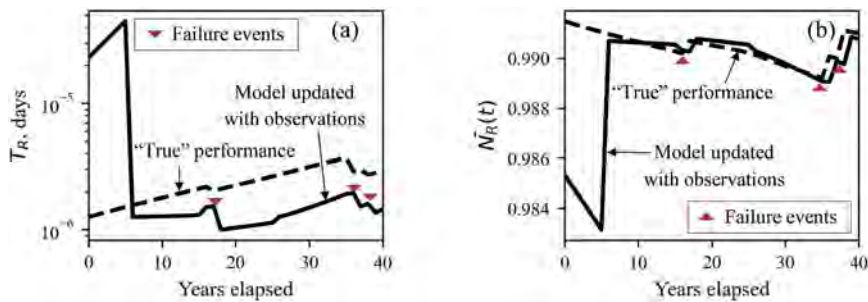

Figure 6. “True” and updated prediction of a) mean network downtime for live loads and b) mean network resilience for seismic demands, both including failure events occurred.

5 CONCLUSIONS

Models for resilience estimation commonly focus on instantaneous infrastructure resilience, lacking the ability to introduce data gathered throughout the system lifecycle. Also, existing models may not be able to improve the model parameters, not being able to cope with real ever-changing conditions. This paper attempts to review the challenges of such modeling frameworks and provides the ‘smart resilience’ concept as a practical solution. Smart resilience modeling refers to algorithms able to continuously learn from new data gathered, cope with shifts in environmental demands, consider variations in social needs and infrastructure uses, handle new monitoring parameters from emerging technologies, and others, adapting to the dynamic conditions of the systems. Hence, it is essential to use ‘smart’ algorithms such as active learning schemes to improve information gain, transfer learning techniques to cope with heterogenous and changing conditions, or recursive Bayesian approaches for continuous updating processes, among others. An illustrative example using a hypothetical transportation network is presented. Deteriorated conditions of aging-bridge parameters (specifically steel rebars) are assumed to be collected as well as the dates of bridge replacements (after failure occurs). The introduction of sequential data gathered to update existing model predictions were shown to improve the accuracy of metrics of interest, such as the bridge-level reliability index and network-level annual expected recovery times and annual mean resilience, demonstrating the importance of working toward smart resilience approaches.

Structural damage estimation using short-time Fourier transform and improved convolution neural networks

C. Shi, Y. Aoues, R. Troian, D. Lemosse & H. Bai

Laboratoire de Mécanique de Normandie (LMN), Rouen, Normandie, France

ABSTRACT: Convolutional Neural Network (CNN) has demonstrated its excellent prospects in vibration-based structural damage detection due to its strong ability of feature learning and processing big data. However, most existing CNN-based damage detection methods can only allow damage pattern recognition, which may lead to the inability to identify and quantify unknown damage patterns. In this study, a new method called modified convolutional neural network based on Short-Time Fourier Transform (STFT) is developed for structural damage detection. The IASC-ASCE benchmark is used to evaluate the proposed method. Firstly, the vibration signals of different damage patterns of the benchmark structure are simulated based on its finite element model; secondly, STFT is performed to obtain their corresponding spectrograms; thirdly the spectrograms related to different damage patterns are fed into the CNN training; finally, a condition-based damage function is proposed to estimate the severity of any damage mode.

1 INTRODUCTION

Human beings in modern society are increasingly dependent on critical civil engineering facilities such as bridges, housing structures, water engineering, power generation systems, etc. Due to human and environmental factors, these infrastructures inevitably suffer structural degradation and deterioration during their service life. Structural damage will make the performance and reliability of the structure degrade. In some extreme cases, such as an earthquake or sudden overload, structural damage may even lead to catastrophic accidents, thus causing substantial economic losses and destructive social impacts. Therefore, driven by product life safety, human life safety, and economic impact, many large engineering structures and infrastructures urgently need effective means to assess their health conditions during service and to control or repair the possible damage. Structural health monitoring has become a new frontier research area in civil and structural engineering.

The study of damage identification methods has become essential in the health monitoring of large and complex structures. Damage to civil structures is diverse, ranging from simple structures (e.g., beam structures, shear structures) to complex structures (e.g., frame structures), all of which require damage quantification. There are various damage identification methods, they can be roughly divided into model-based and non-model-based methods (Shi 2012). Model-based methods are suitable for simple structures, which depend on a mathematical model and assume that the system is linear and time-invariant. Damage diagnosis is achieved by studying the variation of the dynamic parameters of the structure (stiffness, natural frequency, damage rate, etc.). In the non-model approach, sensors extract data from the structure for diagnosis instead of obtaining structural parameters. This approach is suitable for real-time damage detection of complex structures. Such techniques include flexibility-based model updating methods (Kodikara 2016), combined wavelet Hilbert transform (Mahato 2017), etc. Thanks to the increasing computational power and wide availability of low-cost sensors, data-driven

non-model based structural damage methods are more popular, and deep learning algorithms are increasingly used in vibration-based structural damage detection (Elshafey et al., 2010, Grande and Imbimbo 2012, Gu 2018). However, most existing CNN-based damage detection methods can only perform damage pattern recognition, which may lead to the inability to identify and quantify unknown damage patterns (Khodabandehlou 2019). In this study, we propose a new method, using a modified convolutional neural network based on short-time Fourier transform (STFT), for structural damage detection. The IASC-ASCE benchmark is adopted to evaluate the proposed method (Johnson 2004).

In the rest of the paper, the proposed method is described in Section 2. This section overviews four parts: the IASC-ASCE benchmark structure, the structural damage estimation pipeline, the Short Time Fourier Transform, and the proposed improved CNN by adding the “Probability of Damage” (PoD) function. Section 3 firstly introduces the basic damage patterns of benchmark structure used for CNN training and shows the corresponding damage values of the fundamental damage patterns; secondly, defined damage patterns are used for CNN testing, and the performance of the proposed approach is evaluated. Moreover, the structural damage estimation outputs expressed in terms of PoD scores and their correlations are discussed. Conclusions are given in Section 4.

2 DESCRIPTION OF THE PROPOSED METHOD

2.1 Benchmark description

The IASC-ASCE benchmark structure is a four-story, two-bay by two-bay steel-frame scale model structure built in the Earthquake Engineering Research Laboratory at the University of British Columbia, Canada (Johnson 2004). As shown in Figure 1, the footprint dimensions are 2.5 m × 2.5 m and the height of the frame is 3.6 m. Two parallel steel rods are installed diagonally at each bay to provide bracing. In this work, we have used the acceleration signal of 16 nodes of the structure, marked with green points. These measurements points are located at the middle of each side of the structure, two in the x and two in the y directions per floor (called $\ddot{y}_1, \ddot{y}_2, \dots, \ddot{y}_{16}$ in Figure 1).

Figure 1. Model of the benchmark structure and location of 16 measured nodes, marked with green points.

2.2 Structural damage estimation procedure

A structural damage estimation pipeline is summarized in this section. The proposed pipeline can automatically learn the failure features and identify the health condition of the structure from the original vibration signals. The overall procedure of the proposed structural damage estimation pipeline is shown in Figure 2. The vibration signals for different damage modes are acquired at fixed measurement points on different finite element models of the IASC-ASCE benchmark structure. Afterward, the original vibration signal is truncated by a sliding window, which allows the generation of a set of sub-time series. The Short Time Fourier Transform of these generated sub-samples is then used as the input to the CNN. Since the main objective of this paper is to explore the efficacy and significance of the proposed PoD function, the damage quantization module is used. The CNN is trained with the known training set data of the underlying damage pattern, and then a test data set of the unknown damage pattern is used to verify the effectiveness of the proposed method for the detection of the unknown damage pattern.

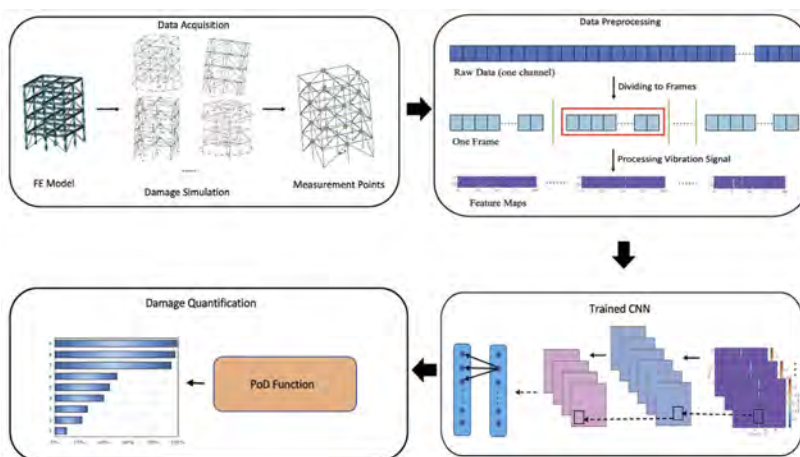

Figure 2. General pipeline of structure damage estimation.

2.3 Short-Time Fourier Transform (STFT)

The Short-Time Fourier Transform (STFT) is a popular method for analyzing nonstationary signals (Griffin and Lim 1984). The STFT obtains the frequency domain distribution of a waveform signal at a specific time through a time window function, and the time distribution of the frequency through the movement of the time window on the time axis, so that the STFT can obtain both the time and frequency domain characteristics of the signal. The visual representation in the time-frequency domain using STFT is called spectrogram. Spectrograms add time to the analysis of the Fast Fourier Transform (FFT) allowing the localization of both time and frequency. The Short-Time Fourier Transform is given by

$$S(\omega, \tau) = \int f(t)g^*(t - \tau)e^{-j\omega t} dt \quad (1)$$

where: “*” is the complex conjugate symbol; $g(t)$ is the time window function; $f(t)$ is the analyzed signal, and the STFT result $S(\omega, \tau)$ reflects the signal component of the analyzed signal at the frequency ω and the moment τ .

We assume that the experimental damage patterns from the paper (Dyke 2003) are used as the basic damage patterns $i(i = 0, 1, \dots, 8)$ of the structure and assign the corresponding damage indexes $Ds_i(i = 0, 1, \dots, 8)$ to them. The more severe the damage condition of the structure, the bigger the value of the damage index, Ds_0 means undamaged. For each damage

pattern, the number of channels of the sampled signal is 16, the sampling frequency is 1000Hz, and the sampling time is 4000s (i.e. 400,000 data points). As shown in the “Data Pre-processing” part of Figure 2, we divide the data for each channel into “Frames”, by defining the “Frame” length as $128 * 128$. For each data “Frame”, we perform the Short-Time Fourier Transform in order to get the spectrogram, the time-length of STFT is $128 * 128 / 1000 = 16.384s$, the frequency-length of STFT is 50Hz (discard useless information in high frequency). Figure 3 shows an example of the spectrograms obtained from the Short-Time Fourier Transform of the vibration signal on the undamaged IASC-ASCE benchmark structure, which contains the information of the damage features. When the structural damage varies, the spectrograms of the corresponding vibration signal also change. Therefore, for one channel of data (4000s), we can get $400,000 / (128 * 128) \approx 244$ spectrograms; for each damage pattern i , we have 16 channels, so we can get $16 * 244 = 3904$ spectrograms; for all damage patterns, we can get $9 * 16 * 244 = 3,5136$ spectrograms.

Figure 3. STFT spectrograms of vibration signal from undamaged IASC-ASCE structure.

2.4 Improved Convolutional Neural Network (CNN)

CNNs are feedforward artificial neural networks inspired by the visual cortex of animals. CNNs have been widely used in object detection in images, videos, and the classification of images (Li 2021). Each CNN consists of five kinds of layers: the input layer, the convolution layer, the pooling layer, the fully connected layer, and the output layer. The input layer is a passive layer that accepts the input image and passes the input to convolutional layers. The convolutional layers apply different filters to the input image to extract characteristic features. These filters are not fixed and are trained by a backpropagation algorithm. The subsampling (pooling) layers reduce the dimension of the convolutional layer output following each convolutional layer. The fully connected layers are similar to the hidden layers of a multilayer perceptron and together with the output layer, produce the output vector of the CNN. As shown in Equation 2, the essence of a convolutional neural network is to enable the original matrix (\mathbf{H}_0) to be transformed through multiple levels of data and mapped to a new mathematical model of feature representation (\mathbf{Y}):

$$\mathbf{Y}(i) = P(L = l_i | \mathbf{H}_0; (\mathbf{W}, \mathbf{b})) \quad (2)$$

where l_i denotes the i -th label category, \mathbf{W} represents the weight matrix, \mathbf{b} is the offset vector. In this study, the spectrograms obtained from the different damage patterns of the IASC-ASCE benchmark structure are used as input “images”. The training data fed into the CNN have a total of 3,5136 “images” corresponding to 9 damage patterns. For this purpose, a CNN with four convolutional layers (kernel size = 3), four max pooling layers (kernel size = 2), one fully connected layer (number of neurons = 9), and a softmax layer as the output layer is adopted. CNNs generally used for structural damage can only output the probabilities of trained damage pattern categories, but not the probabilities of arbitrary untrained damage

patterns. Therefore, we define a “Probability of Damage (Predicted)” (PoD), by decomposing the untrained structural damage patterns into known basic damage patterns as follows:

$$\bar{D} = \sum_{i=1}^n \psi_i D_{S_i} \quad (3)$$

where: \bar{D} is the predicted condition-based damage value, D_{S_i} represents the damage index of basic damage patterns, ψ_i is the probability or the weight that the damage seems to be on the basic damage pattern i ($\sum_{i=1}^n \psi_i = 1$), the output of the activation softmax function of the CNN.

3 RESULTS AND DISCUSSIONS

3.1 Basic damage patterns

A MATLAB-based finite element analysis code is developed by the IASC-ASCE SHM Task Group to generate the simulated structural response data (Johnson 2004). As shown in Table 1 and Figure 4, nine structural damage patterns are simulated on the benchmark frame with damaged elements marked by red. For each case, 16 acceleration signals are recorded by 16 accelerometers under shaker excitation. The structural damage is increased gradually from undamaged (Pattern 0) to very damaged (Pattern 8). The damage cases are introduced either

Table 1. Damage patterns of benchmark structure for CNN Training.

Patterns	Configuration
0	Undamaged
1	Removed braces on 1st floor in one bay on southeast corner
2	Removed braces on 1st and 4th floors in one bay on southeast corner
3	Removed braces on all floors in one bay on southeast corner
4	All east side braces removed
5	Removed braces on all floors on east face, and 2nd floor braces on north face
6	All braces removed on all faces
7	Configuration 7 + loosened bolts on floors 1 and 2 at both ends of beam on east face, north side
8	Configuration 7 + loosened bolts on all floors at both ends of beam on east face, north side

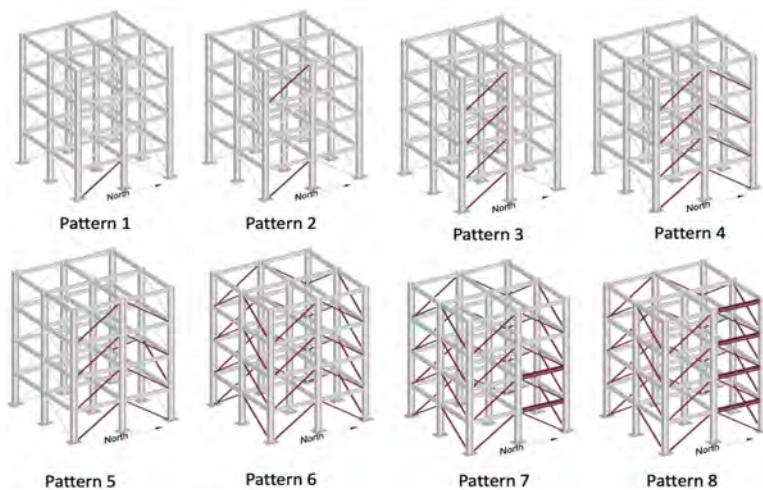

Figure 4. Damage patterns of benchmark structure for CNN Training, damaged elements marked by red.

by the removal of the diagonal braces at specific locations (Patterns 1–6) or by bolt loosening at several joint locations (Patterns 7 and 8).

Firstly, we collect the simulated damage data (16 channels of acceleration signals) generated by the reference structure under these 9 damage patterns; secondly, we slice these damage data and apply Short-Time Fourier Transform to them to obtain the spectrograms of the 9 damage patterns (as shown in Figure 5, Label i represent damage pattern i , here we only list the spectrograms of the first “Frame” of each damage pattern’s first channel); then we use these spectrograms as feature maps to input CNN for training; finally, we apply the PoD equation to output the damage degree under different damage patterns. As shown in Figure 6, we obtain the corresponding damage values for the nine basic damage patterns, ranging from no damage (DP0) to severe damage (DP8). From the bar chart on the right of Figure 6, we can see that the predicted corresponding damage values increase as the damage becomes severe. From the box plot on the left of Figure 6, the spacing of the red lines represents the degree of fluctuation of the values, we can see that the predicted damage values fluctuate more for DP6 and DP8. In this section, our training set and test set are both basic damage patterns, and the prediction results show that our CNN can output relatively accurate damage values.

Figure 5. Short-Time Fourier Transform spectrograms of “Frame” 1 of Channel 1 for 9 damage patterns.

3.2 Structural damage estimation

In order to validate the effectiveness of the proposed STFT-based and improved CNN approach, which is not limited to already learned damage patterns but allows damage assessment of arbitrary damage patterns. Therefore eight additional new cases of structural damage are simulated on the baseline structure. For each case, the acceleration output is recorded by 16 accelerometers under shaker excitation. As shown in Table 2 and Figure 7, the structural damage gradually increases from undamaged (Pattern 0) to very damaged (Pattern 9) with damaged elements marked by red. The damage is caused by the reduction of stiffness at specific locations (Pattern 1), the removal of diagonal braces (Patterns 2-6), or the loosening of bolts at several connection locations (Patterns 7, 8).

Similarly, we first collect the simulated damage data (16 channels of acceleration signals) generated by the benchmark structure under these nine defined damage patterns and slice, and Short-Time Fourier transforms these damage data to obtain the spectrograms of the nine newly defined damage patterns, which are input to the CNN for testing. It is worth noting that the training set of the CNN is still the basic damage patterns at this point; however, the test set is newly generated with different damage patterns. Finally, we apply the PoD equation to output the degree of damage under the defined damage patterns. As shown in Figure 8, the orange bars represent the basic damage patterns, and the blue bars represent newly defined damage patterns, we obtained the corresponding damage values for the nine basic damage patterns and defined

Table 2. Defined damage patterns of benchmark structure for CNN Testing.

Patterns	Configuration
0	Undamaged
1'	2/3 stiffness in one bay on northeast corner on 1st floor
2'	Removed braces on 1st floor on east face, south side and 4th floor on north face, east side
3'	Removed braces on 1st, 2nd and 4th floors in one bay on southeast corner
4'	All east side braces and one bay on northeast corner on 1st floor removed
5'	Removed braces on all floors on east face, and 2nd floor brace on north face, west side
6'	Removed braces on floors 1, 2, 3 on all faces
7'	Configuration 7 + loosened bolts on floor 1 at the end of beam on east face, north side
8'	Configuration 7 + loosened bolts on floors 1, 2, 3 at both ends of beam on east face, north side

Figure 6. Damage values of basic DPs.

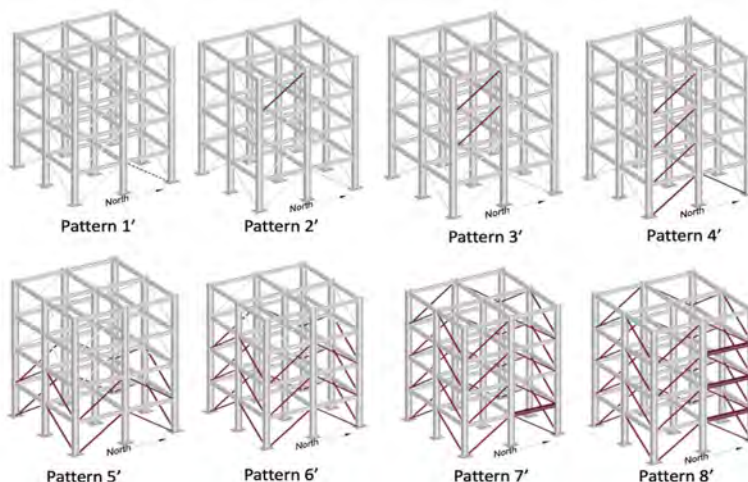

Figure 7. Defined Damage Patterns of benchmark for CNN Testing, damaged elements marked by red.

damage patterns, ranging from no damage (DP0) to severe damage (DP8). And we find that the newly defined damage cases are slightly lower than the basic damage category under each damage category, which basically corresponds to the actual defined structural damage cases.

4 CONCLUSIONS

CNNs have been proven to be an efficient vibration-based structural damage detection tool by many researchers. With the benchmark study data, the method simply processes the raw

Figure 8. Comparison of Damage values for basic DPs and defined DPs.

acceleration data measured under shaker excitation and computes a single score that represents the actual damage state of the monitored structure. The results show that the proposed method is very successful in estimating the actual amount of structural damage for the nine damage scenarios of the benchmark study. In addition, with the introduction of the PoD equation, the proposed method goes beyond the traditional fixed damage pattern recognition and enables the evaluation of arbitrary damage patterns. Moreover, the CNN structure used in this paper is very simple, which means that it is easy to implement from a computational time perspective and does not require large hardware resources. However, the CNN-based approach proposed in this paper can only be utilized to examine the overall condition of the monitored structure. As a future research topic, the possibility of utilizing the structural dynamics analysis to identify the location of structural damage will be investigated.

Dynamic characteristic study of a heritage structure in Tiruchirappalli city using operational modal analysis

S. Anjuna, N. Radhakrishnan & G. George

National Institute of Technology, Tiruchirappalli, Tamil Nadu, India

ABSTRACT: Majority of nations are spending a considerable part of their maintenance budget allocated for construction industry for retrofitting. This situation indicates there is an immediate need for establishment of an efficient health monitoring system. It is a well-known fact that the establishment of a health monitoring system is expensive in the installation stage, but economical in the long run from the perspective of preventive maintenance. Hence, the implementation of the health monitoring system on the bridge has adopted a systematic approach which includes optimization of sensors (triaxial accelerometers), establishment of a real time data acquisition and analysis by installing the LabVIEW based program for the same in the real time controller and validation of the results.

1 INTRODUCTION

Structural Health Monitoring (SHM) is applied as an effective methodology for preventive maintenance. There are numerous examples of its application in health monitoring of religious structures, heritage structures, innovative buildings, dams, bridges etc. However majority of application has been in the field of development of vibration based decision support system for bridge monitoring. There are 2.5 million number of operating bridges in the global road network. It has to be accepted that every bridge will be a prototype, and hence the strategy of decision making will vary for each of them. However the lessons learnt from each case study would be helpful for improving the existing methodologies. In this paper, Cauvery bridge which is also a heritage symbol of Tiruchirappalli city has been adopted for health monitoring. It was during a routine visual inspection by the experts, which lead to the observation that the leaning of rocker bearing creating excessive vibration to the bridge. Even though the fault was later rectified, it was suggested to establish a vibration-based health monitoring system for the structure. The core of the vibration based health monitoring lies in the modal identification, which can later be utilized for system identification. Thus, system identification and modal identification are inter-related objectives. The dynamic characterization of Golden Gate Bridge laid a new insight in to the field of vibration-based health monitoring. The reliability of the monitoring system depends upon the quality of data acquired. Hence, each stage of monitoring programme i.e selection of sensors, their number and location, installation, data acquisition and processing must be done with utmost care. With the availability of modern day sensors and efficient data acquisition systems, it can be desired to develop replace the conventional post processing of the data by a real time monitoring process, where the acquisition and processing are done simultaneously to know the real time behavior of the structure under consideration. This paper explains a systematic approach for health monitoring of a bridge structure, where each of the stages for real time data acquisition has been addressed. The methodology involves development of finite element model of the bridge in SAP 2000, optimization of sensors based on the analytical results, Installation of sensors, Real Time data Acquisition and Processing based on a LabVIEW program installed in a real time controller (NI cRIO 9040) and followed by validation of the results.

2 FINITE ELEMENT MODELLING

The finite element analysis of the bridge was done in SAP 2000 software. The total length of the bridge is 630 m, with 15 spans of 42m. The total width of the bridge deck is 10.5m. All the 15 spans of the bridge act individually as simply supported span. Thus, only single span is considered for analysis. The bridge is modelled as a reinforced concrete bridge with four T Girders of 1.8m depth and 130mm width at 2.5m spacing and eight number of cross diaphragm of depth 1.5m and 100 mm width. The bridge deck has a total thickness of 250 mm and is provided with 7.5m wide carriageway. The material properties were adopted as per the details given by the governing authority. Frame and Shell elements were used for modelling the superstructure and link elements for bearings. Figure 1 shows the model of the bridge in SAP 2000.

Figure 1. Model of the Bridge in SAP 2000.

3 OPTIMISATION OF TRIAXIAL ACCELEROMETERS

Proper planning of the vibration test is very crucial in extracting accurate modal properties. Hence, the most important task in modal analysis is placement of sensors. The Sensor placement strategy adopted in this study maximizes the determinant of Fischer Information Matrix (FIM) and there by maximizing the linear independency and signal strength. The objective of optimization of sensor is to ensure attainment of all the information required as well as avoiding sensor clustering. This methodology allows the vibration analysts to specify the location which they absolutely want to measure the vibration. However, the sensor location of the Analyst's choice can be as small as one and further be expanded. This methodology utilises the mode shapes obtained from FEM Model for pre-test planning.

Stage I: Approach for Modal Expansion

In structural dynamics, the displacement of a structure under dynamic loading is expressed as:

$$\mathbf{x}(t) = \sum_k^n \Phi_k q_k(t) = \Phi \mathbf{q}(t) \quad (1)$$

Where,

$\mathbf{x}(t)$ = Displacement response; $\mathbf{q}(t)$ = Modal Co-ordinates

Φ = Modal matrix corresponding to n selected mode shapes

N = Total Degrees Of Freedom in the FE Model

The vector $\mathbf{x}(t)$ is categorised in to $\mathbf{x}_m(t)$ and $\mathbf{x}_d(t)$ indicating measured and unmeasured part of the response vector $\mathbf{x}(t)$. Let $\mathbf{y}(t)$ denote the response measured and is given by:

$$\mathbf{y}(t) = \mathbf{x}_m(t) + \varepsilon(t) = \Phi_m \mathbf{q}(t) + \varepsilon(t) \quad (2)$$

where, $\varepsilon(t)$ denotes the error during measurement which is inevitable. Thus, it is important to minimise the residual $\varepsilon_y(t)$

$$\varepsilon_y(t) = y(t) - \Phi_m \hat{q}(t) \quad (3)$$

Assumption 1: i) $\varepsilon(t)$ = Gaussian, uncorrelated with zero mean
 ii) Number of sensors are greater than the number of mode shapes
 Thus, Homoscedasticity solution for Modal co-ordinates id expressed as

$$\hat{q}(t) = (\Phi_m^T \Phi_m)^{-1} \Phi_m^T y(t) = \Phi_m^\dagger y(t) \quad (4)$$

Assumption 2: There is equal confidence for all measurement points, then heteroscedasticity of $\hat{q}(t)$ must be consider.

$$\hat{q}(t) = (\Phi_m^T W \Phi_m)^{-1} \Phi_m^T W y(t) \quad (5)$$

W = weighing matrix (diagonal matrix)

$$W = \begin{bmatrix} \sigma_i^2 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \sigma_m^2 \end{bmatrix}$$

σ_i^2 = Measurement variance for each sensor

Where, $\sum_q = (\Phi_m^T W \Phi_m)^{-1}$, \sum_q = Error covariance matrix

For the unmeasured degrees of freedom the estimation error variance for displacement estimate is expressed as:

$$\sum_{\hat{x}_d} = E[(\hat{x}_d - x_d)(\hat{x}_d - x_d)^T] = \Phi_d \sum_q \Phi_d^T \quad (6)$$

The objective for this stage is to minimize mean of trace of estimation error variance for the unmeasured DOFs $\frac{1}{d} tr(\Phi_d \sum_q \Phi_d^T)$

Stage II: Effective Independence and Redundancy Information

Even though minimisation of the error covariance of estimate of unmeasured displacement facilitates attaining reconstruction response of good quality. But, there might be chances of adjacent sensors sharing same information, thus the sensor redundancy must be minimized. Another matter of concern is sensor clustering, which arise due to uneven distribution of stiffness and mass in the structure. These issues are addressed by including triaxial effective independence and redundancy information in the optimisation steps.

As per assumption stated in stage I, the measurement noise can be considered as uncorrelated and equal at all location of sensor.

Thus, the error covariance matrix takes the following expression:

$$\sum_q = E[(q - \hat{q})(q - \hat{q})^T] = \sigma_0^2 (\Phi_m^T \Phi_m)^{-1} = \mathcal{Q}^{-1} \quad (7)$$

\mathcal{Q} representing the Fischer Information Matrix. In Effective Independence the objective is to maximise the FIM (trace or determinant). Thus, \mathcal{Q} can also be represented in terms of contribution from each sensor as:

$$\mathcal{Q} = \frac{1}{\sigma_0^2} \sum_{i=1}^m \Phi_m^{iT} \Phi_m^i = \frac{1}{\sigma_0^2} \sum_{i=1}^m \mathcal{Q}_i \quad (8)$$

m = number of sensor degree of freedoms
 i = i^{th} row of Φ

In the case of triaxial sensors, Equation 8 becomes

$$\mathbf{Q} = \frac{1}{\sigma_0^2} \sum_{i=1}^m \Phi_{3i}^T \Phi_{3i} = \frac{1}{\sigma_0^2} \sum_{i=1}^{m_n} \mathbf{Q}_{3i} \quad (9)$$

\mathbf{Q}_{3i} = elementary FIM at the i^{th} nodes

m_n = number of candidate sensor location, $\sigma_0^2 = 1$ (assumed)

To prevent clustering of sensors redundancy information criterion is used which measures the closeness between information coming from sensors at node i and node j , and is computed using the following equation:

$$R_{ij} = \frac{\|\mathbf{Q}_{3i} - \mathbf{Q}_{3j}\|}{\|\mathbf{Q}_{3i} + \mathbf{Q}_{3j}\|} \quad (10)$$

The R_{ij} value of 1 indicates sensors share no mutual information and a value of 0 indicating the sensors bring the same information. This criterion is considered as the constraint for optimisation here. Let \mathbf{Q}_0 represent the initial information matrix, having rank $u < n$, and the eigen vectors for \mathbf{Q}_0 be ψ_0 . These vectors will be spanning in u - n dimensional space. Thus, the orthogonal projector \mathbf{P} is represented as

$$\mathbf{P} = \psi_0 \psi_0^T \quad (11)$$

The information in the candidate sensor set can be obtained utilizing the projector \mathbf{P}

$\overline{\mathbf{Q}}_c = \mathbf{P} \mathbf{Q}_c \mathbf{P}^T$, where $\overline{\mathbf{Q}}_c$ represents information in the candidate set which is orthogonal to \mathbf{Q}_0 . The objective here is to determine and choose the sensor location which contribute the most to $\overline{\mathbf{Q}}_c$.

Thus, the triaxial effective independence $\overline{EfiT3}_i$ is utilized to measure the decrease in the information with removal of every i^{th} sensor from the candidate set.

$$\overline{EfiT3}_i = 1 - \det[\mathbf{I}_3 - \Phi_{3i} \overline{\mathbf{Q}}_c^\dagger \Phi_{3i}^T] \quad (12)$$

Implementation of Optimization

The methodology explained above was implemented as follows:

- 1) The location where the analysts absolutely wants the sensor to be fixed was chosen.
- 2) First Stage: Formation of Initial Sensor Set based on Sequential Sensor Placement and Tri-axial Effective Independence criterion.
- 3) For all the chosen sensor location (candidate set), \mathbf{Q}_{3i} is calculated and sorted based on the norm. The sensor location with largest norm is selected as first node.
- 4) Sensors in the candidate set are ranked based on the $\overline{EfiT3}_i$ value and the sensors with highest contribution are placed in the initial sensor set till the rank is full.
- 5) Second Stage: For the initial sensor set formed the is calculated and all the sensor nodes having R_{ij} less than the Threshold value R_0 is removed from the initial set. This method can be applied for large complicated finite element models with fine meshes and where tri-axial accelerometers are used for determining both twisting and bending modes. For the formulation of the FIM 12 modes obtained from the FEM Analysis were considered. As, nodes located inside the structure cannot be instrumented, the focus is on the nodes located on the outside surface of the bridge. The candidate sensor set considered for the optimization consisted of 162 sensor positions. The sensor position with largest norm (determinant of the FIM) obtained as 7.577×10^{27} was considered as the first sensor node. The remaining sensor positions were sorted according to the Effective Independence value and those sensors with a redundancy value ranging between 0.4 to 0.5 were considered as the optimal sensor positions.

Hence, from the methodology of optimization adopted it was found that 28 number of triaxial sensor position would be required for conducting a successful vibration study on the bridge, therefore out of 8 accelerometers, 4 of which are stationary accelerometers while rover accelerometers make up the balance 4. Figure 2 shows the adopted sensor layout as per optimization

Figure 2. Adopted Sensor Layout.

4 BRIDGE MONITORING: INSTALLATION OF SENSORS, REAL TIME DATA ACQUISITION AND PROCESSING

An Ambient vibration test was conducted on the bridge to identify the modal properties. The sensors used for instrumentation consists of 8 triaxial accelerometers (5V/g, 0.02-200Hz), NI 9234 I/O Module, NI cRIO 9040 Real Time controller for data Acquisition, Signal Conditioning Module. The real time data acquisition and processing was programmed in LabVIEW. The accelerometers were attached to magnetic mount which was in turn placed on steel plate attached to the bridge structure. The steel plate was mounted to the underside of the bridge using 3M DP 420 adhesive. Figure 3 shows the instrumentation layout. Since cRIO-9040 is a real time controller, it is capable of data acquisition, processing and controlling in real time. The real challenge lies in programming the cRIO-9040 for data acquisition and processing in real time.

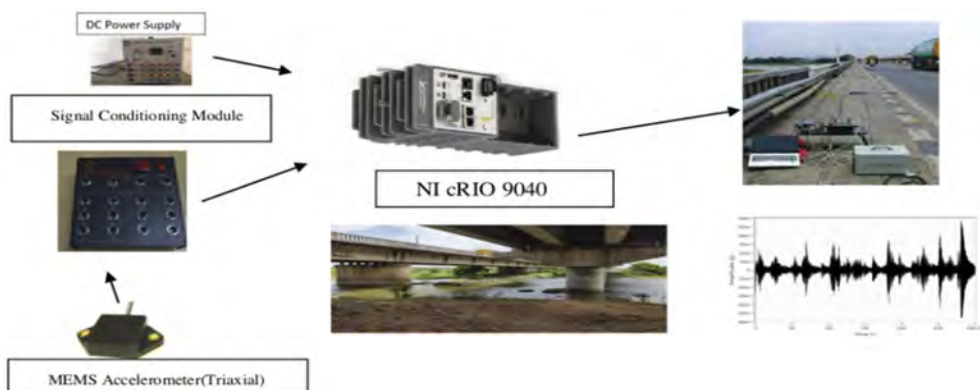

Figure 3. Layout of Instrumentation Adopted.

The LabVIEW programme for data acquisition and processing consists of two parts i) Acquisition of data in the cRIO controller and transferring the data to the computer ii) Displaying the data after receiving from the cRIO on the computer screen as shown in Figure 4

Step1: Using DAQmx Create Task.vi the data acquisition task was created. Once the channels are added, the channels which will be acquiring signals are specified using DAQmx Create Channel.vi. In this VI, the number of channels and the voltage range of sensors are provided. The

sampling rate is specified in DAQmx Sample clock .vi connected to DAQmx Create Channel.vi. Acquisition is started by DAQmx Start Task.vi and the data acquired is stored in a shared variable Data RT. To prevent losing data while sampling and for faster acquisition and transfer, both the programme are executed in stacked sequence. The acquisition is stopped after 45 minutes of data acquisition by a for loop and checking the loop count. The measurement is written in a TDMS file using Write to Measurement File.vi and saved in a file path. The file path is accessed as a constant in the data processing file and the analysis is done every 45 minute the data is taken.

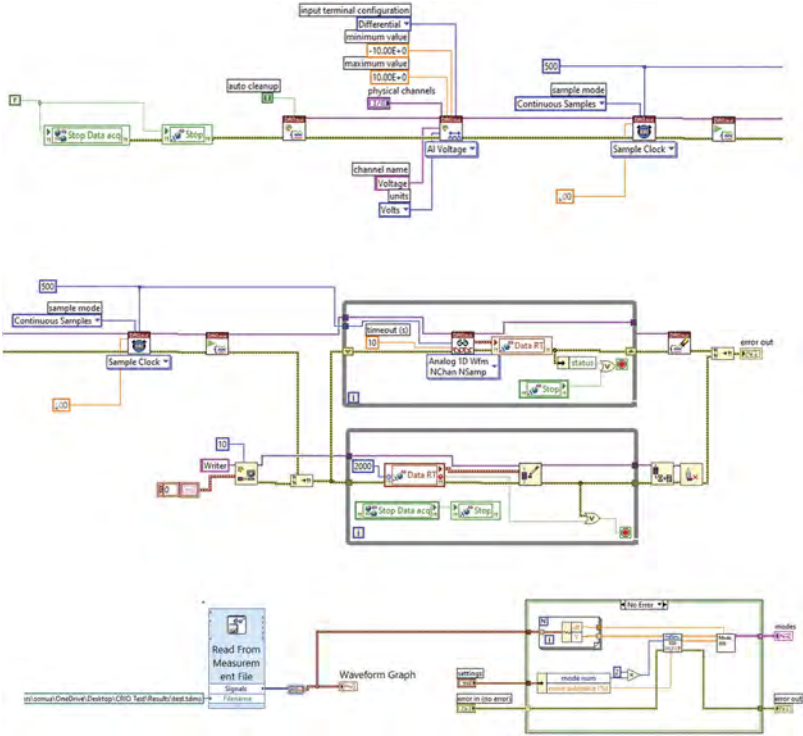

Figure 4. Data Acquisition, Processing and Analysis in Real Time.

5 RESULTS AND DISCUSSION

A comparison is done between the modal frequencies that are obtained from the Finite Element Analysis (FEA) in SAP 2000 and the modal frequencies determined from the Ambient Vibration Test. Good correlation is seen between the results of the first six modes obtained from the experiment and the results of the Finite Element Analysis. Table 1 presents the results from analytical and experimental methods.

Table 1. Modal frequencies obtained using FEM Analysis and OMA.

Mode	FEM Analysis			Modal VIEW			Frequency (Hz)			Damping ratio (ξ) %		
	Frequency (Hz)	Damping ratio(ξ) %		LSCE	FDD	Cov-SSI	LSCE	FDD	Cov-SSI	LSCE	FDD	Cov-SSI
1	2.53	1.06		2.62	2.63	2.62	1.08	1.02	1.04			
2	2.77	3.39		2.73	2.72	2.75	3.44	3.39	3.68			
3	3.75	3.92		3.37	3.44	3.54	3.88	3.90	3.94			
4	6.60	4.52		6.42	6.35	6.46	4.50	4.43	4.68			
5	8.38	4.29		8.90	8.76	8.79	4.20	4.33	4.29			
6	14.96	3.09		14.35	14.16	14.2	3.13	3.19	3.10			

The St-Id results are validated by a comparison that is made between the experimental modal estimates obtained from the three chosen OMA methods (LSCE, FDD, Cov-SSI). The widely used index, Modal Assurance criterion (MAC) is chosen for this study for determining the correlation between the mode shapes. The graphical representation of the MAC matrix obtained using the Cov-SSI method can be seen in Figure 5. From, the figure it is evident that the diagonal values fall in the range of 0.97 to 0.99 thereby showing that there is a good degree of consistency between the mode shapes. The results of the modal analysis conducted using the FEM model show that the range of the modal frequencies is 2.54 Hz-14.97 Hz, while the range of the damping ratio is 1.05%-4.5% as obtained from ModalVIEW. The damping ratios were compared with the results obtained from vibration data analysis in ModalVIEW, in order to test the accuracy of the data analysis code developed in LabVIEW. As good agreement is noted between both the numerical and experimental techniques, the structural model is validated. The modal parameters that are experimentally identified by the OMA methods of LSCE, FDD and Cov-SSI and the analytical results reveal that the range in the modal frequency is from 2.60Hz-14.34 Hz and the damping ratios tend to vary from 1.01% to 4.62 %. In the 3rd mode, the maximum error noted between numerical prediction and experiment in frequency is 11.97%. This error is attributed to uncertainty in modelling. Figure 6 shows the mode shapes obtained from FEM Analysis.

Figure 5. MAC matrix for the obtained mode shapes.

Figure 6. Mode Shapes from SAP 2000.

6 CONCLUSIONS

This research study systematically explains the methodology adopted for monitoring the structural health of bridges. The assessment of the bridge is done by optimal use of sensors and deploying advanced real-time controller on the structure. The conclusions derived from the study are presented as below:

1. The optimization methodology adopted in the study has helped to identify the first six modes of the structure, the inability to detect other modes may be due to insufficient external ambient excitation.
2. An attempt has been done to establish a real-time monitoring of the bridge using real-time controller, and LabVIEW programs installed in the controller were found to give reliable results.
3. Least Square Complex Exponential, Frequency Domain Decomposition, Covariance Driven-Stochastic Subspace Identification algorithms were applied for modal estimation. The acquisition of high-quality data is confirmed by the good agreement observed between the results of the analytical and experimental studies.
4. The programs developed for real time data acquisition and analysis provides a new insight in to the possibilities for establishing real time monitoring based on OMA, which can be successfully applied for other structures also.

ABSTRACT: Bridges are known to be the most fragile components in transportation systems. Furthermore, due to the fact that transportation networks were built many years ago, especially in developed countries, a significant portion of existing bridges have either reached the end of their lifespan or are approaching it. It would be impossible to demolish and replace all of these bridges due to the immense economic burden it would bring. As such, it is crucial to regularly monitor these bridges and create cost-effective maintenance, repair, and renewal plans in response to potential damage scenarios. In this context, long-term structural health monitoring applications appear to be an effective approach. The number of instruments used in these activities and the measurement intervals are essential to their applicability. While increasing the number of measurement points provides more comprehensive information about the structure, it also brings a great economic and operational burden in terms of both the installation cost and the evaluation of the data obtained after the measurement. Therefore, the number of instruments placed on the bridges should be kept to a minimum, while still allowing for accurate determination of the bridge's dynamic behavior. The objective of this study is to efficiently and inexpensively determine the number and placement of accelerometers to be utilized in long-term health monitoring activities. The study aims to investigate the most effective location for the instrumentation and minimize the number of sensors. Additionally, the obtained results were compared, and also the approach's efficiency was evaluated.

1 INTRODUCTION

Determining the dynamic parameters of structures is a current area of focus for civil engineers that is growing in importance. The need to determine these parameters provides crucial information, such as assessing whether newly constructed structures meet design conditions, analyzing existing structures, and identifying existing or potential damage. However, thanks to advancements in technology and scientific methods, it is now possible to determine the dynamic characteristics of structures using a variety of methods.

Furthermore, structural health monitoring systems make it possible for existing structures to be used cost-effectively and minimize structural risks. Additionally, the importance of building health monitoring methods has increased with the use of complex construction structures (Huang et al., 2017; Lin et al., 2017). The primary goal of vibration-based structural health monitoring systems is to determine parameters such as natural frequency, mode shape, and damping ratio, which constitute the structure's dynamic characteristics (Yi et al., 2016). Modal updating, damage detection, and warning systems can be created for structural safety with vibration measurements in structural health monitoring (Liu et al., 2014). However, real-time monitoring of complex structures and instant processing of the data obtained poses

challenging tasks that are difficult to implement and brings many problems to overcome (Cabboi et al., 2017). Therefore, many studies have been carried out in recent decades to perform the autonomous determination of dynamic parameters (Sun et al., 2017).

(Yang et al., 2019) investigated an automated model detection methodology using the Eigensystem Realization Algorithm (ERA) and Fuzzy C-Means (FCM) clustering to separate modes and find the stable ones. (Cabboi et al., 2017) proposed a methodology based on Stochastic Subspace and automated the analysis of mod shape and frequency. (Ubertini et al., 2013) developed a long-term structural health monitoring system with an automated analysis procedure to determine modal frequencies.

However, the high cost of sensors and installation has led researchers to conduct studies to enable vibration-based structural health monitoring using fewer sensors cost-effectively. In this context, different studies have been carried out to detect structural damage and determine the dynamic parameters of the structure by using the optimum number of sensors (Guo et al., 2004; Kim et al., 2000; Chang & Pakzad, 2015; Meo & Zumpano, 2005). Nevertheless, more studies are needed to eliminate the uncertainties arising from the proportionality feature of the mode shapes. Also, it is considered necessary to place each sensor in complex structures as it can contain information about the dynamic behavior of different structure regions. Determining the optimum sensor location is essential for both improving the measurements to be made with the help of sensors and minimizing the cost of structural health monitoring as a result of minimizing the number of sensors in structural health monitoring approaches. For this reason, many different studies are carried out, and different approaches and algorithms are developed to determine sensor locations, considering the cost analysis (Leyder et al., 2018; Papadimitriou & Lombaert, 2012).

Sadeghi Eshkevari et al. (2020) proposed a methodology using mobile sensors and calculating the bridge system's modal frequency by eliminating the vehicle frequency and getting information about the road's roughness and its effects on the measurement. The proposed methods successfully eliminated both vehicle vibration and roughness vibration.

Magalhães et al. (2007) considered a real cabled stayed bridge and obtained the dynamic parameters of this bridge separately using the methods: peak-picking (PP), frequency domain decomposition (FDD), covariance-driven stochastic subspace identification (SSI-COV), and data-driven stochastic subspace identification (SSI-DATA) and compared the modal frequency and damping ratio data in detail. In addition to all these studies, dynamic parameters, especially frequency content are significantly affected by many factors, such as temperature, wind, and climate conditions. For this reason, studies are conducted to determine the dynamic parameters of the structures by considering the environmental effects (Li et al., 2010).

The aim of this study is to determine the modal characteristics of a beam system, such as mode shape, modal frequency content, and damping ratio, using accelerometers placed on a simply supported beam system. In the measurements, the sensors will be handled separately, and the sensors that provide the most information about the dynamic behavior of the beam system will be identified. The goal is to accurately determine the beam system's dynamic parameters using fewer sensors.

2 SET UP AND EXPERIMENTAL MODEL

The experimental model was created using a steel box profile to form a simply supported structure. The box profile has a size of 50 mm x 50 mm and is 2 mm thick. 20 mm diameter steel bars are welded on both ends of the box profile and a roller is placed on one of these bars to create a movable support. The other end of the profile is fixed to the ground. The rod is free to rotate but prevented to translation to achieve an ideal condition and make it easier to predict the support conditions (see Figure 1).

Experimental measurements were obtained using two setups. In the first measurement, accelerometers were positioned at 0.25 m, 0.5 m, 0.75 m, and 1 m distances, as shown in red. In the second measurement, the accelerometer at 0.25 m was kept as a reference point and accelerometers were placed at distances of 1.25 m, 1.5 m, and 1.75 m (see Figure 1).

Figure 1. Sensor position of the experimental beam.

Figure 2. a) and c) Accelerometers on the experimental beam, b) Data acquisition system.

Experimental measurements were performed using the TESTLAB 2010 data acquisition system and field-type accelerometers (see Figure 2). To predict the dynamic behavior of the model, a mathematical model was created and the frequency values corresponding to the first six vertical modes were found to be 31.5 Hz, 125.44 Hz, 279.85 Hz, 490.68 Hz, 750.32 Hz, and 1044.92 Hz, respectively.

Two different sample sizes were used to measure the first three modes. The sample rates were 1000 Hz and 500 Hz, and the recording time was 180 seconds and 360 seconds, respectively. The measurements were made on the model under ambient vibrations, and the oscillation of the model was triggered by applying blows of specific periods and similar intensities to the ground. In the second case, the modal frequencies were more pronounced.

3 MEASUREMENTS

The measurements performed on the simple beam system were divided into two parts. In the first part of the measurements, half of the beam was measured. In the second part, the first accelerometer remained in its original position, while the other three accelerometers were moved to the second half of the beam, and the measurements were repeated. The records of the measurements obtained are shown in the figure below.

The measurements were recorded with a sample interval of 1 kHz for a total of 180 seconds. This duration was determined to be the maximum number of data that can be processed in Excel. In the recordings, small vibrations were applied to the ground to make the beam's modal behavior more discernible.

4 DATA ANALYSIS AND CALCULATION OF THE DYNAMIC PARAMETERS

The mode shapes of a beam were determined by using peak picking and frequency domain decomposition techniques. In peak picking, the natural frequencies of the beam were

identified by analyzing the frequency spectrum of the vibration data. The method used the peaks of the spectrum, which correspond to the natural frequencies of the system, to identify the different modes of vibration. Once the natural frequencies were identified, the corresponding mode shapes were determined by analyzing the vibration data at each frequency. The shape associated with that frequency is the mode shape.

Frequency domain decomposition is a technique that breaks down a frequency spectrum into its individual modes. It can be accomplished using different algorithms, such as Prony's method or the Matrix Pencil (MP) method. This approach takes advantage of the fact that different modes have distinct spectral components, which can be isolated and then reconstructed to obtain the mode shapes. By identifying the various spectral components, each mode can be extracted and the corresponding mode shape can be determined.

Both peak picking and frequency domain decomposition are effective methods for finding the mode shapes of a beam by analyzing its vibration data. These methods can be used individually or together, depending on the specific requirements of the analysis.

Figure 3. a) FFT of the first measurements, b) FFT of the second measurements.

The Matlab program was used to process the acceleration data obtained from the first measurement. First, the autocorrelation functions (ACFs) in Matlab were derived, and the frequency content was obtained. The obtained FFT data are shown in Figure 3. Based on these data, the frequency values of the first three modes of the beam can be determined. These values were found to be (28.81Hz, 115.7 Hz, 220.2 Hz) respectively.

The acceleration data obtained from the second half of the beam was used to repeat the analysis previously summarized in the section. The modal frequency values of the beam were obtained as (28.81Hz, 115.2Hz, and 235.4Hz), which matched the values obtained from the first measurements.

Filtering was applied separately for each frequency. The amplitudes in the regions where the accelerometers were located were determined for the ranges of these frequencies. These amplitudes were proportioned using the largest value as a reference, and the mode shape of the first measurements was obtained.

In the second measurement, filtering was applied to isolate the frequencies of the modes in the regions where they were located. Modal amplitudes were obtained for the locations of the accelerometers. The amplitude value of the first accelerometer, which was used as a reference, was the same as the amplitude value of the reference accelerometer in the same location in the second measurement. The modal amplitudes corresponding to the locations of the accelerometers were proportioned, and the mode shapes of the system were obtained (as shown in Figure 4).

The modal amplitudes corresponding to each accelerometer location were determined, and the mode shapes of the system were obtained by finding high-order polynomials that pass through the relevant points. The ideal case would be a symmetrical mode shape, but due to uncertainties in the support conditions, variations in the beam's material and cross-section, and the asymmetrical load caused by the accelerometers, a slight deviation from symmetry was observed. As the modal frequency values for this system were too high, the study focused on the data of the first three modes only.

Figure 4. Mode shapes of the experimental beam.

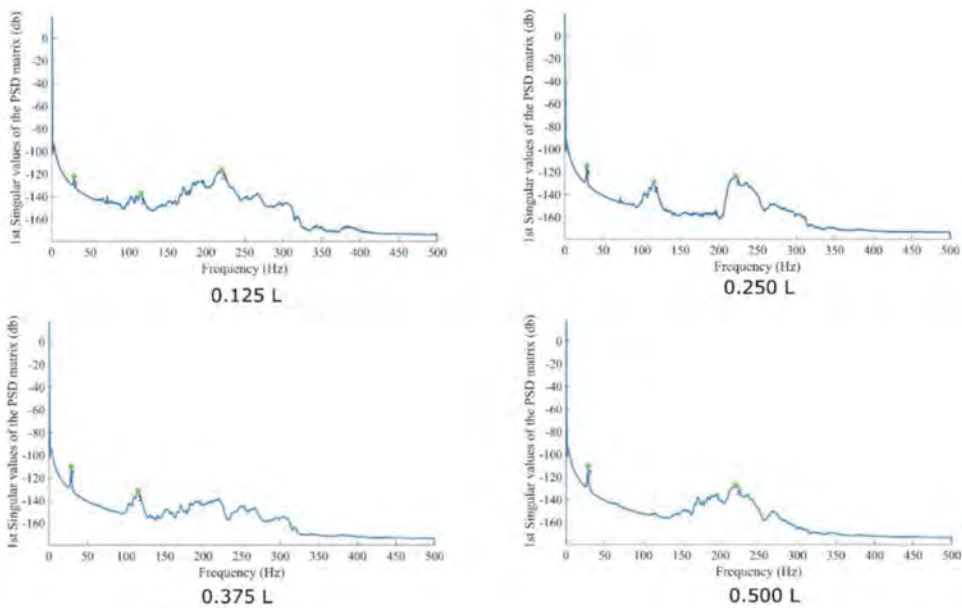

Figure 5. Individual FFT of the acceleration measurement.

The first three modes were identified in the graphics produced using data from an accelerometer located at a distance of $0.125L$ (see Figure 5). These modes are consistent with the modal frequencies obtained using data from seven accelerometers. When the modal frequencies obtained using data from accelerometers at $0.25L$ are considered, it is observed that the first three modes are still present, but with slightly different frequencies compared to the general case. When data from accelerometers at $0.375L$ and $0.5L$ is used, the frequency values of the first two modes and the first and third modes are obtained, respectively. By examining the modal frequencies obtained from each accelerometer in detail, it is found that the first three modes of the structure can be determined using data obtained from the first two accelerometers (see Figure 6).

Initially, all data was used to determine the mode shapes. The mode shapes obtained using data from the first two accelerometers were then compared with the mode shapes found in the initial case. For this system, it is necessary to use data from at least two accelerometers. One accelerometer data is used to determine the amplitude ratio of the relevant mode shape at that point, and the other accelerometer data is used to compare the amplitude values.

Figure 6. Comparison of the mode shape amplitude obtained using first two sensor measurements.

Using data from a single accelerometer, it is possible to determine the frequency values of the first three modes of the system with the help of accelerometers located at distances of $0.125L$ or $0.250L$. However, without multiple accelerometer data, it will not be possible to comment on the shape of the modes. When two accelerometers are used, if the accelerometers are placed at $0.125L$ and $0.250L$ distances, it allows for determination of both the modal frequencies and mode shape of the first three modes of the system. This provides the opportunity to compare the mode shape and identify any possible damage.

5 CONCLUSIONS

As a result of the study, the modal frequencies and mode shapes of a simply supported beam system were obtained by analyzing data from seven accelerometers. Additionally, the damping ratios of these mode shapes were determined. The initial modal frequency values were then reevaluated by using data from two accelerometers, and the compatibility of the mode shape with the initial mode shape was evaluated. It was found that it is possible to monitor a bridge using initial detailed measurements and a small number of accelerometers and measuring instruments in subsequent examinations, making it more cost-effective.

The use of two accelerometers shows that the mode shape and frequency values of the bridge can be accurately determined. Changes in the frequency values of the bridge provide important information about damages in the system. Additionally, differences in mode shapes can also indicate the location and extent of damage. This allows for more efficient and cost-effective structural examinations without the need for a large number of measuring devices for each examination.

The placement of the accelerometers is crucial for accurate frequency content and mode shape determinations with a minimum number of measurements. The study revealed that accelerometers placed at distances of $0.125L$ and $0.250L$ can be used to determine the frequency values and mode shapes of the first 3 modes. Conversely, accelerometers placed at distances of $0.375L$ and $0.5L$ only provided information about the frequency values of two modes, which were also different from each other. This indicates that the mode shape and frequency must be precisely targeted in advance and the accelerometer locations must be carefully selected.

Indirect bridge damage detection using frequencies identified from vibrations of a single two-axle vehicle

Z. Li, W. Lin & Y. Zhang

Department of Civil Engineering, Aalto University, Espoo, Finland

ABSTRACT: Bridge frequency identification using passing vehicles has been demonstrated as a promising approach in the last two decades. Compared to the traditional method that requires sensor systems installed on the bridge, the indirect method only needs a few sensors mounted on passing vehicles, making it potential to monitor a large number of bridges rapidly and economically. However, currently, most studies just checked the existence of the bridge's frequencies in the vehicle's vibrations and explored to identify its frequencies accurately. Few studies investigated the damage detection of bridges using indirectly extracted bridge frequencies. This paper presents an indirect bridge damage detection method using bridge frequencies identified from a passing two-axle vehicle's vibration data. Initially, the bridge's finite element model is carefully built, updated, and divided into several substructures. Damage factors of different substructures are utilized to represent their damage degrees. Then, the bridge's frequencies will be identified from the passing vehicle's vibrations. At this stage, contact-point responses of the vehicle are back-calculated from its accelerations, and the residual contact-point responses of the two axles are employed to eliminate the vehicle's frequencies and inverse effects of road roughness, making the bridge's frequencies highlighted in the frequency domain. Thirdly, an objective function based on numerical experiments is proposed to locate and quantify the damage. The proposed method is verified numerically by a half-car model and a simply supported bridge in this paper. The results indicate that both the locations and degrees of damage can be identified under different influence factors and show great potential in practical applications.

1 INTRODUCTION

The safety of bridge structures has been a concern in the last decades due to their deterioration and collapse (Barker 2022). Structural health monitoring (SHM) can provide essential techniques for bridge health condition assessment (Bao et al. 2019). Mature approaches have been developed by scholars using sensors installed directly on the bridge (the direct method). However, conventional methods typically need a large number of sensors mounted on the target bridge to form a sensing system, which is expensive and time-consuming.

To monitor the bridge indirectly, the drive-by method was proposed by Yang et al. (2004). The idea just requires several sensors adequately installed on the vehicle rather than the bridge (the indirect method), thus is economical and easy-to-operate. Since CP responses have nothing to do with the vehicle, no vehicle frequencies will appear in the frequency-domain spectrum, Yang et al. (2022) proposed to identify the bridge's frequencies using residual CP responses of a half-car model. Employing CP responses of the vehicle can improve the precision of identifying the bridge's frequencies. However, currently, few studies explored locating and quantifying the bridge's damage using the indirectly identified frequencies. The substructure isolation method is one of the effective methods to identify structural damage, in which the substructure is separated from the whole structure and thus can be analyzed individually (Hou et al. 2011, 2019, 2020a; Li et al. 2022). Combined with the indirect method, it has the potential to identify the bridge's damage indirectly.

This paper aims to locate and quantify the bridge's damage using indirectly identified bridge frequencies from the passing vehicle. Firstly, the equations for back-calculating CP responses using the half-car model with four Degrees of freedom (DOFs) are derived. Then, an objective function employing the identified frequencies is proposed. Thirdly, a numerical experiment is carefully designed to verify the proposed method. The remainder of this paper is structured as follows: Section 2 introduces the theoretical foundations for calculating CP responses and building objective functions. Section 3 provides the numerical simulation of a Vehicle Bridge Interaction (VBI) system and discusses several damage cases and influencing factors. Finally, this paper is concluded in Section 4.

2 THEORETICAL FOUNDATIONS

2.1 CP responses

2.1.1 VBI model

This section employs a half-car model with four DOFs, and the bridge is simulated by a simply supported beam, as illustrated in Figure 1. The finite element (FE) model for the VBI system is built in MATLAB.

Figure 1. Half-car model and the simply supported beam.

In Figure 1, four DOFs of the vehicle are illustrated by red arrows. They are vehicle body bounce z_v , body pitching θ_v , and bounces of front and rear axles z_{t1} , z_{t2} . The displacements between the tire and road profile are represented by u_{c1} and u_{c2} . The mass of the vehicle body is m_v , and its pitching moment of inertia is $I_{v\theta}$. The masses for front and rear axles (including wheels) are m_{t1} and m_{t2} , respectively. The distances between the gravity center and front and rear axles are a_1 and a_2 . The stiffness and damping of the suspension system are represented by k_{s1} , k_{s2} , c_{s2} , c_{s2} , and for the tires, they are k_{t1} , k_{t2} , c_{t2} , c_{t2} respectively. The vehicle's speed is denoted by v . The vehicle's dynamic equilibrium equation is represented by Equation (1),

$$\mathbf{M}_v \ddot{\mathbf{z}}(t) + \mathbf{C}_v \dot{\mathbf{z}}(t) + \mathbf{K}_v \mathbf{z}(t) = \mathbf{p}_v \quad (1)$$

where \mathbf{M}_v , \mathbf{C}_v and \mathbf{K}_v are the vehicle's mass, damping, and stiffness matrices; $\ddot{\mathbf{z}}(t)$, $\dot{\mathbf{z}}(t)$ and $\mathbf{z}(t)$ are its acceleration, velocity, and displacement vectors, respectively; \mathbf{p}_v is the input excitation vector for the vehicle. These matrices are shown in Equations (2~5),

$$\mathbf{M}_v = \begin{bmatrix} m_v & 0 & 0 & 0 \\ 0 & I_{v\theta} & 0 & 0 \\ 0 & 0 & m_{t1} & 0 \\ 0 & 0 & 0 & m_{t2} \end{bmatrix} \quad (2)$$

$$\mathbf{C}_v = \begin{bmatrix} c_{s1} + c_{s2} & a_1 c_{s1} - a_2 c_{s2} & -c_{s1} & -c_{s2} \\ a_1 c_{s1} - a_2 c_{s2} & a_1^2 c_{s1} + a_2^2 c_{s2} & -a_1 c_{s1} & a_2 c_{s2} \\ -c_{s1} & -a_1 c_{s1} & c_{s1} + c_{t1} & 0 \\ -c_{s2} & a_2 c_{s2} & 0 & c_{s2} + c_{t2} \end{bmatrix} \quad (3)$$

$$\mathbf{K}_v = \begin{bmatrix} k_{s1} + k_{s2} & a_1 k_{s1} - a_2 k_{s2} & -k_{s1} & -k_{s2} \\ a_1 k_{s1} - a_2 k_{s2} & a_1^2 k_{s1} + a_2^2 k_{s2} & -a_1 k_{s1} & a_2 k_{s2} \\ -k_{s1} & -a_1 k_{s1} & k_{s1} + k_{t1} & 0 \\ -k_{s2} & a_2 k_{s2} & 0 & k_{s2} + k_{t2} \end{bmatrix} \quad (4)$$

$$\mathbf{p}_v = \begin{bmatrix} 0 \\ 0 \\ k_{t1} u_{c1} + c_{t1} \dot{u}_{c1} \\ k_{t2} u_{c2} + c_{t2} \dot{u}_{c2} \end{bmatrix}, \quad \mathbf{z} = \begin{bmatrix} z_v \\ \theta_v \\ z_{t1} \\ z_{t2} \end{bmatrix} \quad (5)$$

where $u_{ci} = u_{bi} + z_{ri}$, $\dot{u}_{ci} = \dot{u}_{bi} + \dot{z}_{ri}$, and u_{bi}, \dot{u}_{bi} are the bridge's deflection and velocity at the i -th contact point.

For the bridge, it is simply supported at each end, as shown in Figure 1. The beam can be divided into N_b Euler-Bernoulli elements and N_s substructures for damage locating purposes. Each node has two DOFs: vertical translation and rotation. The bridge's vibration equations can be denoted by Equation (6),

$$\mathbf{M}_b \ddot{\mathbf{z}}_b(t) + \mathbf{C}_b \dot{\mathbf{z}}_b(t) + \mathbf{K}_b \mathbf{z}_b(t) = \mathbf{p}_b^N \quad (6)$$

where \mathbf{M}_b , \mathbf{C}_b and \mathbf{K}_b are the bridge's mass, damping, and stiffness matrices. In this paper, the damping is simulated by the Rayleigh damping assumption, which can be obtained by $\mathbf{C}_b = \alpha \mathbf{M}_b + \beta \mathbf{K}_b$, where α and β can be obtained when the first two order damping ratios ζ_1, ζ_2 are set beforehand.

The interaction of the vehicle and the bridge is accomplished by the tires. When the tires of the vehicle are not on the bridge's nodes, the Hermitian cubic interpolation function is employed to distribute the CP force to its two adjacent nodes. This process can be finished by Equations (7~10),

$$\mathbf{p}_b^N = \mathbf{N}_c \mathbf{p}_b \quad (7)$$

$$\mathbf{p}_b = \begin{bmatrix} k_{t1}(z_{t1} - u_{c1}) + c_{t1}(\dot{z}_{t1} - \dot{u}_{c1}) - m_v g \cdot \frac{a_2}{a_1 + a_2} - m_{t1} g \\ k_{t2}(z_{t2} - u_{c2}) + c_{t2}(\dot{z}_{t2} - \dot{u}_{c2}) - m_v g \cdot \frac{a_1}{a_1 + a_2} - m_{t2} g \end{bmatrix} \quad (8)$$

$$\mathbf{N}_c = \begin{bmatrix} 0 & \cdots & 0 & \cdots & \boldsymbol{\Phi}_1 & \cdots & 0 \\ 0 & \cdots & \boldsymbol{\Phi}_2 & \cdots & 0 & \cdots & 0 \end{bmatrix}^T \quad (9)$$

$$\boldsymbol{\Phi}_i = \begin{bmatrix} 1 - 3d_i^2 + 2d_i^3 \\ d_i l_e (d_i - 1)^2 \\ 3d_i^2 - 2d_i^3 \\ d_i l_e (d_i^2 - d_i) \end{bmatrix}^T, \quad d_i = \frac{x_i(t) - (j-1)l_e}{l_e} \quad (10)$$

where $x_i(t)$, $i = 1, 2$ is the distance of the i -th contact points on the j -th element to the bridge's left end at t time, and l_e is the length of the bridge's element. By employing the Newmark- β method, we can get the bridge's deflections at nodes, namely \mathbf{z}_b . Then the deflection at contact points can be calculated using $\mathbf{u}_b = \mathbf{N}_c^T \mathbf{z}_b$, and the velocity can be obtained as $\dot{\mathbf{u}}_b = v(\mathbf{N}_c')^T \mathbf{z}_b + \mathbf{N}_c^T \dot{\mathbf{z}}_b$. Therefore, Equation (5) can be updated accordingly. After several iterations, the interaction between the vehicle and the bridge can converge at an acceptable precision.

2.1.2 Road roughness

In this paper, the road roughness is generated according to ISO 8608 (Technical Committee ISO/TC 1995). The procedure can be represented by Equations (11) and (12),

$$r(x) = \sum_{i=1}^N \sqrt{2G_d(n_i)\Delta n} \cos(2\pi n_i x + \theta_i) \quad (11)$$

$$G_d(n_i) = G_d(n_0) \left(\frac{n_i}{n_0}\right)^{-2} \quad (12)$$

where $r(x)$ is the generated road roughness. θ_i is uniformly distributed between 0 and 2π . Δn is selected as 0.01 cycle/m. n_0 is taken as 0.1 cycle/m, and n_i is set as numbers from 0.01 to 10 m^{-1} with an interval of 0.01 m^{-1} . $G_d(n_0)$ will be determined by the road class used in the simulation.

2.1.3 CP response calculation

By disassembling Equation (1), we can get the equilibrium equations related to the wheels as shown in Equations (13) and (14).

$$m_{t1}\ddot{z}_{t1} - c_{s1}(\dot{z}_v - \dot{z}_{t1} + a_1\dot{\theta}_v) - k_{s1}(z_v - z_{t1} + a_1\theta_v) + c_{t1}(\dot{z}_{t1} - \dot{u}_{c1}) + k_{t1}(z_{t1} - u_{c1}) = 0 \quad (13)$$

$$m_{t2}\ddot{z}_{t2} - c_{s2}(\dot{z}_v - \dot{z}_{t2} - a_2\dot{\theta}_v) - k_{s2}(z_v - z_{t2} - a_2\theta_v) + c_{t2}(\dot{z}_{t2} - \dot{u}_{c2}) + k_{t2}(z_{t2} - u_{c2}) = 0 \quad (14)$$

By taking the second order derivative of Equations (13) and (14), and rearranging items related to CP responses, we can get

$$\ddot{u}_{ci} + \frac{c_{ti}}{k_{ti}} \frac{d\ddot{u}_{ci}}{dt} = \Psi_i(t), i = 1, 2. \quad (15)$$

$$\Psi_2(t) = \frac{m_{t1}}{k_{t1}} \frac{d^2\ddot{z}_{t1}}{dt^2} - \frac{c_{s1}}{k_{t1}} \left(\frac{d\ddot{z}_v}{dt} - \frac{d\ddot{z}_{t1}}{dt} - a_1 \frac{d\ddot{\theta}_v}{dt} \right) - \frac{k_{s1}}{k_{t1}} (\ddot{z}_v - \ddot{z}_{t1} - a_1\ddot{\theta}_v) + \ddot{z}_{t1} + \frac{c_{t1}}{k_{t1}} \frac{d\ddot{z}_{t1}}{dt} \quad (16)$$

$$\Psi_2(t) = \frac{m_{t2}}{k_{t2}} \frac{d^2\ddot{z}_{t2}}{dt^2} - \frac{c_{s2}}{k_{t2}} \left(\frac{d\ddot{z}_v}{dt} - \frac{d\ddot{z}_{t2}}{dt} - a_2 \frac{d\ddot{\theta}_v}{dt} \right) - \frac{k_{s2}}{k_{t2}} (\ddot{z}_v - \ddot{z}_{t2} - a_2\ddot{\theta}_v) + \ddot{z}_{t2} + \frac{c_{t2}}{k_{t2}} \frac{d\ddot{z}_{t2}}{dt} \quad (17)$$

In Equations (15~17), m_{ti} , c_{ti} , k_{ti} and k_{si} can be measured in experiments. \ddot{z}_v , $\ddot{\theta}_v$ and \ddot{z}_{ti} are collected accelerations when the vehicle is passing the bridge. a_1 and a_2 are constants shown in Figure 1. For first- and second-order derivatives in Equations (16) and (17), they can be calculated by first-order finite difference formulas and second-order central formulas as shown in Equations (18) and (19).

$$\frac{d\ddot{z}_{ti}}{dt} = \frac{\ddot{z}_{ti}(s) - \ddot{z}_{ti}(s-1)}{\Delta t}, \frac{d\ddot{z}_v}{dt} = \frac{\ddot{z}_v(s) - \ddot{z}_v(s-1)}{\Delta t}, \frac{d\ddot{\theta}_v}{dt} = \frac{\ddot{\theta}_v(s) - \ddot{\theta}_v(s-1)}{\Delta t} \quad (18)$$

$$\frac{d^2\ddot{z}_{ti}}{dt^2} = \frac{\ddot{z}_{ti}(s+1) - 2\ddot{z}_{ti}(s) + \ddot{z}_{ti}(s-1)}{(\Delta t)^2} \quad (19)$$

We can see that Equation (15) is a first-order linear differential equation. Its solution can be represented by Equation (20), and due to the discrete data collection, it can be rewritten as Equation (21),

$$\ddot{u}_{ci}(t) = \begin{cases} \Psi_i(t), i = 1, 2, \text{ if } c_{ti} = 0 \\ \frac{k_{ti}}{c_{ti}} \exp\left(-\frac{k_{ti}}{c_{ti}} t\right) \left(\int_0^t \Psi_i(\tau) \exp\left(\frac{k_{ti}}{c_{ti}} \tau\right) d\tau \right), i = 1, 2., \text{ if } c_{ti} \neq 0 \end{cases} \quad (20)$$

$$\ddot{u}_{ci}(t) = \begin{cases} \Psi_i(t), i = 1, 2, \text{if } c_{ii} = 0 \\ \frac{k_{ii}}{c_{ii}} \left(\sum_{c_{ii}}^{t/\Delta t} \Psi_i|_s \exp\left(\frac{k_{ii}}{c_{ii}}(s\Delta t - t)\right) \Delta t \right), i = 1, 2; s = 1, 2, \dots \text{if } c_{ii} \neq 0 \end{cases} \quad (21)$$

where Δt is the sampling time interval, and s represents the s -th sampling point of the vehicle's accelerations.

2.2 Objective function

After the bridge's frequencies are extracted from the vehicle's vibrations, the next step is to identify the possible damage to the bridge. The proposed method requires a FE model of the undamaged bridge. As introduced in Equation (6), the mass, damping, and stiffness matrices of the undamaged bridge can be represented by \mathbf{M}_b , \mathbf{C}_b , and \mathbf{K}_b . The bridge is divided into N_s substructures, and its damage degree can be denoted by damage factors $\boldsymbol{\mu} = [\mu_1, \mu_2, \dots, \mu_{N_s}]^T$, in which μ_i represents the damage factor of the i -th substructure. If the damage factor $\mu_i < 1$, it means that the i -th substructure is damaged, and the damage degree is $1 - \mu_i$. If \mathbf{K}_{bi} is employed to represent the stiffness matrix of the i -th substructure in the global coordinates, the possibly damaged bridge's stiffness matrix can be calculated by Equation (22),

$$\mathbf{K}_b^d(\boldsymbol{\mu}) = \sum_{i=1}^{N_s} \mu_i \mathbf{K}_{bi} \quad (22)$$

where $\mathbf{K}_b^d(\boldsymbol{\mu})$ is the stiffness matrix of the possibly damaged bridge. The objective function using frequencies can be represented by Equation (23),

$$\Delta(\boldsymbol{\mu}) = \sum_k^K \left(\frac{\hat{\omega}_k(\boldsymbol{\mu}) - \omega_k}{\omega_k} \right)^2 + \lambda \|1 - \boldsymbol{\mu}\| \quad (23)$$

where $\hat{\omega}_k(\boldsymbol{\mu})$ is the natural frequencies calculated by the eigenvalue decomposition of \mathbf{M}_b and $\mathbf{K}_b^d(\boldsymbol{\mu})$. K means the first K order frequencies will be utilized for damage detection. ω_k is the k -th order natural frequency indirectly identified from the passing vehicle. The term $\lambda \|1 - \boldsymbol{\mu}\|$ is the l_1 -norm of $1 - \boldsymbol{\mu}$. Such a term is a typical approach that promotes the sparsity of identified damage (Hernandez 2014; Hou et al. 2020b). The damage factors of the damaged bridge can be obtained by optimizing $\boldsymbol{\mu}$ with an initial value.

3 NUMERICAL SIMULATIONS

3.1 Basic parameters of the VBI system

The basic parameters of the vehicle and the bridge are listed in Table 1, which is referred to the references (Li et al. 2020; He & Yang 2022).

For the vehicle, its speed is 5 m/s when passing the bridge and its frequencies are $f_{v1} \sim f_{v4}$ as shown in Table 1. The axle distance is 4.2 m. For the bridge, it is divided into ten substructures and each substructure includes two finite elements as shown in Figure 2. The bridge is simply supported at each end. The bridge's damping is temporarily set as zero and will be discussed in Section 3.3. The sampling frequency is set as 1 kHz.

For the road roughness, an A-class road with $G_d(n0) = 4e^{-6}$ is employed. Due to the tire contact with the road, the original road roughness is smoothed accordingly. The generated road roughness and its PSD are shown in Figures 3 and 4.

3.2 Bridge frequency identification

The vehicle's vibrations and responses in the frequency domain are shown in Figure 5. It can be seen from Figure 5 (b) that no bridge's frequencies can be identified using the vehicle's vibrations. The bridge's frequencies have been submerged in the road roughness spectrum and the vehicle's frequency-domain responses. It is hard to identify the bridge's frequency, and further damage detection is unachievable.

Table 1. Basic parameters of the vehicle and bridge.

VBI	Parameters (symbol)	Unit	Value
Vehicle	Body mass (m_v)	kg	17735
	Body moment of inertia $I_{v\theta}$	$kg \cdot m^2$	1.47×10^5
	Axle mass (m_{r1}, m_{r2})	kg	1500, 1000
	Suspension damping (c_{s1}, c_{s2})	$N \cdot s/m$	$3 \times 10^4, 4 \times 10^4$
	Tire damping (c_{t1}, c_{t2})	$N \cdot s/m$	0, 0
	Suspension stiffness (k_{s1}, k_{s2})	N/m	$2.47 \times 10^6, 4.23 \times 10^6$
	Tire stiffness (k_{t1}, k_{t2})	N/m	$3.74 \times 10^6, 4.6 \times 10^6$
	Axle distances (a_1, a_2)	m	2.18, 2.02
	Velocity (v)	m/s	5
	Vehicle frequencies ($f_{v1}, f_{v2}, f_{v3}, f_{v4}$)	Hz	1.61, 2.29, 10.35, 15.10
Bridge	Length (l_b)	m	30
	Flexural stiffness (EI)	N/m^2	1.375×10^{10}
	Mass per unit length (\bar{m})	kg/m	2000
	Bridge frequencies (f_{b1}, f_{b2}, f_{b3})	Hz	4.58, 18.31, 41.19

Figure 2. FE model of the bridge.

Figure 3. FE model of the bridge.

Figure 4. PSD of the road roughness.

(a) Vibrations of the vehicle

(b) FFT of the vehicle's vibrations

Figure 5. Vibrations and FFT spectrum of the vehicle.

To solve the problem, the residual CP responses of the vehicle's two wheels are utilized. After the vehicle's acceleration $\ddot{z}_v, \ddot{\theta}_v, \ddot{z}_{r1}, \ddot{z}_{r2}$ are recorded, CP responses of the front and rear wheels can be back-calculated using Equation (21). Then, to eliminate the inverse effects of road roughness, the residual CP responses of the front and rear tires are utilized. A specific calculation for residual CP responses can be found in reference (Yang et al. 2021). The bridge frequency identification results are shown in Figure 6.

Figure 6. Bridge frequency identification results using residual CP responses.

It can be seen that when the residual CP responses are utilized, the bridge's frequencies are outstanding in the frequency spectrum. Also, for the third frequency, it can be noticed that it has been split into two parts: $f_{b3}^{id1} = f_{b3} - 3\pi v/l_b$ and $f_{b3}^{id2} = f_{b3} + 3\pi v/l_b$. Therefore, in the later damage identification process, the employed bridge's third frequency should be $f_{b3} = (f_{b3}^{id1} + f_{b3}^{id2})/2$.

3.3 Damage detection

As discussed in the last sections, it can be seen that when the residual CP responses are employed, the bridge's frequencies can be identified in the frequency domain. However, we can also notice that due to the influence of road roughness, errors in back-calculation of CP responses, and the separation of bridge's frequencies, etc., the accuracy of bridge frequencies cannot be obtained. This section will discuss identifying the bridge's damage using the indirectly identified frequencies. There are two scenarios for the damaged bridge:

- (1) Scenario 1: Minor damage, $\mu = [1, 1, 1, 1, 0.8, 1, 1, 1, 1, 1]$.
- (2) Scenario 2: Medium damage, $\mu = [1, 1, 1, 0.6, 1, 1, 1, 1, 1, 1]$.

The same FE model used in Section 3.2 is employed for damage detection. Initially, the bridge is assumed as healthy, namely, the initial damage factors are $\mu_0 = [1, 1, 1, 1, 1, 1, 1, 1, 1, 1]$. Then the damage factors are optimized using Equation (23). To verify the applicability of the proposed method, the damage identification results using true frequencies (ω_k') of the damaged bridge are also utilized compared with using the indirectly identified frequencies (ω_k) with or without bridge damping. The first three frequencies when the indirect method is employed are utilized for damage detection, namely $K=3$ in Equation (23).

When the bridge damping is not considered, the bridge's frequencies can be identified well (error $\leq 1.2\%$) as shown in Table 2, and the damage detection results are shown in Figure 7 (red bars). It can be seen from Figure 7 that even though there are some errors between the identified frequencies and the true ones, the bridge's damage can be identified with good precision, especially when the damage degree is low. When the damage degree increases, the damage detection accuracy goes down, and some substructures can be wrongly identified as damaged (e.g., substructure 9 in Figure 7 (b)).

Table 2. Frequencies used for damage detection.

Scenarios	Minor damage scenario			Medium damage scenario		
True frequencies of the damaged bridge ω_k'/Hz	4.469	18.252	40.464	4.429	17.279	40.083
Identified frequencies without bridge damping $\omega_{k,0}/Hz$ (error)	4.483 (0.31%)	18.276 (0.13%)	40.172 (0.72%)	4.483 (1.2%)	17.414 (0.78%)	40.000 (0.21%)
Identified frequencies with bridge damping $\omega_{k,d}/Hz$ (error)	4.310 (3.56%)	18.621 (2.02%)	40.517 (0.13%)	4.310 (2.69%)	17.069 (1.22%)	40.510 (1.07%)

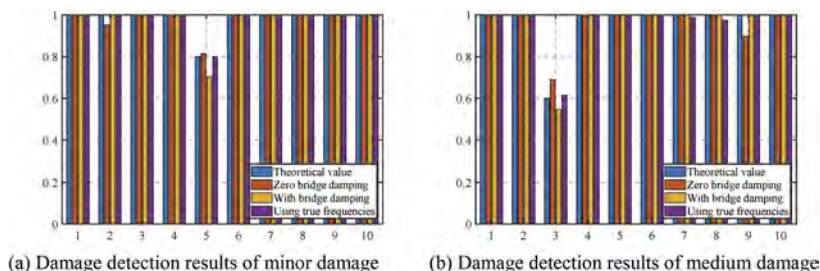

Figure 7. Damage detection results.

When the bridge's damping is assumed as $\zeta_1 = \zeta_2 = 0.01$. The bridge frequency identification errors increase (error $\leq 3.56\%$) as shown in Table 2. Figure 7 (yellow bars) confirms the effectiveness of the proposed objective function on damage detection. Both the position and degree of the bridge's damage can be detected when the damping is considered. But for the low damage scenario, the identification precision for damage degree decreases compared to the zero-bridge damping results.

4 CONCLUSIONS

In this paper, a damage detection strategy using indirectly identified frequencies of the bridge is proposed. A two-axle half-car model and a simply supported beam are utilized to verify the proposed method. The main concluding remarks are drawn below:

- (1) The vehicle's vibrations cannot be directly utilized to identify the bridge's frequencies when the road roughness is considered. By employing residual CP responses, both the vehicle's frequencies and the inverse effects of road roughness can be eliminated, making the bridge's frequencies outstanding and identifiable.
- (2) The bridge's damping plays a negative role in identifying the bridge's frequencies. The errors between true and indirectly identified frequencies will increase when the bridge damping is considered.
- (3) The proposed damage detection method can be used to locate and quantify the damage even though there are minor errors in indirectly identified bridge frequencies, which shows great potential in engineering applications.

Even though the bridge's damage can be detected with good precision, there are several factors that deserve further studies in engineering, such as multiple damage scenarios, high vehicle speed, engine effects, temperature effects, and ongoing traffics. The investigation of the above factors on damage detection will be included in our future studies before laboratory and field tests.

Small-scale damage detection of bridges using machine learning techniques and drive-by inspection methods

Y. Lan, Z. Li, Y. Zhang & W. Lin

Aalto University, Espoo, Finland

ABSTRACT: The drive-by inspection approach for bridge health monitoring has received a lot of interest recently due to its advantages in mobility, economy and efficiency. The feasibility of it has been demonstrated by many studies via numerical simulations, laboratory experiments, and even field tests, when there is a noticeable damage. In terms of minor damages, however, the dynamic features (e.g., frequencies and mode shapes) of the damaged bridge are highly similar to those of the healthy one, for which traditional drive-by methods are likely to perform poorly. Machine learning techniques, which utilize the entire time-domain responses and are sensitive to tiny signal changes, have the potential to identify small-scale damages and achieve higher detection accuracy. This paper compares the performance of different machine learning methods on the indirect framework and proposes a strong classification algorithm for damage identification of bridges. Laboratory experiments were conducted to build the dataset by employing a steel beam and a scale truck model. It presents an early attempt to experimentally validate the feasibility of the drive-by inspection method to identify small structural changes in the bridge.

1 INTRODUCTION

In recent years, bridge maintenance and monitoring have become widespread concerns around the world (Malekjafarian et al. 2015). However, the direct methods for Structural Health Monitoring (SHM) have long been considered as expensive methods due to the enormous costs associated with sensor installation and maintenance (Abdulkarem et al. 2020). Moreover, because the instrumentation is permanently fixed on the bridge as a tailored SHM system, it can be challenging to transfer one monitoring framework to other bridges (Wang et al. 2022). These drawbacks restrain the broad application of direct SHM methods on bridges, and there is a need to develop an alternative strategy without instrumenting the bridge.

The drive-by bridge inspection method, an indirect SHM technique, has gained a lot of interest recently due to its benefits in mobility, economy, and efficiency (Malekjafarian et al. 2015). Studies have investigated the potential of the drive-by method in extracting bridge modal parameters, such as fundamental frequencies and mode shapes, via numerical simulations, laboratory experiments, and field tests (Yang et al. 2004; Lin & Yang 2005; Lan et al. 2022a, 2022b). Changes in modal parameters could indicate bridge deterioration, which is referred to as the modal parameter-based approach (Yang & Yang 2018).

However, most modal parameter-based methods fail to achieve satisfactory performance for small-scale damage detection due to several reasons. First, the bridge frequency, which is used in many studies as a damage indicator, lacks adequate information to indicate damage. They are easily impacted by environmental factors like temperatures (Spiridonakos et al. 2016). Second, mode shapes or their derivations are usually subject to measurement errors, disguising changes from small-scale damage (Zhang et al. 2019). Although there are some approaches based on indicators like displacement profile and moving force, similar problems have been discovered as well (O'Brien et al. 2014; O'Brien & Keenahan 2015; Lan 2021). Machine Learning (ML) methods can leverage the whole time-domain and frequency-domain responses rather than just peaks in the

spectrum (Liu et al. 2020); they are sensitive to small changes in the signal (Zhang et al. 2019). The combination of ML techniques and the drive-by method has the potential to identify small-scale damage and achieve higher detection accuracy.

Currently, compared with the application of ML technology on direct SHM, there have been few studies and implementations of ML techniques on indirect SHM (Wang et al. 2022). Based on Support Vector Machines (SVM), Cerda et al. (2014) successfully identified different bridge damage states with vehicle vibration data. In 2019, Artificial Neural Network (ANN) was first applied to indirect SHM problems by Malekjafarian et al. (2019), obtaining promising results for the damage detection of bridges. These studies verified the “potential” of ML methods in indirect SHM frameworks, but the ability of ML methods for small damage detection has not been fully exploited. On the other hand, since SVM and other normal classifiers may perform poorly for small-scale damages whose dynamic responses are highly similar to those of health, it is advantageous to build a strong classification algorithm that is sensitive to minor damage features.

A combined algorithm based on SVM and AdaBoost may provide a superior performance in this case. Studies show that SVM performs well on health state classification problems (Cerda et al. 2014), and combining it with a boosting algorithm may further improve its accuracy. AdaBoost can be used as a boosting strategy; it forces SVM to focus on misclassified samples from the minority class, preventing the minor damage features from being considered as noises (Kuncheva & Whitaker 2002). Linear and simple classifiers could better separate the high-dimensional spaces composed of vibration data in general, so linear-SVM is selected as the base learner in AdaBoost. However, the integration of linear SVM with AdaBoost is still difficult; it requires a suitable regularization parameter, C , to balance the “complexity” and “diversity” of SVM as the component classifier (Li et al. 2008). An optimization strategy for seeking the appropriate C value is therefore the key to building an efficient combination algorithm of AdaBoost-linear SVM.

This paper compares the performance of different ML methods on the indirect framework and proposes a strong classification algorithm, Optimized AdaBoost-linear SVM (OAB-linear SVM), for damage identification of bridges. Laboratory experiments were conducted to establish the dataset by employing a steel beam and a scale truck model. The paper presents an early attempt to experimentally validate the feasibility of the drive-by method to identify small damage in the bridge. ML models learn to identify bridge health states using raw vehicle acceleration signals as inputs. The model’s performance is evaluated by its accuracy in classifying the test sets of different health statuses. The experimental results from the vehicle are also compared with those acquired directly from the bridge model to show the feasibility of the indirect SHM framework.

2 METHODOLOGY

2.1 Background of different ML models and the proposed method

In this study, five different ML models will be chosen as the classifiers for structural health states, in addition to the proposed algorithm. They are Linear-SVM, RBF-SVM, Gaussian Process (GP), Artificial Neural Network (ANN), and Random Forest (RF). They are algorithms commonly used in structural health state classification problems, and their summaries are as follows:

Linear-SVM: One of the most robust and accurate models of well-known ML algorithms is SVM (Evgeniou & Pontil 2001). The goal of linear-SVM is to find separating hyperplanes that can separate the dataset as reliably as possible into distinct data classes. Ideally, when the data are completely linearly separable, the hyperplanes will be as far as possible from the nearest elements of the classes.

RBF-SVM: RBF-SVM, as one of the nonlinear SVMs, replaces hyperplanes with Gaussian manifolds, but the basic principle remains the same (Evgeniou & Pontil 2001). One can adapt SVM to be a nonlinear classifier, which allows SVM to separate nonlinearly separable support vectors.

GP: GP is a generalization of the Gaussian probability distribution and can be used for classification and regression (Rasmussen & Williams 2005). It is a type of kernel model, similar to SVM, but unlike SVM, it can predict highly calibrated class membership probabilities, although the choice and configuration of the kernel used at the heart of the method can be challenging.

ANN: ANN is based on a collection of connected units or nodes called artificial neurons, which loosely resemble the neurons in a biological brain (Goodfellow et al. 2016). Each connection, like the synapses in a biological brain, can transmit a signal to other neurons. Typically, neurons are aggregated into layers. Different layers may perform different transformations on their inputs. Signals travel from the first layer (the input layer) to the last layer (the output layer), possibly after traversing the layers multiple times.

RF: RF is an extension of the bagging method, which uses feature randomness in addition to bagging to produce an uncorrelated forest of decision trees (Ho 1995). For classification problems, the output of RF is the class selected by most trees. RF generally outperforms decision trees, but its performance can be affected by data characteristics.

OAB-linear SVM: the proposed algorithm employs SVM with a linear kernel as component classifiers in AdaBoost and seeks its best generalization performance in damage detection. SVM is a strong classifier, and there is a need to weaken its learning abilities to benefit from AdaBoost mechanisms. It consists of a training process and an optimizing process, as shown in Tables 1 and 2, respectively. The input data is divided into a training set and a validation set with a ratio of 9:1. In the training process, AdaBoost maintains a weight distribution over training samples, which is initially configured to be uniform. Linear SVM as the component classifier is called repeatedly in a series of cycles, T . Linear SVM trains a classifier, h_t , at each iteration, t , and the distribution, w^t , is updated in each iteration based on the prediction results on the training samples. Correctly classified samples are assigned smaller weights, while misclassified samples are given larger weights. In the optimizing process, a very small C value, C_{ini} , is initially set corresponding to a linear SVM with weak learning ability. Linear SVM with this C value is then trained by AdaBoost to return an accuracy on the validation set. After that, the C value is increased slightly by C_{step} , to improve the learning ability of linear SVM. This procedure is repeated until the final cycle, S , is completed. The classifier with the highest result accuracy is chosen as optimal for the given dataset. The values of C_{ini} , C_{step} , S , and T required for the algorithm are set as 0.01, 0.1, 1000, and 50, respectively.

Table 1. Training process.

Require: training samples with labels, $\{(x_1, y_1), \dots, (x_i, y_i), \dots, (x_N, y_N)\}$, where x_i represents the i -th vector in the training set; $y_i = \{-1, 1\}$ for damaged and healthy labels.

Require: the number of iterations at which boosting is terminated, T .

Initialize the weights of sub-training samples, $w_i^1 = 1/N$ ($i = 1, 2, 3, \dots, N$).

For iteration t in T :

- (1) Train a Linear SVM component classifier, h_t , on the weighted sub-training set.
- (2) Compute the training error of h_t : $\varepsilon_t = \sum_{i=1}^N w_i^t y_i \neq h_t(x_i)$.
- (3) Set the weight of the component classifier h_t : $\alpha_t = \frac{1}{2} \ln \left(\frac{1-\varepsilon_t}{\varepsilon_t} \right)$.
- (4) Update the weights of sub-training samples: $w_i^{t+1} = \frac{w_i^t \exp[-\alpha_t y_i h_t(x_i)]}{C}$, where $\sum_{i=1}^N w_i^{t+1} = 1$.

Output: $f(x) = \text{sign} \left(\sum_{t=1}^T \alpha_t h_t(x) \right)$.

Table 2. Optimizing process.

Require: validation samples with labels, $\{(x_1, y_1), \dots, (x_i, y_i), \dots, (x_M, y_M)\}$.

Require: AdaBoost-linear SVM, $f(x)$.

Require: the number of cycles in updating the regularization parameter, S .

Require: the initial regularization parameter, C_{ini} ; the step of regularization parameter, C_{step} .

For iteration s in S :

- (1) Calculate the accuracy on validation sets with $f(x)$: $\text{accuracy}[s] = \frac{TP+TN}{TP+TN+FP+FN}$, where TP, TN, FP, FN represent true positive, true negative, false positive and false negative predictions in samples.
- (2) Increase C value by C_{step} : $C = C_{step} \times s + C_{ini}$

Output: $F(x) = f_{s,max}(x)$ corresponding to the max accuracy[s].

2.2 Signal processing and diagnostic framework

Raw accelerations collected from the passing vehicle will be processed to build the dataset for ML models. Figure 1 shows the processing procedure for the vehicle accelerations. For each passage, the valid acceleration segment will be cut off after the acquisition of vehicle acceleration, where peaks can be found in the acceleration records of the front axle when the vehicle enters and exits the bridge due to expansion joints at both ends; they can be regarded as indicators for selecting the effective segments. Given the passage time of T , and the sampling frequency of F , there are totally $T \times F$ discrete points in the valid segment. To reduce the influence of noise, a sliding window-based method is used to process the selected data (window length = 10, stride = 1), after which the processed time-domain signals are utilized as inputs for ML models. In the study, the experiments were conducted in a normal laboratory environment, where white noise was the main source of noise. Thus, the Gaussian function is chosen as the window function. The database obtained from vehicle responses has a total of 1600 runs, and it is split into the training set and test set with a ratio of 85%:15%. ML models learn to identify bridge health states via the training set and their performance is evaluated by the accuracy in the test set.

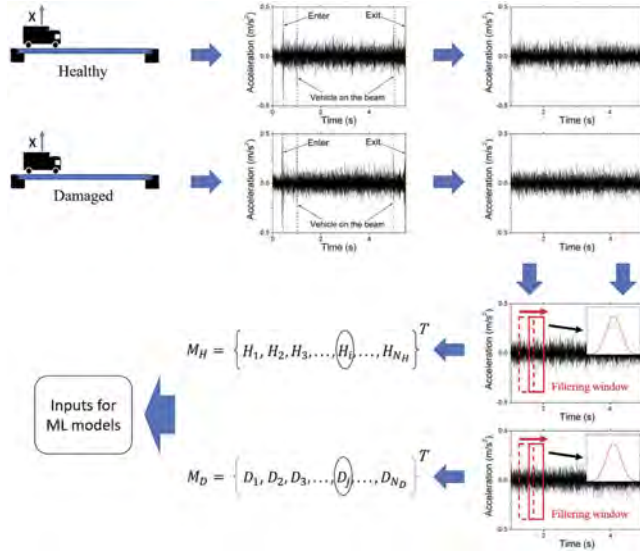

Figure 1. Signal processing procedure.

3 EXPERIMENTAL PROGRAM

Laboratory experiments were performed to validate the methodology using a steel beam and a scale truck model with an engine. Instead of inducing real structural damage, damaged states were simulated by adding masses to the beam to avoid permanent or irreversible destruction. It is a common practice in the laboratory that has been proven feasible by many studies, such as those conducted by Zhang et al. (2019), Liu et al. (2020), and Lan et al. (2023). The data acquisition system, which is PC-driven and has a sampling rate of 2 kHz, is the same for both the beam and the truck model; it is connected with sensors via wires. The sensors used in the study are made by Bruel & Kjaer (TYPE 4371), and relevant specifications are provided as follows: frequency range (0.1 – 12600 Hz), weight (11 gram), and sensitivity (1.0 pC/ms⁻²).

3.1 Bridge and vehicle models

Bridge model: Physical properties of the beam model (HEA400) are listed as follows: elastic modulus $E = 199$ GPa; density $\rho = 7.85 \times 10^3$ kg/m³; length $L = 4.4$ m; section area

$A = 15898 \text{ mm}^2$, and moment of inertia $I = 8.564 \times 10^7 \text{ mm}^4$. The setup and dimension details can be referred to in Figure 2. The setup includes an acceleration ramp, a deceleration ramp, and a guide rail (see Figure 3a) that is used to adjust the path of the vehicle so that it can pass straight through the beam. As artificial damage, masses were added to different locations of the beam (see Figure 3b); the details will be discussed later. For comparison purposes, three accelerometers were also instrumented at $0.1L$, $0.5L$, and $0.9L$ of the steel beam (see Figure 3c), respectively, to obtain the bridge vibrations during the vehicle's passage.

Vehicle model: Tamiya's Mercedes-Benz 1850L was employed as the vehicle model (see Figure 4a). Except for the weight, this engine-driven 1/14 scale model (568 mm \times 202 mm) realistically captures the configuration of a full-sized truck. The self-weight of the vehicle model is 4.05 kg, and a 6-kg mass is added inside the vehicle body; thus, the overall vehicle weight is 10.05 kg. Four accelerometers were mounted on the front of the car, the vehicle body, the rear axle, and the front axle, respectively, as described in Figure 4b, c. The maximum speed of the vehicle model is 0.9 m/s, and this speed is used in the test. Additionally, an acceleration ramp is employed to guarantee the maximum speed can be reached before the vehicle enters the bridge. The velocities maintain similar in each run.

Figure 2. Details of the beam model (unit: mm).

Figure 3. Setup for the beam model: (a) guide rail; (b) added mass; (c) accelerometer.

Figure 4. Setup for the vehicle model: (a) scale vehicle model; (b) sensor installation (top); (c) sensor installation (bottom).

3.2 Experimental dataset

For the diagnostic framework, data from both intact and damaged states of bridges are required. The vehicle was driven across the bridge repeatedly to acquire the dataset for

training and testing the ML models. There are totally 8 cases of health states including the healthy case used as baseline; these cases were collected from 3 damage locations and 5 damage severities, as described in Table 3. The placement of mass at different locations is used to validate the viability of the method; 0.5L (2 m) and 0.6L (2.4 m) stand for the damage locations at and near the mid-span of the bridge, and 0.15L (0.6 m) represents the damage location near the bridge support. Due to the larger vibration responses in the mid-span bridge, the detection performance of the mid-span is usually better than that near the support. 0.15L, as one of the most unfavorable location cases, is chosen to investigate the sensitivity of the method to the bridge damage by using various mass sizes. Each state contains 200 vehicle passages to establish the experimental dataset. Thus, there are 200 (runs) \times 8 (cases) \times 7 (sensors) = 11200 (signals), and each signal has 8000 discrete points corresponding to 4s of “valid segments”.

Table 3. Health state description.

Case No.	Location	Weight	Runs	Case No.	Location	Weight	Runs
0	0	0 (Healthy)	200	4	0.6 m	2 kg (0.4%)	200
1	0.6 m	20 kg (4%)	200	5	0.6 m	1 kg (0.2%)	200
2	0.6 m	10 kg (2%)	200	6	2 m	20 kg (4%)	200
3	0.6 m	5 kg (1%)	200	7	2.4 m	20 kg (4%)	200

4 RESULTS AND ANALYSIS

4.1 Damage indication performance

The main parameters of Linear-SVM, RBF-SVM, GP, ANN, and RF are determined by Grid Search (LaValle & Branicky 2004), as shown in Table 4. While the hyper-parameters of AB-linear SVM are tuned by the proposed optimizing method. The performance of each ML model is assessed via 5-fold cross-validation. The results from the rear axle sensor are illustrated herein, while results from sensors on other positions will be discussed later. Table 5 shows that the accuracy of ML algorithms decreases as the damage becomes less severe. The smallest damage of 1 kg (0.2%) used in the experiment can be successfully detected by ML models with accuracy ranging from 63.3% to 76.7%. The closer the accuracy is to 50% (random guess), the poorer the detection performance is, or the ML model is just not suitable for the SHM framework. Among these models, OAB-linear SVM outperforms other models by better classifying the damage states, which provides higher accuracy. It improves the accuracy by 6.2% on average when compared to the linear SVM, and by 5% to 16.6% compared to other algorithms. This is due to AdaBoost forces the linear SVM as a component classifier to concentrate on misclassified samples from the minority class, avoiding the minor damage features from being considered as noise. It is found that ML methods, especially the proposed algorithm, are of great significance for the identification of minor damages, which can expand the lower limit of detectable damage range.

Table 4. Major parameters of classification algorithms.

Algorithm	Configuration	Algorithm	Configuration
Linear-SVM	C=5	ANN	hidden_layer_sizes=(10, 4), alpha=1, max_iter=1000
RBF-SVM	gamma=0.01, C=5	RF	n_estimators=1000, max_features=20
GP	Kernel=10 * RBF(10)		

4.2 Performance comparison for sensor locations

The above results are acquired from the rear axle sensor, and the results from different sensor locations are presented in Table 6, where the results of the bridge sensor are used here to compare the direct and indirect methods. These results are based on OAB-linear SVM, as it has the highest accuracy, and similar results can be seen in other models. The data for the front-car

Table 5. Classification performance for ML models.

Cases	Details	OAB-linear SVM	Linear-SVM	RBF-SVM	GP	ANN	RF
Case1	0,15L, 20kg	88.3 %	83.3 %	73.3 %	75.0 %	81.7 %	78.3 %
Case2	0,15L, 10kg	85.0 %	78.3 %	70.0 %	71.7 %	78.3 %	75.0 %
Case3	0,15L, 5kg	81.7 %	75.0 %	68.3 %	70.0 %	75.0 %	71.7 %
Case4	0,15L, 2kg	78.3 %	73.3 %	65.0 %	66.7 %	73.3 %	68.3 %
Case5	0,15L, 1kg	76.7 %	70.0 %	63.3 %	65.0 %	71.7 %	66.7 %
Case6	0,5L, 20kg	93.3 %	86.7 %	76.7 %	81.7 %	85.0 %	83.3 %
Case7	0,6L, 20kg	91.7 %	85.0 %	76.7 %	78.3 %	85.0 %	85.0 %

sensor are not included in the table because the contact between the front car and the rail limits its free vibration. It can be observed that there is no significant difference in the accuracy of varied sensor locations, The similarity of results from the vehicle and bridge sensors implies that the indirect SHM framework is equally effective as the direct SHM system. Furthermore, the effectiveness of ML methods is not limited to a specific SHM framework or sensor location.

Table 6. Comparison performance for sensor locations.

Cases	Details	Car body	Rear axle	Front axle	Beam1	Beam2	Beam3
Case1	0,15L, 20kg	88.3 %	88.3 %	86.7 %	88.3 %	88.3 %	88.3 %

5 CONCLUSION

In this paper, the performance of different ML methods is compared, and a strong classification algorithm is proposed for the indirect SHM framework. Laboratory experiments using a steel beam and a scale truck model were performed to obtain the dataset. Additional weights on the beams as “artificial damage” are used to validate the effectiveness of different ML methods and the proposed algorithm in damage detection, especially small damages. Based on the experimental results, the following conclusions can be drawn:

- (1) ML methods are sensitive to damage. The ML methods used in this paper have accuracy ranging from 63.3% to 76.7% for small damage (0.2% severity), among which the proposed algorithm, OAB-linear SVM, shows the highest accuracy of 76.7%. They could expand the lower limit of the detectable damage range, which is of great benefit to the detection of minor damage.
- (2) OAB-linear SVM is demonstrated to outperform other ML models in the study, with improvements ranging from 5% to 16.6%. This could allow it to become a preferable option for damage detection problems.
- (3) The indirect SHM framework can be equally effective as the direct SHM system, and the effectiveness of ML methods is not limited to a specific SHM framework or sensor location.

A frontier of research is the integration of ML models with semi-supervised or unsupervised learning frameworks to build a new generation of smart bridges.

Structural health monitoring of the KW51 bridge based on detailed strain mode shapes: Environmental influences versus simulated damage

D. Anastasopoulos, K. Maes, G. De Roeck, G. Lombaert & E.P.B. Reynders
Department of Civil Engineering, KU Leuven, Leuven, Belgium

ABSTRACT: Strain mode shapes are attractive features for vibration-based monitoring as their sensitivity to local damage is known to be high. However, the assessment of their performance in situ has remained an open problem. This work presents the continuous dynamic strain monitoring of a steel railway bridge with FBGs for one year. The natural frequencies and strain mode shapes of ten modes are automatically identified from operational strain time histories, on an hourly basis. The influence of temperature on these modal characteristics is quantified and then investigated with a FE model of the bridge. A clear influence of temperature on the natural frequency of most modes is identified, especially during frost periods, contrary to the strain mode shapes, which are mostly insensitive to temperature changes, as confirmed also by the FE model. The FE model is employed to investigate also the influence of simulated local damage on the modal characteristics.

1 INTRODUCTION

Vibration-Based Monitoring (VBM) (Fan & Qiao (2010)) aims to identify structural damage by identifying damage-related changes in modal characteristics of a structure. Natural frequencies are the most widely used modal characteristics in VBM. They are mainly sensitive to global stiffness changes and thus, the influence of small-scale damage can be quite limited ((Fan & Qiao (2010)), while their temperature sensitivity can be high enough to hide the presence of damage. Displacement mode shapes are also used in VBM. They are more sensitive to local damage and less sensitive to temperature than natural frequencies but the disadvantage is that a dense grid of accelerometers is required to achieve damage localization ((Fan & Qiao (2010)), which is costly.

Strain mode shapes are an alternative to displacement mode shapes that offer several advantages (Anastasopoulos et al. (2019)). Strain-based features are much more sensitive to local damage than modal displacements and dense grids of strain sensors can be easily achieved when fiber-Bragg gratings (FBG) are employed, due to their multiplexing option. Laboratory experiments on concrete beams have illustrated that strain mode shapes are highly sensitive to local damage, while they are insensitive to temperature changes (Anastasopoulos et al. (2019)). In recent experiments, the strain mode shapes of a railway bridge were monitored with a dense grid of FBGs and were also found to be insensitive to temperatures higher than 0°C (Anastasopoulos et al. (2021)).

The second year of monitoring of this bridge, known as KW51, is presented here. During this period, the bridge was subjected to frost, which did not occur during the first year. The influence of frost on the bridge's strain mode shapes is studied first. Second, the physical interpretation of the influence of temperature on the modal characteristics of the bridge is given. This is achieved through a detailed finite element (FE) model of the bridge. Third, the influence of local stiffness changes on the bridge's modal characteristics is investigated. These changes are simulated in the FE model and the obtained influence is quantified and implemented on the experimentally obtained strain mode shapes. A sensitive *damage index*, which combines information from several modes, is used to detect the induced changes. The present paper is an abbreviated version of a more detailed study to be found in Anastasopoulos et al. (2022).

2 THE KW51 BRIDGE

The KW51 is a 117m steel tied-arch railway bridge (Figure 1) that crosses the Leuven-Dijle Canal in Leuven, Belgium. The deck consists of two main girders and thirty-three transverse beams. The bridge is supported on four neoprene bearings, which directly sit on two concrete abutments.

Figure 1. The KW51 bridge, as seen from its north side.

3 VIBRATION-BASED MONITORING

Two independent monitoring systems have been installed on the bridge. The first one was installed in 2018 to monitor accelerations with uniaxial accelerometers and strains with strain gauges (Maes et al. (2022)) and the second in 2019 to monitor the dynamic long-gauge strains of the main girders of the bridge with FBG sensors in a dense grid (Anastasopoulos et al. (2021)).

3.1 *Dynamic strain sensing system with fiber-Bragg gratings*

Dynamic strains of the bridge have been monitored with 79 FBGs, inscribed in four optical fibers. The FBGs are located at the top surface of the bottom flange of the girders (Figure 2). The fibers are attached to the flanges via a custom clamping system, to measure axial strains. The FBGs measure the average strain between two clamping blocks over a gauge-length of 2.5 m. The strain acquisition is conducted with a FAZ Technologies I4G interrogator. The monitoring begun in February 2019 and ended in March 2021. The findings of the first year of monitoring were presented in Anastasopoulos et al. (2021), next to the detailed description of the monitoring system. In February 2021, negative temperatures occurred that resulted in freezing of the ballast. The influence of frost on the strain mode shapes is investigated here.

Figure 2. Strain monitoring system of the KW51 bridge (top view of the deck). Orange cubes: clamping blocks; blue rectangles: FBGs; C: cabinet with acquisition system; T: temperature sensor. The FBGs are labeled as; NE: northeast, NW: northwest, SE: southeast, SW: southwest.

4 STRAIN-BASED OPERATIONAL MODAL ANALYSIS

Every hour, the monitoring system captures 900 s of ambient and operational dynamic strains at a sampling rate of 1,000 Hz. Each dataset is used for Operational Modal Analysis (OMA), to identify the modal characteristics of the bridge at the corresponding time. More than 10,000 OMAs were conducted during the monitoring period that is being reported here (09/2019 to 03/2021).

The data processing and system identification are conducted with the Matlab toolbox MACEC (Reynders et al. (2021)). The data-driven stochastic subspace identification (SSI-data) method is employed for system identification (Peeters & De Roeck (1999)). The process of mode selection is

automated with the use of hierarchical clustering, as explained in detail in Anastasopoulos et al (2021). Thirteen modes are identified in the frequency range 0-7 Hz, which are classified as deck or arch modes, depending on which part of the bridge is predominantly deformed. The natural frequency, damping ratio and strain mode shape of three of these modes are given in Figure 3.

Figure 3. Strain mode shape, natural frequency and damping ratio of three modes of the KW51 bridge, as identified from a strain-based OMA. Mode 1: 1st lateral bending (arch); Mode 4: 3rd lateral bending (arch); Mode 6: 2nd vertical bending (deck). Top subplots: 3D view; bottom subplots: front (x - z) view.

4.1 Influence of temperature on the identified modal characteristics

The natural frequencies of modes 1, 4 and 6 are plotted as a function of temperature in Figure 4. A bilinear relation between natural frequency and temperature is observed, with a knee point around 0°C. The linear regression between temperature (T) and natural frequency (f) is computed for each mode, both for $T > 0^\circ\text{C}$ and $T < 0^\circ\text{C}$. The relative change of natural frequency for each mode Δf_j [%], for a temperature change of $\Delta T = +5^\circ\text{C}$ is also given.

Figure 4. Natural frequencies of the continuously identified modes 1, 4 and 6 of the KW51 bridge as a function of temperature, as identified from strain-based OMAs using SSI-data (f_j^{SSI}). The dashed lines denote the linear regression of the data $f(T)$ for $T > 0^\circ\text{C}$ (red) and $T < 0^\circ\text{C}$ (blue).

The measured temperature correlates well with the identified natural frequencies. The natural frequencies decrease with increasing temperature, both for positive and negative temperatures. An increase of $\Delta T = 5^\circ\text{C}$ in temperature, when $T > 0^\circ\text{C}$, results in a relative decrease of about $\Delta f_5 = 0.1 - 0.2\%$ for the natural frequencies. However, this behaviour is much stronger for negative temperatures, where a reduction of more than 1% is observed for mode 6 between $T = -6^\circ\text{C}$ and $T = 0^\circ\text{C}$. This significant increase of the natural frequencies for negative temperatures is most probably due to frost of the ballast layer and the formation of ice (Maes et al. (2022)).

The influence of temperature on the strain mode shapes is investigated using the process of Anastasopoulos et al. (2021), for the first year of monitoring. The identified strain mode shapes are clustered into non-overlapping temperature groups k with a range of 3°C , based on the temperature that was recorded during each test. The sample mean $\mu[\psi_j]$ of all strain mode shapes in a group is computed, as well as the sample standard deviation $\sigma[\psi_j]$ and the related $\pm 2\sigma$ confidence interval $\text{CI}[\psi_j]$, which boils down to a 95%CI for normally distributed samples.

The results indicate that the 95% CI of the different temperature groups overlap completely, and they have nearly the same width. This confirms that there is no statistically significant influence of temperature on the strain mode shapes, a conclusion that was also drawn in Anastasopoulos et al. (2021) and thus, these results are not reproduced here. Since strain mode shapes are not influenced by temperature, the statistical uncertainty that is observed on them is probably related to identification errors and it can be further reduced by averaging. Hence, the standard deviation of the sample mean of the entire set of N_k strain mode shapes of a temperature group k is calculated, which is related to the standard deviation of the set as $\sigma[\mu[\psi_j]] = \sigma[\psi_j]/\sqrt{N_k}$.

The narrow confidence intervals of the sample mean of the different temperature groups overlap and they all have nearly the same width for most modes, which strengthens the conclusion that there is no statistically significant influence of the temperature on most strain mode shapes. However, for the higher arch and deck modes, i.e., mode 4 (3rd lateral mode of the arch) a relatively small and uniform influence of frost on the strain mode shapes is observed (Figure 5). The influence is minor but nevertheless statistically significant (Figure 5). The 95% CI of the sample mean of the negative temperature groups is not fully overlapping with these of the positive temperature groups, indicating a uniform influence of negative temperatures on strain mode shapes of mode 4.

Figure 5. Sample mean $\mu[\psi_4^{ssi,(k)}]$ (continuous lines) and 95% CI $[\mu[\psi_4^{ssi,(k)}]]$ (dashed lines) of the sample mean, of the strain mode shapes that have been identified in each temperature group k for mode 4. The top and bottom subplots contain the strain mode shapes at the north and south sides of the bridge, respectively. A more detailed view of the zone from -40m to -30m is also given for the south-west strain mode shapes.

5 FINITE ELEMENT MODEL OF THE BRIDGE

A detailed FE model of the KW51 bridge (Figure 6a) was built in Maes et al. (2022), using the MATLAB toolbox Stabil (François et al. (2021)). The Young’s modulus of the steel is taken as $E_s=200$ GPa, while of the ballast layer as $E_b=550$ MPa. The model was calibrated using a set of modal characteristics identified from a detailed acceleration-based OMA.

A linear reduction of about 1% of the natural frequency for an increase of temperature from 0°C to 40°C is observed in Figure 4. To investigate this behaviour with the FE model, E_s is reduced by 3%, from 206 GPa at -10°C to 200 GPa at 40°C (Figure 6b), a realistic reduction for a temperature increase of C. The frost of the ballast results in a significant increase of the natural frequencies for $T < 0^\circ\text{C}$ (Figure 4). In the FE model, $E_b = 550$ MPa, for $T > 0^\circ\text{C}$, while for $T < 0^\circ\text{C}$ its value is linearly increased to 1750MPa, which was obtained from calibrating the FE model with modal characteristics obtained from the acceleration monitoring system during a frost period.

The frost of the ballast does not occur uniformly or instantaneously, due to its thermal inertia and the uneven exposure to the sun. In practice, E_b increases gradually in time and space from 550 MPa to 1750 MPa, as the frost of the ballast progresses, but this process is difficult to model in detail. Instead, this relationship is considered to be linear with $E_b(0^\circ\text{C} = 550$ MPa and

Figure 6. 3D view (left) of the FE model of the KW51 bridge (Maes et al. (2022)). Temperature versus the Young's modulus of the steel E_s (center) and the ballast E_b (right) as incorporated in the FE model.

$E_b(-6^\circ\text{C})=1750$ MPa (Figure 6c), a simplification that appears to capture the behaviour of the bridge. In order to evaluate the model with the results of the dynamic strain monitoring, the modal characteristics of the bridge are calculated from the FE model assuming five temperatures cases: CT1 ($T = -6^\circ\text{C}$), CT2 ($T = -3^\circ\text{C}$), CT3 ($T = -0^\circ\text{C}$), CT4 ($T = 20^\circ\text{C}$) and CT5 ($T = 40^\circ\text{C}$).

5.1 Influence of temperature on the modal characteristics

The calculated natural frequencies of modes 1, 4 and 6 versus temperature for the five temperature cases are plotted in Figure 7. The experimental natural frequencies versus the corresponding temperature at which they were identified are also included. Overall, the natural frequency-temperature relation is well-captured by the validated FE model. The numerical and the experimental slope of the linear regression are in good agreement, confirming the accuracy of the model, which is used to investigate also the influence of temperature on strain mode shapes.

Figure 7. Natural frequencies of the continuously identified modes 1, 4 and 6 of the KW51 bridge as a function of temperature, as identified from SSI-data (f_j^{SSI}) and calculated from the FE model (f_j^{FE}). The dashed and the dotted lines denote the linear regression of the data $f(T)$ for $T > 0^\circ\text{C}$ (red) and $T < 0^\circ\text{C}$ (blue) for both the experimental (dashed lines) and the numerical (dotted lines) natural frequencies.

In Figure 8, the numerical strain mode shapes of mode 4 are illustrated, as obtained for the five temperature cases. For this mode, a uniform influence of negative temperatures was identified from the experimental results (Figure 5). The FE model confirms that for this higher order mode, a relatively small but uniform influence of negative temperatures on its strain mode shapes exists, i.e., when the ballast freezes. Similar behaviour is observed for other higher order modes and thus, they are not reproduced here. The model confirms also the temperature insensitivity of the low order modes, as for these only minimal changes are observed (if any) on their strain mode shape.

Positive temperatures have no effect on the strain mode shapes of any of the modes as the ballast stiffness no longer (drastically) changes in this temperature range. For the three temperature cases that are simulated, where temperatures of 0°C , 20°C and 40°C are considered, the calculated strain mode shapes completely overlap (Figure 8). This behaviour confirms the temperature insensitivity that is observed in the experimental strain mode shapes, when $T > 0^\circ\text{C}$ (Figure 5).

5.2 Influence of local stiffness changes on the modal characteristics

Since only the main girders of the KW51 are instrumented, it is expected that mainly local mass and stiffness changes in the girders can be detected from the strain mode shapes. The FE model

Figure 8. Strain mode shapes $\psi_{4,CTk}^{fem}$ of mode 4 that have been obtained for the four temperature cases. The top and bottom subplots contain the strain mode shapes at the north and south sides of the bridge, respectively. A detailed view of the zone 25m to 35m is given for the south-east strain mode shapes.

is used to investigate the influence that local stiffness changes on the main girders have on modal characteristics. Such changes can be caused by, e.g., corrosion, and result in a reduced cross-section and thus, stiffness. The stiffness of a beam element of the north girder is modified in the model by reducing its E_s by 10%, 20% and 30% for three stiffness cases (SC_i), respectively.

The numerical strain mode shapes of mode 6 for the three cases and the undamaged bridge are given in Figure 9. A clear and local change of the modal strain amplitude is observed at the

Figure 9. Strain mode shapes $\psi_{FE,i}^{(k)}$ of mode 6 that have been obtained for the four stiffness cases. The top and bottom subplots contain the strain mode shapes at the north and south sides of the bridge, respectively. A detailed view of the zone from 20m to 40m for the north-east strain mode shapes is given.

location of reduced stiffness ($x \approx 35$ m, top subplot), which becomes more pronounced for lower values of elastic modulus. Similar changes are observed on the remaining strain mode shapes.

However, when the original modal strain amplitude is close to zero, no changes can be observed, while in reality, strain mode shapes are subjected to identification uncertainty. This underlines the importance of combining information from several modes in order to increase the chance of identifying local stiffness changes. The following process is adopted, which accounts also for the identification uncertainty of the strain mode shapes that are obtained from the measurements (Figure 5). The modes that are combined are the ones that enjoy the highest identification accuracy and the minimum influence of temperature, even during frost, i.e, modes 1, 2, 3 and 6.

First, a six-month period (03/2020 to 08/2020) is taken as the *reference* period where no stiffness changes occur on the structure. The relative difference is computed between the modal strain i of mode j as identified from the modal test number t , $\psi_{j,i}(t)$, and a reference value $\psi_{j,i}^{ref}$:

$$\Delta\psi_{j,i}(t) [\%] = \frac{\psi_{j,i}(t) - \psi_{j,i}^{ref}}{\psi_{j,i}^{ref}} 100\%, \quad t < t_{dam} \quad (1)$$

where the considered undamaged period stretches from $t = 1$ until $t = t_{dam} - 1$. Possible choices for $\psi_{j,i}^{ref}$ include the modal strains identified during the first test, or an average value over a period during which the structure is known to be in undamaged condition. In what follows, the second option is followed such that $\psi_{j,i}^{ref} = \frac{1}{t_{dam}-1} \sum_{t=1}^{t_{dam}-1} \psi_{j,i}(t)$. The relative amplitude change of the modal strain at $x \approx 35$ m of the north-east strain mode shapes, where the stiffness change is implemented in the FE model is calculated for all tests within the undamaged period and for modes 1, 2, 3 and 6. The mean and the 95% CI over the same period are also calculated.

Second, a six-month *damage* period is considered (09/2020 to 03/2021) during which, the modal strain amplitude of each identified mode is modified according to the observed amplitude changes in the FE model for the different stiffness cases. The relative change is obtained as:

$$\Delta\psi_{j,i}^{(k)}(t) [\%] = \frac{\lambda_{j,i}^{(k)} \psi_{j,i}(t) - \psi_{j,i}^{ref}}{\psi_{j,i}^{ref}} 100\%, \quad t \geq t_{dam}, \quad \text{and} \quad \lambda_{j,i}^{(k)} = \frac{\psi_{FE,j,i}^{(k)}}{\psi_{FE,j,i}^{(0)}} \quad (2)$$

Third, a 24-hour rolling average is introduced to reduce the uncertainty in the data. Therefore, $\psi_{j,i}(t)$ is replaced by a rolling 24-hour average $\hat{\psi}_{j,i}(t)$ in Eqs. 1 and 2. In Figure 10, the relative change of the modal strain amplitude before and after the introduction of the stiffness changes is given, as calculated for a rolling 24-hour average over the considered periods for mode 6. The reduced uncertainty results in narrow 95% CI, which allow for detecting all damage cases. Similar behaviour is observed for modes 1 and 2, while mode 3 is not influenced by the stiffness changes, as the modal strain at $x \approx 35$ coincides with a nodal point for mode 3.

Figure 10. Relative change of the modal strain amplitude with respect to the reference value during the undamaged period (blue) and during the period with simulated damage cases SC_k ; (a) $k = 1$ (red), (b) $k = 2$ (green) and (c) $k = 3$ (magenta). The graphs are obtained for the 24-hour rolling average modal strain at $x \approx 35$ m of the north-east strain mode shapes. The continuous lines and the dashed lines denote the mean and the 95% CI of the relative modal strain amplitude change of each mode and period.

Finally, the information of the various modes is combined in a *damage index* (DI). The average of the relative changes of a modal strain i over all modes j is taken in order to yield the aggregate DI for each damage case k :

$$\widehat{DI}_i^{(k)} [\%] = \frac{\sum_{j=1}^{n_m} |\Delta\hat{\psi}_{j,i}^{(k)}|}{n_m} \quad (3)$$

The DI, as obtained at the location of the damage for the three damage cases is given in Figure 11. It can be observed that the DI changes shortly after the start of the damage period and is sensitive in all induced damage cases. The change in the DI exceeds the identification uncertainty for all cases and thus, damage can be identified with high confidence.

Last, the influence of the reduced stiffness on the natural frequencies is investigated. Natural frequencies are slightly reduced, even for the 30% reduction case, where the relative changes of natural frequencies, range from $\approx 0.01\%$ to 0.03% . The low sensitivity of natural frequencies to local stiffness changes, when compared to their sensitivity to temperature, underlines the difficulty to identify these changes without introducing data normalization techniques (Maes et al. (2022)).

Figure 11. Damage Index (DI) as obtained during the undamaged period (blue) and during the period with simulated damage cases SCk ; (a) $k = 1$ (red), (b) $k = 2$ (green) and (c) $k = 3$ (magenta). The DI is obtained for the 24-hour rolling average modal strain at $x \approx 35$ m of the north-east strain mode shapes. The continuous lines denote the mean DI of each period.

6 CONCLUSIONS

The dynamic strains of the KW51 bridge were monitored with long-gauge FBG sensors for a two-years period. During the second year, the bridge was subjected to frost.

The influence of frost is found to be significant on natural frequencies, causing amplitude changes up to 1.7% for a temperature drop from 0°C to -5°C . This change is much higher than the one caused by a positive temperature change from 0°C to $+5^{\circ}\text{C}$, which is up to 0.15% for the same modes. This behaviour is found to be a result of the frost of the ballast layer.

The strain mode shapes of the lower order deck and arch modes were found to be insensitive to temperature, even during frost periods. For higher order modes, a small and uniform influence is observed during frost periods, as a result of the frost of the ballast. For $T > 0^{\circ}\text{C}$ though, no influence is observed in the temperature range $0^{\circ}\text{C} - 36^{\circ}\text{C}$ as the ballast stiffness no longer (drastically) changes in this range. This behaviour is confirmed also by the FE model.

The sensitivity of strain mode shapes to local damage is also studied. For this reason, the stiffness of a girder is locally reduced in a FE model. This reduction causes local amplitude changes in the strain mode shapes, which can be clearly detected even when the identification uncertainty is accounted for, thanks to a damage index that combines information from all modes.

ABSTRACT: This paper proposes a high-resolution seismic monitoring framework that employs dissipated energy as a feature for damage detection and localization in instrumented building structures. The methodology consists of (1) implementing a nonlinear state observer to reconstruct the dynamic response at all degrees of freedom (DoF) of a structural model, (2) employing the reconstructed response to estimate element-by-element forces and displacements, and (3) using estimated displacement, forces, and constitutive laws to estimate element-level dissipated energy. The main advantages of the proposed energy-based approach are that i) the proposed feature is physically meaningful and correlates well with the level of cyclic damage experienced during strong earthquakes, ii) dissipated energy can be reconstructed from element-level stress-strain fields that can be estimated from global acceleration measurements, and (iii) dissipated energy can be calibrated using experimental data. The effectiveness of the proposed energy-based seismic monitoring framework is investigated using data from the Van Nuys hotel tested, a seven-story reinforced concrete (RC) building instrumented by the California Strong Motion Instrumentation (CSMIP) Program (Station 24386). The Van Nuys building experienced insignificant structural and mostly nonstructural damage during the 1992 Big Bear earthquake. Two years later, the building was severely damaged during the 1994 Northridge earthquake, in which localized damage occurred in five of the nine columns on the fourth story (between floors four and five) of the south longitudinal frame.

1 INTRODUCTION

Vibration measurements from structures can be used for various purposes, including but not limited to model calibration, code verification, structural health monitoring, and vibration control. Researchers and engineers have recognized the importance of seismic instrumentation in the past two decades for quantitative and rapid performance assessment of buildings during and immediately following earthquakes (Porter et al. 2004; Celebi et al. 2004; Roohi and Hernandez 2020; Cheraghzade and Roohi 2022; Yazdanpanah et al. 2023). Despite the immediate appeal, technical, logistical, and economic challenges are associated with seismic instrumentation and performance assessment in the case of instrumented buildings. Building instrumentation and its maintenance can be expensive, and budget constraints may not allow for exhaustive floor-by-floor or component-level instrumentation. These buildings exhibit a high degree of nonlinear behavior even during moderate ground motions, which makes it challenging to interpret the measured seismic response and provide a quantitative measure of the estimated level of damage caused by an earthquake.

To address the challenges highlighted, this paper presents a nonlinear model-based state observer (NMBO) to enhance a high-fidelity nonlinear finite element model of the building

with a limited number of response measurements during the seismic event and reconstruct the complete dynamic response of the building. This approach deviates from model-driven approaches that update the model parameters. Instead, it performs nonlinear FE model-data fusion by feeding the sensor measurements as corrective forces applied to a modified FE model of the building. This enhanced model provides estimates of all relevant response quantities, such as inter-story drift and element forces, with their corresponding uncertainty. The performance of NMBO for nonlinear state estimation has been validated using case studies of real-world instrumented steel, reinforced concrete, and woodframe buildings (Hernandez et al. 2018; Roohi and Hernandez 2020; Roohi et al. 2021b; Hernandez et al. 2019)

The NMBO is employed to propose a methodology for reconstructing element-by-element dissipated energy and seismic damage indices in minimally instrumented buildings to perform high-resolution seismic monitoring. The methodology first employs the NMBO to estimate the complete seismic response of an instrumented building. The estimated response is then used as input to mechanics-based damage models to quantify element-level damage indices and perform seismic damage diagnosis and prognosis of a building. The proposed framework is validated using real measured data from the Van Nuys hotel tested, a seven-story reinforced concrete (RC) building instrumented by the California Strong Motion Instrumentation (CSMIP) Program (Station 24386). The Van Nuys building experienced insignificant structural and mostly nonstructural damage during the 1992 Big Bear earthquake. Two years later, the building was severely damaged during the 1994 Northridge earthquake, in which localized damage occurred in five of the nine columns on the fourth story (between floors four and five) of the south longitudinal frame.

2 SYSTEM OF INTEREST AND MEASUREMENT MODEL

This paper focuses on typical building structures in which floor diaphragms can be assumed to be rigid for in-plane deformations. For this type of structures, the response to seismically induced ground acceleration can be accurately modeled by the following simultaneous set of nonlinear differential equations

$$\mathbf{M}\ddot{q}(t) + \mathbf{C}_D\dot{q}(t) + F_r(q(t)) = -\mathbf{M}\mathbf{b}_1\ddot{u}_g(t) + \mathbf{b}_2\omega(t) \quad (1)$$

The vector $q(t) \in \mathbb{R}^n$ represents the relative displacement (with respect to the ground) of all stories. For most buildings of interest, this results in three independent components per floor (two lateral displacements and a rotation about the vertical axis). The number of degrees of freedom is denoted as n , $\mathbf{M} = \mathbf{M}^T \in \mathbb{R}^{n \times n}$ is the mass matrix, $\mathbf{C}_D = \mathbf{C}_D^T \in \mathbb{R}^{n \times n}$ is the damping matrix, $F_r(\cdot)$ is the resultant global restoring force vector which is obtained from the contribution of individual shear wall restoring forces to the global diaphragm coordinates. The matrix $\mathbf{b}_1 \in \mathbb{R}^{n \times r}$ is the influence matrix of the r ground acceleration time histories defined by the vector $\ddot{u}_g(t) \in \mathbb{R}^r$. The matrix $\mathbf{b}_2 \in \mathbb{R}^{n \times p}$ defines the spatial distribution of the vector $\omega(t) \in \mathbb{R}^p$, which in the context of this paper represents the process noise generated by unmeasured excitations and/or modeling errors.

This paper assumes that measurements $y(t)$ of the dynamic response of the structure consist of horizontal accelerations measured in three independent and non-intersecting directions. Vertical accelerations are typically also measured; however, this paper focuses only on horizontal acceleration measurements. The vector of m acceleration measurements $y(t)$ is modeled as

$$y(t) = -\mathbf{c}_2\mathbf{M}^{-1}[\mathbf{C}_D\dot{q}(t) + F_r(q(t)) - \mathbf{b}_2\omega(t)] + v(t) \quad (2)$$

where $\mathbf{c}_2 \in \mathbb{R}^{m \times n}$ is a Boolean matrix that maps the DoFs to the measurements, and $v(t) \in \mathbb{R}^{m \times 1}$ is the measurement noise.

3 NONLINEAR MODEL-BASED STATE OBSERVER (NMBO)

A nonlinear state observer for state estimation in nonlinear systems can be written in a state-space form as

$$\dot{\hat{x}}(t) = \mathbf{f}(\hat{x}(t)) + \mathbf{G}(y(t) - \mathbf{C}\hat{x}(t)) \quad (3)$$

where $\hat{x}(t)$ denotes mean state estimate, \mathbf{G} is a feedback gain, \mathbf{C} is the measurement matrix and is the measurement. We expand nonlinear function $\mathbf{f}(\cdot)$ using a Taylor series around the current estimate of the state vector and obtain a first-order approximation by dropping higher-order terms of power series as follows

$$\dot{\hat{x}}(t) = \mathbf{A}_{\hat{x}(t)}\hat{x}(t) + \mathbf{G}[y(t) - \mathbf{C}\hat{x}(t)] = (\mathbf{A}_{\hat{x}(t)} - \mathbf{GC})\hat{x}(t) + \mathbf{G}y(t) \quad (4)$$

We assume that velocity estimates are equal to the derivative of the estimates of displacement and choose the upper partition of feedback gain to be zero. The lower partition to be $\mathbf{M}^{-1}\mathbf{c}_2^T\mathbf{E}$, where matrix \mathbf{E} is a matrix free to be selected in order to minimize the trace of the state error covariance and maps the DoFs to the measurements. This choice of \mathbf{G} makes the observer realizable as a modified finite element model of the system with added grounded dampers and excited by corrective forces obtained from velocity measurements scaled by added damper values. In second-order form, the proposed nonlinear model-based state observer (NMBO) estimate of displacement response is given by

$$\mathbf{M}\ddot{\hat{q}}(t) + (\mathbf{C}_D + \mathbf{c}_2^T\mathbf{E}\mathbf{c}_2)\dot{\hat{q}}(t) + \mathbf{F}_r(\hat{q}(t)) = \mathbf{c}_2^T\mathbf{E}y(t) \quad (5)$$

where $\hat{q}(t)$ is the time history of the estimated response at all DoFs of the model, and $y(t)$ is noise-contaminated velocity measurements obtained from acceleration measurements. The main advantage of the NMBO is that the nonlinear state observer can be implemented in advanced structural simulation software packages. This allows the state observer to be computationally efficient in the propagation of the state estimate through the nonlinear dynamics of a system.

To determine the feedback gain matrix \mathbf{E} , the objective function to be minimized is the trace of the estimation error covariance matrix. Since for a general nonlinear multi-variable case, a closed-form solution for the optimal matrix \mathbf{E} has not been found, a numerical optimization algorithm is used. To derive the objective optimization function, Equation 5 is linearized as follows

$$\mathbf{M}\ddot{\hat{q}}(t) + (\mathbf{C}_D + \mathbf{c}_2^T\mathbf{E}\mathbf{c}_2)\dot{\hat{q}}(t) + \mathbf{K}_0\hat{q}(t) = \mathbf{c}_2^T\mathbf{E}y(t) \quad (6)$$

where the elements of the stiffness matrix \mathbf{K}_0 are given by

$$\mathbf{K}_{0_{ij}} = \left. \frac{\partial \mathbf{F}_{r,i}}{\partial q_j} \right|_{q_j} = 0 \quad (7)$$

By defining the state error as $e = q - \hat{q}$, the expression for the state estimation error is given by

$$\mathbf{M}\ddot{e}(t) + (\mathbf{C}_D + \mathbf{c}_2^T\mathbf{E}\mathbf{c}_2)\dot{e}(t) + \mathbf{K}_0e(t) = b_2u(t) - \mathbf{c}_2^T\mathbf{E}v(t) \quad (8)$$

To derive an expression for the state error covariance, we take Fourier transforms of both sides of Equation 8 and obtain the following

$$(\mathbf{M}\omega^2 + (\mathbf{C}_D + \mathbf{c}_2^T\mathbf{E}\mathbf{c}_2)i\omega + \mathbf{K}_0)e(\omega) = b_2u(\omega) - \mathbf{c}_2^T\mathbf{E}v(\omega) \quad (9)$$

with \mathbf{H}_o defined as

$$\mathbf{H}_o = (-\mathbf{M}\omega^2 + (\mathbf{C}_D + \mathbf{c}_2^T\mathbf{E}\mathbf{c}_2)i\omega + \mathbf{K}_0)^{-1} \quad (10)$$

From Equation 9, the expression for the state error estimate in the frequency domain is

$$e(\omega) = \mathbf{H}_o(b_2u(\omega) - \mathbf{c}_2^T\mathbf{E}v(\omega)) \quad (11)$$

and the error spectral density matrix Φ_{ee} is given by

$$\Phi_{ee}(\omega) = \mathbf{H}_o \mathbf{b}_2 S_{ww}(\omega) \mathbf{b}_2^T \mathbf{H}_o^* + \mathbf{H}_o \mathbf{c}_2^T \mathbf{E} S_{vv}(\omega) \mathbf{E}^T \mathbf{c}_2 \mathbf{H}_o^* \quad (12)$$

where the matrices $\Phi_{ww}(\omega)$ and $\Phi_{vv}(\omega)$ are the power spectral density of the uncertain excitation on the system and measurement noise, respectively. To select the \mathbf{E} matrix, the following optimization problem must be solved

$$\begin{aligned} & \underset{\mathbf{E}}{\text{minimize}} && J = \text{tr}(\mathbf{P}) \\ & \text{subject to} && \mathbf{E} \in \mathbb{R}^+ \end{aligned} \quad (13)$$

where \mathbf{P} is the displacement estimation error covariance matrix given by

$$\mathbf{P} = \mathbb{E} \left[(q(t) - \hat{q}(t)) - (q(t) - \hat{q}(t))^T \right] = \int_{-\infty}^{+\infty} \Phi_{ee}(\omega) d\omega \quad (14)$$

With this selection of the feedback matrix \mathbf{E} , the NMBO becomes a modified nonlinear model of the system with added grounded dampers obtained from a linearized model of the system in the measurement locations and excited by forces that are linear combinations of the measurements proportional to the added dampers. The performance of NMBO has been previously studied compared to the Unscented Kalman Filter (UKF), demonstrating that NMBO outperforms other existing state-of-the-art nonlinear state observers in reconstructing the dynamical response of large-scale instrumented structures (Roohi et al. 2021).

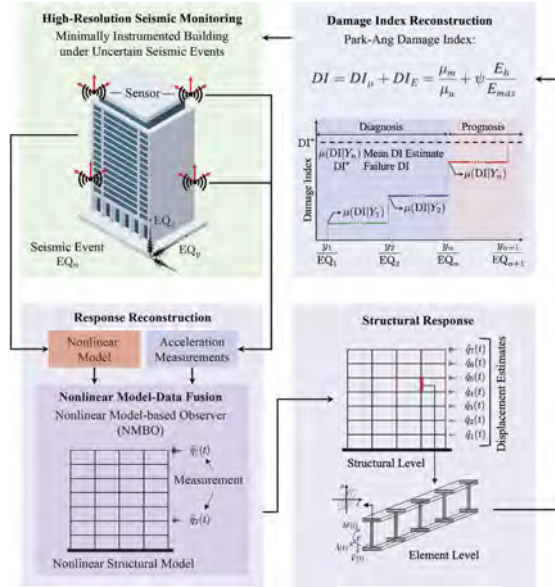

Figure 1. Summary of the proposed methodology for high-resolution seismic monitoring.

4 METHOD OF APPROACH

The methodology consists of (1) implementing a nonlinear state observer to reconstruct the dynamic response at all degrees of freedom (DoF) of a structural model, (2) employing the reconstructed response to estimate element-by-element forces and displacements, and (3) using estimated displacement, forces, and constitutive laws to estimate element-level dissipated energy. The main advantages of the proposed energy-based approach are that i) the proposed feature is physically meaningful and correlates well with the level of cyclic damage experienced during strong earthquakes, ii) dissipated energy can be estimated from element-level stress-strain fields reconstructed from global acceleration measurements, and (iii) dissipated energy can be calibrated

Figure 2. Schematic representation and photo records of seismic damage following 1992 Big Bear and 1994 Northridge earthquakes.

using experimental data. To implement the methodology, the NMBO uses response measurements of an instrumented building, typically in the form of accelerations, to reconstruct the complete dynamic response of the structure. From the reconstructed response, the seismic damage index (DI) for every structural element is estimated using a mechanics-based low-cycle fatigue damage model. The reconstructed response is then used for high-resolution seismic monitoring by performing damage detection, localization, and quantification. This paper employs the Park and Ang (1985) damage model for the estimation of element-level damage indices given by

$$DI = DI_{\mu} + DI_E = \frac{\mu_m}{\mu_u} + \psi \frac{E_h}{E_{max}} \quad (15)$$

where DI_{μ} and DI_E = damage due to excessive deformation and dissipated hysteretic energy, respectively; μ_m = maximum ductility experienced during the earthquake; μ_u = ultimate ductility capacity under monotonic loading; ψ = calibration parameter; E_{max} = maximum hysteretic energy dissipation capacity for all relevant failure modes; and E_h is the dissipated hysteretic energy, which can be calculated using element-level stress-strain or force-displacement demand estimates of NMBO by integrating the area under hysteresis loops as follows:

$$E_h = \frac{1}{2} \int \epsilon^T \sigma dV \quad (16)$$

where σ and ϵ = stress and strain demands, respectively, and V = total volume of an element. In distributed plasticity beam-column elements, where energy dissipation occurs primarily due to flexure, the dissipated hysteretic energy (E_h) can be calculated by integrating the moment-curvature response along the element, as follows:

$$E_h = \int_0^L M \phi dx = \sum_{j=1}^{N_p} (M \phi|_{x=\xi_j}) \omega_j \quad (17)$$

where M and ϕ = moment and curvature response of elements, respectively; N_p = number of integration points along the element; and ξ_j and ω_j = locations and associated weights of integration points, respectively. Although this paper restricts our attention to flexure-related damage, other energy dissipation mechanisms, such as those, due to shear and axial deformation, can also be readily included if needed.

5 CASE STUDY: VAN NUYS HOTEL TESTBED

This section illustrates the proposed framework using seismic response measurements from Van Nuy's hotel. The CSMIP instrumented this building as Station 24386, and the recorded

data of this building are available from several earthquakes, including the 1971 San Fernando, 1987 Whittier Narrows, 1992 Big Bear, and 1994 Northridge earthquakes. From these data, measurements during the 1992 Big Bear and 1994 Northridge earthquakes are used in this study to demonstrate the proposed framework. The history of damage to the Van Nuys building is well-documented due to its instrumentation and inspection following earthquakes. The documents reveal that the building underwent minimal structural and mostly nonstructural damage before the 1994 Northridge earthquake. However, this earthquake caused extensive damage to the building, particularly in the south longitudinal frame. Five of nine columns on the fourth story suffered significant damage due to inadequate transverse reinforcements. Shear cracks of five centimeters or more and bending of the longitudinal reinforcement were easily visible. The building was red-tagged following the post-earthquake inspection. Figure 2 depicts the seismic damage in the south frame caused by the Northridge earthquake and shows the location of sensors at the ground, 1st, 2nd, 5th, and 7th floors. (Trifunac and Ivanovic 2003).

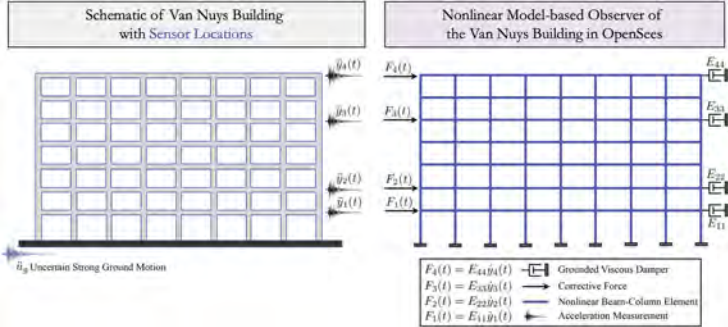

Figure 3. Schematic of Van Nuys hotel tested with sensor locations (left); and NMBO with corresponding added viscous dampers and corrective forces in measurement locations (right).

Figure 4. Implementation of the proposed methodology for reconstructing element-level dissipated energy and damage indices for high-resolution monitoring of the Van Nuys Hotel tested.

A two-dimensional fixed-base model was utilized in the OpenSEES environment to implement the nonlinear FE model of the building. This model represents one of the longitudinal frames of the building. The modeling approach employed beams and columns using the distributed plasticity modeling method. Force-based beam-column elements were used to accurately determine yielding and plastic deformations along the element's integration points. The nonlinear response of force-based elements was evaluated using the Gauss-Lobatto integration method. Each beam and column element was discretized using four integration points, and the cross-section of each element was subdivided into fibers. The uniaxial Concrete01 material was used to construct a Kent-Scott-Park object with a degraded linear unloading and reloading stiffness and zero tensile strength. The longitudinal reinforcing steel was modeled using the uniaxial Steel01 material as

a bilinear model with kinematic hardening, with elasticity modulus and strain hardening parameters assumed to be 200GPa and 0.01, respectively. An unconfined concrete model was defined to model concrete due to insufficient transverse reinforcement in the beams and columns.

Figure 5. Comparison of displacement estimates using NMBO and open-loop FE analysis with measurements in non-instrumented fourth (left) and instrumented seventh (right) stories during Big Bear earthquake.

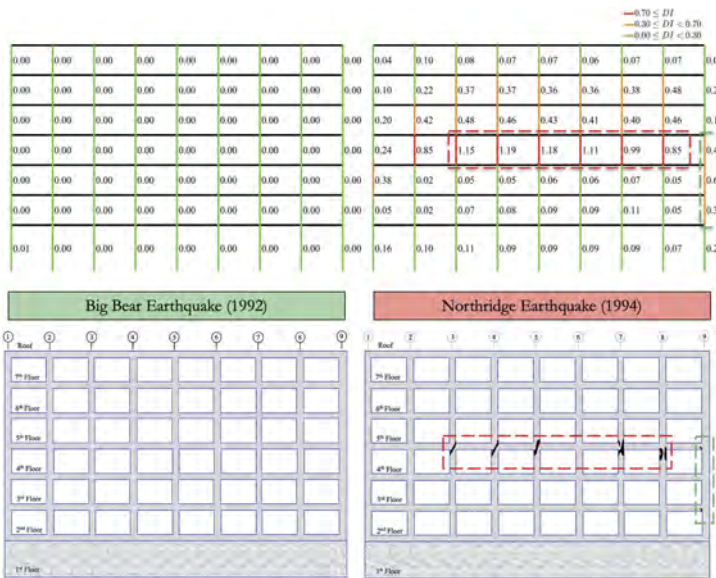

Figure 6. Reconstructed element-by-element damage indices using the measured response during the 1992 Big Bear earthquake (left) and 1994 Northridge earthquake (right).

To implement the NMBO in OpenSEES, the Van Nuys building was modeled using a nonlinear FE model and response measurements. The formulation of the NMBO is presented in the following subsections, detailing the step-by-step process. In order to estimate the complete seismic response, dynamic analysis was performed on the modified OpenSEES nonlinear FE model, which had grounded dampers added at measurement locations and was subjected to corrective forces. Figure 3 shows the schematic of the Van Nuys hotel testbed, including the location of accelerometers and the NMBO, which includes added viscous dampers and corrective forces at measurement locations.

The NMBO model was used to implement the proposed methodology schematically summarized in Figure 4. Figure 5 compares displacement estimates using NMBO with estimates obtained from open-loop FE analysis and actual measurements in instrumented 7th and non-instrumented fourth stories during the Big Bear earthquake. Measured represents the measured response, FE Model represents the open-loop FE analysis of the OpenSEES model under measured ground motion, and NMBO represents the estimated response using the OpenSEES NMBO with sensor measurements from measured locations along with 1σ estimation uncertainty bound. As can be seen, the NMBO accurately reconstructs the response at both instrumented and non-instrumented floors. Upon further examination of the entire time

frame for both earthquakes, it is apparent that the NMBO estimations and their variance from the true value fall within the confidence interval. Subsequently, the reconstructed response was input to the Park-Ang damage model to reconstruct element-level damage indices and use them for damage detection, localization, and quantification. Figure 6 schematically depicts the seismic damage suffered during the Northridge earthquake to compare the reconstructed DIs with the building's actual performance. The shear cracks with width ≥ 5 cm are highlighted with a red dash box, and the shear cracks ($0.5 \text{ cm} \leq \text{width} \leq 1 \text{ cm}$) are highlighted with a green dashed box. As can be seen, the element-by-element comparison of estimated DIs with post-earthquake inspection results confirms the accuracy of the damage localization using the proposed mechanistic approach.

6 CONCLUSIONS

This paper presents the development of a high-resolution seismic monitoring framework that employs dissipated energy as a feature for damage assessment in instrumented buildings. A nonlinear model-based observer (NMBO) is derived from combining a nonlinear structural model of a minimally instrumented building and its response measurements to reconstruct the complete dynamic response of the system. The reconstructed response is then input to a mechanics-based low-cycle fatigue damage model to estimate element-by-element damage indices and perform high-resolution seismic monitoring. The proposed approach was validated using data from the Van Nuys Hotel testbed. The proposed framework correctly estimated the linear behavior and no damage during the Big Bear earthquake and identified the major damage locations in the beam/column joints on the south frame's fourth floor during the Northridge earthquake. To the authors' best knowledge, the results presented in this paper constitute the most accurate and highest resolution damage estimates obtained for the Van Nuys hotel tested.

ABSTRACT: This contribution is devoted to a prestressed concrete road bridge structure in Pforzheim, Germany, which has been in operation since 1953. Due to the limited accessibility of certain prestressed concrete members, a reliable assessment based on periodic visual inspections only is not ensured. Therefore, an in-depth full scale vibrational analysis was performed according to DIN 1076 (1999) in order to assess the structural integrity and maintenance condition of the superstructure. A follow-up assessment in 2020 is compared with a baseline investigation from 2003, having been conducted by the same organisations in a similar manner.

1 INTRODUCTION

1.1 *Scope of investigation*

The scope of this investigation is based on a long-term track record of assessment projects from VCE, e.g. described in Wenzel (2005, 2009) or Veit-Egerer et al. (2008, 2018, 2019, 2022):

- A non-destructive dynamic measurement of the bridge deck using a dense grid of accelerometers to determine the mechanical behaviour of the load-bearing prestressed concrete structure under unrestricted traffic.
- Analysis of structural degradation, evaluation of structural integrity based on the collected data. In particular, the focus lies on the buried tension/compression members in the abutment area.
- Additionally, Finite Element models of the bridge were developed in order to determine reference parameters by means of modal analysis. The models were used both to compare the results of the follow-up measurement 2020 to the respective numerical values and to quantify the expected changes in modal parameters due to a retrofitting measure in 2006.
- The investigation is concluded by the means of an overall assessment comparing the measured reference data from 2003 with the measurement 2020 to display the progression of structural maintenance condition of the bridge over time.
- Subsequently, the findings from the performed bridge analysis are transferred into recommendations for short- and midterm measures in terms of bridge maintenance, retrofit or reconstruction.

1.2 *Bridge description*

The investigated prestressed concrete road bridge is located in Pforzheim, Germany and has been in operation since 1953. A key feature of this frame bridge is the design of the side spans,

consisting of frame legs constructed as separated tension and compression members (Figure 1). These prestressed concrete members are buried in the ground and therefore not accessible for conventional periodic visual inspections according to DIN 1076 (1999).

The main span has a length of 37.1 m, the side spans are 4.3 m long. The bridge consists of two separated superstructures (total width 14 m), which are both made of a double T-beam (Figure 2).

The bridge deck has been retrofitted by the means of an additional layer of reinforced concrete in 2006.

Figure 1. Longitudinal bridge section with emphasis on certain structural properties (dashed line: tension members, solid line: compression members).

Figure 2. Cross-section of the superstructure.

2 DESCRIPTION OF MEASUREMENT

The follow-up dynamic measurement of the bridge deck was performed in November 2020, using a dense grid of accelerometers along both sidewalks (Figure 3). The measurement was conducted under unrestricted road traffic, for approximately half a day. Both the sensor layout and the meteorological conditions were comparable to the baseline investigation carried out in 2003 (VCE & BBV, 2004).

Figure 3. Monitoring sensor layout.

3 DYNAMIC BEHAVIOUR

3.1 General

The assessment of structural integrity and maintenance condition of this bridge was based on the following indicators:

- Eigenfrequencies
- Mode shapes
- Energy dissipation (damping)
- Evaluation of structural integrity (spectrograms)
- Vibration intensity analysis

Additionally, numerical models of the superstructure were developed to provide reference values for the bridge structure.

The following sections will focus only on the decisive parameters in the assessment of this bridge. A more in-depth analysis of all indicators can be found in the full report (VCE & BBV, 2021a).

3.2 Frequency analysis & dynamic system identification 2020

The frequency spectra obtained from the measurement data 2020 (Figure 4) show a distinct dynamic characteristic for both structures. The dominant eigenfrequencies are already clearly visible from the raw spectra in all three analysed directions.

In addition, two other sources contributing to the bridges' dynamic characteristics can be seen from the spectra:

- Even though the two superstructures are statically independent, they share the pavement and thus there is interaction between both superstructures.
- Urban traffic management leading to frequent traffic jams on the bridge.

Figure 4. ANPSD vertical, 0.2-30 Hz (direction Brötzingen).

Table 1 summarises the decisive eigenfrequencies and describes the respective type of dynamic response, which is referring to an analysis of the corresponding mode shapes derived from the measurement.

The comparison of the eigenfrequencies direction Brötzingen and direction south shows a high level of conformity between both superstructures. This indicates a comparable structural maintenance condition.

Table 1. Dynamic system identification 2020 (one measurement for each of the separate superstructures).

No.	Type of loading	measured eigenfrequency 2020 direction Brötzingen [Hz]	measured eigenfrequency 2020 direction south [Hz]	specification on on type of dynamic response
1	1 st bending mode	4.74	4.70	1BT
2	1 st torsional mode	6.76	6.72	1TL
3	2 nd bending mode	10.73	11.39	2BT
4	2 nd torsional mode	14.08	14.11	2TL
5	3 rd bending mode	20.55	20.25	3BT

3.3 FEM modelling

Two reference FEM models were prepared in order to determine modal parameters by numerical simulation. These models reflect the undamaged condition of the bridge 2020 and 2003 (after and before the retrofitting measure).

For simplification, only one of the two identical superstructures was modelled – according to drawings provided by the bridge owner (Figure 5). Initially, the models were reduced to the primary load-bearing structure: edge beams and pavement were only included as modal masses and thus not contributing to the bridge’s stiffness. The models focus on the main span of the bridge, the rigid connection to the prestressed side spans is implemented as fixed support.

This idealisation represents the limit state of non-deteriorated frame with fully intact prestressed tension members in the abutment area.

Figure 5. FEM model of the main span.

The results of the computational analysis are shown in Table 2. The comparison of both models provides an expected average increase for the considered decisive eigenfrequencies in the range of 5% due to the retrofitting of the bridge deck with an additional reinforced concrete layer.

Table 2. Eigenfrequencies obtained from numerical modelling (both directions).

No.	FEM model 2020 [Hz]	FEM model 2023 [Hz]	DELTA [%] 2020 vs. 2003	specification on on type of dynamic response
1	4.24	4.09	3.7	1BT
2	5.24	4.94	6.0	1TL
3	9.54	9.11	4.7	2BT
4	11.10	10.42	6.6	2TL
5	16.06	15.41	4.2	3BT
		Mean:	5.0	

3.4 Comparison of the follow-up measurement 2020 with the baseline measurement 2003

3.3.1 Eigenfrequencies

Table 3 compares the eigenfrequencies derived from the follow-up measurement in 2020 to the baseline measurement in 2003. Both bridge decks show an average increase of eigenfrequencies of 4.5%, which is in good accordance with the models' output of 5.0%. This confirms that the additional concrete layer fulfils the purpose of providing additional stiffness to the structure.

Table 3. Measured Eigenfrequencies (both directions).

No.	direction Bröt- zingen 2020 [Hz]	direction Bröt- zingen 2003 [Hz]	DELTA [%] 2020 vs. 2003	direction south 2020 [Hz]	direction south 2003 [Hz]	DELTA [%] 2020 vs. 2003
1	4.74	4.49	5.6	4.70	4.55	3.2
2	6.76	6.33	6.8	6.72	6.34	6.0
3	10.73	10.86	-1.2	11.39	10.88	4.6
4	14.08	13.36	5.4	14.11	13.38	5.4
5	20.55	19.62	4.7	20.25	19.40	4.4
		Mean: 4.3			Mean: 4.7	

3.4.2 Evaluation of structural integrity

So-called trend spectrograms are an essential evaluation tool for full-scale measurements on bridge structures. They visualise the signal either in a frequency-time or a frequency-bridge-length waterfall plot; the colour scaling represents the energy content of the oscillation and therefore the respective intensity. In the present case, trend spectrograms over time were chosen to evaluate the stability of the decisive eigenfrequencies within the follow-up measurement on one hand. On the other hand, by including both data from the baseline measurement and the follow-up measurement in one plot (Figure 6) it is possible to assess the progression of structural integrity over time.

Distinctive stable eigenfrequencies over time indicate a regular load-bearing behaviour under the prevailing load regime. For the baseline assessment in 2003, this was the case under the given operational circumstances (see Section 3.2). The follow-up assessment produces even more stable trends and a lift of all decisive eigenfrequencies of approximately 5% can be seen. Thus, the retrofitting measure has an effective and positive impact both in terms of overall stiffness as well as in terms of the system's ability to cope with the given dynamic loading.

3.4.3 Vibration intensity analysis

Intensive dynamic loading causes fatigue failure of structures. The vibration intensity represents the energy impact into the structure. The intensity for the investigated bridge object is determined at all sensor positions and is included into a diagram, which represents the corresponding risk level. According to the classification by Beards (1996), the vibration intensity is subdivided into four regions, ranging from low probability of damage due to dynamic stress (Region I) up to very high probability of damage (Region IV).

In 2003, the bridge structure responded more sensitive to traffic impact loading than in 2020, with structural response in vertical direction showing vibration intensity close to Region II. (Figure 7 – left). Region II indicates impact conditions, where damage might be caused by continuous dynamic stress. However, in 2020 the vibration intensities have lowered, which is attributed to the positive impact of the retrofitting measure (Figure 7 – right).

3.5 Comparison of the measurement with the numerical model

Table 4 and 5 summarise the results of the measurements 2020 and 2003 and the respective FEM models. A mean difference between measurement and modelling of approximately 22% for both the baseline and the follow-up measurement could be identified. This indicates an unchanged maintenance condition of the primary load-bearing structure. Moreover, no signs of effective mechanical degradation since the baseline measurement have been detected.

Figure 6. Trend spectrogram vertical, 0.2-15 Hz (direction Brötzingen).

Figure 7. Measured vibration intensity 2003 (left) and 2020 (right) (direction Brötzingen).

In general, a delta of +22% in measured frequencies compared to a vital FEM model states a very good mechanical condition of the prestressed concrete structure.

Table 4. Comparison: numerical model vs. measurement 2020.

FEM model No.	FEM model 2020 [Hz]	Measurement Brötzingen 2020 [Hz]	DELTA [%] FEM vs. measurement	Measurement south 2020 [Hz]	DELTA [%] FEM vs. measurement
1	4.24	4.74	11.8	4.70	10.8
2	5.24	6.76	29.1	6.72	28.3
3	9.54	10.73	12.5	11.39	19.4
4	11.10	14.08	26.8	14.11	27.0
5	16.06	20.55	27.9	20.25	26.1
		Mean:	21.6	Mean:	22.3

However, there are certain limits to this comparison due to simplifications in the FEM modelling. To complete this assessment, the reasons and the composition within the obtained difference of 22% between measurements and modelling have been investigated:

Table 5. Comparison: numerical model vs. measurement 2003.

No.	FEM model 2003 [Hz]	Measurement Brötzingen 2003 [Hz]	DELTA [%] FEM vs. measurement	Measurement south 2003 [Hz]	DELTA [%] FEM vs. measurement
1	4.09	4.49	9.8	4.55	11.2
2	4.94	6.33	28.2	6.34	28.4
3	9.11	10.86	19.3	10.88	19.5
4	10.42	13.36	28.2	13.38	28.4
5	15.41	19.62	27.3	19.40	25.9
			Mean: 22.5		Mean: 22.7

- First of all, neither the bridges' pavement nor the edge beams were included in the models, only their modal masses were considered. This is estimated to add a maximum of 3% (pavement) and 5% (edge beams) to the bridges' stiffness in terms of frequency if modelled more precisely.
- Furthermore, modelling the bridge as a monolithic concrete cross-section whereas in reality it is a composite cross-section, containing both normal reinforcement and prestressing steel, results in lower frequencies in the model (5%).
- Past assessment projects, e.g. VCE & BBV (2021b) have shown that the increase of modulus of elasticity in uncracked concrete over time can have a positive hidden impact on the evaluation of structural integrity of existing prestressed concrete bridge structures. Eurocode 2 (DIN EN 1992-1-1 (2011)) provides a possibility to quantify this increase in concrete strength over time; for the investigated bridge the authors derived an effect of at least 6% on the eigenfrequencies.

In total, these identified and validated contributions to the delta between measurement and FEM model sum up to 19% (from the given initial deviation of 22%). The remaining difference between measurement and FEM model (+3%) is within the expected modelling uncertainty.

4 CONCLUSIONS

The non-destructive dynamic measurement of Brötzingen Brücke provides insight on the following matters:

- The full functionality of the buried tension/compression members in the abutment area is confirmed by comparing the measurement results with a numerical model in terms of an idealised, non-deteriorated frame with intact prestressed tension members in the abutment area.
- The effectiveness of the retrofitting measure in 2006 can be seen by the increase of eigenfrequencies between baseline and follow-up measurement of 5%. This increase matches the reference value obtained from numerical modelling and the positive effect is confirmed both by trend spectrograms and vibration intensity analyses.
- The eigenfrequencies derived from the measurement are on average 22% higher than the eigenfrequencies obtained from the intact FEM model.
- Both the follow-up and the baseline measurement show the same deviation (+22% in frequencies) when compared to the respective FEM model. This means that the structural maintenance condition has not changed over time.
- The reasons and the composition within the obtained difference between measurements and modelling have been investigated in a conservative manner and confirmed the extent of 22%.
- Even when remaining modelling uncertainties are taken into account, this result states a very good mechanical condition of the prestressed concrete bridge.

It can be concluded that the conducted full-scale vibrational analysis as an additional in-depth assessment according to DIN 1076 (1999) provides an added value to the regular periodic visual inspection by addressing the mechanical evaluation of structural resistance and its possible change over time.

Laboratory validation of an Arduino based accelerometer designed for SHM applications

S. Komarizadehasl, E. Delgado, G. Ramos & Jose Turmo

Department of Civil and Environment Engineering, Universitat Politècnica de Catalunya, BarcelonaTech

J. A. Lozano-Galant

Department of Civil Engineering, Universidad de Castilla-La Mancha

ABSTRACT: Nowadays, low-cost sensors based on low-cost microcontrollers and microprocessors are gaining a lot of attention from researchers. This increasing interest is due to the fact that the implementation of low-cost solutions may make Structural Health Monitoring (SHM) applicable and affordable to structures with a low budget for their SHM. However, many of the present solutions do not have comparable accuracy and resolution with those of the traditional commercial accelerometers. Also, the noise density of these newly developed prototypes has not been checked through laboratory experiments. In fact, the characteristics of the designed and created accelerometer are simply copied from the datasheet of the chipset used to develop the solution. Moreover, the sampling frequency of the majority of the available low-cost solutions usually is lower than 100 Hz. This paper presents a consistent work with the development of a low-cost wireless accelerometer with a sampling frequency of 333 Hz and noise density of $51\mu\text{g}/\sqrt{\text{Hz}}$. This accelerometer's accuracy, noise density, and reliability are evaluated through a series of laboratory experiments. It is essential to mention that this accelerometer does not need any additional data acquisition equipment and is self-sufficient.

1 INTRODUCTION

Civil infrastructures and structures might be considered the leading basis of modern society; consequently, their health state is of the highest importance (J. Lei, Xu, & Turmo, 2018). Evaluating structures along with their health-state assessment is needed to reduce reparation costs, maintenance, and, eventually, for certifying infrastructure/structure safety (Peng, Nogal, Casas, & Turmo, 2021b). Structural Health Monitoring (SHM) applications issue statistics on structures' functioning states and their structural responses (Peng, Nogal, Casas, & Turmo, 2021a) (X. Lei, Xia, Komarizadehasl, & Sun, 2022).

For measuring the structural responses (such as deflections, strains, rotation, temperature, humidity, and accelerations) over time, sensors are widely used in SHM systems (Komarizadehasl, Komary, et al., 2022). The recorded information of the sensors is then used for structural performance estimations (Komarizadehasl, Lozano, Lozano-Galant, Ramos, & Turmo, 2022). In fact, natural phenomena can be categorized as static or quasi-static and dynamic (Atencio, Komarizadehasl, Lozano-Galant, & Aguilera, 2022). On the one hand, some environmental elements (such as temperature or humidity) change very slowly, so they can be considered to perform either as quasi-static or static (Farré-Checa, Komarizadehasl, Ma, Lozano-Galant, & Turmo, 2022). On the contrary, some events (such as traffic-induced vibrations, ambient activities, and waves from seismic activities) are considered dynamic because their changing rate is significantly affected by the time (Mobaraki et al., 2022).

According to the literature (see, e.g., (Komary et al., 2023)), most civil structures' significant natural frequencies vary between 0.2 and 100.0 Hz. It should also be noted that most of the ambient vibrations in civil structures are characterized by low amplitudes (Tran-Ngoc et al., 2018). In fact, the acceleration amplitude of these structures can be as low as 0.04 g. This characteristic shows the necessity of using accelerometers with low noise density and high sensitivity for SHM of bridges (Tran-Ngoc et al., 2018). The commercial MEMS accelerometers have a bandwidth of a few kHz. However, their design for higher frequencies has a lower noise density (Lee & Eun, 2022). Finally, it should be highlighted that the sensitivity of an accelerometer has an indirect ratio with the squared value of the resonant frequency. For that reason, the higher the accelerometer's sampling frequency, the lower its sensitivity (Farrar, Park, Allen, & Todd, 2006). For that, many researchers tried to develop low-cost MEMS accelerometers with limited sampling frequency and vibration amplitude range for civil SHM (Shi, Zhang, Jiao, Zhao, & Cao, 2021)

The literature review shows a lack of consistent work, including all the following points in single inception for a low-cost accelerometer: (1) access to the time through Internet, for accurate sensor synchronization, (2) wireless control, (3) scheduling for a synchronized data acquisition experiment, and, finally, (4) measuring the ND and data resolution after the system was wired and (5) performing experimental eigenfrequency analyses on actual infrastructures.

Recently a Cost Hyper Efficient Arduino Product (CHEAP) was introduced by Komarizadehasl et al. (Komarizadehasl, Mobaraki, Ma, Lozano-Galant, & Turmo, 2021). Different laboratory tests were performed to validate CHEAP's performance, and the results of CHEAP were compared with those of two commercial seismic accelerometers (PCB 393A03 and PCB 356B18).

This paper aims to adapt CHEAP to solve all the detected problems and to develop a new Low-cost Adaptable Reliable Accelerometer (LARA). A laboratory test campaign was designed to validate LARA's performance against its older version. In this set of experiments, frequencies ranging from 0.1 Hz to 32 Hz and acceleration amplitudes in the range of [0.001–9.806 m/s^2] were tested. Furthermore, another field test is performed on a short-span foot-bridge in Barcelona. In this experiment, the eigenfrequencies of LARA are compared with a commercial dynamic sensor (HI-INC) (Komarizadehasl, Lozano, et al., 2022). HI-INC is a dynamic inclinometer with a sampling frequency of 250 Hz.

2 TRIAXLE WIRELESS LOW-COST ADAPTABLE RELIABLE ACCELEROMETER (LA-RA) WITH POST-SYNCHRONIZATION CAPABILITY

Recently a Cost Hyper Efficient Arduino Product (CHEAP) was introduced by Komarizadehasl et al. (Komarizadehasl et al., 2021). LARA is an upgraded version of CHEAP that has a frequency sampling of 333 Hz, an acceleration range of ± 2.0 g, and effective bandwidth of 165 Hz. LARA is built into two parts: (1) A sensing part: this contains the aligned accelerometers and the multiplexor, which is shown in Figure 1. It should be noted that LARA consists of five aligned low-cost MEMS accelerometers. It is since when the results of a few accelerometers with unique inherent dynamic noises are averaged, the signal under study remains invariable. And (2) an acquisition part: consisting of an Arduino and a Raspberry Pi.

LARA has the following more features that CHEAP did not have: (1) higher bandwidth: achieving a faster sampling frequency (333 Hz) by efficiently rewriting all the library codes, (2) independency: this accelerometer is not dependent on any connected computer for data acquisition. LARA has an attached low-cost microprocessor that allows the acquired data to be saved on an SD card or any portable flash or hard drive, (3) triaxial data acquisition: having all the accelerometers of LARA in x , y , and z direction aligned makes the final product suitable for triaxial data acquisition—besides, if needed, it can work as a uniaxial, biaxial accelerometer, (4) low Noise Density, (5) Internet timestamp and synchronization: the Network Time Protocol (NTP) of LARA is activated, (6) Experimental analysis: in this paper, a short span was instrumented, and the eigenvalue analyses of LARA are compared with those of

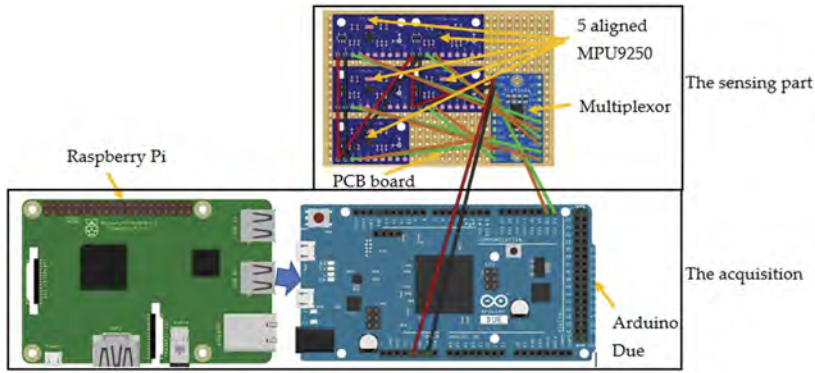

Figure 1. The sensing and acquisition part of LARA.

certified vibration sensing devices, and (7) wireless accessibility: the user can have access to the saved data wirelessly through the Internet. Therefore, LARA can be controlled, get upgraded through online commands and data can be recorded.

3 LABORATORY TESTS AND RESULTS

3.1 Sensitivity, ND, and resolution evaluation

This section compares the sensitivity, ND, and resolution of a single MPU9250 accelerometer with CHEAP and LARA.

The accelerometers' sensitivity can be defined as the ratio of the input (induced vibrations of the shaking table) to the output (the information reported by the accelerometer). The ADC formula for calculating the LSB is shown in Equation (1) (Elhatab, Uddin, & OBrien, 2019).

$$LSB = \frac{Input\ voltage}{2^{(number\ of\ bits)}} \quad (1)$$

In Equation (1), with an input voltage of 2.5 and an ADC scale of 16, each unit of LSB is equivalent to 0.03814 mv. In this way, with 16,384 LSB/g for acceleration amplitude range of ± 2.0 g, the comparable sensitivity of MPU9250, CHEAP, and LARA is calculated as 625 mV/g.

To calculate ND and resolution of the devices, a long-term test was performed. The ND results of the different accelerometers are calculated using Equation (2) (Kwong, 2017).

$$ND = \sqrt{\frac{\sum_1^N (x_i - \mu)^2}{N * f}} \quad (2)$$

In Equation (2), the x_i is the reported values of the accelerometers in the time-domain, μ is the average of all x_i values, N is the number of used samples, and f is the sampling frequency of the accelerometer.

The calculated ND of MPU9250, CHEAP, and LARA for the z -directions are 390, 162, and 81 $\mu\text{g}/\sqrt{\text{Hz}}$, respectively. In addition, the ND of LARA for both x and y directions is 51 $\mu\text{g}/\sqrt{\text{Hz}}$.

Since the evaluation of the accelerometer's resolution depends on the number of samples ("Data Acquisition Handbook," n.d.), for a fair comparison between devices with various sampling frequencies, the same number of the acquired samples were used in the test. For

illustrating the resolution of the accelerometers, their reported data have been transformed from time-domain to frequency-domain by a Fast Fourier Transform (FFT). The results for different sensors are reported in Figure 2.

Analysing the frequency domain diagrams of acquired data of LARA for all the axes, it was obtained that the resolution of LARA for x and y axes is 0.00005 m/s^2 . The resolution for x and y -directions is 44% better than the z -axis because of the absence of gravitational acceleration of the earth in those directions. As a result, the resolution of this accelerometer is evaluated as 0.00005 m/s^2 .

Figure 2. Frequency domain diagrams for z axis of: (a) MPU9250, (b) CHEAP, and (c) LARA.

3.2 Frequency validation

An experiment to validate the frequency report of LARA is presented in this section. A jack that could induce displacements with a known frequency was used. Although the jack is very accurate in reproducing a specific frequency, its performance is limited in movement. Therefore, for every experiment, the jack presents a report. This report is the time-domain information of the activities of its lower jaw.

The vibration platform used in this paper (INSTRON 8803) was programmed using Wave-Matrix2 Dynamic Software. This jack can create various waveform types with the frequency range of 0.1 to 100 Hz and its resonant frequency is 134 Hz. The movement direction of the vibration platform was in z -direction.

For validating the accelerometers' accuracy, 11 tests with various frequency ranges (from 0.1 Hz to 32 Hz) were performed. For finding the frequency report of the accelerometers, the accelerometers' time-domain raw data were converted to the frequency domain by an FFT program written in the MATLAB software.

The accelerometer's frequency error is estimated by calculating the percentage error of the plot value from the reference value of the excitation device. Table 1 compares the frequency errors of LARA, CHEAP, and MPU9250 with the jack's reference values.

Analysis of Table 1 shows that a single MPU9250 is reporting the same frequency error as the CHEAP from 2 Hz on. Since this MPU9250 is one of the CHEAP accelerometers, its frequency report is synchronized with CHEAP. It can also be deduced from this table that a single MPU9250 has not enough resolution for frequencies smaller than 2 Hz. Further analysis of Table 1 shows that CHEAP cannot visualize signals with a frequency smaller than 0.4

Table 1. Frequency validation of the accelerometers.

Frequency (Hz)	LARA's error (%)	CHEAP'S error (%)	MPU9250'S error (%)
0.1	0.450		
0.2	0.295		
0.3	0.260		
0.4	0.050	0.470	
0.5	0.006	0.011	
2	0.005	0.025	0.025
4	0.000	0.000	0.000
8	0.003	0.003	0.003
10	0.004	0.004	0.004
16	0.001	0.001	0.001
32	0.003	0.003	0.003

Hz either. In fact, LARA has a broader range of frequency than MPU9250 and CHEAP and can locate signals up to 0.1 Hz with 0.5% of error. In fact, the frequency range of LARA, based on the presented information, is between 0.1 Hz and its bandwidth (165 Hz).

3.3 Acceleration amplitude validation

An experiment was carried out with the jack to compare the acceleration acquisition of MPU925, CHEAP, and LARA. The jack was calibrated to move with a frequency of 4 Hz and a displacement range of 0.1 mm from its null axis. During each test, the jack reported its time-domain information with a sampling frequency of 500.

For validating the accelerometers' accuracy, their acceleration amplitude report of the sensors was converted to displacements. Then, high-pass and low-pass filters removed signals with frequencies smaller than 0.1 Hz and bigger than 1/10 of the accelerometer's bandwidth. These filters are MATLAB functions that can filter the signals out of the interest range. Finally, the FFT analysis was carried out.

The results of the FTT Analysis shows that even though all accelerometers are reporting the same frequency, they measure the induced signal's magnitude inconsistently. MPU9250, CHEAP, and LARA have measured the jack's displacement as 0.098913, 0.10023, and 0.10068 mm. Further analysis shows that CHEAP and LARA's magnitude report has less than 0.5% error from each other. In fact, CHEAP and LARA have measured the jack's displacements with 1.55% and 1.2% errors from the introduced displacement measurement of the jack.

4 REAL STRUCTURE TEST AND RESULTS

This section presents a field test carried out on a short-span bridge for comparing the measured eigenfrequencies of LARA with those of a high-precision sensor. The footbridge is shown in Figure 3. As shown, it is connected to an elevator box and from the other side, it is located on an abutment.

After mounting the sensors to the bridge, they were connected to the rest of the monitoring components (power bank, USB 4G dongle, Arduino, and Raspberry Pi) manually. It is important to highlight that to enable its communication throughout the Internet, the Raspberry Pi was previously configured with a WiFi hotspot. In fact, after its assemblage on site the Raspberry Pi was used to initiate the data acquisition process remotely, using the Virtual Network Computing (VNC) software (Atencio et al., 2022). The acquired data was first collected on the memory card of the Raspberry Pi. Then, when the data acquisition process finished, the obtained data were moved to a computer using the VNC software. The location of the commercial dynamic sensor (HI-INC) and LARA on the mid-span of the bridge.

Figure 3. A picture of the pass way bridge.

Table 2 presents results of the eigenfrequency analysis of LARA and the used high-precision inclinometer dynamic (HI-INC).

Table 2. Comparison of the first three mode steps frequencies of LARA with HI-INC.

Mode Number	HI-INC	LARA	Difference
1	3.90 Hz	3.85 Hz	1.28%
2	7.91 Hz	7.91 Hz	0.20%
3	9.94 Hz	9.93 Hz	0.88%
4	26.25 Hz	26.01 Hz	0.91%
5	42.81 Hz	41.70 Hz	0.27%

Comparing the measured eigenfrequencies of LARA with those of HI-INC shows a maximum error of 1.28%.

5 CONCLUSION

Developing low-cost sensors is essential for Structural Health Monitoring (SHM) of structures with a low budget for their SHM assessments. These sensors can allow engineers to leave the equipment on the structure for monitoring. In previous works, a Cost Hyper Efficient Arduino Product (CHEAP) was introduced, and its performance was validated in laboratory experiments. By upgrading both hardware and software of the CHEAP, a new triaxial Low-cost Adaptable Reliable Accelerometer (LARA) is introduced. The advantages of LARA with respect to CHEAP are:

- (1) By rewriting codes, LARA achieved a faster sampling frequency.
- (2) Having a connected Raspberry Pi to the Internet made LARA independent of any attached computer for data sampling.
- (3) Having aligned correctly, its accelerometers made LARA triaxial.
- (4) Having a better and more efficient connection reduced LARA's ND.
- (5) Having the time of the Internet for future data synchronization.
- (6) Being completely wireless excluded the need for an engineer's presence on the site for data acquisition.

To evaluate the LARA performance, resolution, and ND, a set of laboratory experiments was performed. These obtained results show that LARA has less ND ratio than MPU9250 and CHEAP for the same number of acquired data. Furthermore, comparing the effects of MPU9250, CHEAP, and LARA with the reports of the shaking table show that LARA is more accurate in reporting both frequency and acceleration amplitude than MPU9250 and CHEAP in a laboratory experiment with the same time duration.

A field test on a footbridge in Barcelona with a span length of 14 m has been carried out using LARA accelerometer. The generated frequencies of the eigenfrequency analysis from LARA have been validated with a commercial high-precision sensor (HI-INC).

Pre-posterior effectiveness of modal extraction techniques for vibrational tests design

A. Lotti, D. Tonelli, S. Zorzi & D. Zonta

University of Trento, Trento, Italy

E. Tubaldi

University of Strathclyde, Glasgow, UK

ABSTRACT: When designing forced vibration tests, engineers must choose the performances of structural health monitoring (SHM) systems, such as sampling frequency and duration of the acquisition, which influence the accuracy of the modal parameters extracted from SHM data. However, this choice must be taken a priori before installing sensors and having any measurements available. In this paper, we propose an approach for forced vibration tests design that provides the expected uncertainty of modal parameters to be extracted from SHM data before performing the test (i.e., a pre-posteriori). Then, we present an experimental campaign of forced vibration tests on a small-scale structure monitored by an SHM system. We repeated the tests by changing the performances of the SHM system to investigate the sensitivity of the modal parameters' accuracy to SHM system performances. The results suggest that the pre-posterior approach provides the expected uncertainties of modal parameters which are in line with those extracted experimentally.

1 INTRODUCTION

Several bridge failures have characterized the last decade, some of which caused great concern in the public community (Calvi et al., 2019). Effective and rapid actions are required to extensively check the condition state of bridges and perform maintenance work on the most degraded ones (Giordano et al., 2022). Structural health monitoring (SHM) can provide helpful information to rapidly identify damage initiation and propagation and assess the reliability of the monitored structures (Bado & Casas, 2021; Tonelli et al., 2022). In particular, vibration-based SHM is one of the most used techniques for identifying variations in structural responses, e.g., resulting from natural degradation and structural damages. When designing forced vibration tests, engineers must choose the performances of SHM systems, such a sampling frequency (f_s), duration of the acquisition (T), signal-to-noise ratio (SNR), and bit resolution (n_{bit}). These performances influence the accuracy of the modal parameters extracted a posteriori from SHM measurements (Chang & Kim, 2016; Giordano et al., 2021; Maia, 1998). However, operators must choose the performances before installing the sensors and having any measurements available (i.e., a priori). Therefore, it is necessary to define a procedure that estimates the expected uncertainty of modal parameters before performing the test (i.e., a pre-posteriori) (Caspani et al., 2022). This paper addresses this need and presents the pre-posterior approach that has been adopted by the Italian Technical Committee UNI/CT 021/GL 08 'Structural Monitoring Group' and will be integrated into the new version of the Italian Standard UNI 10985: Vibrations on bridges and viaducts (UNI Ente Italiano di Normazione, 2002). Then, we present an experimental campaign of forced vibration tests carried out on a small-scale structure with two degrees of freedom, aiming to validate this pre-posterior approach. The campaign consists of artificial impulse excitation tests performed through an instrumented hammer. Finally, we discuss the results and draw conclusions.

2 PRE-POSTERIOR APPROACH FOR MODAL EXTRACTION

This section presents the approach for estimating the pre-posterior uncertainty of modal parameters extracted from artificial impulse excitation tests. In general, the a posteriori uncertainty of the extracted parameters depends on the extraction method used, which in this case is the curve fitting method of the frequency response function (FRF). The formulation presented in this section consists of practical guidelines and assumes as known the uncertainty in the amplitude of the FRF σ_H and the frequency resolution Δf_H .

2.1 Pre-posterior uncertainty of the frequency response function

The amplitude of the experimental FRF extracted from a vibration test is always characterized by an uncertainty σ_H , which depends on the duration of the test and the uncertainty in the acceleration measurements. To evaluate the effectiveness of the vibration test during its design phase – when we do not have measurements yet – we must estimate an expected value of σ_H . There is not a commonly recognised method to do that. Therefore, we developed an algorithm that estimates σ_H by comparing (i) the analytic FRF resulting from a predictive model based on the geometrical and mechanical properties of the structure, with (ii) the experimental FRF we expect will result from a vibration test, characterized by an uncertainty that propagates from measurements.

(i) We define a predictive model of the structure at hand based on measured geometrical and mechanical properties. This model is defined by a mass matrix and stiffness matrix. We solve the eigenvalue problem and obtain the modal properties (e.g., natural frequencies f_k and mode shapes $\phi^{(k)}$). We assume the value of damping ratio ζ_k based on the structural type and materials. Then, we calculate the analytic FRF of the structure, defined as the ratio between the output acceleration A_r at storey r and the input force at storey e , F_e , both expressed in the frequency domain:

$$H_{re}(if) = \frac{A_r(if)}{F_e(if)} = \left[\sum_{k=1}^N \frac{\phi_r^{(k)} \phi_e^{(k)}}{(f_k^2 + 2if\zeta_k f_k - f^2)} \right] \cdot f^2 \quad (1)$$

(ii) We generate a set of M FRFs, each obtained by adding to the FRF calculated in (i) a Gaussian noise with a coefficient of variation V_H – it depends on the sensors' performances. Then, we discretise the FRFs for a fixed value of resolution Δf_H (Figure 1.a), which depends on the duration of the test. Now, the M discretised FRFs represent the variability we expect to have in the experimental FRF due to the measurement uncertainty. We fit the FRFs (Figure 1. b), we considered the resonance condition ($f = f_k$) and calculate the FRFs amplitude.

For each fitted FRF, we calculated the difference in the amplitude between the fitted FRF and the analytic FRF (Figure 1.c): we obtained M residuals. The pre-posterior uncertainty σ_H is the standard deviation of the distribution of the M residuals.

Figure 1. Algorithm for the estimation of σ_H : (1.a) adding noise to FRF model and discretising with resolution Δf_H , (1.b) fitting of the discretised FRF, (1.c) calculating the residual e .

2.2 Forced testing with artificial impulse excitation

Our pre-posterior approach assumes that the expected uncertainty in the estimation of the natural frequencies σ_f is of the same order of magnitude as the frequency resolution of the FRF:

$$\sigma_f \cong \Delta f_H = 1/T_{\text{eff}} \quad (2)$$

where T_{eff} is the effective acquisition time, defined as the minimum between the (i) time of acquisition and (ii) the time required for damping the free oscillations, i.e., the oscillations become smaller than the measurement noise σ_N . The following formula gives the amplitude of the free oscillations (in displacement):

$$|x(t, f)| = |x_{\text{max}} e^{-\zeta 2\pi f t} \sin(2\pi f t)| = |x_{\text{max}}| e^{-\zeta 2\pi f t} \quad (3)$$

where x_{max} denotes the maximum amplitude of the response (in displacement); ζ is the damping ratio; f is the natural frequency. We impose the condition (ii) for the calculation of T_{eff} (f):

$$|x(t, f)| = \sigma_N \quad (4)$$

From which we obtain:

$$T_{\text{eff}}(f) = \frac{1}{\zeta 2\pi f} \ln\left(\frac{x_{\text{max}}}{\sigma_N}\right) \quad (5)$$

By combining Equation 2 and Equation 5, we can express the uncertainty σ_f as:

$$\sigma_f \cong \frac{1}{T_{\text{eff}}(f)} = \frac{\zeta 2\pi f}{\ln\left(\frac{x_{\text{max}}}{\sigma_N}\right)} \quad (6)$$

The expected uncertainty in the estimation of the damping ratios σ_{ζ_k} can be calculated as a first approximation through error propagation. Let us focus on the resonance condition for the k -th mode ($f = f_k$). Therefore, the FRF H_{re} as inertance (i.e., accelerance) becomes:

$$H_{re}(f = f_k) = \frac{\phi_r^{(k)} \phi_e^{(k)}}{2\zeta_k} \quad (7)$$

where e corresponds to the degree of freedom (DoF) *excited* and r to the DoF where the *response* is monitored.

If we propagate the uncertainty of the damping ratio ζ_k through Equation 7 by neglecting the variability of the mode shapes (i.e., assuming to perform the curve fitting around the resonance point $f = f_k$ by changing only ζ_k), we obtain the relationship between the uncertainties σ_H and σ_{ζ_k} :

$$\sigma_H = \frac{\partial H_{re}(f = f_k)}{\partial \zeta_k} \sigma_{\zeta_k} \rightarrow \sigma_{\zeta_k} = \left(\frac{\partial H_{re}(f = f_k)}{\partial \zeta_k}\right)^{-1} \sigma_H \quad (8)$$

The sensitivity $\partial H_{re}(f = f_k)/\partial \zeta_k$ is given by the following expression:

$$\frac{\partial H_{re}(f = f_k)}{\partial \zeta_k} = \frac{\phi_r^{(k)} \phi_e^{(k)}}{2} \left(-\frac{1}{\zeta_k^2}\right) \quad (9)$$

By neglecting the sign, we obtain:

$$\sigma_{\zeta_k} = \frac{2\zeta_k^2}{\phi_r^{(k)} \phi_e^{(k)}} \sigma_H = \zeta_k \frac{2\zeta_k}{\phi_r^{(k)} \phi_e^{(k)}} \sigma_H = \zeta_k \frac{\sigma_H}{H_{re}(f = f_k)} \quad (10)$$

Also, the expected uncertainty in the estimation of the mode shapes can be approximated through error propagation. Let us condense the mode shapes into a single factor $A_{re}^{(k)}$:

$$A_{re}^{(k)} = \phi_r^{(k)} \phi_e^{(k)} \quad (11)$$

Again, let us focus on the resonance condition for the k -th mode ($f = f_k$). In this case, if we propagate the uncertainty of the mode shapes through Equation 7 by neglecting the variability of the damping ratio (i.e., assuming to perform the curve fitting around the resonance point $f = f_k$ by changing only $A_{re}^{(k)}$), we obtain the relationship between the uncertainties σ_H and $\sigma_{A_{re}^{(k)}}$:

$$\sigma_H = \frac{\partial H_{re}(f = f_k)}{\partial A_{re}^{(k)}} \sigma_{A_{re}^{(k)}} \quad (12)$$

The sensitivity $\partial H_{re}(f = f_k)/\partial A_{re}^{(k)}$ is given by the following expression:

$$\frac{\partial H_{re}(f = f_k)}{\partial A_{re}^{(k)}} = \frac{1}{2\zeta_k} \quad (13)$$

By substituting Equation 13 into Equation 12, we obtain the following expression:

$$\sigma_{A_{re}^{(k)}} = 2\zeta_k \sigma_H \quad (14)$$

We can identify two cases at this stage:

$r = e$, the estimation of the modal component at the point where the excitation is applied, with $A_{rr}^{(k)} = (\phi_r^{(k)})^2$.

$r \neq e$, the estimation of the modal component at a different point from where the excitation is applied, with $A_{re}^{(k)} = \phi_r^{(k)} \phi_e^{(k)}$.

In the first case, the modal component $\phi_r^{(k)}$ can be determined by Equation 15. Through error propagation, we obtain $\sigma_{\phi_r^{(k)}}$ from Equation 16:

$$\phi_r^{(k)} = \sqrt{A_{rr}^{(k)}} \quad (15)$$

$$\sigma_{\phi_r^{(k)}} = \frac{\partial \phi_r^{(k)}}{\partial A_{rr}^{(k)}} \sigma_{A_{rr}^{(k)}} = \frac{1}{2\sqrt{A_{rr}^{(k)}}} \sigma_{A_{rr}^{(k)}} = \frac{1}{2} \phi_r^{(k)} \frac{\sigma_{A_{rr}^{(k)}}}{A_{rr}^{(k)}} \quad (16)$$

In the second case, the modal component $\phi_e^{(k)}$ can be determined by Equation 17. Through error propagation, we obtain $\sigma_{\phi_e^{(k)}}$ from Equation 18:

$$\phi_e^{(k)} = \frac{A_{re}^{(k)}}{\phi_r^{(k)}} \quad (17)$$

$$\sigma_{\phi_e^{(k)}}^2 = \left(\frac{\partial \phi_e^{(k)}}{\partial A_{re}^{(k)}} \right)^2 \sigma_{A_{re}^{(k)}}^2 + \left(\frac{\partial \phi_e^{(k)}}{\partial \phi_r^{(k)}} \right)^2 \sigma_{\phi_r^{(k)}}^2 \quad (18)$$

Finally, by combining Equation 18 and Equation 16 and under the hypotheses $\sigma_{A_{re}^{(k)}} = \sigma_{A_{rr}^{(k)}}$, and $\phi_e^{(k)} = c \phi_r^{(k)}$, we obtain:

$$\sigma_{\phi_e^{(k)}} = \frac{\sigma_{A_{re}^{(k)}}}{\phi_r^{(k)}} \sqrt{1 + \left(\frac{\phi_e^{(k)}}{2\phi_r^{(k)}} \right)^2} \quad (19)$$

3 ESTIMATION OF PRE-POSTERIOR AND POSTERIOR UNCERTAINTIES

Modal extraction can be performed in both time and frequency domains. A summary of these methods can be found in (Ewins, 2000). In this paper, we focus only on a frequency domain extraction technique based on the estimation of the experimental FRF. To validate the pre-posterior approach, we carried out an experimental campaign of artificial impulse vibration tests on a two Degrees of Freedom (DoF) shear-type steel frame (Figure 2). We performed the tests under controlled conditions in the laboratory of the Department of Civil and Environmental Engineering of the University of Strathclyde. Table 1 reports the datasheets of the instrumentation used: PCB 393B04 piezoelectric accelerometers, NI 9234 data acquisition module with chassis c-DAQ NI 9189, instrumented hammer PCB 086C03, and a shaking table series LO.F.H.I.S. ND1301.

3.1 Pre-posterior estimation of modal parameters

With Equations 6-10-16-19 introduced in Section 2, we estimated the expected uncertainty (i.e., the uncertainty a pre-posteriori) of the modal parameters by using only the prior knowledge of the structure. We studied the eigenvalue problem of the structural model based on the stiffness and mass matrixes defined a priori and determined the mean values a priori of the

natural frequencies and the mode shapes. Furthermore, we adopted the mean values of damping ratios equal to $\zeta_1 = \zeta_2 = 0.2\%$. For the estimation of σ_H , we used the algorithm explained in Section 2.1 and assumed the coefficient of variation of the FRF equal to $V_H = 2\%$. Then, we assumed the maximum expected amplitude of the response (in displacement) equal to $x_{\max} = 0.01$ m (Equation 6).

Given that we performed the tests in the laboratory under controlled conditions, we neglected the contributions due to mechanical background noise and temperature variation. Therefore, we calculated the background noise by considering only the contribution related to the electrical noise of the accelerometer and acquisition module:

$$\sigma_N = (\sigma_{N,NI9234}^2 + \sigma_{N,PCB393B04}^2)^{1/2} = 3.92 \cdot 10^{-5} \text{m/s}^2$$

The expected uncertainty of the modal parameters extracted with the pre-posterior approach is given in Table 2.

3.2 Posterior estimation of model parameters

We performed each test five times to take into account the variability of the test itself (e.g., reproducibility of the laboratory conditions and the operator activity). Moreover, we simulated different vibrational SHM systems with different performances to study the sensitivity of

modal parameters extracted from data. In particular, we simulated the changes in the SHM systems' performances by varying sampling frequency (f_s), duration of the test (T), signal-to-noise ratio (SNR) and bit resolution (n_{bit}) during the data processing directly on the signal acquired. Figure 3 schematise these changes.

We extracted the modal parameters by performing a non-linear regression on the experimental FRF of the 2 DoF system (Figure 4). The fitting was performed on by using the model described by Equation 1. Posterior uncertainties of modal parameters extracted from the experimental tests through non linear regression are shown in Section 4 in Figures 5 – 7, along with the pre-posterior uncertainties.

4 COMPARISON, DISCUSSION, AND VALIDATION

This chapter discusses the most significant comparisons between the modal parameters' uncertainties extracted with the pre-posterior and posterior approaches described in Section 3. The comparison was made for different SHM system's performances: sampling frequency (f_s), duration of the test (T), signal-to-noise ratio (SNR) and bit resolution (n_{bit}). Here we discuss the effect of T , SNR , and n_{bit} on artificial impulse excitation tests.

In Figure 5, the posterior standard deviations σ_{f_1} and σ_{f_2} of the steel frame's natural frequencies f_1 and f_2 are shown as a function of T and SNR . Figure 5 also shows the pre-posterior uncertainties estimated according to Equation 6, which are independent of T and SNR . We observe that the posterior standard deviations are highly affected by the performances of the SHM system: as SNR decreases ($SNR < 3$ dB), the difference between posterior and pre-posterior uncertainties σ_{f_1} and σ_{f_2} becomes increasingly prominent. On the other hand, by increasing the duration of the test ($T > 40$ s), the posterior standard deviations tend

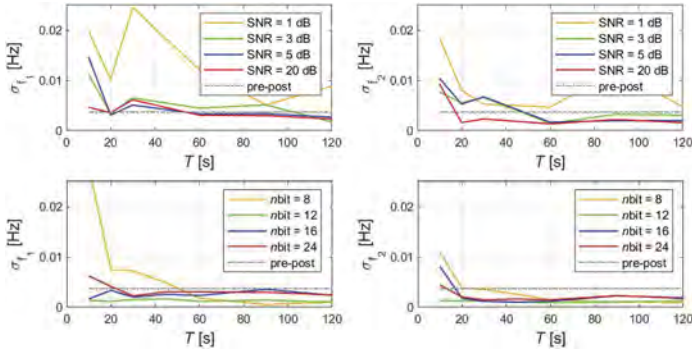

Figure 5. Standard deviation a posteriori (coloured lines) and pre-posteriori (dashed lines, label pre-post) of natural frequencies f_1 , and f_2 as a function of (T, SNR) and (T, n_{bit}) for fixed $f_s = 5128$ Hz.

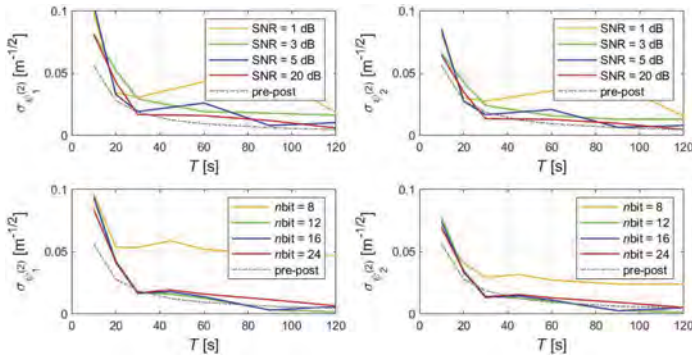

Figure 6. Standard deviation a posteriori (coloured lines) and pre-posteriori (dashed lines, label pre-post) of mode shape $\phi^{(2)}$ as a function of (T, SNR) and (T, n_{bit}) for fixed $f_s = 5128$ Hz.

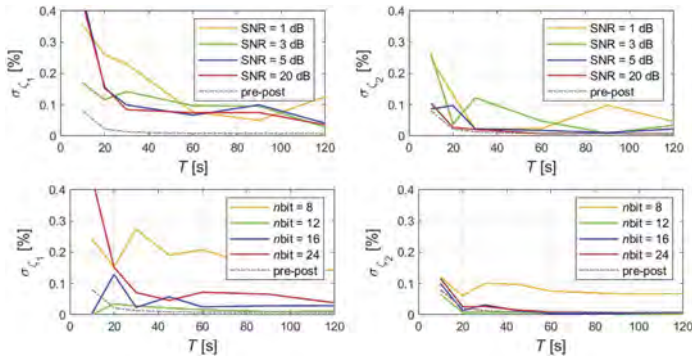

Figure 7. Standard deviation a posteriori (coloured lines) and pre-posteriori (dashed lines, label pre-post) of damping ratios ζ_1 , and ζ_2 as a function of (T, SNR) and (T, n_{bit}) for fixed $f_s = 5128$ Hz.

to their pre-posterior values. The same trend can be observed in the case of mode shapes (Figure 6): for high values of duration of the test ($T > 60$ s), signal-to-noise ratio ($SNR > 20$ dB), and bit resolution ($n_{bit} > 8$), the standard deviations estimated a posteriori are more similar to the pre-posterior value. As another example, Figure 7 shows the standard deviations related to the damping ratios as a function of SNR and T , and of n_{bit} and T .

5 CONCLUSIONS

This paper proposes an approach aiming at quantifying the pre-posterior uncertainty of modal parameters extracted through vibrational tests and verifies its effectiveness through a campaign of laboratory tests. The approach was applied to a two-degrees-of-freedom shear-type steel frame. The structure was studied under controlled conditions by using dynamic tests, in particular forced impulse excitation tests. The modal extraction technique was applied by varying the performances of the monitoring system, including sampling rate, duration of the test, signal-to-noise ratio, and bit resolution. The posterior standard deviation was calculated from the experimental results and compared to the estimated pre-posterior uncertainties.

We observed that the pre-posterior approach accurately predicts the posterior uncertainty of the modal parameters (same order of magnitude), at least in this case of a small structure under laboratory conditions. Moreover, we observed that the difference between these posterior and pre-posterior uncertainties is mainly affected by the duration of the test. For short duration of the test ($T < 40$ s), the influence of signal-to-noise ratio and bit resolution becomes more significant. In future experimentation, we will repeat the activity described in this paper for vibrational test design for real-scale structures.

Structural reliability assessment of RC shield tunnels with nonuniform steel corrosion

Z. He & C. He

MOE Key Laboratory of Transportation Tunnel Engineering, Southwest Jiaotong University, Chengdu, China

ABSTRACT: Steel corrosion is a dominant source for the deterioration of reinforced concrete (RC) structures, which is always spatially nonuniform and discretely distributed in the RC components. Owing to the statically indeterminate features of tunnel structures, both the mechanical responses (e.g., bending moment and axial force) and the ultimate bearing capacity of segmental linings will be affected substantially with the increase in steel corrosion. In this paper, a probabilistic model for simulating the spatial variation of steel corrosion is proposed in conjunction with a random field and the effect of sustained load. An approach for estimating the residual $M-N$ capacity (i.e., residual bending moment and corresponding axial force) of corroded segment section is introduced. Monte Carlo simulation (MCS) incorporated with finite difference method (FDM) is performed to investigate the failure probability of corroded RC shield tunnels. Dangerous segmental lining sections of shield tunnels with the evolution of steel corrosion deterioration are revealed based on an illustrative example.

1 INTRODUCTION

For a reinforced concrete (RC) shield tunnel in an aggressive environment, premature steel corrosion and serious concrete cracking of tunnel linings have been extensively observed. Because of the effect of spatially distributed corrosion damages, reduction of strength and stiffness of the segmental linings will inevitably happen at some local areas, which shall substantially affect the long-term safety of a RC shield tunnel. To provide rational decisions on the timing of repair and intervention plans for a deteriorated tunnel structure, it is important to have an accurate investigation on the mechanical response and estimation on the reliability along the sections of segmental lining by incorporating the spatial variability of steel corrosion.

Kudo and Guo (1994) and Sun (2011) have initiatively studied the durability of RC shield tunnels based on an underwater tunnel in Japan and China, respectively. Next, significant attentions have been given to the evolution of steel corrosion in RC segment under chloride attacks or stray current (Li et al., 2018; Yu et al., 2020), the estimation on ultimate bearing capacity and failure mechanism of RC tunnel linings (Zhang et al., 2022), and the reliability-based performance assessment of deteriorated shield tunnels (He et al., 2020; Zhang et al., 2021). However, these studies are far from the requirements to accurately evaluate the structural performance of a corrosion-affected RC tunnels due to the assumption of uniform steel corrosion in tunnel lining.

In this paper, a probabilistic approach for evaluating the structural performance of deteriorated RC shield tunnels is introduced. A random field integrated with lognormal distribution is established to simulate the nonuniform steel corrosion in a bearing segment. A random field-based numerical model for the corrosion-affected RC segmental lining and an analytical model to evaluate the load-bearing capacity of a corroded RC segment are developed. Finally,

Monte Carlo simulation (MCS) incorporated with finite difference method (FDM) is performed to investigate the failure probability of corroded RC shield tunnel. The effects of corrosion degree and nonuniformity of the external steel reinforcements on structural performance of a RC shield tunnel are revealed in an illustrative example.

2 STOCHASTIC MODEL FOR NONUNIFORM STEEL CORROSION IN SEGMENT UNDER SUSTAINED LOAD

2.1 Non-Gaussian random field

A random field can be described as a set of indexed random variables describing the random nature of a system in space and time (Vanmarcke, 1983), which can be characterized by the main statistical information of the variables of interest (e.g., mean, variance, probability distribution, and correlation function, etc.). Due to its simplicity and accuracy, CMD is adopted herein to generate the random variables associated with the spatial distribution of steel corrosion. According to Srivaranun et al. (2022), a log-normal random field S with n location in space is adopted herein to describe the nonuniform steel corrosion, which can be produced as follow:

$$\mathbf{S} = \exp(\mu_{\ln s} \cdot \mathbf{T} + \sigma_{\ln s} \cdot \mathbf{L} \times \mathbf{U}) \quad (1)$$

$$\mu_{\ln s} = \ln \mu_s - \frac{1}{2} \sigma_{\ln s}^2 \quad (2)$$

$$\sigma_{\ln s} = \sqrt{\ln \left[1 + (\sigma_s / \mu_s)^2 \right]} \quad (3)$$

where μ_s and σ_s represent the mean and the standard deviation of non-normalized corrosion property, respectively; \mathbf{T} is a unit vector with dimensions of $n \times 1$; \mathbf{U} is a standard Gaussian vector with n independent random variables (i.e., $n \times 1$ dimension); \mathbf{L} is a decomposition matrix for the correlation matrix \mathbf{R} of a normalized random variable among all locations (i.e., $n \times n$ dimension), which satisfies $\mathbf{L}\mathbf{L}^T = \mathbf{R}$ and is typically realized using Cholesky decomposition (Agarwal et al., 2014).

2.2 Correlation matrix associated with the corrosion of circumferential steel reinforcements in tunnel lining

The correlation coefficient ρ (i.e., the elements in the correlation matrix \mathbf{R}) represents the spatial correlation between the variables (e.g., steel corrosion levels A_{loss}) at two locations (i.e., the center of field elements), which can be calculated with a prescribed autocorrelation function (Li et al., 2018). Generally, the correlation coefficient increases to unity as the correlated elements become closer. Regarding the spatial-variant steel corrosion in a circumferential tunnel lining, ρ is approximated in this study based on an assumed 1D exponential correlation function:

$$\rho = \begin{cases} \exp \left[-\sqrt{\left(\frac{|\theta_2 - \theta_1| r_c}{L_c} \right)^2} \right], & |\theta_2 - \theta_1| \leq \pi \\ \exp \left[-\sqrt{\left(\frac{(2\pi - |\theta_2 - \theta_1|) r_c}{L_c} \right)^2} \right], & |\theta_2 - \theta_1| > \pi \end{cases} \quad (4)$$

where θ_1 and θ_2 are the radian from the right waist of tunnel to the center of steel elements; r_c is the radius associated with the location of corroded rebar in a circular segmental lining; L_c represents the correlation length of the steel corrosion level in the longitudinal direction of a rebar. In term of the non-Gaussian random field, Nataf transformation for the correlation matrix is required (Li et al., 2011).

For a bearing RC segment, the spatial correlation of A_{loss} along the length of rebars (i.e., correlation length L_c) has been empirically derived and discussed based on Equation 4 based on the experimental results (see He et al. (2022) for more details); L_c ranges from 58 mm to 142 mm by the regression analysis, with respect to the RC segmental specimen corroded under different load levels. Since the RC segmental linings works under complex mechanical conditions and the internal force always varies with the location of tunnel segments, L_c was set as 100 mm for the correlation coefficient ρ for the bearing RC segments in this study.

3 APPROACH FOR ESTIMATING STRUCTURAL PERFORMANCE OF RC SHIELD TUNNEL WITH NONUNIFORM STEEL CORROSION

3.1 Numerical model of spatial-variant corrosion damaged RC segment

For a corrosion-affected RC shield tunnel, spatial-variant damages of RC segments occur due to the nonuniform steel corrosion. A simplified method reducing the integral rigidity and strength of RC segmental linings shall be difficult to reveal the structural behaviors accurately. To have a rational estimation on structural performance of the deteriorated RC shield tunnel, structural numerical analysis has to be performed by incorporating the stochastic modeling of the spatial variability of corrosion damages in RC segments.

Figure 1 shows a three-dimensional (3D) numerical model of the corrosion-affected RC segments in FLAC3D v5.0. One tunnel segment ring was modeled to illustrate the nonlinear response of tunnel structures. Six deteriorated RC segments were assembled using the longitudinal joints. Segment concrete was modeled by eight-node brick element; two-node beam element was used to model the circumferential reinforcements in the extrados and the intrados of segment. Stirrup and steel-concrete interface were not considered due to the model simplification. To simulate the joint effect of shield tunnel, three-node interface element was adopted to model the longitudinal joints between the adjacent segments.

Figure 1. Modeling of spatial-variant damaged RC shield tunnel due to steel corrosion.

Input material parameters are associated with the properties of segment concrete, steel reinforcements and segment joints. According to the samples of spatial steel corrosion distributions, reduced cross-sectional area of reinforcements was modeled in each corroded steel element. To characterize the local effect of steel corrosion on the deterioration of segment concrete, the corrosion-affected concrete was represented as the concrete elements linked with these corroded rebars; reduced compressive strength was assigned to the corrosion-affected concrete elements based on the corrosion level of nearest steel elements. The modeling details and material parameters for a deteriorated RC tunnel structure are same with that in He et al. (2022).

3.2 Ultimate load-bearing capacity of corroded RC segment

For a RC shield tunnel, the segmental linings suffer from the combined actions of axial compression forces and flexural bending moments. The estimation on ultimate bearing capacity of

corroded RC segments shall be performed by considering the eccentricity of internal forces and the degree of corrosion damages, which always vary with the locations of the cross-section of segmental lining. In this study, normal cross-section analysis was performed to establish the analytical model for estimating ultimate bearing capacity along the sections of corroded RC segment in conjunction with the average corrosion ratio-based approach. The basic hypotheses of normal cross-section analysis based on the damage features of corrosion-affected RC segments are given as follows: (1) the strains vary linearly over the depth of cross section of segment (i.e., plain section assumption); (2) the corrosion deterioration of reinforcements is characterized only by reducing steel cross-section area (i.e., no strength loss); (3) the concrete cover in compressive zone is ignored when compressive steel bars are corroded; (4) the effects of loss/degradation of steel-concrete bond and the corrosion of stirrups are not taken into account.

Based on the approach associated with the conventional section analysis of a non-corroded RC component, the analytical model for a corrosion-affected RC segment was developed for three loading cases, including large eccentricity compression, small eccentricity compression and axial compression. The detailed procedure for the section analysis using force and moment equilibrium has been presented in He et al. (2022). Herein, an example $M-N$ curves for a deteriorated RC segment are given in Figure 2 illustrating the effect of steel reinforcement corrosion in tensile or compressive side.

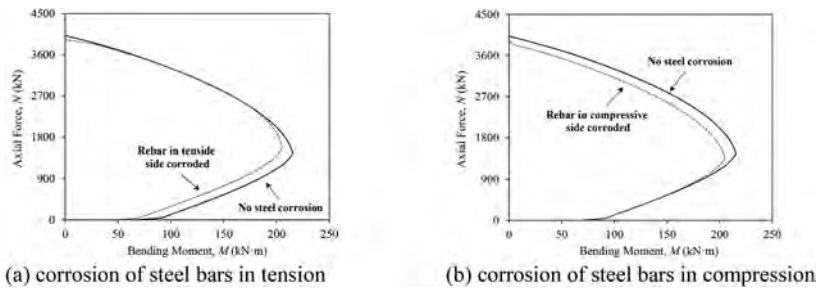

Figure 2. Interaction diagrams for $M-N$ of a corroded RC segment.

3.3 Structural reliability of corrosion-affected RC shield tunnel

Because of natural randomness (e.g., soil properties) and a series of possible corrosion distributions of steel reinforcements, it is necessary to estimate the performance of a corrosion-affected shield tunnel based on reliability analysis. Considering the failure of tunnel structure is always determined as the ultimate limit state that the combined internal forces of axial compression N and flexural bending M exceed the ultimate bearing capacity (i.e., N_u-M_u envelope) at any normal sections of segments (Gong et al. 2014). A performance function for the reliability estimation at each section of the corrosion-affected RC shield tunnel is applied through the axial compression force $N(\theta, A_{loss})$. The structural failure probability $P(\theta, A_{loss})$ is defined as:

$$P(\theta, A_{loss}) = P[Z(\theta, A_{loss}) = N_u(\theta, A_{loss}, e) - N(\theta, A_{loss}) \leq 0] \quad (5)$$

where P is the failure probability at each section in the circumferential direction of segmental lining; A_{loss} is the steel cross-section area loss at a specified location along the length of nonuniform corroded reinforcements; θ is the location of section in the counterclockwise direction from the right waist of tunnel; e is the eccentricity, determined as $e = M(\theta, A_{loss})/N(\theta, A_{loss})$.

4 ILLUSTRATIVE EXAMPLE

The shield tunnel studied here is assumed to be located at Shenzhen. The depth of the shield tunnel is assumed to be 20 m; the structure is in a homogeneous layer of mud rock; the diameter

of segmental lining is 6.7 m. Monte Carlo simulation (MCS) incorporating numerical method was conducted to investigate the structural performance of a deteriorated RC shield tunnel. The parameters of the random variables representing the uncertainties of geotechnical condition are given in Table 1, including the density (ρ_m), ground stiffness (E_m), cohesion force (c_m) and friction angle (ϕ_m) of mud rock. For the corroded RC segmental lining, the spatial variability of steel cross-section loss was modeled as a stationary random field with a log-normal distribution ($\mu = mA_{loss}$ and $\sigma = 0.2$) and a correlation length of 0.1m. Both uniform and nonuniform corrosion with the average steel cross-section area losses (mA_{loss}) of 0%, 15% and 30% have been considered for the steel reinforcements at the extrados of the segmental lining. A sample size of 1000 has been performed in the MC analysis.

Table 1. Statistical information of the uncertain geotechnical parameters.

Geotechnical parameter	Distribution	Mean	Standard Deviation
Density, ρ_m (kg/m ³)	Lognormal	1730	501.7
Elasticity modulus, E_m (GPa)	Lognormal	0.6	0.3
Cohesive force, c_m (kPa)	Lognormal	75	2.475
Friction angle, ϕ_m (°)	Lognormal	22	2.2

Figure 3 demonstrates that the failure probabilities along the sections of the segmental lining in RC shield tunnel due to the corrosion of external reinforcements. As show in Figure 3a, the segment joints around 45°, 135°, 200° and 350° always withstand a high failure risk due to the large and increasing failure probability; tunnel crown and waists exhibit to be safe as a result of the small failure probabilities at these sections. Note that the highest failure probabilities generally happen at the vicinity of segment joints around 45° and 135° as the increase in the degree of steel corrosion. Regarding the influence of the uniform or spatial-variant corrosions of external reinforcements, a similar failure probability distribution along the sections is revealed in Figure 3b, while the assumption of uniform corrosion can lead to an overestimation on the failure probability of segmental lining. Therefore, a consideration on the spatial variability of steel corrosion can substantially help in improving the accuracy of the reliability estimation of a corrosion-affected RC shield tunnel.

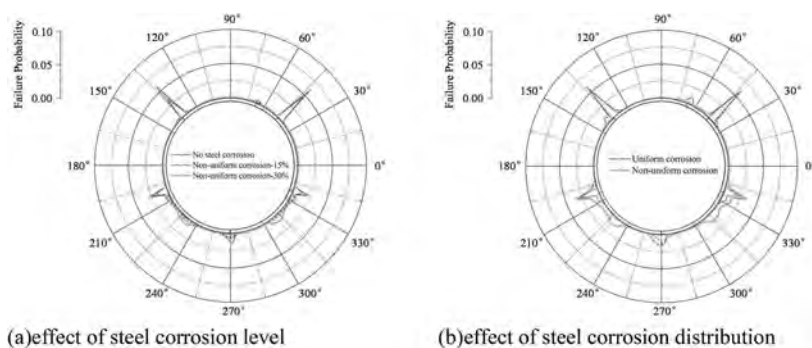

Figure 3. Failure probability along the sections of RC segment lining.

5 CONCLUSIONS

A random field-based approach was implemented to model the spatial variability of steel corrosion in RC segment under the sustained loading. Lognormal distribution was adopted to characteristic the statistical characteristic of steel corrosion in the bearing RC segment. In structural reliability assessment, the segment joints are exposed to be a high hazard in a corrosion-affected RC shield tunnel; these locations exhibit a growth in the failure probabilities

with the increase of steel corrosion. Because ignoring the nonuniformity of steel corrosion shall result in an overestimation on the local failure probabilities of RC segmental lining, it is important to estimate the structural performance of a deteriorated RC shield tunnel incorporating the spatial variability of steel corrosion.

UBMS Research Group (URG), Mumbai, India

ABSTRACT: Bridge management plays an important role to ensure the sustainability of bridge infrastructure. Life cycle analysis [LCCA] of such ageing bridge structures has to be based on dynamic, robust, and real-time information. The performance of the ageing bridge structure under live loading needs to be monitored. Performance data will need to be used for triggering interventions. GABM enables deterioration model based on dynamic, real-time monitoring data under live load conditions. Monitoring is periodic and for short time durations. Monitoring results in time series data revealing the possible decrements in the performance of the bridge structure. Decrements in performance are linked to increments in distress occurring in the bridge. Deterioration models based on such evaluated increments in distress results in more realistic prediction about the future behavior of the bridge. Sustainability yields maximize the Economic, Social, and Environment benefits.

1 INTRODUCTION

Bridges are a significant part of infrastructure development. The performance of in-service bridges is of great concern to asset owners and civil engineers in this era with rapid growth in public awareness of infrastructure safety. (Ignacia 2022) The structures start to deteriorate from the time of completion of construction and continue as time passes, prominently due to environmental and physical factors such as corrosion, carbonation, impact, fatigue, etc. According to Irina Stipanovic, structural infrastructure failures are happening because of catastrophic events and these events are a result of climate change. However, only this factor is not responsible for failure. A large number of infrastructures all over the world are over 50 years old and suffer from extensive deterioration that affects their serviceability. The high costs associated with preserving the ageing structures in conjunction with the limited funds allocated for their maintenance pose significant technical and financial challenges, which require systematic approaches for risk-informed condition assessment.

This scenario calls for decision-making to be based on reliable accurate information regarding the progression of distress which is the basis of the deterioration process. Most Bridge Management protocols are dependent upon the judgement of engineers inspecting the bridge (Joshi 2022). The data collected by the engineering staff will need to be supplemented with factual data related to the performance of bridge elements showing distress (Michael 2014). It is an established fact that an increment in distress results in decrement in performance. By using Structural health monitoring (SHM), it is possible to monitor the bridge periodically. It is possible to monitor the response of the bridge structure which reveals changes to the material and geometric properties. SHM is important for maintenance planning to find a cost-effective solution to reduce costs and extend the life of critical assets like bridges. SHM for bridge structures is generally referred to, for the damage detection or characterization strategy for real-time assessment of structural condition. Structural Health Monitoring of distressed bridges elements over short durations will yield the required factual information about the

elements. Periodic records of such short-term monitoring will result in creating time series of data.

The challenge is to correlate this decrement in performance to increments of distress. The correlation will allow changing the Cause matrix to Performance-based cause matrix. Cause matrix enables formation of Deterioration model which forms the basis for risk estimates and further optimization of fund allocations. Increment in distress generates a scenario where in we can modify the Cause matrix generated by the prognosis of the bridge inspection engineer/team. From acceptance of judgmental prognosis, we have a solution wherein the Cause matrix is modified by actual observation of performance of the bridge and its elements. Integration of SHM within the analytics of GABM [Global Analytics for Bridge Management] steers the decision-making process away from person dependent judgement to factual observation and performance based decision-making procedure.

Life Cycle Cost Analysis (LCCA) is a useful tool for selecting the most reasonable scheme from an economic standpoint. The challenge is to use the LCCA within Bridge Management. SHM integration helps to get a more realistic view of LCCA. The paper presents a methodology of using LCCA within Bridge Management. LCCA, is used to choose the best economic design for both structural integrity and durability. Comparison of alternative design approaches, strategies, identification of cost-effective improvement, Project's budget, cum economic viability assessment, and long-term financial planning all are possible within LCCA. LCCA is a process of evaluating the total costs over the life of a bridge. Total costs include initial costs and project future costs such as maintenance, repair, rehabilitation, and reconstruction (discounted to today's money value). LCCA and total cost incurred from construction to the end of service life evaluation are the basis for decision-making for project selection among various alternatives. LCCA is also used to evaluate different design features of a bridge for selecting the best option among alternatives.

2 STRUCTURAL HEALTH MONITORING INTEGRATION IN GABM

Structural Health Monitoring [SHM] have been in use for investigating the behaviour of the structures since decades. What initially started with steel structures soon encompassed the concrete structures also. SHM is today possible either by close contact or remotely. Various techniques are available to analyse the data generated by SHM. This analysis makes it possible to identify the performance of the structure (Joshi 2022, Markov 2014).

This performance to be used in Bridge Management needs to be converted to known parameters for which data has been collected over the past many years. SHM historically was never linked to identifying the various causes that lead to the deterioration of structures. Again, past research in this has provided various techniques that make it possible to identify the location, extent, and severity of distress.

The challenge was to correlate this performance or identified distress to the three cause processes of deterioration. Such correlation could make it possible to generate the Cause matrix. The cause matrix is the starting point of any further applications of analytics in Bridge management. The three principal processes identified by EN1504 are the Physical process, the Mechanical process, and the Chemical process (Michael 2014). Further, these principal processes are subdivided into 11 sub-processes. The rating assigned to these 11 sub-processes forms the Cause matrix. Three main reasons are identified and listed out for the need to identify the location of the damage is critical to the structural evaluation and the deterioration process (Joshi 2022, Cao 2018, Hugh 2003).

Different modes of failure are location dependant and assume criticality based on their location along the length of the element. The strength of the element as evaluated using the deteriorated cross section affects the load capacity of the member along the length of the element. None of the existing BMS including GABM can provide accurate digitized data relating to

the location of the damage or distress (Joshi 2022, Markov 2014). GABM allows for using the cause matrix as the base for the evaluation of the deterioration process.

These shortcomings within BMS are required to be overcome by using all available new innovative technologies. Integration of technologies, which can provide data regarding the correct geospatial location of distress would be the first phase in the refinement. Moreover, the next phase is to be identifying the critically distressed elements and evaluate the performance of such severe distress elements under live loading using Structural health monitoring [SHM] for short durations only. Using this data as base data, we shall need to repeat SHM observations over time to create a time series data that is used to compare with base data collected initially.

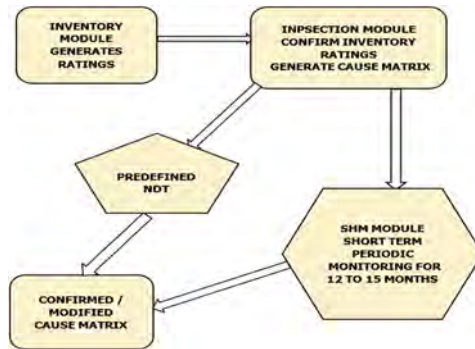

Figure 1. Process of data utilization within GABM.

The solution of partial Integration of SHM with GABM provides to utilize the performance to evaluate the deterioration process in bridges or any other infrastructure (Joshi 2022). This solution is able to develop a deterioration model based on performance monitoring. The results should yield sufficient information regarding the present status and types of distress and severity of distress resulting from causes. SHM will provide confirmation of the type of distress, its extent and its severity. Based on this SHM, will confirm the prognosis and resultant cause matrix is updated to be used for all further analytics within GABM

Presently this is done by Non-Destructive testing. SHM will replace NDT. SHM conducted on distressing elements for the periodic short term will yield time series data relating to changes in the performance of the bridge element on which SHM is conducted. This change in performance can assist in the application of modification to the cause matrix. A modified cause matrix will result in more realistic and factual deterioration modelling.

2.1 Application of deterioration models to LCCA

Because of the rising interest in predicting the future condition of infrastructure assets. The focus is mainly on the importance of safety, construction materials used and structural functionality. The deterioration model is a link between a structural condition that assesses the extent and severity of damages, and the factors affecting structural deterioration such as age, material properties, environmental conditions, etc. The deterioration model is intended to describe the process and mechanisms by which assets deteriorate and even fail through their service life.

Based on the assigned ratings primary cause of distress can be identified. All other contributory causes are called secondary causes. These observations conclude the inspection process.

Moreover, it involves confirmation of the prognosis. To date, this confirmation was done by Non-destructive testing techniques. The confirmed Cause Matrix is used as the first of the important data. The system starts with the help of data collated during the Bridge Information System [BIS] namely Inventory, Inspection and Testing process helps to confirm the prognosis of the Deterioration process.

Small-duration SHM monitoring under live loads will result in the identification of such changes over time. The first such monitoring should be implemented based on identified distress and cause matrix-generated post-Inspection. In GABM, to ensure the optimization of funds, the assignment of available budgetary allocations for rehabilitation intervention is allotted to bridges which qualify for such allocation. Other bridges are stored in the list of Bridges under Observation and Monitoring [BUOM] Bridges in this BUOM are subjected to short-term SHM over 12 to 15 months.

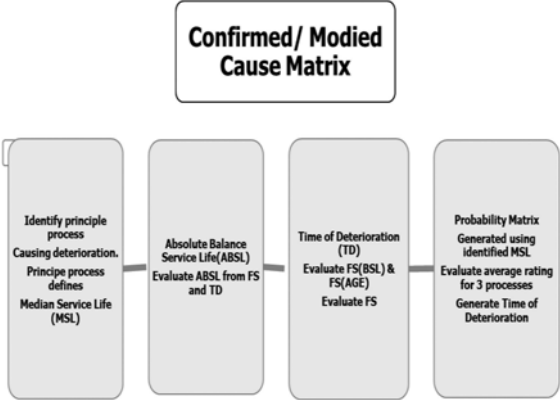

Figure 2. Analytics flow chart Cause matrix to Deterioration model.

After this initial monitoring, repetitive short-duration monitoring is applied. The time lapse between two sets of monitoring can be defined by the severity of distress observed in the first set of the Inspection cycle. Such time series data will yield a decrement in performance, which is related to increments in distress zone and severity.

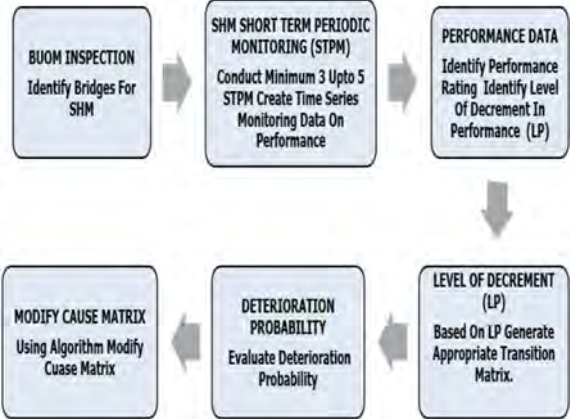

Figure 3. Flow chart of partial integration of SHM and GABM.

2.2 Two types of SHM to achieve the objective are as follows

Remote or No contact SHM: System wherein the parameters essential like Vibration, acceleration, frequency, strain, and displacement is captured by technology without being in contact with the bridge or bridge elements.

Close Contact SHM: System wherein major strain, stress, linear displacement, inclination, vibration, frequency, acceleration, and corrosion potential is measured by sensors [Strain Gauges, Linear Variable Differential Transformer (LVDT), Tilt Meter, Inclinator Sensors, Acoustic Emission Sensors (AE), Fibre Optic Sensors, Corrosion Sensors, Accelerometer] in close contact with various desired components/ elements of bridges.

Both the “No contact” and “Close Contact” systems will yield results that identify typical changes in performance parameters to determine the correlation between the decrease in performance parameters and an increase in distress zone and severity.

Research in the application of computing algorithms to SHM to evaluate the performance of the structure under live loads has resulted in over 15 known and tested techniques to evaluate performance and link it to the extent and severity of distress. SHM-based parameter observes the performance between Initial Scenario and Operational Scenario which shows the “Presence of Distress situation” of structure.

GABM provides a solution for partial integration of SHM with Bridge management analytics. The resultant deterioration model prepared is more realistic and based on factual performance data. Further analytics applications will yield more reliable results.

3 LIFE CYCLE COST ANALYSIS (LCCA) FOR USING RESULTS DERIVED FROM SHM

Structural Health Monitoring (SHM) provides operational performance, early warning data, future prediction, and analysis. It is widely used in many bridge infrastructures, which helps the behavior of the structure and access the real-time monitoring of the structure using different technologies and sensors. The idea to utilize the results from various SHM elements of the bridge structure will help to better analyze the results that are generated from the LCCA to determine and calculate the economic design from various alternatives prepared to maintain the structural integrity, and restore the durability of the structure.

3.1 Necessity of LCCA for bridges

LCCA is a cost-centric approach for determining the most cost-effective alternative. The life-span of various bridge components is determined by their rate of deterioration. The pier and foundation are more vulnerable to deterioration because of environmental or collision impacts. The environmental exposure of steel components influences quickly the steel corrodes. A bridge is a long-term, multi-year investment, and the cost to an agency for a bridge is never a one-time expense. Bridge components require preservation and maintenance actions to counter the effects of deterioration throughout their Service Life. Each design alternative must first show it reliably achieves project requirements such as service life, structural stability, and desired level of maintenance (Irina 2020, Wiie 2011, Satish 2015).

Conventional LCCA results in an evaluation of Internal Rate of Return [IRR] which is mostly dependent on direct costs and benefits. Bridge structure connects two area which otherwise are not connected. Such unconnected areas could be residential, commercial or island zones. This connection adds value and intangible benefits to the area which it connects. This results in generation of employment opportunity for population of the residential area. Such increased employment potential results in a general increase of turnover of the organizations operating in the commercial zones. Island zones get better availability of consumer goods at cheaper cost resulting in saving due to the connections that the bridge provides. The Bridge also results in increased emission of gases and degradation of forest cover due to increase in traffic in the area brought under influence of the bridge. This is intangible cost arising due to bridge in the area. Evaluation of all such intangible or indirect costs and

benefits yield the realistic IRR. Such IRR can be termed as the IRR including Intangible impact. Application of LCCA to evaluate both tangible and intangible impact of the bridge on the area is applied within GABM.

Evaluation of the best-suited bridge to be allocated funds for rehabilitation interventions can now be altered based on the Sustainability Index [SI] evaluated from the LCCA which calculated IRR including Intangible impact. Every bridge on the list of BOUM is subjected to LCCA which yields SI for the bridge. Every bridge on the list of BOUM is subjected to LCCA which yields SI for the bridge.

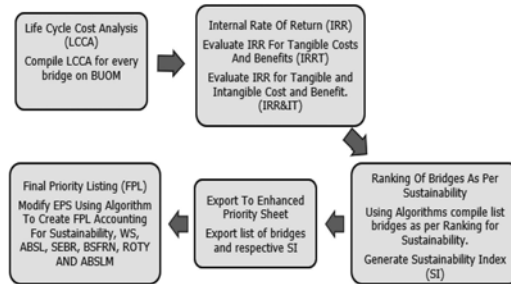

Figure 4. Flow chart of LCCA in GABM.

This SI matrix is then exported to Economic Priority sheet [EPS]. Application of algorithm results in Final Priority Listing [FPL] which is accounts for Sustainability, Sum of Critical weightage and Influence weightage, type of road, Absolute Balance service life [ABSL] of the bridge, Structural, Functional and Socio-Economic ratings of the bridge.

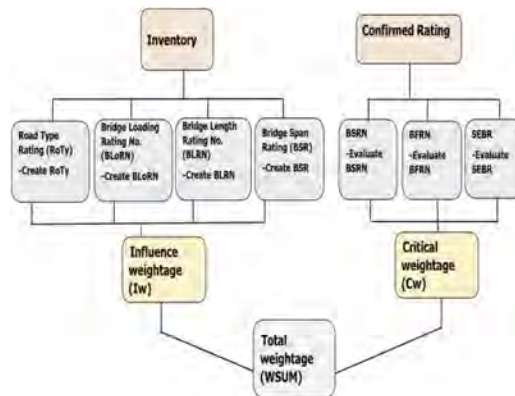

Figure 5. Flow chart of GABM Priority and Ranking.

Bridges selected for rehabilitation interventions based on FPL ensure that the optimization of fund allocation not only follows technical and commercial principles of allocation but also ensure that rehabilitated bridges will enhance the Sustainability of the network.

4 RESULTANT SUSTAINABILITY

Sustainability is defined as the preservation of the present environmental, economic and social structure of the society for the present generation and also ensuring that the same is maintained for the future generation (Mohammaderza 2014) . The decision-making within any Bridge

Management system should ensure Sustainability (Mmm group 2015) . GABM empowers the application of Sustainability within the management of the life cycle of the bridge.

LCCA is a decision-making tool particularly useful from the conceptualization of the bridge to its decommissioning. It ensures to evaluation rate of return for the design of Bridges as it predicts lifetime expenses and supports the inspections management and the maintenance activities. Bridges or any other infrastructure should be seen as a key part of the economic activity and well-being of a given community (Joshi 2022).

Currently, the use of sustainable materials in the construction of bridges is increasing ensuring a positive impact on the environment, economic and social parameters. LCCA which ensure this can be applied as a tool for calculating and comparing the life cycle cost of a projects (Hugh 2003, Goh 2009).

While a structure is designed from economic, technical and safety perspectives, the environmental performance was often not considered in the decision-making process. GABM enables maintenance, strengthening, repair, and rehabilitation of bridges if interventions are applied timely. This ensures maximizing the life span of bridges without the need for replacement. Such interventions ensure to reduce the cost of the life cycle and reduce the impact on the environment by reducing the usage of raw materials. These interventions enhance the environmental and economic management in the entire life cycle by maximizing the benefits for the given costs. The timely provision of interventions ensures economic benefits by managing the cost-effectiveness in the design of such interventions, by ensuring to reduce the detour travel time, congestions, and traffic jams delay resulting in avoidance of productivity loss and its impact on the reduction of GDP of the area of influence of the bridge. Such intervention also ensures to enhance a social benefit by reduction or avoidance of failure/ collapse and increased reliability of network which impacts the safety during travel, life loss, timely delivery of goods and raw materials which are crucial to maintaining the productivity which ensures stable GDP. Environmental goals of minimizing the carbon emissions are ensured by avoidance of traffic jams, and longer journey time due to detours in case of closure of the bridge for a longer period when collapse occurs.

Sustainability ensures to delivery of the optimal level of service safely to existing and future bridge users in the most cost-effective way. LCCA enables us to prioritize investments on the assets that need it most. This optimization is ensured by a risk-based analysis to identify cost-effective investments during conceptualization, designing, construction, and during the entire operational life of the bridge.

5 CONCLUSIONS

Several infrastructure networks are currently facing issues, such as increasing annual maintenance costs, ageing infrastructure, as well as climate change impacts. The main purpose of the reliability-based life cycle analysis of the ageing structures model presented is to satisfy the required performance. This needs to also consider and ensure the economic, social, and environmental impacts of different maintenance and safety strategies.

Management needs reliable data, which is collated during Inventory and Inspection process. In the inspection process, the inspectors record certain information regarding distress structure and based on observations, the inspector comes to conclusion. The accuracy of the result depends on the experience and judgement of the engineer. Most of the infrastructure management systems rely on this judgement. Mostly majority of the networks are faced with ageing problems. Bridge structures constructed before or during the last five decades face aging scenario. This necessitates the need to have realistic management systems. Within GABM the functionalities of deterioration modelling, risk analysis and fund allocation were till date based on theoretical evaluation and observation of increments of distress in the bridge. GABM system has evolved over time to provide solutions to users. GABM management procedures include the impact of Sustainability of infrastructure, Life Cycle Cost Analysis (LCCA), and Structural Health Monitoring (SHM). The main forte of the approach is to identify the cause of distress structure and then apply short duration real-time monitoring to determine the changes in behaviour of the ageing bridge under live loads. This helps engineers to record performance and

the changes. Application of developed algorithms correlates current deterioration of the structures to the decision-making process. This approach enhances the observation and judgement based conclusions of engineers to realistic performance based approach.

The Bridge Management Analytics include the use of accurate and realistic data for the generation of deterioration models, the inclusion of socio-economic parameters to assess the benefits [direct and indirect] that accrue to the area of influence under the bridge. Finally, LCCA tool is utilized to assess the life cycle costs impacts that are used in the decision-making during the entire life cycle. Data from various several Socio-Economic parameters collated under GABM protocol enables to ensure that the evaluation of intangible advantages or costs that result from a bridge structure are applied to access the economic impact. Using enhanced LCCA technique, ensures the decision-making process is based on realistic approach. Through this approach, sustainability goals are also guaranteed, ensuring that a structure fulfils present requirements without endangering the ability of future generations to satisfy their own. A sustainable course of action should preserve the harmony of the three key factors of social, economic, and environmental issues. Sustainable bridges support the environmental, social, and economic systems that we depend on. Life cycle analysis of ageing structures based on reliability approach ensures Sustainability and Economic growth.

Baseline digital twin models for key performance management of prefabricated bridges

C.S. Shim, G.T. Roh, M.U. Kang & Y.H. Lee
Chung-Ang University, Seoul, Korea

ABSTRACT: Prefabricated bridge members requires more strict quality management for easier assembly. Design for manufacturing and assembly(DfMA) has been started to be adopted for bridge structures. In this paper, digital engineering models are developed to consider these new requirements. Rule-based modeling is used to create the 3D geometry models which has automatic model update by geometry inspection data at the stage of fabrication, erection and completion of the assembly. Prestress and connections are essentially included in the prefabricated bridge. Designed values should be updated through quality inspection process. For preassembly check, data templates for prefabricated members are proposed and a pilot application is performed for a prestressed concrete bridge. Camber, lateral deformation, stress conditions are selected as key performance indices of the prestressed concrete girder. A simple sensing system is applied to the girder from the beginning of fabrication to the end of assembly. When the bridge is completed, the owner can have a baseline digital twin model of the bridge. Data and digital engineering models are delivered to the maintenance system.

1 INTRODUCTION

1.1 *DfMA&M for a prefabricated bridge*

OSC is an innovative technology that the construction industry is most actively attempting. Prefabricated members are eco-friendlier than their precast counterparts because of generation of minimal waste and energy efficiency. DfMA (Design for Manufacture and Assembly) allows parts of construction projects to take place off-site, which can reduce project length, cost, material use, and worker injuries. To enable DfMA, designers require more systematic information considering whole life-cycle of a structure. Prefabricated structures have various connections. The final assembly of the structure is done on-site. As in the manufacturing industry, the performance of the prefabricated structures needs to be assessed continuously from the completion of the construction. Therefore, DfMA&M (Design for Manufacture, Assembly and Maintenance) is a concept for the prefabrication in construction industry.

Definition of maturity levels of DTs for construction was proposed from 0 to 5 (Evans et al. 2019). They provide different principles and their usage according to the levels. However, more specific definition for the maintenance is required. Zhang et al., (2022) proposes a framework to utilize digital twins for construction site management. One of the technical difficulties is in accumulating knowledge from design to construction in improving the process and decision making. Another challenge in the nontechnical side is that human participation is essential for decision making despite low-level operations done autonomously.

Digital models of precast concrete members are generated from design calculations considering design codes and specifications. The models are utilized to assist preassembly checks and instructions to control geometry errors of each member (Shim et al. 2018, Nguyen et al. 2022). To realize a fully prefabricated bridge, predefined digital models for each member and required data for the assembly are essential. Nguyen et al. (2022) suggested digital engineering

models for DfMA of the prefabricated bridges. The digital models are continuously updated by inspected geometry changes during fabrication, time-depended deformation, and assembly. Through this process, the as-built models are submitted to a bridge owner for the maintenance. Mixed reality using the digital twin models (DTMs) for improving semantic information visualization of bridge maintenance system was utilized (Nguyen et al. 2022). These data during the project delivery are required to build a baseline digital twin model by combining with measured sensing data for key performance of the prefabricated bridge.

1.2 Key performance indicators for a prestressed concrete girder

For the maintenance of a prestressed concrete bridge, the main parameters are long-term properties of concrete, remained prestressing force, and corrosion of prestressing steels. There are multiple stages such as fabrication, prestressing, dead load by bridge decks, composite section, and second dead load by the pavement and the barrier. Long-term behavior of the prestressed concrete girder such as deflection, stress change by creep, shrinkage, and relaxation needs to be monitored by collecting data at each stage. When the data are accumulated for a prefabricated member, design can be much improved for more reliable prediction of life-cycle performance.

In this paper, a baseline digital twin model for full-prefabricated bridge superstructure is suggested. Data templates for collecting information are created from design calculation to the completion of a bridge. Digitalized inspections of geometry and an efficient sensing system are included in the process of the model update.

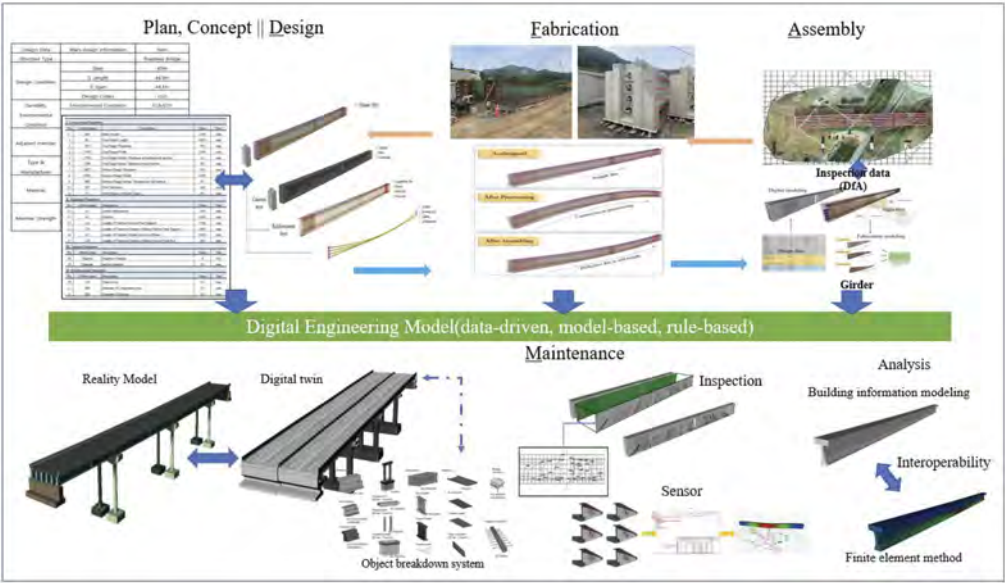

Figure 1. Digital model and its data-frame during its life-cycle based on DfMA & M.

2 DEFINITION OF DIGITAL TWIN MODEL

2.1 Digital geometry model

The first level of DTM is to define exact geometry of the structural members. A structure is a deformable object by loadings and time-depended properties such as creep. Current BIM (building information modeling) models should be revised by the change of geometry. A prefabricated bridge consists of individual structural members and connections. Due to the change of geometry, predefined constraints between parameters are essential for DfMA. For example, full-depth prefabricated bridge decks are assembled with multiple prestressed concrete (PSC) girders as shown in Figure 2. Parameters for the preassembly of the members

are location of the shear pockets in the precast deck and location of shear connectors on the top flange of the girders. During the fabrication stage, two sets of the data are collected by a scanning device such as a LIDAR. Digitalized inspection provides the predefined coordinates for the assembly check.

Due to prestressing of the girders and time-dependent behavior, the PSC girders have deformation resulting in the change of locations of the connectors. After the erection of the girders, these deformations should be captured by a UAV-scanning. A length-adjustable lateral beam can be designed to accommodate the unexpected lateral deformation by prestressing. Before assembly between the decks and the girders, assembly instructions are generated by the preassembly simulation. The data for the geometry control of the prefabricated bridge is important to build a digital twin model at the construction stage. Unknown design parameters such as the elastic modulus of concrete and the effective prestressing forces after jacking can be obtained.

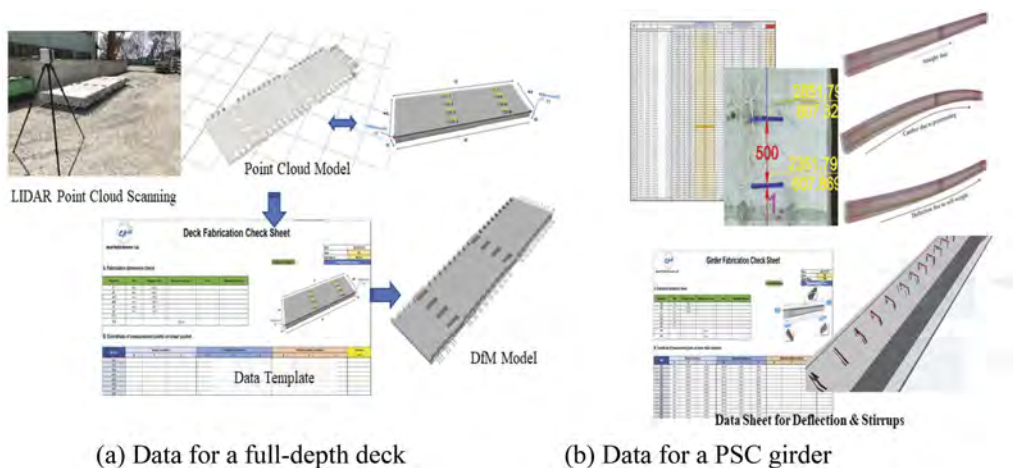

Figure 2. Data for DfMA application of a prefabricated bridge.

2.2 Analysis model

The second level of DTM is to enable the simulation of structural behavior of a structure. Two-way interoperable data exchange is required to realize the second level. From the digital geometry model with meta-data including the material properties and the effective prestressing force, a simulation model is generated. In this paper, the OpenSeesPY is selected for the analysis. The girder is modeled by *dispBeamColumn* element. Data for the generation of the analysis model are extracted from the geometry model, which is one-way data transfer. Analyzed results such as deformation and stress contour are imported to the DTM for the visualization of the structural behavior. For the baseline model, data from material tests and inspection tasks should replace the initial design data. For multiple girder bridges, it is required to select an indicating member to represent the time-dependent behavior of the whole girders.

At the time of prestressing, the prestressing forces (elongation data) and resulting camber values are obtained by a fabricator. The measured flexural stiffness of each girder can update the analysis models, and the data are stored in the digital twin models of the girders. Time-dependent deformation and deformation by additional loadings are monitored by a sensing system for the indicating member. Through this process, the baseline digital twin model at the bridge completion stage can be obtained for O&M tasks.

2.3 Model update by sensing data

The third level of DTM is to enable the prediction of future performance of a structure by accumulating data through sensing and analysis. A structural health monitoring system is not commonly used for girder bridges. A sensing system for updating of the digital twin model is

suggested and developed. Embedded sensors and a temperature sensor are monitored by a sensing system with an E-paper that requires very low power to visualize the sensor data. Before concrete casting, the sensors are installed and the sensing system is connected at the time of prestressing.

Figure 3 presents the data delivery from design to completion of the bridge construction. The initial data are assumed values. The 3D geometry of the member generates the analysis model with concrete and prestressing tendons. During fabrication, the initial model is updated by the prestressing force and the relevant camber. Then, sensor data monitored at a predefined period update the analysis model and geometry of the DTM. The DTM is continuously updated at the stage of assembly, composite action, 1st dead load, and 2nd dead load. As-built digital twin model is the baseline model for the maintenance of the bridge.

During the operation period, the most important issue of the prestressed concrete girder bridge is corrosion of the internal tendons. The internal corrosion cannot be visually observed and has a huge impact on the safety and service life of a bridge. Once the baseline DTM is established at the completion time of the bridge construction, the key performance indicator is the section loss of the internal tendons by the corrosion. The twin model can be used in the periodical inspection and assessment for prediction as well as structural evaluation of the bridge.

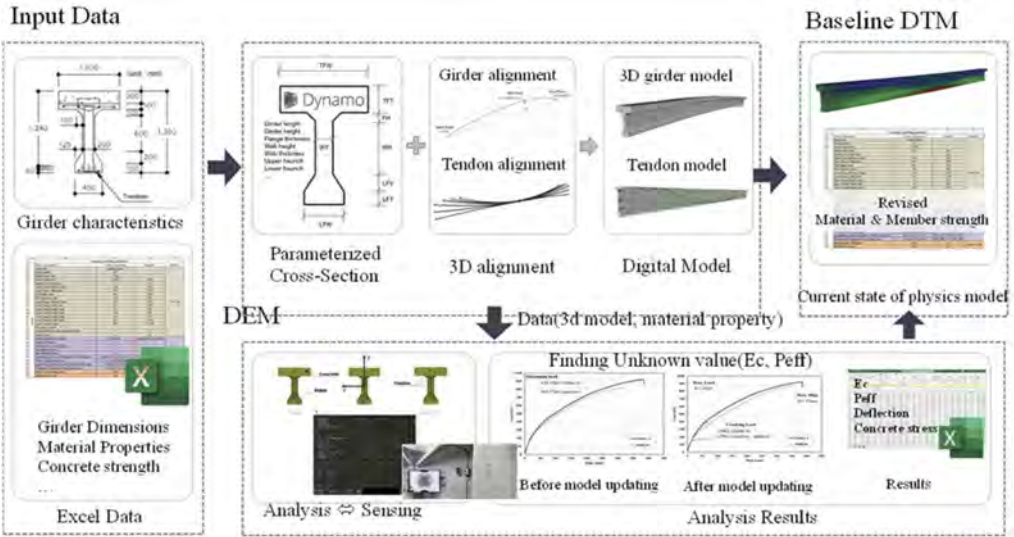

Figure 3. Flow chart for digital interoperability between BIM & Analysis.

3 IMPLEMENTATION TO A PREFABRICATED BRIDGE

3.1 A prestressed concrete girder bridge

A national research program on smart construction is in progress in Korea. The proposed digital twin concept and the developed technologies are being implemented to a expressway bridge. The bridge consists of prestressed concrete girders with span length of 35m and 50m. Figure 4 shows the bridge layout and the assembly stage. Steel lateral beams and full-depth precast decks are assembled with the PSC girders. The required data for the update of the DTM are obtained by an official inspection process to control geometry quality.

3.2 Implementation

A national research program on smart construction is in progress in Korea. The proposed digital twin models and the information delivery at each stage are being applied to the bridge.

Figure 4. A PSC bridge for implementation.

Figure 5. Baseline digital twin model and its update process.

An external girder near an abutment was selected as the indicating member. From the design calculation, the expected response in terms of deflection and strain values at several locations is collected. Figure 5 presents the process of the model update by the captured data during the fabrication and the assembly. Key parameters are the elastic modulus of concrete, remained prestressing forces, and section loss by the possible internal damage of the tendons. The sensing system has a target operation period of 10 years after the completion. There is a linked R&D program to build a digital twin model for existing bridges that have service life longer than 30 years. The internal corrosion of the tendon is the main interest for the assessment of the existing PSC girder (Jeon et al. 2021).

4 CONCLUSIONS

Prefabricated structures must provide productized specifications and performance. We proposed a digital twin model that can evaluate this long-term performance even though the concrete prefabricated structures have uncertainties in material properties and long-term behavior. Interoperability between 3D digital geometry modeling and the finite element analysis through the open platform, which can actively reflect geometry changes at each construction stage, was secured through data exchange. A procedure for updating the digital twin model using data acquired during the manufacturing and assembly process was presented. A low-power sensing system was used to monitor the initial performance of the structures and to update and verify the digital twin model. At the completion of the construction, the bridge's owner can have an efficient and reliable baseline digital twin model for maintenance.

ACKNOWLEDGEMENT

This research was conducted with the support of the “National R&D Project for Smart Construction Technology (RS-2020-KA156007)” funded by the Korea Agency for Infrastructure Technology Advancement under the Ministry of Land, Infrastructure and Transport, and managed by the Korea Expressway Corporation.

Analysing the impact of local factors on the life-cycle of metallic bridge girders

G. Calvert & M. Hamer

Advanced Analytics, Technical Authority, Network Rail

L. Neves & J. Andrews

Resilience Engineering Research Group, University of Nottingham

ABSTRACT: A fundamental component of a life cycle analysis of a bridge is the modelling of asset condition post-construction. To enhance the accuracy of bridge deterioration models, several studies have calibrated models based on cohorts that incorporate structural characteristics and local factors. However, it is common that these characteristics are independently modelled to avoid sparse cohorts. In this study, a bridge element deterioration model is developed that can simultaneously incorporate multiple structural and local characteristics. The incorporation of multiple co-variates is made possible by an approach that exploits the multiple defect deterioration model proposed by Calvert et al. (2021). The model is tested on a cohort of 36,075 metallic bridge girders from bridges on the British railway network. The modelling approach is shown to provide statistically significant improvements in the prediction accuracy of deterioration. Moreover, a life cycle analysis outlines the significant cost and condition differences between benign and aggressive cohorts.

1 INTRODUCTION

The asset management of civil infrastructure is a critical task for transportation organisations, with maintenance, rehabilitation, and replacement activities requiring huge amounts of resources. To forecast resource requirements and maximise the impact of allocated resources, infrastructure asset managers use strategic lifecycle costing models to support decision making. To evaluate the lifecycle of civil infrastructure post-construction one needs the means to evaluate how the asset deteriorates and a means to evaluate the effectiveness of asset interventions. The accurate evaluation of the entire lifecycle is contingent on the deterioration modelling being accurate.

There are a plethora of methodologies to model structural deterioration of bridges (Frangopol, Dong & Sabatino 2017), however, for strategic network level modelling Markov modelling calibrated using condition data from visual inspections is the most common. The use of condition data to calibrate deterioration models does have its limitations given the somewhat arbitrary condition scales used and the subjectivity of the examiners when recording the assessments. Despite the limitations of the condition data, the use of such is data is widespread amongst asset managers due to the relative abundance of data compared to more empirical measurements.

There are different hierarchical modelling frameworks for the strategic modelling of bridges (Hamer, Calvert & Neves 2022), ranging from the highest level of network level evaluations for a portfolio of bridges to the lowest level of modelling at component level. An evaluation of a whole structure can be performed by assuming that the components form some configuration of a series-parallel system. Most transportation agencies assign and predict a single condition score for each component. However, the assessment of components using a single condition score is somewhat arbitrary and does not adequately describe the diverse physical process of deterioration.

In previous studies, it has been shown that it is possible to strategically model bridge components using a methodology that enables the evaluation of multiple degradation modes simultaneously (Calvert, et al. 2020, Calvert, et al. 2021). Moreover, in previous studies it has been shown that the calibration of deterioration models using condition data should be

conducted such that co-variables such as geographical location, bridge loading and structural positioning should be used to form cohorts. In this paper, a cohort analysis will be performed such that the deterioration of bridge components with multiple defect mechanisms and multiple co-variables can be evaluated simultaneously.

2 MULTIPLE DEFECT DETERIORATION MODELLING

In previous studies a Dynamic Bayesian Network (DBN) model has been used to evaluate the progression of multiple deterioration mechanisms on metallic bridge components (Calvert, et al. 2021). The defects evaluated in the modelled components included, the deterioration of paintwork/coating, corrosion and a mechanism named Structural Component Failure (SCF) which incorporated instances of buckling permanent distortion/displacement and tearing/fracture. A visualisation of the multiple defect deterioration DBN model is shown in Figure 1.

Figure 1. Dynamic Bayesian Network deterioration model.

Bridges represent a diverse asset class, with each bridge having its own distinct composition of structural elements. To facilitate intervention co-ordination and strategy development, bridges are commonly described by a hierarchical decomposition of elements. For example, at Network Rail the hierarchy for structural assets is defined by asset groups (e.g. underbridge), asset sub-groups (e.g. construction material), major elements (e.g. deck) and minor elements (e.g. inner main girder). When aggregating minor elements to determine an overall score for a bridge, particular minor elements have a designation of being a principal loading bearing element, which are used to attribute a greater weighting for elements that are structurally integral to the loading capability of a bridge.

A railway underbridge has the railway line going over the deck of the bridge. Conversely, a railway overbridge has the railway line going under the deck of the bridge. It is generally expected that an underbridge will deteriorate at a faster rate than the overbridge given that the underbridge has the loading of the railway on its deck. The MGE and MGI classifications are used to denote the exposed and inner main girders, respectively. The term of main girder is used to describe a longitudinal main girder or beam that spans between the abutments, piers or columns. The outer two beams on any deck are classified as MGE with the remaining main girders classified as MGI. For this study, main girders will be used as the component type to be analysed.

Model calibration cohorts that divide exam records by an element belonging to an underbridge or overbridge, and whether an element is an inner or exposed have been shown by previous studies to be statistically significant (Yianni, et al. 2016). For this study, such model calibration cohorts were found to be statistically significant for the multiple defect DBN model when compared to a generic cohort for main girders. This analysis was assessed by using a likelihood ratio test, the Akaike Information Criterion (AIC) and the Bayesian Information Criterion (BIC).

The DBN model parameters were calibrated using a method of maximum likelihood on Network Rail bridge condition data from visual inspections. The condition data is recorded using a condition scale known as Severity Extent (SevEx) and it can be used to note the absence or presence of each defect and the extensiveness of each defect if present. The calibrated parameters for inner and exposed main girders are shown in the table below.

3 ADDITIONAL DETERIORATION FACTORS

The deterioration models in this study are calibrated using inspection records rather than experimental data, although it is still critical that the aforementioned properties that alter deterioration behaviour are considered in the model calibration. Previous studies have analysed additional properties that can influence deterioration such as traffic volumes, asset age, coastal proximity, structure type amongst others (Huang, Mao & Lee 2010, Morcoux, Rivard & Hanna 2002, Yianni, et al. 2016) and shown that their consideration is statistically significant to calibrated deterioration models. However, the early studies were often limited to analysing properties independently, which is problematic for scenarios when more than one property has been identified as influencing deterioration, as an asset manager wants to incorporate all of the properties simultaneously.

3.1 Coastal proximity

Bridges situated in close proximity to the coast are exposed to high atmospheric salinity and prevailing winds, which can accelerate the deterioration of structural components. To determine the proximity of a bridge to the coast, the co-ordinates of the bridge were evaluated against 51,043 reference co-ordinates of the coastline from the Global Self-consistent, Hierarchical, High-resolution Geography Database (GSHHG). Upon determining the proximity to the coast for all bridges, the bridges were split into two cohorts: CP1 – Less than or equal to 10 km from the coast and CP2 – More than 10 km from the coast.

3.2 Material

Across a network of bridges and even a bridge, metallic bridge elements can be constructed out of different metal materials. These different metals will corrode at different rates. For example, Agrawal, Kawaguchi & Chen (2010) analysed highway bridges in New York state, where from approximately 1968, metal bridges were constructed using weathering steel, which was a different steel composition than was typically used before 1968, called ‘steel’. In the Weibull-based analysis, weathering steel was found to deteriorate at a slower rate than the steel after 20 years.

The Network Rail portfolio contains metal bridges constructed out of cast iron, wrought iron, early steel, weathering steel and steel. ‘Early Steel’ is steel that was manufactured prior to 1956 and ‘Steel’ denotes steel manufactured from 1956 onwards. For the purposes of this study, three cohorts were formed based on material type: M1 – Wrought Iron, M2 – Early

Steel and M3 – Steel. Cast iron was omitted from the study due to discrepancies in the recording of condition for this material at Network Rail.

3.3 Track category

For road bridges, it is common to consider the traffic volume and road system when determining cohorts for model calibration (Scherer & Glagola 1994). Road traffic volume is commonly measured using Annual Average Daily Traffic (AADT). The road system indicates the type of road system a bridge is situated on e.g. interstate/motorway, primary or secondary. Moreover, Zhang & Cai (2012) shown that increased vehicle speed has a negative effect on fatigue reliability of bridge components.

Track categorisation considers annual tonnage for a section of track and the designated line speed for trains on that section of track. The categories are used to specify requirements relating to design, maintenance, renewal and inspection of track. For railway underbridges, track category can be used as an indicator of traffic loading and route type. Tonnage is measured using Equivalent Million Gross Tonnes Per Annum (EMGTPA), which accounts for the variations caused by different rolling stock. The calculation that Network Rail uses for EMGTPA is similar to the calculation for “theoretical traffic load” specified by the International Union of Railways (UIC 2019). Line speed is measured in miles per hour and track sections with a greater permitted line speed are typically located on strategically important routes e.g. mainline services. At Network Rail there are seven track categories, Cat 1, 1A, 2, 3, 4, 5 and 6. For this study, there are two track category cohorts considered: TC1 – (Cat 1, 1A and 2) and TC2 – (Cat 3, 4, 5 and 6).

The boundary between the track category definitions is a line speed of 91 mph between 0 and 7.2 EMGTPA. For annual tonnage greater than 7.2 EMGTPA, the line speed is defined as $-55 \cdot \log(w) + 200$, where w is the annual tonnage in EMGTPA of the track section. The boundaries for categories are based on historical and experimental data.

4 INCORPORATING MULTIPLE FACTORS INTO MULTIPLE DEFECT MODEL

For this study, the condition records of 36,075 main girders are considered. When additional properties are incorporated into the model, the records used in model calibration are split into smaller cohorts. The inclusion of coastal proximity, material type, track category and being an inner or exposed girder in a more detailed model will increasingly limit the size of the available data for specific instances of model calibration.

If distinct rates or a scaling factor permutation were calibrated that did not maintain the monotonic increase, the model could output the perverse scenario that the more degraded an influencing defect is, the slower the corresponding defect degradation rate is. For example, if the rate for $(C1 \rightarrow C2)|Pa3$ is 0.675 and the rate for $(C1 \rightarrow C2)|Pa4$ is 0.55, the model would be returning a lowering rate of corrosion as the paintwork condition degrades. This scenario would ultimately disincentivise paintwork maintenance interventions when performing a life cycle analysis, which goes against engineering judgement. To include multiple properties simultaneously, they could be strategically input into the model on a per defect basis.

The multiple defect model shown in Figure 1 incorporates the underbridge/overbridge and exposed/inner status of the component for all of the defects in the deterioration model. However, each of the additional properties that influence deterioration is then input to the existing model for a particular defect type. The paintwork scaling factors are specific to the proximity of the bridge component to the coast. The corrosion scaling factors are specific to the material type that the bridge component is constructed out of. The SCF scaling factors are specific to the component’s bridge track category.

The relationship between the local, structural and material properties is shown in Figure 2. This particular model configuration ensures that there are minimal additional parameters being added to the model to avoid the over parameterisation of the condition data. However, if a girder being close to the coast results in increased paintwork degradation, corrosion will occur at a greater rate due to the worse paintwork condition. Similarly, if a particular material

Figure 2. Influencing properties for defect deterioration model.

type corrodes at a faster rate, the instances of SCF occurring will increase due to the causal influence between those defects.

As a case study, the enhanced multiple defect deterioration model from the previous section was calibrated using the Network Rail condition records for railway underbridges. The scaling factors that maximised the log-likelihood function for the condition records used in calibration are shown in Table 2 for paintwork, corrosion and SCF.

Table 2. Scaling factors for DBN model based on additional characteristics.

	Pa Scaling Factors		C Scaling Factors			SCF Scaling Factors	
	CP1	CP2	M1	M2	M3	TC1	TC2
MGI	1.3580	0.9096	1.4048	1.2562	0.8108	1.6822	0.7235
MGE	1.2223	0.9210	1.4031	1.2966	0.7621	1.1430	0.9354

It can be observed that for each of the scaling factors, components with the more aggressive properties, i.e. CP1, M1, M2 and TC1, have a value greater than one and the components with the less aggressive properties, i.e. CP2, M3 and TC2, have a factor value less than one. This enables the components with aggressive properties to deteriorate at a faster rate than the baseline rate and conversely, the components with less aggressive properties can deteriorate at a slower rate than the baseline rates. Consequently, each component would have a contextualised deterioration rates for its composition of local, structural and material properties.

Engineering expertise would suggest that the closer a bridge is to the coast, the greater the rate of deterioration, similarly, wrought iron and early steel would deteriorate faster than steel and finally that the greater the bridge loading or line speed is, the greater the rate of deterioration. This is observed in the deterioration factor values and the values obtained in the initial case study adhere to the following inequalities,

$$\gamma_{Pa}^{CP1} \geq \gamma_{Pa}^{CP2}, \quad (1)$$

$$\gamma_C^{M1} \geq \gamma_C^{M2}, \quad (2)$$

$$\gamma_C^{M2} \geq \gamma_C^{M3}, \quad (3)$$

$$\gamma_{SCF}^{TC1} \geq \gamma_{SCF}^{TC2}, \quad (4)$$

where γ is a scaling factor and the subscript indicates the defect and the superscript denotes the relevant deterioration factor cohort.

4.1 Model selection

For the initial case study for underbridges there are two models, Model A with 28 Parameters (Baseline transition rates) and Model B with 42 Parameters (28 Baseline parameters, 7 scaling factors for MGI and 7 scaling factors for MGE). The likelihood ratio test statistic is 875.5, which gives a p-value that is infinitesimal ($<10^{-5}$) and suggests that the difference between Model A and B is statistically significant. This is again supported by Model B having the lowest value for AIC and BIC, making it the preferred candidate model despite its increased parameters.

4.2 Life cycle analysis

To evaluate the implications of main girders being modelling with additional characteristics, a life cycle analysis was performed to evaluate the effects of the different deterioration properties under different maintenance strategies. The following cohorts of deterioration properties were considered:

- Cohort 1 - MGI-BU Baseline
- Cohort 2 - MGI-BU, M1, CP1, TC1 (aggressive properties)
- Cohort 3 - MGI-BU, M3, CP2, TC2 (benign properties)
- Cohort 4 - MGE-BU Baseline
- Cohort 5 - MGE-BU, M1, CP1, TC1 (aggressive properties)
- Cohort 6 - MGE-BU, M3, CP2, TC2 (benign properties)

The different cohorts will be assessed using three different maintenance strategies, Strategy A - Fixed renewal of paintwork every five years, Strategy B - Fixed renewal of paintwork every ten years and Strategy C - No paintwork-only interventions. A life cycle analysis was performed using a Petri model which simulated the deterioration of a component, inspection regime and application of each maintenance strategy. The Petri net model is described in (Calvert, et al. 2021).

To compare between the different cohorts and strategies, there are two Key Performance Indicators (KPI) considered for the 35-year simulation period: Average total Time in Poor Condition (ATPC) and Average Total Costs. The study KPIs are presented in Figure 3 as a scatter plot, where it can be observed that there are three clusters formed from different cohorts and maintenance strategies. The red ellipse includes the KPIs for Cohorts 2 and 5 under strategies A, B and C; these cohorts represented the most aggressive scaling factors, with wrought iron, a coastal proximity of within 10km of the coast and belonging to a track category with the greatest loading/highest line speeds. Conversely, the green ellipse includes the cohorts from the least aggressive scaling factors. The yellow ellipse includes the KPI results for the baseline parameters for inner and exposed main girders.

From Figure 3 it is observable that both the scaling factors and the maintenance strategy have a great impact on the resultant KPIs. The traditional breakdown of inner and exposed main girders returns a smaller difference in KPIs when compared to the differences between KPIs between the same element type and different deterioration properties. For any of the simulated results, for any given strategy, the following expressions hold true,

$$Cost_1 - Cost_3 < Cost_2 - Cost_1, \quad (5)$$

$$Cost_4 - Cost_6 < Cost_5 - Cost_4, \quad (6)$$

$$ATPC_1 - ATPC_3 < ATPC_2 - ATPC_1, \quad (7)$$

$$ATPC_4 - ATPC_6 < ATPC_5 - ATPC_4, \quad (8)$$

where the numeric subscript denotes the cohort identifier. From (5) and (6), it can be stated that the savings in total cost for the least aggressive cohort compared to the baseline is less than the added expense of the most aggressive cohort compared to the baseline. Similarly, from (7) and (8), the reduction in ATPC for the least aggressive cohort to the baseline is less than the increase in ATPC for the most aggressive cohort compared to the baseline. Such observations have huge importance when allocating resources in a constrained budget scenario. The difference in cost and ATPC between the least aggressive and baseline cohorts, and the difference between the most aggressive and baseline cohorts were expected not to be equal. Moreover, there are more components that feature in the less aggressive cohort than the most aggressive cohort. Consequently, it would make sense that the values obtained by the least aggressive cohort are closer to the baseline values, as the baseline cohort is ultimately an average result based on the composition of all cohorts, so will be skewed to larger cohorts.

For each cohort there is a general trend that the ATPC increases from Strategy A to B to C. However, the reduced ATPC comes at a cost, with a trend that Strategy A is the most expensive and Strategy C is the least expensive. These observed trends correspond with what engineering expertise would predict as Strategy A dictates a more regular preventative maintenance schedule.

It can be stated that the cohorts (Cohorts 2 and 5) with the most aggressive properties, i.e. CP1, M1 and TC1, return the upper limit for total cost and ATPC. Conversely, the cohorts (Cohorts 3 and 6) with the least aggressive properties, i.e. CP2, M3 and TC2, returns the lower limit for total cost and ATPC. It was expected that the least aggressive and most aggressive cohorts would act as bounds for cost and ATPC indicators. Moreover, the baseline cohorts (Cohorts 1 and 4) return values for total cost and ATPC between the two limits, which conforms with the expectation that the baseline cohorts serve as an average based on the asset composition of the calibration data.

Figure 3. Scatter plot of cost and condition KPIs, where $i-j$ denotes the Cohort ID and Strategy ID respectively.

5 CONCLUSION

The study in this paper analysed deterioration rates for main girders from metallic bridges. An initial set of deterioration rates were calibrated for the traditional cohort breakdown of underbridges/overbridges and inner/exposed main girders using condition records from the bridge inspection regime on the British railway. Statistical analysis confirmed that the inclusion of these structural properties increases the accuracy of the multiple defect deterioration model without over fitting the model due to the additional parameters.

Existing literature has shown that there are additional properties aside from the aforementioned structural properties that alter the deterioration rates of bridge components. In this study the deterioration factors of coastal proximity, component material type, bridge loading and railway line speed were considered. Commonly, properties that alter deterioration rates are identified by calibrating models by data cohort splitting, however, this typically results in the inability of including multiple factors due to data sparsity. This paper presented a novel approach to incorporate multiple deterioration factors by including the factors on a per defect basis with the defects also having causal influences. The incorporation of the deterioration factors was shown to provide a statistically significant improvement in model accuracy.

Finally, the enhanced deterioration model with the multiple deterioration factors integrated into a wider asset management Petri Net model to perform a life cycle analysis. The life cycle analysis revealed that the different deterioration factors returned quite diverse values for the considered KPIs of average total time in poor condition and average total cost. Moreover, the incorporation of the deterioration factors in the life cycle analysis enables increased decision support capabilities for asset managers by facilitating targeted intervention strategy development particularly for constrained budget scenarios and developing equitable resource allocation for different administrative regions. In future work and in the advent of additional data, additional deterioration properties may be identified and included in the metallic bridge component deterioration model. Moreover, properties may be identified for additional material types.

Quantifying the effects of long duration ground motions on the lifetime seismic losses of aging highway bridges

S. Shekhar

B. Panchireddi

Gallagher Re, Mumbai, India

J. Ghosh

Indian Institute of Technology Bombay, Mumbai, India

ABSTRACT: Despite the propensity of long duration earthquakes in subduction zones, little attention has been paid on life-time seismic loss assessment of highway bridges that are simultaneously undergoing prolonged corrosion deterioration. Consequently, this paper investigates the combined effect of ground motion duration and corrosion deterioration on lifetime seismic vulnerability and loss assessment of highway bridges. A representative case-study multi-span simply supported bridge located in Seattle is considered, where long duration earthquakes are more likely to occur. Two sets of spectrally equivalent long and short duration ground motions are considered to perform nonlinear dynamic analyses of the three-dimensional bridge analytical model. It is observed that the consideration of the effects of long duration ground motion significantly increases the failure probability of the bridge components in comparison to the short duration record set. Additionally, lifetime corrosion deterioration is found to aggravate the influence of long duration earthquakes on the seismic vulnerability of the case-study highway bridge. The seismic life-cycle cost analysis considering regional seismic hazard curve and probabilistic repair strategies reveal significantly higher seismic losses from long duration earthquakes in comparison with short duration earthquakes.

1 INTRODUCTION

Large subduction zone earthquakes in the recent past, such as those from Sumatra, Indonesia (M_w 9.1, 2004); Wenchuan, China, (M_w 8.0, 2008); Maule, Chile (M_w 8.8, 2010); Iquique, Chile (M_w 8.2, 2014), and Tohoku, Japan (M_w 9.0, 2011); have underlined the potential for substantial financial losses, as well as human casualties. Ground motion time-history records from subduction earthquakes are typically observed to be longer in duration than those from shallow crustal earthquakes and therefore could aggravate damage to infrastructure systems, such as highway bridges. Recognizing the damaging effects of long duration ground motions, in the recent past several researchers have investigated the influence of ground motion duration on the seismic vulnerability of building typologies (Raghunandan and Liel 2013; Chandramohan et al. 2016; Barbosa et al. 2017; Belejo et al. 2017). Pertaining to highway bridges, Ou et al. (2014) and Lopez et al. (2020) has demonstrated the influence of ground motion duration on the hysteretic response, displacement capacity, and failure modes of reinforced concrete bridge columns. Recently, Kabir et al. (2019) has numerically demonstrated that highway bridge component and system-level failure probabilities are more dominated by long duration records than near-fault and far-field ground motions. Despite these observations, there has been a historic lack of consideration of ground motion duration aspects towards seismic life-cycle cost analysis of highway bridge structures.

In addition to susceptibility to intermittent earthquake hazards, highway bridges may also be continuously exposed to harsh environmental conditions resulting in aging and deterioration of critical load-resisting components. Recent studies identify chloride-induced corrosion as the most common cause of environmental degradation for highway bridges. This deterioration mechanism causes significant strength degradation of critical bridge components such as columns, bearings, and bridge decks, among others, and if not properly monitored and managed, can result in a significant reduction in structural functionality and losses, particularly during extreme events such as earthquakes. Consequently, in the past decade, several studies have focused on lifetime seismic loss assessment of highway bridges under joint aging and seismic threats (Alipour et al. 2011; Ghosh and Padgett 2011; Dong et al. 2013; Dong and Frangopol 2016; Shekhar et al. 2018). While these investigations focus on the simultaneous effect of aging and earthquake loads on the lifetime seismic losses, the impact of long duration ground motions that may be critical for the structural safety of deteriorating highway bridges remains unaccounted. For deteriorating bridges, only recently, Panchireddi et al. (2021) has examined the influence of ground motion duration from subduction sources on bridge fragility, and a methodical evaluation towards seismic life-cycle cost analysis still remains unaddressed.

Addressing the gaps, this study focuses on understanding and quantifying the differences in lifetime seismic losses of aging highway bridges when subjected to long or short duration earthquake ground motions. For this purpose, a case-study multi-span simply supported highway bridge in marine splash exposure condition located in subduction earthquake zone within Seattle, U.S. is selected. Next, suites of spectrally equivalent short and long duration ground motions are adopted, followed by an incremental dynamic analysis-based framework for seismic fragility assessment of the bridge structure as it continues to age along the service life. The seismic fragility curves for the as-built and aging structure are then convolved with the regional hazard information to compute lifetime seismic losses.

2 REPRESENTATIVE CASE-STUDY AGING BRIDGE: DETERIORATION MECHANISMS AND FINITE ELEMENT MODEL

To demonstrate the influence of ground motion duration on lifetime seismic loss assessment of aging highway bridges, this study considers Seattle, Washington as the case-study region. Located within the Pacific Northwest Cascadia region, past historical events reveal that Seattle is prone to both short duration (crustal) and long duration (subduction) earthquakes. Additionally, highway bridges in the case-study Seattle region are also prone to aging and corrosion deterioration due to continuous exposure to chlorides from the Pacific Ocean. This study considers a multi-span simply supported (MSSS) concrete girder bridge for the case-study example (Panchireddi et al. 2021). This bridge type is prevalent in Washington state and accounts for more than 21% of all highway bridges in this region (FHWA 2019).

While multiple bridge components experience continuous corrosion deterioration during their design life, corrosion deterioration of reinforced concrete (RC) bridge columns significantly impact the seismic response (Andisheh et al. 2016) and hence considered in this study. Corrosion deterioration in RC bridge columns initiates after a time-gap referred to as corrosion initiation time. During this period, chloride ions progressively ingress into the concrete cover and depassivates the reinforcing steel initiating corrosion. This study utilizes the widely adopted probabilistic model proposed by Duracrete (2000) to predict corrosion initiation time that depends on concrete cover depth, chloride diffusion coefficient, equilibrium chloride concentration, and critical chloride concentration, among others. Based on the probabilistic analysis considering the uncertainty of the above-mentioned parameters from Duracrete (2000), the mean corrosion initiation time of case-study bridge columns is estimated as 10 years. Following corrosion initiation, in the propagation phase, corrosion deterioration primarily leads to reduction in the cross-sectional area of the embedded reinforcing steel along with other secondary effects such as reduction in mechanical properties of steel and concrete. The time-dependent corrosion rate for the marine-splash environmental exposure condition is adopted from the work of Vu and Stewart (2000). Figure 1 depicts the mean time-dependent degradation of the steel rebar area along

with the lower and upper limits of the uncertainty band representing 5th and 95th percentile confidence bounds. At the end of 75 years of service life, 11.3% mean reduction in reinforcing steel area is observed. Although not shown here, at the end of service life, the deteriorated RC columns also undergo 5.7%, 58.1%, 6.4%, and 76.9% mean reduction in the steel strength, ultimate strain, concrete core strength, and cover concrete strength, respectively – signifying the need to consider these secondary effects in the lifetime performance assessment of highway bridges.

Figure 1. Variation of mean reinforcing steel area with time along with the lower and upper limits of the uncertainty band representing 5th and 95th percentile confidence bounds.

A three-dimensional detailed finite element model of the case-study bridge is developed using the finite element package OpenSees (McKenna et al. 2000) incorporating corrosion deterioration effects. More details on finite element model of the case-study bridge can be found in Panchireddi et al. (2021). Note that for the deteriorated bridge, the consequences of chloride-induced corrosion, such as area loss of steel and secondary effects such as reduction mechanical properties of steel and concrete are incorporated by altering the properties of column fiber defined cross-section.

3 SUITE OF SHORT AND LONG DURATION GROUND MOTION RECORDS

To study the impact of duration on aging bridge vulnerability and loss assessment, this study adopts the short and long duration ground motion suites from Chandramohan et al. (2016). The short duration ground motion set consists of 22 orthogonal pairs of shallow crustal earthquake records from the FEMA P695 far-field accelerograms (FEMA 2009). All the 44 (22 × 2) individual ground motions are found to be relatively short with *significant duration* ($D_{S_{5-75}}$) lesser than 25 s and hence are referred as short duration ground motions (Barbosa et al. 2017; Belejo et al. 2017). Note the *significant duration* is described by the time interval over a specific range of the Arias Intensity (5–75% or 5–95% of peak value (Trifunac and Brady 1975), and has been widely regarded as an appropriate indicator to investigate the effects of ground motion duration in the past studies (Raghunandan and Liel 2013; Chandramohan et al. 2016).

For each short duration ground motion, a corresponding long duration record with $D_{S_{5-75}}$ more than 25 s and closely matched response spectra is chosen. From the past subduction earthquakes across the globe including recent Wenchuan (China, 2008), Maule (Chile, 2010), and Tohoku (Japan, 2011), among others, a total of 44 long duration ground motions are selected that are spectrally equivalent with the 44 (22 × 2) short duration ground motions. The spectral equivalent long duration ground motions are obtained based on algorithm proposed by Chandramohan et al. (2016). Figure 2(a) shows the comparison of mean response spectra of short and long duration earthquake ground motion set. It is observed that the mean response spectra of both ground motion set closely matches underlining the spectral

equivalence. It is worthwhile to note that the differences in seismic response of structures when subjected to spectrally equivalent short and long duration ground motion pair can be primarily attributed to the duration aspect alone. Figure 2 (b) shows the significant duration of two ground motion set. The $D_{S_{5-75}}$ values of chosen long duration ground motions are larger than 25 s with overall geometric mean of $D_{S_{5-75}}$ value as 63.15 s. The geometric mean of $D_{S_{5-75}}$ value of short duration ground motions is 5.32 s.

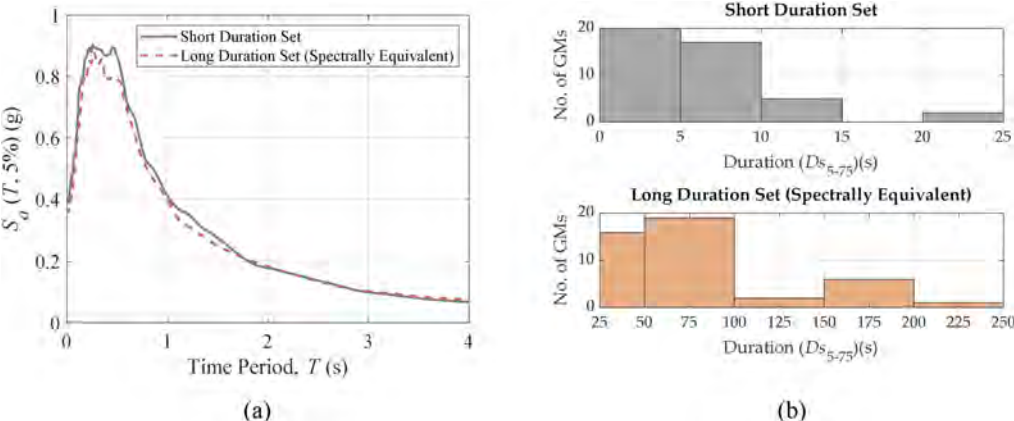

Figure 2. (a) Comparison of mean response spectra of short and long duration earthquake record sets, and (b) Histograms of the 5–75 % significant duration ($D_{S_{5-75}}$) of the ground motions in the spectrally equivalent long and short duration record sets.

4 SEISMIC FRAGILITY ANALYSIS CONSIDERING GROUND MOTION DURATION AND AGING EFFECTS

Seismic fragility curves constitute important precursors to life-cycle cost assessment of highway bridges. For both short and long duration ground motion sets, seismic fragility curves are developed at 0 years (Pristine), 25 years, 50 years, and 75 years. The bridge component fragility curve at any intermediate year (required for life-cycle analysis) are approximated using interpolation. The incremental dynamic analysis (IDA) is used to quantify seismic demand of highway bridge components. For both short and spectrally equivalent long duration ground motion sets a series of non-linear time-history analysis is performed at various scaled intensity levels and bridge components response are measured using engineering demand parameters (*EDPs*). The Park and Ang damage index (Park et al. 1985) is used as an *EDP* for bridge columns that measures seismic damage as a combination of maximal ductility demand and dissipated hysteretic energy. For bearings and abutments, maximum shear strain and maximum passive displacement, respectively are used as *EDP*. The corresponding limit states for various damage states of bridge components are adopted from past literature and reported in Panchireddi et al. (2021).

Utilizing the IDA results and limit state capacity of various damage states, the seismic fragility curves are developed for different bridge components considering short and long duration record sets. Figure 3 (a) shows the moderate damage state component fragility curves of the MSSS concrete bridge in as-built condition for short and long duration ground motion record sets. As the figure reveals, bearings are the most vulnerable component in both record sets followed by columns and abutments. In comparison to the short duration ground motion set, the long duration ground motion set results in higher vulnerability across all components. This is expected since the components will be subjected to a greater number of load reversals and energy demands for long duration records resulting in increase in damage and failure likelihood. The median fragility estimates (*PGA* corresponding to 50% failure probability denoted

as median PGA here) of moderate damage state for long duration record set are 21%, 9%, and 12% lower than that obtained from short duration record set for columns, elastomeric bearings, and abutments, respectively. Figure 3 (b) shows the combined influence of corrosion deterioration and ground motion duration on the seismic fragility curves of bridge columns for extensive damage state. As the figure reveals, both duration and aging have significant impact on the seismic vulnerability of bridge columns. The corrosion of bridge columns results in a reduction of strength and stiffness, and consequently, longer duration ground motions due to higher number of inelastic cycles cause more damage accumulation in bridge columns resulting in the increase in seismic demand and failure probability.

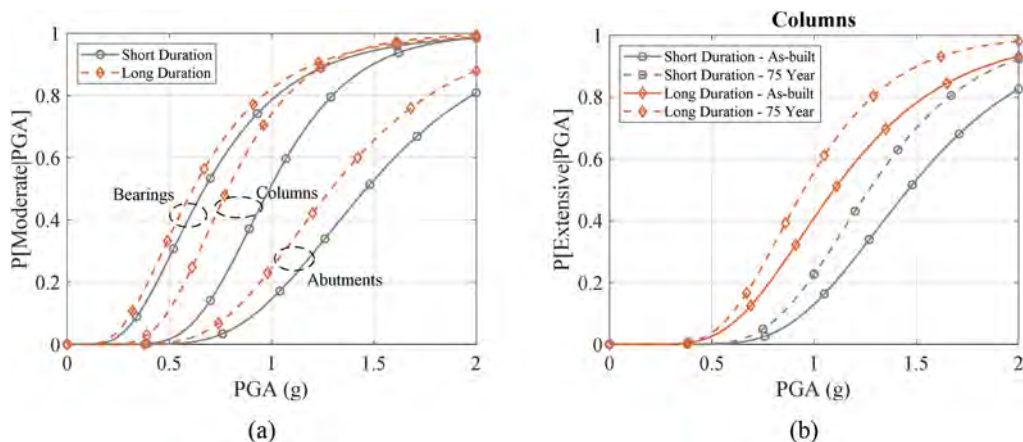

Figure 3. (a) Impact of ground motion duration on seismic fragility of as-built case-study bridge components, and (b) Joint impact of ground motion duration and corrosion deterioration on seismic fragility of as-built and 75-year-old corroded bridge columns.

5 SEISMIC LIFE-CYCLE COST ANALYSIS

Seismic life-cycle cost ($SLCC$) analysis of highway bridges requires information related to the regional hazard curves, seismic fragility of bridge structures across different damage states and associated repair cost information. The following sections first describes the seismic life-cycle cost procedure, followed by discussion on seismic hazard, adopted component repair strategies and associated cost. Finally, expected seismic life-cycle cost considering duration and aging effects is presented for the case-study bridge located in Seattle, Washington.

5.1 Seismic life-cycle cost formulation

The present study adopts a probabilistic approach introduced in Ghosh and Padgett (2011) and later improved by Sebastiani (2016) for seismic life-cycle cost estimation of aging highway bridges. This framework accounts for time-varying seismic fragility curves of bridge components, regional hazard information, uncertainty in component repair techniques and associated repair costs, and the contribution of multiple correlated bridge components to arrive at bridge system level life-cycle costs. Utilizing this methodology, for particular bridge component m the expected seismic life-cycle cost from repairs over a period of time T is computed as:

$$E[SLCC_{m,H}] = \sum_{t=1}^T \sum_{ds=1}^{DS} \sum_{j=1}^J \left[\lambda_{m,ds,H}(t) e^{-\sum_{\tau=1}^{t-1} \lambda_{m,ds,H}(\tau)} \times \frac{P(C_{m,ds,j}) C_{m,ds,j}}{(1 + \alpha)^t} \right] \quad (1)$$

where, $\lambda_{m,ds,H}(t)$ is the time-varying mean annual rate of failure for damage state ds only for hazard H (short duration crustal earthquakes, or long duration subduction earthquakes), DS is the total number of damage states for the m^{th} bridge component under consideration, $P(C_{m,ds,j})$ is the probability of choosing the j^{th} repair strategies with an associated cost $C_{m,ds,j}$, J being the total number of viable repair strategies for the bridge component for that particular damage state and α is the discount ratio to convert future costs into present values. This study considers a design service life (T) of 75 years and after-inflation risk-free discount ratio (α) of 3% to bring future costs to present values. More detail on the adopted repair strategies for different bridge components and the associated probabilities is elaborated in the subsequent section.

For rare hazard events, such as earthquakes, the mean annual rate of failure can be approximated by the annual probability of failure due to damage state ds only as:

$$\lambda_{m,ds,H}(t) = P_{m,ds,H}^{Annual}(t) - P_{m,ds+1,H}^{Annual}(t) \quad (2)$$

The annual failure probability for bridge component m in damage state ds , $P_{m,ds,H}^{Annual}(t)$ is typically calculated as a convolution between the seismic fragility and hazard curve as:

$$P_{m,ds,H}^{Annual}(t) = \int_a \left[Fragility_{m,ds,H}(t) | PGA = a \right] \left| \frac{dH(a)}{d(a)} \right| d(a) \quad (3)$$

where, $Fragility_{m,ds,H}(t) = a$ represents the probability of damage state exceedance at time t for short duration or long duration earthquakes, given the earthquake intensity $PGA = a$, and $H(a)$ is obtained from the seismic hazard information. The expected life-cycle cost of the overall bridge system is calculated as the sum of cost of individual bridge components.

5.2 Seismic hazard, component repair strategy and associated costs

The seismic hazard at a site is represented by the seismic hazard curve that quantifies the annual probability of exceedance of ground motion intensities. The seismic hazard curve of Seattle, Washington is obtained from USGS (2015) considering earthquakes from crustal and subduction sources. Note that this study considers total lumped hazard curve to obtain mean annual rate of failure and lifetime losses, for accurate seismic loss assessment future work will consider deaggregated seismic hazard curves from crustal and subduction sources. Multiple repair strategies may exist for the same level of damage to a particular bridge component following seismic events and adoption of one repair strategy over another depends on the discretion of the engineer or availability of materials, among other factors. This study considers such uncertainties in repair procedure and probability of adopting one repair strategy over another ($[P(C_{m,ds,j})]$ in Equation 1) are adopted from the web based survey conducted by Padgett and DesRoches (2007) for different critical bridge components such as columns, bearings, abutments, among others.

5.3 Expected seismic life-cycle cost

The duration-dependent time-varying seismic fragility curves for different bridge components obtained in Section 4 are used in conjunction with regional seismic hazard information and probable repair strategies and associated costs to estimate the expected seismic life-cycle cost of the aging case-study bridge. Figure 4 shows the total system-level seismic life-cycle costs of the case-study MSSS bridge for short and long duration record sets. The seismic life-cycle cost obtained from long duration record set are 62% higher than those obtained from short duration record set. A higher system-level seismic losses is expected from the long duration record sets, as case-study bridge components are more vulnerable to long duration ground motions as shown earlier in Figure 3. The figure also demonstrates the contribution of different bridge components to system-level seismic life-cycle costs, indicated by the total length of the colored bar chart. For both short and long duration ground motions record sets, elastomeric bearings

contribute most towards total losses followed by columns and abutments. These findings are consistent with the observed component-level seismic fragility curves (shown earlier in Figure 3 (a)), wherein elastomeric bearings emerge as the most vulnerable components, thereby contributing highest to the system losses. Additionally, elastomeric bearing failure potentially leads to deck unseating, resulting in substantial repair costs. The percentage contribution from columns, elastomeric bearings, and abutments towards system-level losses considering short duration ground motions record set are 10%, 88%, and 2%, respectively. These percentage contributions are 26%, 72%, and 2%, respectively, for long duration ground motions record set. It is also worthwhile to note that for both record sets, the complete damage state-induced repairs dominate the overall loss with 44% contribution towards total losses for short duration record set and 54% for the long duration record set. Additionally, for long duration record set, non-consideration of aging and deterioration in seismic life-cycle cost analysis leads to 16% and 8% underestimation in seismic losses of columns and bridge system.

Figure 4. Contribution of different bridge components to system-level losses for short and long duration ground motions record sets.

6 CONCLUSIONS

This study investigates the combined influence of ground motion duration and corrosion deterioration on seismic life-cycle costs for highway bridges. In this regard, a multi-span simply supported concrete girder bridge located in Seattle, Washington, is chosen as the representative case-study structure. Two different sets of time-varying fragility functions for short and long duration ground motions record sets are derived using the incremental dynamic analyses. The duration-dependent time-evolving seismic fragility curves of critical bridge components are convolved with regional seismic hazard information, and bridge components probable repair techniques to compute component and system-level expected seismic life-cycle costs. Results reveal a significant increase in the vulnerability and lifetime economic losses of bridge components and system under the joint consideration of long duration earthquake shock and corrosion deterioration.

The component-level seismic fragility curves indicate that long duration ground motions affect the bridge components more than short duration records. The long duration record set cause 50% probability of extensive damage for as-built columns at 24.8% lower *PGA* compared to short duration record set. For bridge columns, the combined effect of corrosion deterioration and duration significantly influences the failure probability. The percentage change in median *PGA* of extensive damage state due to the joint influence of duration and aging are 27%, 30%, and 35%, respectively, for 25, 50, and 75-year-old corroded bridge columns. Seismic life-cycle cost analysis of the case-study MSSS bridge reveals higher seismic losses from long duration earthquakes. The

system-level losses considering long duration ground motions are 62% higher than corresponding losses obtained from short duration record set. Additionally, for bridges located in subduction zones, non-consideration of long duration earthquake shock and corrosion deterioration leads to underestimation of seismic losses by 69%. Based on the above findings, for highway bridges located in subduction zones and prone to harsh environmental exposure, this study recommends the consideration of duration and aging aspects for the seismic design.

Seismic demand hazard assessment for RC bridges considering cumulative damage over time

D. Herrera & D. Tolentino

Departamento de materiales, Universidad Autónoma Metropolitana (UAM), CDMX, México

ABSTRACT: Natural disasters may significantly affect the functionality of highway transportation systems causing unacceptable socioeconomic losses. With the aim to estimate the instant at which a given damage threshold is exceeded, an approach to calculate numerical exceedance demand rates that considers the cumulative damage due to earthquakes over time is presented. The uncertainties related to mechanical and geometric properties as well as the occurrence of seismic loads are considered. The approach is illustrated on two continuous reinforced concrete bridges designed to comply with a drift threshold equal to 0.002. The systems are located in Acapulco, Guerrero, Mexico. Fragility and exceedance demand rates are estimated for different times of interest. The contribution of cumulative damage in the estimation of both fragility curves and exceedance demand rates over time is discussed.

1 INTRODUCTION

Many Mexican cities are located in earthquake-prone regions such as Mexico City and Acapulco City, making them vulnerable to infrastructure damage and devastation in terms of human lives and economic losses. Communities take years to recover from economic and social destruction caused by earthquakes. Therefore, earthquake mitigation is paramount in reducing loss of life and structural damage. To facilitate the recovery period that follows a seismic event, it is essential to estimate the damage condition from a probabilistic point of view to calculate the expected structural damage to local infrastructures. In case of reinforced concrete road bridges, it is essential to keep them at acceptable safety levels during their lifespan because they contribute to the economic growth of cities by promoting tourism, improving the response to needs or requests from communities, fostering the movement of merchandise, emergency equipment, passengers as well as the increase in surplus value in the area. In Mexico, more than 96% of all passengers are transported through the highways and 80% of the merchandise is mobilized in the country through these. The above generates about 2.5 million jobs and a contribution of 4.8% to the National Gross Domestic Product (GDP) (INEGI, 2021; INEGI, 2022).

Reinforced concrete bridges are subjected to different kind of environmental loads over time, researchers have proposed different approaches to estimate the structural performance of bridges under seismic loads using experimental and analytical techniques (Lehman et al. 2004, Yadav et al. 2017). In addition to deterministic response evaluation, probabilistic performance measures by considering uncertainty in hazard, material parameters, modeling variables and deterioration parameters have gained popularity in recent past such as seismic fragility assessment (Shinozuka et al., 2000, Nielson & DesRoches, 2007, Choe et al. 2008, 2009, Ghosh & Padgett, 2010, Pan et al. 2010). Severe damage to bridges and other vulnerable system components can cause economic losses associated with essential maintenance and repair interventions and economic consequences due to lack of network connectivity and downtime (Zhou et al. 2010; Decò et al. 2013). Bocchini and Frangopol (2011, 2012) developed a stochastic computational approach for fragility analysis and cost-based prioritization of interventions on spatially distributed bridges in transportation networks under disruptive

events. Recently, the seismic resilience of the life cycle and the vulnerability of the transportation bridge network have been studied under multiple hazards (Capacci & Biondini, 2020, Capacci et al., 2020). On the other hand, different methodologies have been proposed to consider the effect of cumulative damage over time due to seismic sequences (Cui et al. 2019; Panchireddi and Ghosh, 2019; Tolentino et al. 2020).

The probabilistic estimation of demand exceedance rates is a useful tool for decision-making and risk mitigation in structural systems, since it allows to determine the return period at which a given threshold of damage is exceeded. Various researchers have proposed different methodologies to obtain demand exceedance rates such as Mackie and Stojadinović (2001) that present an analysis of seismic demand on reinforced concrete bridges located in California. Demand exceedance rates are also estimated for reinforced concrete buildings (Liu et al. 2016). A methodology has been proposed to obtain demand hazard curves in gravity dams (Gavabar & Alembagheri, 2018). Demand exceedance rates are estimated in structural steel buildings (Maleki et al. 2019; Deylami and Mahdavi-pour, 2016; Afsar Dizaj et al. 2018).

The main objective of this article is to estimate numerical demand exceedance rates considering the effect of cumulative damage due to earthquakes over time. As observed in the cited works, demand exceedance rates are usually obtained through closed-form mathematical expressions and the possible damage caused by seismic sequences over time is not considered. Demand exceedance rates are obtained on two reinforced concrete bridges designed to comply with a drift threshold equal to 0.002.

2 DEMAND EXCEEDANCE RATES OVER TIME

The mean value of the exceedance demand rate, $v_D(d)$, proposed by Cornell et al. (2002) is extended to consider the possible cumulative damage at the instant t as follows:

$$v_D(d, t) = \int_0^t \int_0^\infty \int_0^\infty |v(\dot{y})| P(D_{seismic} \geq d|y, t) f_{D_{seismic}}(d|t) dy dddt \tag{1}$$

where $v(\dot{y})$ represents the first derivative of the mean annual failure; $P(D_{seismic} \geq d|y, t)$ is the structural fragility due to earthquakes at instant t and $f_{D_{seismic}}(d|t)$ is the probability density function of demand at the instant, t .

3 UNCERTAINTIES, SEISMIC EVENTS AND WAITING TIMES

The uncertainties related to materials construction and manufacturing processes help account for potential bias that needs to be considered when using nominal properties. Uncertainties have a significant influence on increasing or decreasing the structural response. When the structural response is expressed in terms of a reliability indicator, the system can exhibit desirable or undesirable reliability levels due to consideration of uncertainties. Table 1 shows the mechanical uncertainties of the materials. The geometric uncertainties of the structural sections are shown in Table 2. The uncertainties associated with the structural and non-structural elements are shown in Table 3.

Table 1. Mechanical uncertainties of materials.

Material	Nominal resistance (MPa)	Mean (MPa)	C.V.	Reference
Concrete	27.60	34.22	0.15	(Nowak et al. 2011)
	31.00	37.21	0.14	
	41.40	47.61	0.125	
Steel reinforcement	412	448.85	0.0369	(Rodríguez & Botero, 1995)

Table 2. Geometric uncertainties of structural elements (Ellinwood et al. 1980).

	Bias factor	C.V.
Slab elements	+7.62E-04	6.60E-03
Beams height	-5.334E-03	6.35E-03
Beam width	+2.54E-03	3.81E-03
Columns dimensions	+1.524E-03	6.35E-03
Cover	+8.128E-03	4.318E-03

Table 3. Uncertainties for structural and nonstructural elements (Nowak & Szerszen, 1998).

	Bias factor	C.V.	Distribution function
Factory items	1.03	0.08	Normal
Site elements	1.05	0.10	Normal
Asphalt	0.075*	0.25	Normal
Non-structural elements	1.03-1.05	0.08-0.01	Normal

The ground motion data set used as input for the seismic estimation has been used from two seismographic stations close to the study case (Tolentino & Carrillo-Bueno, 2018). The data set complies with 46 ground motions recorded during the past several decades. The mean epicentral distance is equal to 170.58 km and the dominant period of the soil site is around 0.51 s. The simulation of intensities of each seismic movement was carried out based on the seismic hazard curve, SHC, of the site for the fundamental period of the structure. The SHC indicates the number of times that that a certain level of intensity is exceeding per unit of time. It is assumed that the SHC of each structure is known. The simulation of intensities is carried out based on the cumulative distribution function, CDF, of the SHC as shown in the following equation:

$$F(y) = 1 - \frac{(y/y_0)^{-r}(y_{\max} - y/y_{\max} - y_0)^\varepsilon}{v_0} \quad (2)$$

where y_0 is the seismic intensity necessary to produce damage to structure; y_{\max} represents the maximum spectral acceleration in the SHC; r and ε are fitting constants of the SHC. With the aim to simulate waiting times between seismic events, it is assumed that these follow a stochastic Poisson process then, the events follow an exponential distribution (Melchers & Beck, 2017). Performing some mathematical steps on the CFD of the exponential distribution, the waiting times between seismic occurrences, T_i , are obtained as shown in the following equation:

$$T_i = - \left| \frac{\ln(u)}{v_0} \right| \quad (3)$$

4 NONLINEAR MODELLING AND CUMULATIVE DAMAGE

Structures are exposed to different environmental loads over time. If the occurrence of environmental load or solicitation is similar to the solicitation that governed the design, there is a high probability that the structure presents certain damage. The structural damage can be estimated by means of concentrated plasticity considering that plastic hinges occur at a distance close to the ends of the elements. The structure under study is modeled by using Ruaumoko 3D program (Carr, 2003). It is assumed that columns and cap beams elements provide the lateral stiffness of the system. Furthermore, the bridge deck only transmits dead loads. The modified Takeda hysteresis rule is used to estimate the plastic hinges. On the other hand, if no maintenance actions are performed after the occurrence of an intense seismic load,

the system could accumulate damage and if this process is repeated, it is probable that the system would present undesirable reliability levels in a short period of time. To identify the possible cumulative damage, the following steps show the damage accumulation process.

1. n simulated bridges are generated with simulated properties.
2. Simulation of intensities associated with n simulated models are generated.
3. $i = 1$
4. The i – th simulated intensity is associated with the n – th structural model related with an instant of interest, t . Then, the i -th simulated intensity and the $(i+1)$ – th simulated intensity are scaled by a factor $\beta_m = i_{sim}/i_T$, which is the result of the ratio between the simulated intensity and the spectral acceleration associated with the dominant period of the structure, T . The structural response is obtained by extracting the maximum drift, $D_{i,y,t}$, at the bridge deck.
5. A seismic record, $S_{k,i}$, is randomly selected and is multiplied by a scale factor, ψ_e , that produces the drift value, $D_{i,y,t}$, obtained in step 4.
6. $i = i + 1$
7. A seismic record, r_{i-1} , is associated with the $(i+2)$ – th simulated intensity and it is scaled by the factor β_m . Then, the system is subjected to two seismic loads, $S_{k,i}$ plus r_{i-1} and the maximum drift, $D_{(i-1),y,t}$, is obtained.
8. The process is repeated from step 5 to 7.

5 APPLICATION EXAMPLE

Demand exceedance rates are obtained based on two reinforced concrete bridges. The first case, referred to as case A that consists of four lanes, a height of 9 m and a total length of 175 m. Case study B is a RC bridge that consists of 4 spans with a total length of 130 m and 8 m of height clearance. Table 4 shows the dimensions and reinforcement of columns and cap beams sections of both study cases. Each system has a compressive strength, f'_c , equal to 30 MPa for columns and cap beams while a value of 45 MPa is considered for AASHTO beams. The structures are designed to comply with a drift level equal to 0.002 and these are located in Acapulco, Mexico. Case A and B reports a fundamental period equal to 0.34 and 0.28 s, respectively. It is important to mention that both case studies have five circular columns, nine AASHTO type VI beams, and a total width equal to 18.06 m.

Table 4. Geometry and design of structural elements.

Case study	Structural element	Geometry (m)	Rebar (m)	Cover thickness (m)
A	Columns	$\phi = 2$	38- ϕ 0.03175	0.05
	Cap beams	$b = 2; h = 1.4$	16- ϕ 0.0254	0.05
B	Columns	$\phi = 1.85$	34- ϕ 0.0254	0.05
	Cap beams	$b = 2; h = 1.5$	16- ϕ 0.0254	0.05

5.1 Structural demand over time

The structural demand over time is obtained by means of nonlinear dynamic analysis. Fifty bridges with simulated properties are considered for each case study. The cumulative damage is estimated using the procedure described in section 4. Different instants of time such as 0, 50, 75, 100 and 125 years are considered. Figure 1a and b show the median value of demand for different time instants for case A and B, respectively. In Figure 1a is observed that the initial ordinates of the demand increase as time progresses ($y/g = 0.10$). These initial ordinates present values of 0.00087, 0.00165, 0.00242, 0.00312 and 0.00385. This implies that for intensities equal to 0.10 y/g , the seismic demand increases by 90.51%, 178.83%, 258.67% and 342.86% for the instants of 0, 50, 75, 100 and 125 years. The above suggest that the structure experimented damage over time. For the case of the instant of 50 years at 0.20 y/g , it is

obtained a value of $\bar{D}_{|y,t}$ equal to 0.0032 thus, the pre-establish design drift threshold of 0.002 has been reached at 50 years. Besides, it is observed an increment of 184.96% from 0 to 125 years for intensities equal to 0.20 Sa/g. On the other hand, it can be observed that the collapse condition is reached when seismic intensities present values higher than 0.70 y/g. Figure 1b shows the structural demand over time obtained for study case B. Figure 1b provides the following data: a) the median demand value at 0.10 y/g is equal to 0.00088 for the case of no damage; for the subsequent time instants, an initial ordinate due to cumulative damage is noted and b) the median of the demand is equal to 0.00115, 0.00161, 0.00207 and 0.0028 for the instants of 50, 75, 100 and 125 years. This implies that the demand caused by earthquakes increases of around 31.04%, 82.66%, 134.28% and 216.95%.

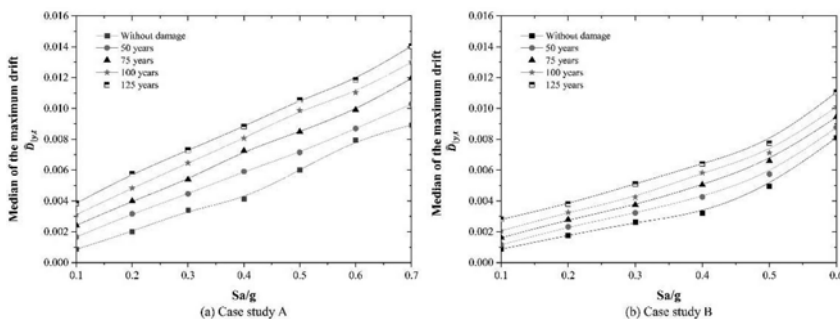

Figure 1. Median of the demand for: a) case A and b) case B.

5.2 Structural demand over time

Fragility curve over time indicates the probability of exceeding a certain level of demand at the instant t . This reliability indicator is estimated as follows (Tolentino et al. 2020):

$$P(D_{seismic} \geq d|y, t) = 1 - \Phi\left(\frac{\ln(d) - \ln(\bar{D}_{|y,t})}{\sigma_{\ln D_{|y,t}}}\right) \quad (4)$$

where $\bar{D}_{|y,t}$ is the median of the demand related to a particular damage due to earthquakes for a given intensity y at a time instant t ; d is a predefined demand threshold; $\sigma_{\ln D_{|y,t}}$ is the standard deviation of the natural logarithm of demand for an intensity y at time t . Figure 2 shows the fragility curves obtained for the case study A and B considering time instants of 0, 50, 75, 100 and 125 years associated to different drift thresholds such as 0.002, 0.004, 0.006 and 0.012. Figure 2a-d shows the fragility curves obtained for the study case A. Figure 2a shows that the probability of exceeding 0.002 is close to zero for intensities smaller than 0.10 y/g for 0 and 50 years. Besides, it is observed that for intensities greater than 0.50 y/g, the probability close to one is reached. It is important to observe that there are different initial ordinates associated with intensities of 0.10 y/g, this is due to the consideration of cumulative damage due to earthquakes over time. Figure 2b illustrates that the probability of exceeding 0.004 is reached for intensities greater than 0.65 y/g and there are probabilities close to zero for the cases of 0 and 50 years for intensities not greater than 0.20 y/g. On the other hand, Figure 2c shows that the probability of exceeding the drift threshold of 0.006 is reached after 0.70 y/g for all instants. Probabilities of exceedance close to zero are reached before 0.25 y/g for the instants of 0 and 50 years. Figure 2d shows that the probability of exceeding the drift threshold of 0.012 at any point in time is close to one. On the other hand, Figure 2e-h shows the fragility curves obtained for the study case B. Figure 4e shows that the probability of exceeding 0.002 is near to zero for y/g values minor than 0.20 at the instant equal to zero. In contrast, the probability of exceeding 0.002 is near to one for values greater than 0.55 y/g for all cases. Figure 2f shows that 0.004 is exceeded when values greater than 0.60 y/g are presented and the

probability is close to zero for the instants of 0 and 50 years for intensities not greater than 0.25 y/g. Figure 2g shows that values greater than 0.60 y/g exceedance the drift threshold of 0.006 for times of 75, 100 and 125 years. The probability of exceedance 0.006 is near to zero for values lower than 0.30 y/g for instants of 0 and 50 years. For 75 years, the probability is close to zero for y/g values less than 0.20. The greatest probability of exceeding the value of 0.012 is equal to 0.38 (see Figure 2h), this implies that there is a certain probability that the structure collapse at 0.7 y/g at any time. Based on the above, it is noticed that the case of study A is more vulnerable than the case study B, this is mainly due to differences in geometry and steel reinforcement between both cases.

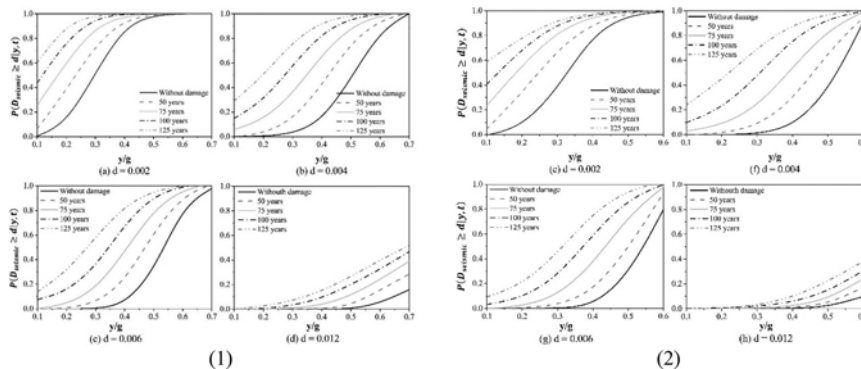

Figure 2. Fragility curves over time: (1) case study A and (2) case study B.

5.3 Mean annual demand exceedance rate over time

Demand exceedance rates indicate the frequency that a drift level is exceeded at a certain instant, t . It is essential to mention that the inverse of a demand exceedance rate is the return period, which provides information about the exceedance of a certain damage threshold in terms of time. Figure 3a and b show the exceedance rates for periods 0, 50, 75, 100 and 125 years for both cases A and B, respectively. Figure 3a illustrates the subsequent details: a) the design level (0.002) has exceedance rates equal to 0.0159, 0.0182, 0.0214, 0.0263 and 0.0314 for times of 0, 50, 75, 100 and 125 years, respectively, b) the mean annual exceedance rate increases as cumulative damage is increased over time with a mean percentage of 18.44%, c) differences of 13.97% between 0 and 50 years for 0.002 are presented. d) at the instant of 75 years, it is obtained an exceedance rate equal to 0.0214 associated with a return period equal to 46.76 years. Figure 3b shows the following information: a) the drift threshold of 0.002 present increments of 11.03%, 29.49%, 55.57%, and 83.85% for time instants of 0, 50, 75, 100, and 125 years, respectively, b) at $t = 75$ years the mean exceedance rate is equal to 0.0167 which is associated with a return period of 59.53 years, c) the mean exceedance rate of the design threshold increases up to 20.14% and 40.11% for the instants of 100 and 125 years, compared to the instant of 75 years. d) for the instant $t = 0$ years (without damage), it is observed that the exceedance rate of the drift threshold of 0.012 is equal to 0.00026 associated with a return period of 3838.78 years, which implies that the structure will not collapse under this limit state condition.

6 CONCLUSIONS

An approach to obtain numerical exceedance demand rates that consider cumulative damage caused by seismic sequences was proposed. Uncertainties associated with mechanical and geometrical properties were considered. The approach was illustrated in two continuous bridges designed to comply with a value of drift equal to 0.002. Different instants were considered to estimate the possible damage due to earthquakes over time. Fragility curves were obtained considering different time instants such as 0, 50, 75, 100 and 125 years associated to the drifts

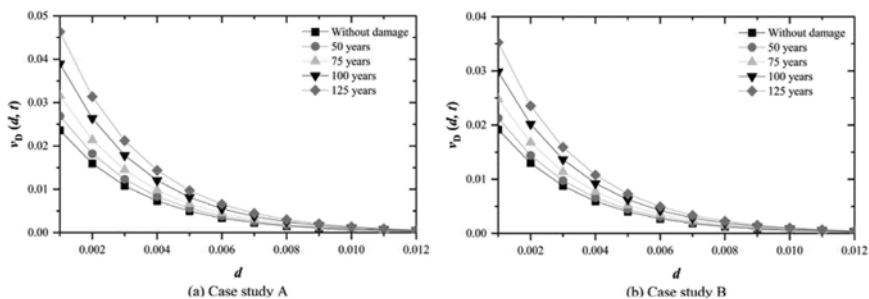

Figure 3. Demand exceedance rates over time for: a) case A and b) case B.

of 0.002, 0.004, 0.006, and 0.012. The effect of cumulative damage due to earthquakes leads the structures to present high probabilities of exceeding all drift thresholds for the intensities under study. Demand exceedance rates were determined for different instants considering drift thresholds between 0.001 and 0.012. In accordance with the recommendations of AASHTO regulations (AASHTO, 2012), the lifespan of the bridges must be guaranteed for a period of 75 years; with this, the demand seismic hazard at 75 years indicates that the design drift threshold is exceeding after 46.76 and 59.53 years for the study case A and B, respectively. The above implies that the structures have a high probability of exceeding the design drift threshold before reaching the lifespan. These does not imply that the structures will be at risk of collapse, but there is a high probability that they could present certain damage. The proposed approach allows evaluating future conditions considering the effect of cumulative damage caused by seismic loads.

The information provided by such evaluation is helpful in the decision-making process during the design of new structures. Moreover, the exceedance demand rate associated to a certain limit state indicates the reserves of structural strength that the system has in a certain instant of time. The approach can be taken as the basis for maintenance and inspection plans with the aim of preserving the structure with adequate reliability levels.

Development of maintenance systems for bridge members

K. Kwon, Y. Choi & J.S. Kong

School of Civil, Environmental and Architectural Engineering, Korea University, Seoul, Korea

ABSTRACT: Recently, the number and total length of Korean bridges are increasing aged 30 years after completion of construction. In particular, 46% of bridges are more than 20 years old, and the ratio of old bridges will surge after 10 years. In fact, the collapse of the “Seongsu Bridge” occurred in 1994, and the cause of the collapse is a failure of proper maintenance, and there is a need for an active bridge maintenance scenario. So, there is a growing social interest in bridges and infrastructure that has deteriorated. Also, studies on performance prediction and maintenance decision making of structures are underway. Therefore, the trend of increase in maintenance costs can be expected, thus more rational bridge maintenance is needed. Therefore, in this study, the condition of the bridge is predicted by using a deterioration model using bridge maintenance data in Korea so that a limited maintenance budget can be effectively utilized. And through the degradation model, a cost optimization technique is used. Therefore, it is possible to reduce the maintenance budget and support realistic maintenance decision-making model compared to the existing maintenance scenarios.

1 INSTRUCTIONS

1.1 *Background*

Currently, the number of infrastructure facilities for bridges in Korea is steadily increasing as shown in Figure 1. In addition, the proportion of aging facilities that have been used for 30 years is increasing. Therefore, social interest in the maintenance and management of bridges is currently increasing. Therefore, in the case of the Republic of Korea, it has been changed from post-preventive maintenance, which is taken in case of an accident on a bridge, to proactive maintenance, which is taken before an accident occurs. For proactive purposes, research is being actively conducted to plan maintenance in advance by collecting maintenance data and predicting the status and performance of the bridge through data analysis. However, despite the research on bridge maintenance and social interest, the SOC field budget is decreasing as shown in Figure 1. Therefore, the budget is insufficient due to the increase in maintenance costs.

In fact, a period of rapid increase in aging infrastructure is expected, and due to a lack of budget and careless management of facilities, large-scale accidents actually occurred. Representative examples in Korea include the collapse of Seongsu Bridge (1994), the collapse of the Morandi Bridge in Janova, Italy (2018), and the collapse of the arch bridge in Taiwan (2019). Therefore, in order to prevent such a large-scale accident, it is necessary to efficiently use the bridge maintenance budget in a limited budget. In this study, an optimal maintenance scenario is proposed for performing preliminary maintenance of bridges.

Using the results of the bridge performance prediction to propose an optimal maintenance scenario, a maintenance scenario was derived to derive the optimal maintenance/reinforcement time and cost converted to the present value by applying the concept of a halving rate during the target life.

Figure 1. Bridge statistics in South Korea.

The currently developed bridge optimal maintenance scenario study is as follows. (Liu, M, 2005) applied a multi-purpose optimization technique based on genetic algorithms to create maintenance plans for old bridges. (Eslam Mohammed, 2022). established bridge maintenance plans at the project level and network level through Chaotic-based optimization model. (N Erdogan, 2021) prioritized optimal maintenance plans using optimization algorithms. And recently, a study on the condition of bridges using machine learning models is being conducted. For example, (Assad, 2020) classified the state of the deck using the k-neighbor (KNN) method and the artificial neural network (ANN) method classified according to distance. Also, (Choi, 2020) uses the LSTM method to predict the performance of the concrete deck to consider the time-series characteristics of the bridge deck members.

1.2 Objectives

For the development of the optimal maintenance system for this study, the steps are composed of 4 steps and are as follows: First, we collected bridge data and inspection history information through the Korean Bridge Integrated Management System (BMS), and established a model for condition pre-diction. Second, a model was used to quantitatively evaluate the cost and effectiveness of bridge maintenance through BMS repair and reinforcement data and expert surveys. Third, to derive the optimal system-level maintenance scenario, the maintenance combination was selected by analyzing the de-pendent relationship analysis and damage correction effects of replacement with members. Finally, we propose an optimal bridge maintenance scenario using the state prediction model and the LCC model of the bridge using genetic algorithms. And we checked the efficiency compared to the existing member level evaluation.

2 BRIDGE STATUS PREDICITON MODEL

2.1 Data set

In order to perform optimal maintenance of road bridges, a bridge condition prediction model is required. Most of the recent bridge condition prediction models predict the condition with bridge inspection history data, which is a performance-based bridge maintenance method, which is mainly analyzed by the change in the performance index of the constituent members of the bridge according to the usage time. Here, the performance index means the defect index obtained by converting the condition grade obtained through inspection and diagnosis into points. The definition of the defect index is as follows and summarized in Table 1.

In addition, the bridge condition inspections evaluated by the Korean BMS are largely divided into regular inspections, precise safety inspections, and emergency inspections. The bridge inspection data used in this study predicted the condition of the bridge using precision diagnosis data.

Table 1. Definition of the defect index of bridges.

Condition state	A	B	C	D	E
Defect Index	0.1	0.2	0.4	0.7	1
Range of defects	$0 \leq X < 0.13$	$0 \leq X < 0.13$	$0.26 \leq X < 0.49$	$0.49 \leq X < 0.79$	$0.79 \leq X < 1$
Condition index	0.9	0.8	0.6	0.3	0

2.2 Prediction model of bridge member status rate

In the case of the status grade data of Korean bridges, it is widely distributed in rate B, and when all data are simply regression analyzed, there is a problem that the degradation tendency of the bridge cannot be grasped. Therefore, in this study, the result of calculating the deterioration slope over time by classifying the bridge member and span without using the state grade of the entire bridge was used. In addition, the deterioration equation was used to derive the optimal scenario for bridge maintenance.

In order to develop a model for predicting the state of the bridge used, the dependent variable of the bridge maintenance data was set as the defect index, and the independent variable was designated as the common year, and the maintenance data for each bridge member was subjected to a single variable regression analysis. At this time, the degradation rate for each member of the bridge was calculated. Regression analysis was conducted by designating the dependent variable as the degradation rate of the individual bridges of the short variable regression analysis using the calculated member-specific degradation rate, and the independent variable as the maximum span, ADTT, average humidity, and surface chloride. The multivariate regression equation used a quadratic polynomial in the univariate regression analysis, and as a result of comparing and analyzing the Cross Term effects of the variable tubes, the effects of each other are insufficient, so it is expressed as Equation 1

$$\beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \beta_4 x_4 + \beta_5^2 x_1^2 + \beta_6^2 x_2^2 + \beta_7^2 x_3^2 + \beta_8^2 x_4^2 \quad (1)$$

where x_1 = maximum span length; x_2 = average daily truck traffic(ADTT); x_3 = average humidity; and x_4 = amount of surface chloride

2.3 Cost and evaluation model for repair reinforcement

For optimal maintenance of a bridge, a model that can quantitatively predict and evaluate the maintenance costs and effects required during the life cycle of the structure is required. Therefore, in this study, a quantified model for the cost and effect of repair and reinforcement was presented. In order to calculate the expected cost according to the status index of each member, the representative repair and reinforcement method for each member was selected by referring to the BMS "Guidelines for Writing Bridge&Tunnel Survey" in Korea. In addition, using this data, a DB on the cost and effect of repair reinforcement was established through a survey by the managing director of the inspection diagnosis service and repair reinforcement report analysis. In addition, the expected cost according to the status index of each member evaluated in this study was expressed as shown in Equation 2-4 below based on the DB.

$$E(U_{ele}(c.i)) = \sum_1^n (U_{ele}^{RAM}(c.i) \times Q_{ele}^{RAM}(c.i) \times F_{ele}^{RAM}(c.i)) \quad (2)$$

where $E(U_{ele}(c.i))$ = Expected cost of unit price by condition index (c.i) of element (ele); $U_{ele}^{RAM}(c.i)$ = Unit price of representative Application Method; $Q_{ele}^{RAM}(c.i)$ = rate of representative Application Method; $F_{ele}^{RAM}(c.i)$ = Frequency of representative Application Method and n = Number of representative Application Method

$$C_{ele}(c.i) = E(C_{ele}(c.i)) \times M_{ele} \quad (3)$$

where $C_{ele}(c.i)$ = Repair and reinforcement costs; and M_{ele} = Total member quantity.

$$E(B_{ele}(c.i)) = \sum_1^n (B_{ele}^{RAM}(c.i) \times F_{ele}^{RAM}(c.i)) \quad (4)$$

where $E(B_{ele}(c.i))$ = Expected value of the state improvement index by state index (c.i) of the element (ele); and $B_{ele}^{RAM}(c.i)$ = State improvement index of Representative application method(RAM);

The expected cost of repair and reinforcement costs according to the status grade of the member can be expressed as the product of the unit price of the representative repair and reinforcement method and the frequency of application of the method to the total quantity. In the case of the total quantity applied, the difference in the status index before and after the repair and reinforcement measures was assumed, and in the case of the frequency of application of the representative method, it was calculated based on the number of applications of the public law for damage by state grade.

3 OPTIMAL MAINTENANCE SCENARIO

In order to establish an efficient bridge maintenance strategy, it is necessary to estimate the optimal bridge maintenance cost by considering the life cycle performance and cost model. Figure 2-3 is the concept of a bridge maintenance scenario using the developed degradation model. Figure 2 shows that in existing maintenance scenario, it is difficult for bridge inspectors to consider the correlation and degradation rate of each member for repair and reinforcement during the life of the structure, so it is difficult to estimate efficient maintenance costs. However, as show in Figure 3, this study analyzed the dependency of replacement by each member and the tendency of degradation acceleration due to the damage transition effect by providing a system level maintenance scenario, and selected a maintenance combination to suggest an optimal system level maintenance scenario.

Figure 2. Concept graph of existing maintenance scenario.

The existing maintenance scenario is a method of replacement or repair when repair reinforcement reaches a specific state during the target life of the structures. However, in the system-level maintenance scenario, it is necessary to consider the maintenance combination of various members rather than separately considering the maintenance of each opening member. This is because members in the upper structure of the bridge are replaced by slabs and floor plates when replacing walls, and overlapping costs such as replacing floor plates when replacing girder, and replacing bridge packaging when replacing floor plates. However, the use of system-level maintenance scenarios can be expected to eliminate duplicate costs by adjusting the timing of absent action.

Figure 3. Concept graph of System level maintenance scenario.

3.1 Development of optimal maintenance scenario

The purpose of this study is to find the repair and reinforcement time and cost to minimize the system-level life cycle cost considering the replacement fault system and damage transition effect of the members while maintaining the optimal maintenance level during the target function for optimal maintenance is as Equation 5–7.

$$RRC = \sum_{K=1}^n \frac{1}{(1+q)^{tk}} c_{ele}(c.i_k) \quad (5)$$

where $C_{ele}(c.i_k)$ = Repair and reinforcement cost function at condition index in bridge element; and q = Discount rate.

$$EC = \sum_{K=1}^T \frac{1}{(1+q)^t} c^{rins}(t) + c^{pins}(t) + c^{psdia}(t) \quad (6)$$

where $c^{rins}(t)$ = Regular inspection cost at time t ; $c^{pins}(t)$ = Precise inspection cost at time t ; and $c^{psdia}(t)$ = Precise safety diagnosis cost at time t .

$$LCC_{ele}(C.I) = \sum_{K=1}^n \frac{1}{(1+q)^{tk}} c_{ele}(c.i_k) + \sum_{K=1}^T \frac{1}{(1+q)^t} c^{rins}(t) + c^{pins}(t) + c^{psdia}(t) \quad (7)$$

where $LCC_{ele}(C.I)$ = Maintenance costs for the target lifetime.

Using the optimization method, the optimal maintenance concept is shown in Figure 4. Figure 4 shows the optimal maintenance scenario flow chart and constraints using the GA method.

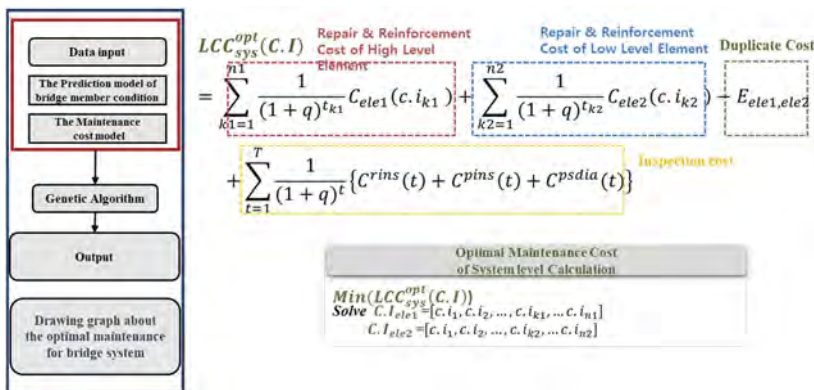

Figure 4. Optimal algorithm for bridge maintenance about time point and cost using G.A.

4 APPLICATION OF GENETIC ALGORITHM

This section describes the optimization method that is applied to the planning problem of maintenance measures based on cost minimization and quality maximization. In this study, GA optimization be adopted for the combination problem due to the large number of combinations. And Ga is maintains a population of candidate solutions for the problem at hand, and makes it evolve by iteratively applying a set of stochastic operators. In addition, as illustrated global minimum (or maximum) can be achieved well because it does not use gradient methods unlike other existing optimizations. As show in Figure 5 is GA Basic structure.

Figure 5. Genetic Algorithm of basics structure & Concepts.

5 VERIFICIATION OF OPTIPMAL MAINTENANCE COST

This chart Compare the existing maintenance costs with the optimal maintenance costs at the single element level. The life cycle costs are the sum of the repair & reinforcement cost, inspection cost and so on, but the study will only perform an analysis of t he repair and reinforcement costs. Existing maintenance costs were calculated by assuming that improvement action were carried out on specific conditions. The optimal maintenance costs were calculated the condition index at the point of repair and reinforcement that minimizes the life cycle cost.

In this study target bridge is Samseong Bridge. The bridge is a steel box girder bridge, and total span length is 53 meters and width 24 meters, location is Deoksan-myeon, Yesan-gun, Chungcheongnam-do, Republic of Korea and Traffic passage is National Road (Opening: 2007. 12.21). Input values for concrete deck and Asphalt Pavement include deterioration rate, cost model and total volume.

6 PROPOSAL OF MAINTENANCE SCENARIO AND VERIFICATION OF OPTIMAL MAINTENANCE COST

6.1 *Optimal maintenance cost (Concrete deck)*

Compare Existing Maintenance Scenario costs and Optimal Maintenance Scenario Costs. Figure 6 shows the different maintenance systems about Concrete Deck. blue line is the existing management maintenance scenario for the concrete deck. It is assumed that current maintenance is carried out in the status grade (C), It is assumed that current maintenance is carried out in the status grade (C). a target life is 100 years and a discount rate of 2%. because The discount rate was set to 1.01 % by reflecting the actual discount rate for a decade by Economic Statistics System (ECOS) in the bank of Korea. In conclusion, using the LCC Cost Model, we calculated the total cost. Existing Maintenance Cost is 260,312,000 KRW, and Optimal Maintenance Cost of Element Level is 196,771,157 KRW and The optimal scenario is that when the condition index(B) is reached, the reinforcement, occurs approximately 50 years after the replacement occurs. Finally, Cost Efficiency of Optimal Maintenance Cost (Element Level) is 24%. so it is possible to predict 24% cost savings through optimal preventive maintenance at element level

Figure 6. Compare existing maintenance cost and optimal maintenance cost (Concrete deck).

6.2 Optimal maintenance cost (Pavement)

Compare Existing Maintenance Scenario costs and Optimal Maintenance Scenario Costs about Asphalt Pavement. Figure 7 shows the different maintenance systems about Concrete Deck. as well as blue line is the existing management maintenance scenario for the concrete deck. Also, it is assumed that current maintenance is carried out in the status grade (D), It is assumed that current maintenance is carried out in the status grade (D), Element replacement if less than 0.35 is reached, a target life is 100 years and a discount rate of 2%. ratio of deterioration rate(α) is 20%. Finally, Compare the two scenarios, the Existing Replacement were performed 11-year cycle and the optimal Replacement 15.4year cycle except for the last cycle. And existing maintenance cost is 195,688,000 KRW and Optimal Maintenance Cost of Element Level is 176,255,000 KRW therefore, Cost Efficiency of Optimal Maintenance Cost of Element Level is 10%. So, it is possible to predict 1cost savings through optimal preventive maintenance at element level.

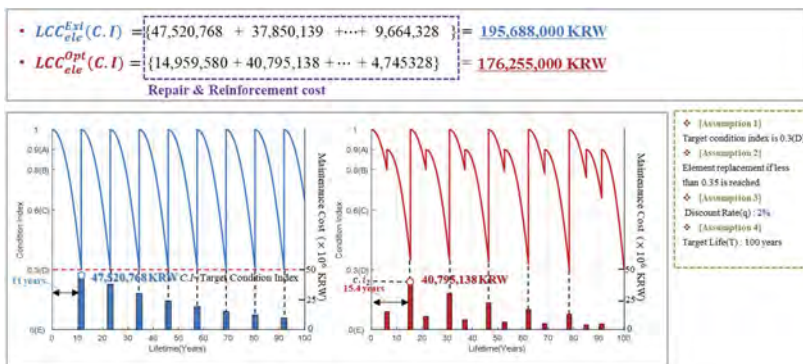

Figure 7. Compare existing maintenance cost and optimal maintenance cost (pavement).

7 CONCLUSIONS

In this study, a maintenance scenario was proposed using optimization methods. In this study result is expected to reduce the repair and reinforcement costs caused by non-optimized maintenance plans. For examples, Using the GA algorithm, we confirm that the optimal maintenance scenario cost is 18.81% less than the existing maintenance scenario cost of concrete deck & asphalts pavements. So, it was found that the optimization method using optimal algorithm is effective. And if updating deterioration model of the optimal maintenance scenario with the Rating profile obtained from the actual inspection is expected to be a more reliable algorithm.

Durability analysis and optimization of a prestressed concrete bridge strengthened by a fiber reinforced concrete layer

Institute for Structural Analysis, Karlsruhe Institute of Technology, Germany

ABSTRACT: The durability of reinforced concrete (RC) structures is influenced by uncertain service loads and material properties, which must be taken into account in service life-oriented structural design. The consideration of aleatory and epistemic uncertainties allows probabilistic service life predictions in the context of service life design, replacing the classical safety factors.

In the context of this article, the service life of a prestressed concrete bridge strengthened with a fiber reinforced concrete (FRC) layer is to be maximized. The L3378 bridge near Fulda-Lehnerz in Germany will be used as a reference structure. The bridge consists of four prefabricated prestressed RC girders with T-girder cross-section, supplemented by an RC layer and an additional FRC layer. The FRC layer is made of ultra-high-performance fiber reinforced concrete (UHPFRC) and is intended to increase the load-bearing capacity while also serving as a waterproofing layer.

For the optimization, finite element simulations are performed to determine the most sensitive parameters. The fiber orientation of the UHPFRC layer, the prestressing force and position, the bond between concrete and steel, and the material properties are investigated, and then the most sensitive parameters are applied as uncertain parameters for the maximization of the service life, while the cost of material is to be minimized. Although the reference structure is build new, the presented design approach is also applicable to the strengthening of existing structures to extend their service life. For this reason, the original design is finally compared with a conventional design without FRC layer in terms of failure probability considering stochastic live loads and polymorphic uncertainties.

1 INTRODUCTION

Reinforced and prestressed concrete bridges are designed for a long service life, but often have to be repaired at an early stage due to excessive cracks. One way to minimize these cracks, is the use of alternative materials such as fiber-reinforced concrete (FRC). FRC combines conventional concrete with randomly oriented fibers added during the mixing process. These fibers improve the concrete ductility after cracking, which is traditionally remedied with reinforcement. FRC can be specifically customized to meet particular requirements due to different fiber materials including steel, glass and carbon fibers, different fiber geometries such as microfibers or macrofibers with different anchorage, different fiber content, and a variety of concrete mixture (Holschemacher et al. 2017). One example is the bridge L3378 near Fulda-Lehnerz in Germany, which is strengthened by an additional thin ultra-high-performance fiber reinforced concrete (UHPFRC) layer, while the rest of the cross-section consists of reinforced normal weight concrete (RC). This UHPFRC layer consists of an ultra-high strength concrete with steel micro fibers (Pelke et al. 2018). Difficulties arise in the design of bridges with FRC, because there are currently no adequate design codes for the design of bridges with FRC structures. For this reason, within the scope of this paper, a reliability design optimization approach considering polymorphic uncertainties (Edler et al. 2019) is applied to reduce the required steel reinforcement. Aleatory uncertainties are characterized by a known variability given by a large number of data, and therefore, are modeled by stochastic

distributions. However, if only a few data is available, i.e. a lack of knowledge (e.g. the fiber orientation), it is called epistemic uncertainty and modeled by intervals or fuzzy numbers (Möller & Beer 2008). In the context of this paper, aleatory and epistemic uncertainties are intended to replace classical safety factors. For the optimization, a multilevel model is utilized for the analysis of FRC structures, whereby the influence on the structural response can be directly evaluated based on a selected fiber type, content and orientation (Zhan & Meschke 2016). The post-cracking behavior of plain concrete (PC), RC, and FRC structures using finite element (FE) analysis is described by a discrete crack approach using interface elements (Ortiz & Pandolfi 1999). The post-cracking behavior is derived from the tensile separation law for the particular material.

2 MATERIAL MODEL FOR REINFORCED CONCRETE AND FIBER REINFORCED CONCRETE

A discrete crack finite element model (Ortiz & Pandolfi 1999) is utilized to model the cracking behavior of concrete under tension. This model is characterized by cohesive interface elements, which are inserted between linear-elastic triangular finite elements (i.e. bulk elements). The fracture behavior of plain and fiber reinforced concrete is modeled by the sum of two separate nonlinear traction-separation laws $t = t^{\text{concrete}} + t^{\text{fibers}}$ within the integration point of each of the interface element.

2.1 Material model for plain concrete

Considering the behavior of plain concrete with exponential softening first, we obtain the following traction-separation relationship

$$t^{\text{concrete}}(\omega) = f_{ct} \exp\left(-\frac{\omega f_{ct}}{G_f}\right), \quad (1)$$

where ω is the effective crack separation (Gudzucic & Meschke 2021), f_{ct} the tensile strength and G_f the fracture energy.

2.2 Extension for fiber reinforced concrete

Once cracks initiate in FRC, fibers provide a bridging traction acting on the crack faces to keep the crack width small. This is considered via the traction-separation relationship $t^{\text{fibers}}(\omega)$, which takes also the fiber orientation and the fiber geometry into account. This traction-separation relationship is determined by integrating the pullout force-displacement relations $F(\omega, \theta, \tilde{x})$ of all crack-bridging fibers, taking into account their inclination to the crack surface θ and the embedding lengths \tilde{x} . This results, according to Wang et al. (1989), in a function of the smeared fiber pull-out forces

$$t^{\text{fibers}}(\omega) = \frac{c_f}{A_f} \cdot \int_0^{L_f/2} \left[\int_0^{\arccos(2\tilde{x}/L_f)} F(\omega, \theta, \tilde{x}) p(\theta) d\theta \right] p(\tilde{x}) d\tilde{x}, \quad (2)$$

where c_f describes the volume fraction A_f and L_f the fiber cross section and the fiber length, respectively, and $p(\theta)$ the probability density of the fiber orientation. The spatial orientation of the fibers depends on the dimensions of the structural component and the casting direction. In order to take these factors into account, a method to calculate the probability density $p(\theta)$, based on a given fiber orientation profile $\lambda_{\text{cast}} = [a, b, c]$ was developed in Zhan & Meschke (2016). Here, an ellipsoid represents the spatial preference of fibers in the global coordinate system (Figure 1, center). It should be noted that an isotropic fiber orientation is described graphically by a sphere with the fiber orientation profile $\lambda_{\text{cast}} = [0.33, 0.33, 0.33]$. Considering a homogeneous fiber distribution, within the structural component, $p(\tilde{x})$ is equal to $\frac{L_f}{2}$ (Wang et al. 1989). Since obtaining the traction-separation relationship of the fiber-reinforced

concrete can only be evaluated numerically, it is replaced within the FE model by an analytical, parameterized surrogate function

$$t^{\text{fibers}}(\omega) = t_1 \left(\omega_u - \frac{\omega}{\omega_u} \right) + t_2 \omega \exp(c_1 - c_2 \omega). \quad (3)$$

The coefficients t_1, t_2, c_1, c_2 are determined by fitting the surrogate function to the numerical evaluation of Eq. 2 and ω_u represents the ultimate crack opening.

Figure 1. Multi-level modelling of FRC. Integration of the pull-out response of all fibers crossing a representative crack and considering their orientation to calculate the traction-separation law.

2.3 Embedded rebar model

The reinforcement is considered by a discretization-independent embedded rebar model with geometrically linear truss elements. The properties of steel are taken into account with an elastoplastic material behavior using the v . Mises yield criterion with linear hardening. The interaction between reinforcing steel and concrete is considered with a bond-slip law using the *fib* Model Code 1990. The internal force contribution of the reinforcement slip with respect to the bulk matrix is penalized to enforce a displacement constraint between the rebar and the concrete (Gall et al. 2018).

3 BRIDGE WITH ULTRA-HIGH-PERFORMANCE CONCRETE LAYER

The bridge L3378 has a standard RQ 11 cross-section with two lanes and a width of 8.0 m. The structure replaces a two-span, flat-founded reinforced concrete slab girder from 1967, whose condition rating had dropped to 3.5 in the last structural inspections. A repair was not economical due to the continued increase in traffic load. The new design includes the two-span prestressed concrete deck with span widths of 17.10 m and 20.41 m and a total static height of 1.05 m. The cross-section contains three different horizontal components. The base consists of 2 single-span girders, each consisting of four T-shaped precast prestressed concrete girders of strength class C45/55 with a height of 0.85m (see Figure 2a). The precast concrete is supplemented by a 0.13m thick in-situ concrete of strength class C35/45. The cross-section is finished horizontally at the top with a 0.07m thick reinforced ultra-high-performance reinforced concrete (UHPRC) layer strengthened with steel microfibers (Pelke et al. 2018). The final bridge is presented in Figure 2b and the material properties are listed in Tables 1 and 2.

3.1 Sensitivity analysis

Since usually a large number of realizations is needed for probabilistic service life prediction, the bridge is reduced to a 2D model with a constant line load of $q = 100$ kN/m. The microfibers in the top layer are used to limit the cracks at the middle support, but this is only possible if the fibers are aligned longitudinally to the beam. The fiber orientation is considered by a spherical distribution of the probability density function $p(\theta)$ (see Eq. 2), with the orientation profile $\lambda_{cast} = \left[\lambda_f, \frac{1-\lambda_f}{2}, \frac{1-\lambda_f}{2} \right]$. The semi-major axis λ_f is modeled as an interval $\lambda_f = [0.30, 0.45]$. This interval bandwidth is based on the experimental results of Tiberti et al. (2018), where 140 equally sized bending beams with two different casting processes were examined with respect to their fiber orientation within the cross section. The measured inclination between 53.1° and 34.9° corresponds to the fiber orientation parameter λ_f in the range of 0.30 to 0.45.

Figure 2. Schematic representation of the bridge a) in the first state of construction and b) in the final state of construction.

Table 1. Material properties of concrete.

Property		C45/55	C35/45	UHPC	HPC	Unit
Young's modulus	E	36,000	34,000	50,000	40,000	[N/mm ²]

Table 2. Material properties of steel.

Property		St1570/1770	B500	Unit
Young's modulus	E	195,000	200,000	[N/mm ²]
Yield stress	σ_{ys}	1770	500	[N/mm ²]

In Figure 3a), the maximum crack width w_{max} at the top edge of the cross-section is plotted as a function of the applied load q for different cases of fiber orientation within the UHPRC layer. Contrary to expectations, the fiber orientation has an influence on the initiation of the cracks at the top edge. This is due to the fact that the in-situ concrete layer has a significantly lower tensile strength than the fiber-reinforced concrete layer, and thus, the in-situ concrete layer starts to crack first (see Figure 4b)). Consequently, the crack starts in the middle of the cross-section and grows towards the top. Especially with horizontal fiber orientation ($\lambda_f = 0.45$), this crack propagation is limited through the fibers. However, as soon as the crack reaches the upper edge, the fibers can hardly limit the crack width, since even with horizontal fiber orientation ($\lambda_f = 0.45$), the crack width increases rapidly. Nevertheless, the maximum allowable crack width of $w_{crit} = 0.2$ mm according to Eurocode 2 is maintained for all three cases at the design load of $q = 100$ kN/m.

Beside the fiber orientation, the crack width may be influenced by other effects, e.g. an increase in the design load or a decrease in the prestressing force. Both scenarios are likely to happen in reality. For example, due to creep and shrinkage of the concrete, the prestressing force is time-variant, i.e., not equal to the initially applied prestressing force. This loss depends on various factors such as the age of the concrete, temperature and humidity during prestressing. For simplicity, according to the design guidelines (Eurocode 2) for this structure, a prestressing loss of 15% may be considered. To illustrate the influence of the prestressing loss, the maximum crack width w_{max} is plotted as a function of the applied load q for $\lambda_f = 0.45$ and $P_{loss} = 15\%$ in Figure 3 a), as well. Here, even for a horizontal fiber orientation ($\lambda_f = 0.45$) at the design load of $q = 100$ kN/m the maximum crack width $w_{cr} = 0.27$ mm is clearly above the maximum allowable crack width of $w_{crit} = 0.2$ mm (Eurocode 2).

In the following, an alternative design (variant B) will be investigated. In order to better emphasize the positive effects of fiber-reinforced concrete, the upper two layers are combined,

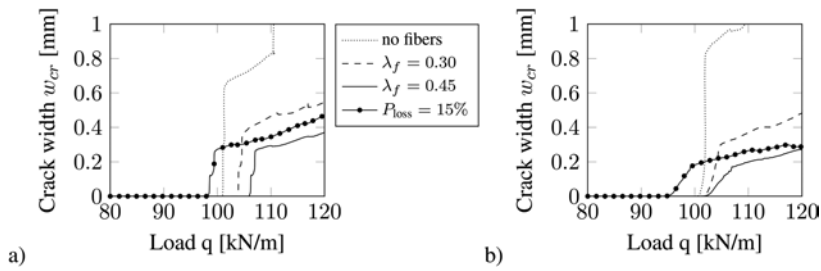

Figure 3. Crack width depending on the load for different fiber orientation and different prestressing force for a) variant A and b) variant B.

Figure 4. Illustration of crack initiation of variant A.

Figure 5. Illustration of crack initiation of variant B.

meaning the bridge consists of the prestressed precast beam and a 0.2 m thick fiber-reinforced HPC layer (see Figure 5a). The material properties are summarized in Table 1. Since fibers with hook end are able to limit the crack width even better than normal fibers or microfibers, for variant B steel fibers of type DRAMIX 60 are utilized. The use of such steel fibers in HPC has already been validated in Gudzulic et al. (2020). In Figure 3b), the maximum crack width w_{max} is plotted as a function of the applied load q for the same scenarios as for the original design (variant A). In variant B due to the significantly lower tensile strength compared to variant A, cracking begins at a lower applied load q . However, especially in case of fibers with horizontal orientation ($\lambda_f = 0.45$), the crack width is limited even at a higher loads. Moreover, with horizontal fiber orientation ($\lambda_f = 0.45$) and a prestressing loss of $P_{loss} = 15\%$, the maximum crack width ($w_{cr} = 0.18$ mm) is beneath the maximum allowable crack width of $w_{crit} = 0.2$ mm at the design load of $q = 100$ kN/m.

3.2 Reliability design optimization

In the following, a reliability design optimization is performed for variant A and variant B considering uncertainties in loading, prestressing loss and fiber orientation. In addition, a reliability design optimization for a third variant (variant B0), which investigates the influence of fibers on the objective function, is performed. For this purpose, variant B was modeled without fibers. In other words, for variant B0 all material properties and layer thicknesses correspond to those of variant B and only the top layer is high performance concrete (HPC), instead of a high performance fiber reinforced concrete (HPFRC). Due to more steel fibers in variant B compared to variant A and variant B0, the aim is to reduce the steel reinforcement, to save costs, by still maintaining the serviceability. The objective is to minimize the total steel reinforcement A_s at the

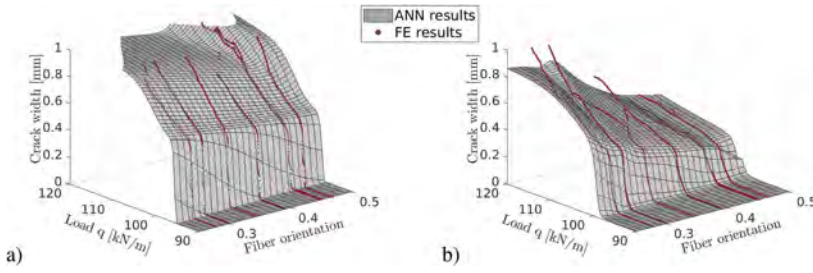

Figure 6. Crack width depends on the load and the fiber orientation for a fixed prestressing loss of $P_{loss} = 10\%$ and amount of reinforcement of $A_{s1} = 18\text{Ø}16\text{mm}$, $A_{s2} = 14\text{Ø}14\text{mm}$ and $A_{s3} = 0$ for a) variant A and b) variant B.

middle support by constraining the failure probability, which is based on a maximal acceptable crack width of $w_{cr} = 0.2\text{mm}$. This can be formulated for variant A and B as

$$\begin{aligned} \min : \quad & \hat{Z}(A_s) = A_s \\ \text{s.t. :} \quad & c(A_s, q, \lambda_f, P_{loss}) = P_f(\omega_{cr}(A_s, q, \lambda_f, P_{loss}) \leq 0.2) - P_{f,acc} \leq 0, \end{aligned} \quad (4)$$

and for variant B0 as

$$\begin{aligned} \min : \quad & \hat{Z}(A_s) = A_s \\ \text{s.t. :} \quad & c(A_s, q, P_{loss}) = P_f(\omega_{cr}(A_s, q, P_{loss}) \leq 0.2) - P_{f,acc} \leq 0. \end{aligned} \quad (5)$$

In Eq.4 and 5, the accepted probability of failure is described by $P_{f,acc} = \Phi(-\beta)$, where Φ is the cumulative distribution function of the standard normal distribution and β is the reliability index, which is set to be $\beta = 1.5$ in case of serviceability, according to DIN EN 1990. The load q and the prestressing loss P_{loss} are described as a priori, random variables, using Gaussian distributions with different mean values $\mu(q)$ kN/m and variance $\sigma(q) = 1$ kN/m for the load and a mean value $\mu(P_{loss}) = 10\%$ and variance $\sigma(P_{loss}) = 1\%$ for the prestressing loss. One optimization was performed for each of the various mean values of the load to investigate the influence of the load on the optimal amount of reinforcement. The fiber orientation parameter is considered as an interval $\lambda_f = [0.30; 0.45]$ for variant A and B. The total steel reinforcement is the sum of the support reinforcement $A_s = A_{s1} + A_{s2} + A_{s3}$ (see Figure 4 a) and Figure 5a)), where A_{s1} is kept constant as a minimum of $A_{s,min} = A_{s1} = 18\text{Ø}16\text{mm}$ is needed according to the design guidelines, while A_{s2} and A_{s3} are within the interval $[4\text{Ø}8\text{mm}; 18\text{Ø}16\text{mm}]$. This range was chosen since, considering the existing cross-section width of 2.85 m, it is not reasonable to place less than four rebars in one row and $18\text{Ø}16\text{mm}$ per row is the existing amount of reinforcement of Variant A. For the optimization, the Particle Swarm Optimization (PSO) (Kennedy & Eberhart 1995) is applied with an extension to consider aleatory and epistemic uncertainties (Edler et al. 2019).

For the optimization, the FE simulations performed for each variant, is replaced by artificial neural networks (ANN) with feed forward architecture to speed up the computation time (Freitag et al. 2020). For all three variants, the same 150 models are generated, using Latin hypercube sampling (LHS) of prestress loss and amount of support reinforcement. In addition, for variant A and B the fiber orientation has been sampled as well. For variant A and B, an ANN with four input parameters (λ_f , P_{loss} , A_s and q), two layers with 10 and 5 hidden neurons and one output neuron w_{cr} (4-10-5-1) is sufficient to approximate the FE simulations with an accuracy of $R = 0.992$ for variant A and $R = 0.989$ for variant B, respectively. For variant B0, an ANN with three input parameters (P_{loss} , A_s and q), two layers with 8 and 4 hidden neurons and one output neuron w_{cr} (3-8-4-1) is adequate to approximate the FE simulations with an accuracy of $R = 0.908$. At this point, it should be noted that it is ensured that all ANN provide sufficiently accurate results especially in the range $w_{cr} \leq 0.2\text{mm}$, for subsequent optimization.

Figure 6 presents the results obtained by the ANN and the FE simulations for crack width versus fiber orientation and load for variant A (a) and B (b). It may be observed that the fiber orientation influences the crack width in variant B significantly more than for variant A, while the crack width increases for variant A at smaller load than for variant B independent of the fiber orientation.

3.3 Results

For a better illustration, the total amount of steel (sum of steel reinforcement and steel fibers) is presented in Figure 7 as the steel weight m rather than the area of steel A_s . In Figure 7a), the minimum required weight of steel reinforcement m_{rebar} , for which the constraint is fulfilled ($w_{\text{cr}}(A_s, q, \lambda_f, P_{\text{loss}}) \leq 0.2 \text{ mm}$), is given as a function of the mean value of the load, for variant A (black) and variant B (purple) for $\lambda_f = 0.30$ (dashed line) and 0.45 (solid line), for each variant and also for variant B0 (dotted line). The maximum load, at which the constraint is still fulfilled, is marked with a circle.

For variant A, the amount of reinforcement barely depends on the fiber orientation and much more one the mean value of the load. Only the minimum reinforcement is required, up to a mean value of the load of $\mu(q) = 93.2 \text{ kN/m}$ for $\lambda_f = 0.30$ and $\mu(q) = 93.5 \text{ kN/m}$ for $\lambda_f = 0.45$. With further increase in the load, the required amount of reinforcement increases, the maximum amount of reinforcement is required for $\lambda_f = 0.30$ at $\mu(q) = 98.0 \text{ kN/m}$ and for $\lambda_f = 0.45$ at $\mu(q) = 99.2 \text{ kN/m}$. At higher mean value of the load, the constraint ($w_{\text{cr}}(A_s, q, \lambda_f, P_{\text{loss}}) \leq 0.2 \text{ mm}$) is not fulfilled anymore. This means that, even with optimal fiber orientation, the serviceability limit state is not met at the design load of $q = 100 \text{ kN/m}$, if uncertain loads and prestressing losses are taken into account.

For variant B, the minimum required amount of reinforcement is influenced by the fiber orientation and the mean value of the load. Only the minimum reinforcement is required, up to a load of $\mu(q) = 96.2 \text{ kN/m}$ for $\lambda_f = 0.30$ and $\mu(q) = 99.3 \text{ kN/m}$ for $\lambda_f = 0.45$. With further increasing mean value of the load, variant B requires rapidly more reinforcement for fiber orientation of $\lambda_f = 0.30$ as the the maximum amount of reinforcement is required at $\mu(q) = 99.4 \text{ kN/m}$, while for $\lambda_f = 0.45$ the maximum amount of reinforcement is not required until $\mu(q) = 103.5 \text{ kN/m}$. Consequently, the serviceability limit state is met for variant B, with consideration of uncertainties, for the design load as well as for higher mean value of the load but only for a good fiber orientation of $\lambda_f = 0.45$. Finally, comparing variant B and variant B0 (without fibers), it can be observed that, especially with a small amount of reinforcement, the fibers contribute significantly to the crack width reduction for any fiber orientation. If more reinforcement is required due to the load, the function of variant B rises just as quickly as one with fiber orientation $\lambda_f = 0.30$.

In Figure 7b), the minimum required total weight of steel ($m_{\text{tot}} = m_{\text{fibers}} + m_{\text{rebar}}$, where $m_{\text{fibers,A}} = 1.06 \text{ t}$, $m_{\text{fibers,B}} = 1.21 \text{ t}$ and $m_{\text{rebar}} = m_{\text{As,1}} + m_{\text{As,2}} + m_{\text{As,3}}$) is given as a function of the mean value of the load. Here, it can be seen that variant B is the most economical choice for a mean value of the load higher than $\mu(q) = 94 \text{ kN/m}$, if it can be ensured that $\lambda_f = 0.41$. Meaning, if a horizontal fiber orientation can be ensured, due to the casting process, and thus the interval range of the fiber orientation can be reduced to $\lambda_f = [0.41; 0.45]$, variant B is to be preferred.

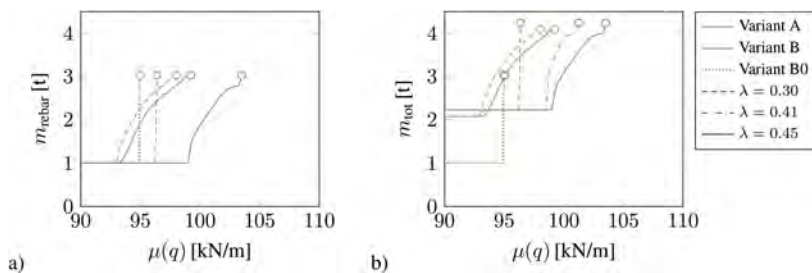

Figure 7. Optimization results for a) Weight of required reinforcement for different mean value of the load and b) Total weight of steel for different mean value of the load.

4 CONCLUSION

In this contribution, a prestressed bridge strengthened with fiber-reinforced concrete was investigated with respect to its maximum crack widths. It was observed that due to different types of concrete, cracks occur within the cross-section already at loads smaller than the design load. For this reason, an alternative cross-section of only two instead of three different concrete types has been presented (variant B). Variant B consists of a thicker fiber concrete layer with fewer but larger fibers, which significantly reduces the crack widths. In addition, less steel reinforcement is needed for the same load, and thus reducing the total amount of steel. In the next step, in addition to the cracks above the support, the cracks in the field should also be investigated, as well as the load-bearing capacity of both variants. Moreover, it would also be possible to add the concrete layer thickness as additional design variable in order to also optimize the required concrete material volume.

ABSTRACT: Aging civil infrastructure and increasing traffic loads lead to deteriorating assets and the need for regular manual inspections, which generally entail at least partial closure of the asset and operational downtime. These costly inspections can be overcome by employing autonomous unmanned aircraft systems (UAS) to carry out the required inspections. Utilizing a variety of sensor configurations, AI-based analysis, and data fusion through a web-based interface, more objective comparisons between infrastructure assets can be obtained quickly. Within the dtcc.bw-MISDRO project the Norderehbbrücke of the German Autobahn, Freihafenelbbrücke of the Hamburg Port Authority, a railway bridge over the river Oste from Deutsche Bahn and a barrage over the river Weser from the German Federal Waterways and Shipping Authority are to be inspected via UAS with visual cameras, lidar, hyperspectral imaging and further sensors to detect typical steel defects. In this paper the planned non-destructive testing methods for automatic defect detection, the automatic path planning, and the design of the UAS are presented.

1 INTRODUCTION

Germany's federal infrastructure network contains approximately 52,000 motorway bridges, 26,000 railway bridges and 2,300 hydraulic structures. Every three years, these structures are subjected alternately to a major inspection and a minor inspection to check for damage and defects in the structure and ensure that they are safe for traffic. The result is a condition score between 1.0 and 4.0; a score of 1.0 corresponds to a very good structural condition and a score of 4.0 corresponding to an unsatisfactory condition with an immediate need for action. Many structures are in poor condition due to their age and the sharp increase in heavy goods traffic. Currently, the condition rating for 17 % of federal motorway bridges, 35 % of railway bridges and 75 % of hydraulic structures is 3 or worse (Bundesanstalt für Straßenwesen, 2021; Bundesanstalt für Wasserbau, 2018; DB Netz AG, 2022). The inspection of the structures is carried out by specially trained civil engineers, using inspection equipment, elevated work platforms, pier access equipment and road-rail vehicles for support. This process requires a section-by-section closure of the structure, leading to increased traffic delays, worker danger, and significant economic losses. Each infrastructure operator in Germany has their own inspection guidelines and building management system. DIN 1076 is the standard norm for inspection of infrastructure and influences the guidelines for train bridges and hydraulic structures (DIN, Normenausschuss Bauwesen, 1999). Unmanned aircraft system (UAS)-based inspection techniques offer the potential to drastically reduce the economic impact of the inspections, as aerial inspection can be performed without interfering in the operation of the asset and the technology can inspect significantly larger areas per unit of time

than a human inspector. In addition, the subsequent algorithm-based analysis makes the evaluation more objective and independent of the individual inspector. In the dtcc.bw project MISDRO, a joint-research project by the Helmut-Schmidt-University/University of the Federal Armed Forces and the companies “BuP. Boll Beraten und Planen”, “Emqopter”, “Synergeticon” and “Wölfel Engineering”, four steel infrastructure structures belonging to the associated partners Autobahn GmbH, DB Netz AG, Hamburg Port Authority and the Federal Waterways and Shipping Administration will be examined by UAS.

In this paper, we present a review of relevant inspection guidelines and the research work in this field in Germany. In addition, we present our unmanned aircraft system, the algorithmic flight planning and the proposed non-destructive testing methods for steel structures.

2 STATE OF THE ART OF UAS-BASED INSPECTION IN GERMANY

Automation of structural inspection by UAS is an active field of research. A review by Feroz and Dabous emphasizes the lack of standardizations, changes in weather conditions, limited battery capacity, and legal frameworks as limiting factors for general use. The focus of the research was on RGB imaging and analysis of concrete damage (Feroz and Abu Dabous, 2021). The article “Review of Robotic Infrastructure Inspection Systems” emphasizes changing environmental disturbances and GPS-denied scenarios as future challenges for UAVs and furthermore localization and control methods for sensor data. Cracking and corrosion are well detectable, while it is much more difficult to detect mechanical deformations (Lattanzi and Miller, 2017). In German-speaking countries, research on UAS-based bridge inspection is being pursued in several projects. Blankenbach from the Geodetic Institute of RWTH Aachen University researches it in the projects TwinGen, RiverCloud, and BIMxD structure inspector XR. At Bauhaus University Weimar, Morgenthal conducted research in the project “Assessment of Aging Infrastructure Structures with Digital Technologies (AISTEC)” to detect small cracks in concrete using high-resolution RGB cameras on UAS. Predecessor projects were “Unmanned Aerial Systems for Condition Assessment of Structures” from June 2013 to April 2015 and the continuation of the project from January 2017 to June 2018. The final report on the first project confirmed the basic practicality of UAS for inspections in support of human inspectors. Data acquisition time can be significantly shortened and qualitatively increased with the use of UAS. Additionally, this study proved that cracks and spalling could be reliably detected by the UAS (Morgenthal et al., 2015). The follow-up project investigated the fusion of the RGB image data with thermal images and the integration of the data into existing BIM software tools. Here, the size of the data sets and the heterogeneity of the data were noted. Additional research is required specifically in the areas of data analysis and data modeling (Hallermann et al., 2019). In 2022, the current status on the integration of inspection data into a BIM model was published (Taraben et al., 2022). In Austria, the project “RISK-MON - Plant Inspection and RISK MONitoring with High Performance Drones and Sensors” was running until the end of 2019. Important results from this study were the systematic analysis of the applicability of cameras, laser scanners, thermography, multispectral analysis and georadar for UAS and the determination of the best operating conditions for the drone. In this regard, images of concrete were also taken under laboratory conditions using a hyperspectral camera in the wavelength range from 900 to 1700 nm (Bergmeister et al., 2022). The research institutions of several infrastructure operators in Germany are currently researching drone-based inspections (Makiello, 2022; Morgenthal et al., 2021). Deutsche Bahn is investigating drone-based inspections for environmental and nature protection in the project “Digital Remote Sensing and Route Inspection using Unmanned Aerial Systems (Drones)”. Meanwhile, UAS-based inspection systems with RGB cameras and laser scanners are also being used commercially by companies such as “STRUCINSPECT”, “TopSeven”, and “Guido Morgenthal Technologies in Civil Engineering”. Previous work and applications of UAS-based inspection systems have focused predominantly on reinforced concrete structures, using primarily RGB cameras, with additional information also being provided by various combinations of thermal imaging cameras and laser scanners. Common to all projects is the

use of RGB cameras and laser scanners being adopted as the primary sensor technology. To the best of the authors' knowledge, the use of UAS-based inspection systems for the condition assessment of steel structures has received only small research attention.

3 METHODS FOR UAS-BASED INSPECTION OF CIVIL STEEL STRUCTURES

3.1 *Typical defects of steel infrastructure*

Analysing the German inspection guidelines and inspection reports of the Norderelbbrücke, Freihafenelbbrücke in Hamburg, the barrage Dörverden over the river Weser, and a railway bridge over the river Oste, the typical defects and their cause and consequence on steel infrastructure are categorized into corrosion, fractures, biota, moisture and deformation. The objective of the inspection is to detect these types of defects with high accuracy and assess their impact on the load-bearing capabilities of the structures, such that any repair work can be identified as early as possible. Another categorization scheme for the main defects of steel structures was developed in the Duratinet project and comprises the categories contamination, deformation, deterioration, discontinuity, displacement and loss of material. In our classification scheme, the categories displacement and loss of material are enveloped into the category deformation, while for deterioration and contamination are replaced by the categories of corrosion and coating, and biota. This scheme is a more sensor-orientated than a defect type orientated scheme (Correia et al., 2012).

Corrosion and protection coating defects on German motorway bridges are evaluated according to the German guideline "Richtlinien für die Erhaltung des Korrosionsschutzes von Stahlbauten", where color changes, e.g. from dirt, vegetation, salt on the corrosion protection system, should be noted. The thickness of the protection layer should be according to the minimum designed layer thickness and at least more than 200 µm if the planned thickness is not known. Occasional cracks of the protection layer or more occurrences should be noted. Visible corrosion should also be detected. In addition cracking and delamination of the coating system should be noted if they are detectable by 10x magnification. For fractures e.g., from fatigue, every fracture or suspected fracture in the steel structure should be noted and observed for changes. Biota defects should be understood as a general defect, containing flora, fauna and funga, i.e. bird droppings, algae, clams, fungi, dirt and further biological components which typically do not belong on a steel structure. Every instance of biota detected should be noted. Moisture and water content on steel structure occurs due to defects of the drainage or design flaws and leads to increased corrosion of the structure and should be analysed. Every steel deformation, e.g. dents, should be noted. There is no limit on the minimum detectable deformation. This also includes other changes in the geometry, for example, missing or loose rivets and screws. In summary, we use corrosion, coating, fractures, biota, moisture and deformation as inspection categories.

3.2 *UAS-based non-destructive testing methods for steel structures*

To detect defects via UAS, factors limiting the selection of the suitable sensor arrays are the sensors' size, weight, observation distance and image resolution. Within this project, a measurement distance of 3 to 10 m to the structure is considered as feasible. Drones with a take-off weight of 10 kg can typically carry a payload of 3 kg. This payload contains a gimbal to suppress vibration and orientate the sensor to the area of interest and should be bottom- and top-mountable to inspect floor beams. The first iteration of the drone setup used in the project has a maximum payload of 1,7 kg excluding the gimbal. In Germany, the inspector must be within reach of the structure to perform a visual inspection. Additional tools such as a hammer, a crack-width card or magnifying glasses are often used for inspecting areas of particular interest. For the analysis of steel structures, other common non-destructive testing (NDT) methods are, for example, endoscopy, ultrasound, thermography, magnetic particle inspection, eddy-current testing, hardness test and dye penetrant inspection. However, the majority of these methods are either contact-based NDT methods or contact-less methods that should be conducted as close as possible to the structure. As a result, most of these conventional methods are not suitable for drone-based inspections. There is ongoing research focused on developing contact-based methods for UAS, however, they come with the disadvantage

of a much lower inspection rate (inspected surface per hour) when compared to contact-less methods. For this reason, only electromagnetic (EM)-based detection methods appear to be suitable. The usable spectral range of EM-based methods is restricted by scattering, absorption and hazard characteristics of the radiation. Microwave-based methods (e.g. radar) are applicable but neglected in this work, as they use larger antennas and their precision is lower than using visual inspection methods (e.g. lidar). Bathymetric lidar is not considered in this project, as sensors for UAS weigh about 5 kg. In summary, the visual spectral range (380-780 nm), near-infrared (NIR, 780-1400 nm), short wavelength infrared (SWIR, 1400-3000 nm) and thermal infrared (3000-15000 nm) are applicable for UAS-based inspection. Imaging techniques using this spectral range are: RGB-, panchromatic-, multispectral-, hyperspectral-, thermographic-cameras and lidar.

3.3 *Illumination*

The radiation can be measured by the imaging techniques passively during daylight, but for specific tasks, additional illumination is beneficial. The emission spectrum, light direction, pulse time, coherence and polarisation of the additional light source are configurable. Coherence and polarisation are important for interferometry or polarisation microscopy, but not applicable on vibrating drones. Different orientations of the light source are used for Shape-from-Shading (SfS), highlighting differences in surface height. The pulse time is used in time of flight measurement methods (ToF) like lidar. For drone-based lidar, accuracies of about 1 cm are reported, but dent deformation are typically in the millimeter range (Bergmeister et al., 2022). Another method of illumination, which can be used for this range is structured light. Here, accuracies of 5 mm at a distance of 3 m for low-cost sensors up to 0.03 mm are reported (Cao et al., 2021). When using structured light, reflections can cause difficulties for reconstruction. Thus, illumination is only used if necessary in shadowed areas and for SfS, ToF and Structured light measurements at the steel structures. Because LED lamps, energy saving lamps, and lasers have an irregular emission spectrum, thermal light bulbs or halogen lamps should be used when a more continuous illumination spectrum is necessary for multispectral or hyperspectral imaging.

3.4 *Hyperspectral imaging*

The advantage of multispectral and hyperspectral imaging (HSI) is the ability to acquire a spectrum for comparison with the spectral fingerprint of specific materials, e.g. vegetation, water, and corrosion. HSI is commonly used in remote sensing of the earth atmosphere and many different spectral indices have been developed to detect specific materials. One example is the identification of vegetation by using the (hyperspectral) Normalized Difference Vegetation Index (NDVI).

Depending on the sensor, multispectral and hyperspectral cameras are sensitive to the NIR and SWIR range. Currently, there is no general recommendation which spectral range is preferable for inspection. It has been shown that the SWIR range is applicable for corrosion detection (Zahiri et al., 2022), but a drawback of SWIR cameras is their absence of the visual range, which is important for the calculation of more common spectral indices in remote sensing, like vegetation indices. Disadvantages of HSI setups are their cost, lower resolution and more complex white balance adjustment. For white balance with RGB cameras the intensity of the three colour bands must be adjusted, for which automatic algorithms exist. For HSI, more than one hundred spectral bands must be adjusted with a reflectance target. After the balance adjustment, changing levels of illumination, which can be caused by changing weather conditions or shading of the structure, result in necessary readjustments. Furthermore, the probability of over-saturating one of the many spectral bands increases.

3.5 *Applied UAS-based NDT methods within the MISDRO project*

The selected NDT methods in the MISDRO-project, their typical spectral range and main application area are presented in Table 1. As the cost, image size, and the inspection rate differs between sensors, the RGB camera is used as a first tool for acquiring an overview of the structure.

After around 30 minutes of flight time of a UAS, a battery change is necessary. On this change, the recorded data disk is transferred to a gateway computer, which further analyses the data and determines areas of interest which possibly contain defects or their indicators and recommends the next sensor configuration.

For the evaluation of the different sensors, test specimens are developed and a database is created from images of different structures. The database is used for training and testing machine learning methods for image segmentation of typical steel defects. Finally, the final inspection results are projected onto a BIM model of the structures.

Table 1. Deployed NDT methods within the MISDRO project.

NDT method	Spectral range (nm)	Main Application area
RGB camera	380 - 780 nm	Corrosion, Coating, Fractures,
Biota, Deformation		
- Shape-from-Shading		Coating, Fractures
- Structured Light		Deformation
Panchromatic camera	380 - 780 nm	Fractures
NIR-Hyperspectral camera	350 - 1000 nm	Corrosion, Coating, Biota, Moisture
Thermography camera	7.5 - 13.5 μ m	Fractures, Moisture
Lidar	typ. 900 nm	Deformation

4 SPECIFICATION OF THE UNMANNED AIRCRAFT SYSTEM

4.1 Hardware of the UAS

For the MISDRO project a UAS is developed and customized by *Emqopter* from Würzburg, Germany. To ensure a maximum of flexibility there is a switchable mounting system for the gimbal holding the sensors used for inspection. Moreover, in order to allow an inspection from all directions, it is possible to attach the gimbal both to the top and the bottom of the flight platform. The UAS itself is designed in a X-configuration with eight rotors in total, two for each arm. For the positioning, computation and communication the following parts are most important. Parts marked with a * are not finally selected for now. The basic hardware components and how they are connected is presented in Figure 1.

Computation units

- Flightcontroller *Pixhawk 6X*
- *Gigabyte BRIX* Onboard PC (*Intel i7 10710*)
- Microcontroller unit for datafusion

Positioning sensors

- *Here2-* and *Here3-* GPS system
- *Poszyx Creator One* positioning system
- *Holybro* telemetry module 433 MHz
- Lidar sensor*
- Ultrasonic sensor*

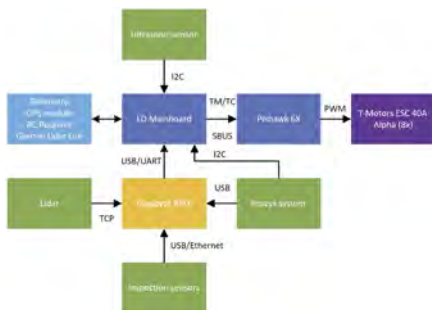

Figure 1. Basic concept of the used hardware setup on the UAS.

Figure 2. Simulation environment in Gazebo with a model of the Travehafenbrücke and a UAS.

4.2 Process of inspection

The inspection can be split up in two major steps. In the first step (Pre-computation), a flight mission based on an already existing BIM model of the inspected infrastructure is created. The second part (Live-computation) receives and executes this mission, maintaining a live map of the environment and a simple collision avoidance for the UAS. The concept is structured as follows.

4.2.1 Pre-computation

Creating a model of the desired infrastructure: To ensure that all relevant information is captured in a model of an infrastructure, mainly two different representations are created for the infrastructures stated above: A BIM model representing the civil engineering aspects and a pointcloud model of the whole environment, which is used for the calculation of a path along the desired inspection points. As an example, a basic BIM model of the Travehafenbrücke is shown in Figure 3a. The model has been created with the help of existing building plans. Moreover, a pointcloud model of the same infrastructure is shown in the top left of Figure 3b. For this case it is just a sampled version of the BIM model, but it can also be recorded on the actual building with a lidar.

Figure 3. Different model types of the Travehafenbrücke located in Hamburg.

Computation of a Voxelmap: Since the pointcloud consists of a huge amount of data which is not necessarily needed for a path planning algorithm, it is filtered for redundant points and represented in a Voxelmap with a constant spacing. This process is repeated for different spacings, so different resolutions of the object can be taken into account. For the current state of the project this is a sufficient approach. However, literature shows that equidistant spacing ends up with a significantly worse performance in terms of calculation time compared to approaches that only use small spacing around obstacles. For example, cell division as presented in (Yuan et al., 2022) or other tools and methods can be implemented to improve the algorithm in terms of calculation time and the amount of produced data.

Offline mission planning: The mission planning algorithm takes a Voxelmap and a starting point of the UAS as an input. To define a subspace that can be reached by the drone, a Voxelmap with a sufficient grid spacing depending on the size of the UAS is taken as an input for a wavefront-algorithm (Nam et al., 2016). Any voxel that can be reached by the wavefront outgoing at the starting point is marked. The remaining voxels are obviously surrounded or cut off by obstacles and therefore not members of the reachable subspace. Based on this representation of the environment the occupied voxels are used to create inspection points based on parameters depending on a defined safety distance, the size of the drone and the method of the inspection. The algorithm is forced to create the inspection points at a defined distance and in a 90° angle to the surface of the obstacle. Therefore, the plane normal vector is taken into account. Points can only be created at unoccupied voxels which are members of the reachable subspace. In the bottom right of Figure 3b all inspection points associated to the pointcloud model are presented. The inspection points created are saved and then sorted to obtain an optimal route along all inspection points. Currently, the route is determined using the basic routing algorithm of the Google OR Toolbox (Perron and Furnon, 2023). The optimization problem solved by this algorithm is called “travelling salesman problem” in the literature. The costfunction of this optimization is based on the euclidean distance of the waypoints and an additional penalty for movements up- or downwards, representing the increased energy consumption of the drone during those flight maneuvers. Future adjustments of this approach will aim at a capacity which is “picked up” in every step between waypoints in order

to create several routes with a maximal length. Thereby, the maximum lifetime of the battery packs can be taken into account. Based on the created sequence a basic gridbased path planning algorithm (Hart et al., 1968) is used to create a way between the inspection points. Literature shows many different approaches for this kind of problems, both gridbased and non-gridbased (Han, 2019). Further tests for this part of the algorithm are planned.

4.2.2 Live-computation

The mission created by the pre-computation is fundamental for the live mission of the UAS. At this stage of the project the missions have only been tested on simulations. Figure 2 shows a picture of an UAS during the simulative flight along the model of the Travehafenbrücke. A deployment on the real infrastructure is planned for the year 2023, where the following tasks have to be solved by the flight controller and the sensors of the UAS.

Reference system and SLAM: To perform a real and autonomous flight along the desired points, which are passed to the flightcontroller after the pre-computation, an adjustment has to be made in terms of the coordinates of the waypoints. The UAS sensors create a live map of the environment, yet the infrastructure and its pre-computation model have to match in terms of a reference coordinate system, so that the Voxelmap can be transferred into the real world. Therefore, the UAS uses the ultrasonic reference system and the lidar - both mentioned in section 4.1 - to create a live map. A SLAM (Simultaneous Localization and Mapping) algorithm then matches the infrastructure model of the pre-computation to the live map to allow a conversion from the computational grid into the real worlds coordinate system.

Live controller: As mentioned in section 4.1 the *Pixhawk 6X* is implemented on the UAS. The implemented flight controller uses a cascaded structure of PID-controllers to perform the flightmission. Further, different control approaches are currently tested to increase the performance compared to the code provided by the *PX4* software. The literature shows that many different types have been tested to perform a UAS mission, however, the results of a model predictive approach and an energy-based trajectory controller are taken into account for now (Fritsch, 2014; Tzoumanikas et al., 2020). Since this process is not finished yet, no final decisions can be presented here. The results will be presented in a future paper.

Additional features: In addition to the flight controller, future work will also focus on additional features and safety options. Therefore, different sensors will be tested to implement a collision avoidance ensuring the safety of the UAS. At the current state of the project only a simple collision “detect and avoid” system is implemented on the UAS basically stopping the drone if an obstacle is detected. For a more optimized solution dynamic path adjustments are a goal to reach, so that the autonomy of the system can be guaranteed.

5 CONCLUSION

After reviewing NDT methods for steel structures, the implemented sensors for UAS-based inspections within the MISDRO project are RGB-, panchromatic-, thermal-, NIR-hyperspectral cameras and lidar to detect the typical defects corrosion, fatigue, deformation, moisture and biota. Regarding the UAV flight missions have been tested on a simulation successfully. Future work will therefore focus on the implementation of the SLAM and reference system, so that information provided by the pre-computation can be optimally used by the UAS. The main difficulty for this will be the implementation of a system, which can operate under the absence of a GPS signal, which sometimes occurs during flights below a bridge or in areas with bad signal strength. In terms of the control algorithm used by the flight controller a final decision will be made in the near future. Also different performance enhancements and features will be added to the pre-computation and the UAS. In the next steps, they are applied on the Norderelbbrücke and Freihafenelbbrücke in Hamburg, the train bridge over the river Oste and the weir Dörverden to collect data for training and evaluating different machine learning algorithms. Furthermore, the creation of an image dataset of typical structural steel damage with visual and hyperspectral images is planned in order to train and validate ML models. The dataset will be used to test different spectral indices to determine the optimal spectral bands for moisture, corrosion and different biota detection. Challenging are

the light conditions at the structure, as they can change during an aerial survey. With the help of the 3D models, different lighting situations and damage cases can be simulated. The detected damages are finally stored in a central database and visualized with a web interface, including 3D display, so that those responsible for the building can immediately see the current condition and do a quick assessment and initiation of further measures is possible.

ABSTRACT: Buildings account for more than 40% of global energy consumption and up to a third of global greenhouse gas emissions in developed and developing countries. Electricity is currently the primary energy used for cooling buildings and appliances, but most countries use fossil fuels for heating. Both energy sources cause significant CO₂ emissions. Plants and vegetation improve air quality and reduce greenhouse gas emissions directly by absorbing greenhouse gases such as carbon dioxide from the atmosphere or indirectly by reducing energy use. Further, plants reduce the roof temperature by providing shade on roof surfaces. Large-scale implementation of rooftop gardens substantially reduces energy consumption and ultimately lowers energy costs but impact the overall weight of the building and require additional construction cost. Therefore, the impact of green roofs on various structural and thermal performances of buildings varies for extensive intensive or semi-intensive systems. These interacting impacts warrant a lifecycle analysis to optimize the extent of green roof applications concerning sustainability performance measures, including energy, emissions, water, and waste. This paper addresses the lifecycle analyses of green roofs in the hot summer Mediterranean climate like Rome in Italy or similar cities in the region. The target climate is essential to indicate the value of green roofs in warming climates around the globe. Moreover, results translate energy consumption to releasing greenhouse gas emissions and measures of water and waste related to structural or thermal operations. Conclusions enable building professionals to assess the challenges and opportunities of green roof applications on new and existing buildings.

1 INTRODUCTION

The concentrations of carbon dioxide (CO₂), methane (CH₄), nitrous oxide (N₂O), and other halocarbons are rising in the atmosphere due to human activity, according to observations from global monitoring stations (MacCracken 2001). Because of their ability to warm the climate, these gases are collectively known as greenhouse gases (MacCracken 2001). Carbon dioxide comes first and foremost on the list of all the greenhouse gases produced by human activities. The primary cause of the production of this gas is the excessive combustion of fossil fuels like coal and oil (Shahzad 2015). Cement production also releases carbon dioxide into the atmosphere (Shahzad 2015). Due to the continual raises in the earth's temperature for greenhouse gases, these gases are contributing negatively to global warming's devastation (Shahzad 2015). Buildings now account for more than 40% of the energy consumed worldwide and up to a third of the greenhouse gas emissions (Huovila et al. 2009). Additionally, the buildings and construction sector is a substantial source of non-CO₂ GHG emissions due to halocarbons, CFCs, HCFCs, and hydrofluorocarbons (HFCs) as insulation materials, cooling agents, and refrigerants

(Huovila et al. 2009). In six American cities, the peak urban electric consumption increased from 2% to 4% for every one °C increase in the daily maximum temperature above the threshold of 15 to 20 °C (Bianchini & Hewage 2012).

Buildings consume energy primarily in two ways: first, to maximize heating, ventilation, and air conditioning to maintain the interior as comfortable as possible; and second, to produce electricity to operate the necessary domestic applications, both of which result in a rise in global CO₂ emissions (Hughes et al. 2011). Currently, electricity is the primary energy source used for heating and appliances in buildings, while most nations use fossil fuels for cooling, which are significant contributors to carbon emissions (Chalmers 2014). Elective policies can result in energy-efficient and climate-resilient structures, hence reducing the increase of greenhouse gas (GHG) emissions (Chalmers 2014). The most severe result of global warming is increased sea levels because melting glaciers and ice sheets would result in higher water levels in the seas, rivers, and lakes, which may cause massive flooding (Shahzad 2015).

A practical solution to sustain the future development of resilient infrastructure relies on quantitative measures of energy, waste, water, and greenhouse gas emissions aligned with social equity and justice (Iskandar et al. 2022; Nelson & Tehrani 2018; Tehrani 2019; Tehrani 2022; Tehrani & Nelson 2022). These measures typically represent a bottom-up estimate of infrastructure development tasks throughout the lifecycle of engineered systems (Tehrani et al. 2013; Tehrani & Dadkhah 2018; Tehrani et al. 2019). Further, the objective approach to infrastructure resilience in response to future disasters requires an assessment of climate change consequences in various climate zones (Kalantari et al. 2023). This paper utilizes similar techniques to address a gap in applying green roofs for sustainable and resilient development.

2 LITERATURE REVIEW

2.1 *Benefit of vegetation*

Integrating plants and other wildlife can benefit cities (Dastan Diznab & Tehrani 2022). For example, plants can provide shade for buildings and pavements and cool buildings, thereby reducing energy use and slowing the deterioration of pavements, lowering the cost of maintaining them (Alhashimi et al. 2018). By absorbing greenhouse gases like carbon dioxide from the atmosphere, plants, and vegetation can also improve air quality and reduce greenhouse gas emissions, or they can do so indirectly due to the decreased energy use (Alhashimi et al. 2018).

2.2 *Effect of vegetation on buildings*

In every climate, green roofs are the best option for lowering the temperature of the exterior roof surface (Barreca 2016). Although green roofs are possible for pollution management and lowering indoor temperatures, it is vital to consider several variables, such as initial high construction costs, high maintenance expenses, and roof leakage issues (Dauda & Alibaba 2020). The major drawback of green roofs is their high cost, which is significantly more than the cost of regular roofs due to their unique design, which includes many more layers than the standard roof, as well as the fact that they are built of expensive, imported materials (Drozd 2019). The weight of a green roof is another drawback (Hemati et al. 2021). It is significantly taller than a typical roof. Because of this, the structure's load capacity must be raised, adding to the structure's weight (Drozd 2019). The dark surfaces (concrete and asphalt) and the lack of vegetation raise the warmth in metropolitan areas (Bianchini & Hewage 2012).

2.3 *Benefits of green roofs*

The life cycle evaluation is significantly impacted by the energy advantages that the various types of green roofs offer, and when energy demands are low and roof replacement cycles are short, the materials used to build the roof are crucial (Kosareo & Ries 2007). By offering a one-time tax abatement, the City of New York made it easier to build green roofs. If the green roof accounts for at least 50% of the total roof area, the building owner can receive a tax break of \$48/m² (Bianchini & Hewage 2012). Green roofs may also contribute to food security in various communities (Tehrani & Zamani-Alaei 2020).

2.4 Roof gardens and different types

A roof garden is an excellent approach to improving city buildings through landscape design, which may turn unused space into a helpful area that offers ecological and economic services (Jafari et al. 2015).

Benefits of longevity While conventional roofs only last roughly 20 years, green roofs are predicted to last between 40 and 55 years (Bianchini & Hewage 2012).

There are three different kinds of green roofs, according to the International Green Roof Association (2013); Extensive green roofs, semi-intensive green roofs, and intensive green roofs. Extensive green roofs are appropriate for less demanding and slow-growing plant communities since they contain little nutrients and are not particularly deep. Semi-Intensive Green Roofs have more options because of the characteristics of having a deeper ground level, different grasses, herbaceous perennials, and shrubs like lavender can be planted, but tall-growing bushes and trees are still absent. Lawns, perennials, shrubs, and trees, as well as other garden-related items, may all be planted, and extra amenities, walkways, seats, playgrounds, and even ponds can be built on the intensive green roofs because designing is not limited to these roofs (Jafari et al. 2015). Figure 1 shows different types of green roofs and their characteristics.

Figure 1. Different types of green roofs and their characteristics (Raji et al. 2015).

3 METHODOLOGY

As one of the most sophisticated building energy simulation tools that include a green roof model, EnergyPlus was chosen as the simulation platform for investigating the influence of green roofs on the thermal performance of buildings (Tehrani et al. 2018; Silva 2014). A building's hourly energy consumption may be modeled using the EnergyPlus simulation model under user-specified construction, internal loads, schedules, and weather (Sailor 2008). Based on interior and outdoor environmental conditions, EnergyPlus simulates energy flows for heating, cooling, lighting, ventilation, and other functions (Silva 2014). EnergyPlus has several advantages as the simulation platform for using the green roof model, including the advancement, updates, and widespread application for buildings (Sailor 2008). Two input files are needed to run a simulation; a building input data file (IDF) containing all the study case's features and a weather data file containing information about the location's climate.

This study examines the studies of green roofs in Rome, Italy, or other cities with a Mediterranean climate (Köppen climate classification: Csa), which has moderate winters and warm to hot summers. The research's hypothesis states that the rooftop garden building experienced much lower internal temperatures due to natural shading. Additionally, the rooftop garden would minimize heat flow through the roof, slowing the release of heat and lowering the demand for cooling or heating by the experiment of building a model house with a rooftop garden.

Many studies looked at the impact of growth media characteristics, including moisture content, relative density, and growing medium thickness, on the thermal efficiency of green roofs (Raji et al. 2015). Permpituck and Namprakai (2012) compared two sets of green roofs with

soil thicknesses of 10 cm and 20 cm to a bare roof, and their findings demonstrate a considerable decrease in energy consumption (31% and 37%) and heat transmission (59% and 96%) for soil depths of 10 cm and 20 cm as compared to a bare roof (Raji et al. 2015).

3.1 Building model

Choosing material was based on the templates of open studio software for the 3C climate zone. The building model used for this paper had three floors with two units in each building; each unit's area is considered 110 m² (the average apartment area in Italy). In the building, 24 windows have been placed, 8 of which are 1.3 meters in 1.3 meters, and the other 16 are 1.3 meters in 2 meters. The 1.3 by 1.3 windows affect an area of 77 square meters, and the 1.3 by 2 affect 16.5 square meters of each house.

EnergyPlus software has two specific inputs; IDF (building model + windows information + material) and weather file. Chart 1 shows the monthly average temperature of Rome in the year 2021 taken from EnergyPlus.

Chart 1. Monthly average temperature of Rome.

The heating, ventilation, and air conditioning (HVAC) system was chosen to be “PTAC” based on residential buildings and the 3C climate zone (Goel et al. 2017). A packaged terminal air conditioner or PTAC is a ductless, through-the-wall heating and cooling system. For heating, it is considered that gas is used, and for cooling, it is considered that electricity is used. The air-conditioning system works with a setpoint temperature of 21°C in the summer and 28°C in the winter.

3.2 Green roof model

For green roofs, there is a mixture of soil and lightweight expanded clay aggregate, which expanded clay acts as insulation and drainage (Tehrani 1998; Gerami et al. 2007). Expanded clay serves as the filter and drainage layer in this study. Invigoration of Roots and Soil Improvement might be noted as an advantage of applying expanded clay (Boudaghpour & Hashemi 2008). The soil layer was defined for green roofs in the Energyplus model based on the 30% expanded clay mixture matrix to 70% soil. The mechanical properties of this mixture are conductivity: 0.272 - density:866 - specific heat: 1140. Also, in this study, a 45-year life span was assigned to the green roof options (Kosareo & Ries 2007). In Table 1, the input is given to the software. Table 2 shows the input for different layers of green roofs in the software, and Table 3 shows the thickness input for different green roofs. It should be noted that although the EGR has a life expectancy of more than 40 years, it is challenging to do a meaningful feasibility analysis over such a lengthy time frame (Giama 2021). The conventional roof has a thermal installation equal to 0.07 meters and a waterproof membrane with a thickness of 0.005 meters.

3.3 Embodied energy and CO₂ emissions used for building a roof garden

In Table 4, the data for CO₂ sequestration is available. These data reflect calculations of emissions using environmental product declarations and other energy conversion coefficients for various materials and construction equipment. Production and fuel consumption rates follow standard construction practice guidelines.

Table 1. Input for different green roofs.

Green roof type	Leaf area index	Height of plant (m)	Soil thickness (m)
Extensive	1	0.05	0.1
Semi-intensive	2.5	0.5	0.35
Intensive	5	1	0.7

Table 2. Input for different layers of green roof in the software.

Material	Description	Energy (kW.h/kg)	CO ₂ emissions (kg CO ₂ /kg)	Density (kg/m ³)
Installation	Polystyrene foam	24.58	6.12	33.7
Waterproof Membrane	Bituminous membranes	0.5605	0.64	1100
Roof Barrier	Polyethylene	23.571	3.27	920
Protection layer	Polypropylene	20.932	3.64	905
Substrate	63% crushed brick -7% compost-30% LECA	1.01039	0.294	858.7

(Koroxenidis & Theodosiou 2021)

Table 3. Thickness input for different green roofs (m).

Material	Extensive	Semi-intensive	Intensive
Installation	0.049	0.049	0.049
Waterproof Membrane	0.004	0.005	0.006
Roof Barrier	0.0005	0.0008	0.001
Protection layer	0.002	0.004	0.008
Substrate	0.1	0.35	0.7

(Koroxenidis & Theodosiou 2021)

Table 4. CO₂ sequestration.

Green roof type	Annual CO ₂ Reduction (kg CO ₂ .m ⁻² .yr ⁻¹)
Extensive	0.5547
Semi-intensive	1.3868
Intensive	2.7736

(Kuronuma et al. 2018)

4 RESULTS

4.1 Energy consumption

This paper has studied four different cases: a building without a green roof, an extensive green roof, a semi-intensive green roof, and an intensive green roof. Also, in the reviewed model, it is assumed that only electricity is used for cooling in the hot season, and natural gas is used for heating in the cold season. Chart 2 shows the total energy used in building with different roofs. The chart shows that the most energy used in the building is when a conventional roof is used, and the minor energy usage goes to intensive green roofs. However, differences can be seen when the energies are divided into those used in heating and cooling systems. It is seen that extensive roofs use more electricity than conventional roofs. Analyses show that insulation plays a much more critical role in cooling systems than the type of green roof. This theory is based on defined thicknesses for components similar to conventional roofs, insulation, and waterproofing in types of green roofs. The thickness of the insulation and waterproofing membrane in the modeled conventional roof is more than the extensive roof and is near the semi-intensive roof but less than the intensive roof. This difference is seen in chart 2. Table 5 indicates the energy percentage saved using green roofs. Based on this table, it can be concluded that the effect of semi-intensive green roofs on saving electricity is insignificant compared to conventional roofs and that extensive roofs do not save electricity. In general, Intensive green roofs save more energy than others. Also, it is seen that green roofs have a much more noticeable impact in saving the energy of the heating system.

Chart 2. Total HVAC Energy Consumption.

Table 5. Energy percentage saved while using green roofs.

Green roof type	Cooling System (%)	Heating System (%)
Extensive	-4.394	6.362
Semi-intensive	0.346	13.283
Intensive	3.183	17.588

As mentioned, a 45-year life span was assigned to the green roof options. Assuming that we consider the amount of impact on energy for all types of green roofs constant throughout their lifespan, the amount of energy saved during their lifetime can be calculated. This energy is then compared with embodied energy. The energy saved in extensive and semi-intensive green roofs is more than the energy needed to produce these structures. It is also notable that although intensive roofs saved more annual energy than other types, the embodied energy was more than the energy saved in all their life.

Chart 3. Energy saved and energy consumption in different roof gardens (kW.h).

4.2 CO₂ emission saving comparison of different roof gardens

This study used a life cycle assessment to calculate the CO₂ emissions from the production process and maintenance practices of different green roofs. We assessed the CO₂ payoff for modular green roofs by calculating their CO₂ payback time. CO₂ payback is the time it takes for a green roof system's CO₂ reduction to offset the CO₂ emitted during production and maintenance. The CO₂ payback consists of two major parts; The reduction owing to sequestration, which is the process of capturing and storing atmospheric carbon dioxide done by vegetation, and the CO₂ reduction owing to energy saving. The sequestration is calculated based on previous studies and for each roof garden based on the leaf area index (LAI).

On the other hand, the energy saving in this study is the energy saved in electricity and natural gases, which have different CO₂ emission rates. Chart 4 indicates the total CO₂ payback during 45 years of each type of roof garden. Also, Chart 4 shows the embodied CO₂ needed and the CO₂ payback and saving for each type of roof garden. Based on this diagram, it can be concluded that all roof guards offset the effect of carbon dioxide during their lifetime.

Chart 4. Total CO₂ payback during 45 years of the existence of each type of roof garden.

5 CONCLUSION

This study quantified the CO₂ emitted during the production and maintenance of a hypothetical modular green roof and estimated the CO₂ reduction from energy savings and CO₂ sequestration. The study results show that CO₂ emissions are offset through CO₂ sequestration and energy savings during the lifespan and even less than the life span, which indicates that green roofs contribute to atmospheric CO₂ reduction and global warming mitigation within their lifespan.

The studies of this paper showed that intensive green roofs do not offset their embedded energy. Also, in this study, we concluded that extensive and semi-intensive green roofs compensate for their construction and maintenance energy during their lifetime. Based on this conclusion and examining energy inflation in Italy, we can conclude which is more optimal from a financial point of view.

The amount of time required to retrieve the CO₂ emitted from the construction phase for extensive, semi-intensive and intensive green roofs are 41.5, 32, and 36 years and the time required to retrieve the energy consumed from the construction phase for extensive, semi-intensive and intensive green roofs are 39.5, 35.4 and 47.5 years.

In this study, many parameters were not investigated, such as the type of plants and the amount of energy required for maintenance and different CO₂ sequestrations. These are parameters in need of further studies.

ABSTRACT: Asphalt pavement should be represented as a series system of limit state functions associated with the international roughness index, rut depth, alligator cracking, and transverse cracking. Traditional regression-based prediction models are too simplified to account for the relationship between pavement performance and the operating conditions associated with climate, traffic, pavement structure and property parameters. In this study, a deep learning model based on bidirectional long short-term memory neural networks is trained using the long-term pavement performance database to learn the nonlinear and complex relationship between four performance indicators and their associated parameters. Based on multiple time-variant limit-state functions incorporating the uncertainties associated with these parameters, deep learning model prediction, and international roughness index measurement, Monte Carlo simulation is conducted to estimate the system reliability of the asphalt pavement. In an illustrative example, the effects of different parameters on the life-cycle system reliability are investigated based on two pavement sections.

1 INTRODUCTION

As an integral part of roadway networks, asphalt pavements may start to deteriorate from the day they enter into service due to a multitude of stressors such as increasing traffic loads, various climatic conditions, and the associated material deterioration of asphalt mixture (Xin 2021). If they are not managed timely and effectively, a significant decrease or even failure in structural functionality and safety of asphalt pavements could occur. This jeopardizes the mobility of freight and commodities for economic vitality and access to a range of users for societal benefits. According to the 2021 Report Card for America's Infrastructure (ASCE 2021), over four million miles of public roadways are carrying people and goods to their destinations every day; however, more than 40% of these vital lifelines are now in poor or mediocre condition. Reliability-based performance indicators and single- and multi-objective optimal methodologies under uncertainty are gaining increased attention as effective tools for finding rational maintenance and rehabilitation strategies during the life-cycle management of infrastructure systems (Frangopol 1985; Frangopol 1995; Frangopol and Das 1999; Yang et al. 2004; Frangopol 2011; Ghosn et al. 2016; Frangopol et al. 2017; Garcia-Segura et al. 2017; Akiyama et al. 2020). Therefore, it is essential to accurately estimate the life-cycle asphalt pavement performance with the aid of deterioration modeling methodologies that consider various uncertainties.

Traditionally, prediction models used for life-cycle assessment of asphalt pavement performance include purely mechanistic, mechanistic-empirical (M-E), regression-based, and subjective (Haas & Hudson 2015). These models are either with low prediction accuracy (e.g., regression-based) or too complicated (e.g., M-E). Xin et al. (2021a, 2021b, 2022) first adopted artificial neural networks (ANN) and long short-term memory (LSTM) networks to predict the performance indicator of the international roughness index (*IRI*) for new and in-service asphalt pavement. The obtained prediction accuracy is larger than that of regression equations used in the mechanistic-empirical pavement design guide (MEPDG) by the American Association of State Highway and Transportation Officials (AASHTO, 2020). This demonstrates the ability of machine learning models in the automatic and efficient understanding of the complex relationship between pavement performance and the associated operating conditions including climate, traffic, and pavement structure and property parameters. However, the above research only considered one performance indicator (i.e., *IRI*) and several associated parameters. In fact, asphalt pavement is a series system characterized by multiple failure modes associated with *IRI*, rut depth (*RUT*), alligator cracking (*AC*), and transverse cracking (*TC*), and considered failed if any one of the indicators exceeds the corresponding threshold (AASHTO, 2020).

In this paper, a more sophisticated deep learning (DL) model based on bidirectional long short-term memory (BiLSTM) neural networks is constructed, trained, and applied to learn the relationship between the performance indicators and the associated parameters using the long-term pavement performance (LTPP) database. The DL model with BiLSTM neural networks not only can learn the long-term dependencies between input sequence data (compared with ANN) but also process the input sequence data both ways (chronologically and anti-chronologically), which could catch patterns that may be overlooked by a unidirectional long-short term memory neural network (Greff et al. 2017; Chollet 2021). Based on the accurate predictions of the performance indicators by the DL model, while incorporating the uncertainties associated with climate, traffic, and pavement structure and property parameters, DL model prediction, and *IRI* measurement, Monte Carlo simulation (MCS) is conducted to calculate the system reliability of the asphalt pavement. The effects of fourteen parameters on the life-cycle system reliability are investigated based on two LTPP pavement sections in the United States.

2 DEEP LEARNING-BASED SYSTEM RELIABILITY

2.1 General procedure

Figure 1 presents the flowchart of the system reliability estimation methodology of asphalt pavement based on the deep learning model with BiLSTM memory networks. This flowchart consists of two main parts:

- (1) Training database collected from the LTPP program and prediction of performance indicators using the trained BiLSTM-based deep learning model.
- (2) System reliability analysis of asphalt pavement considering the uncertainties associated with several input parameters, DL model prediction, and *IRI* measurement.

2.2 Database for model training

The LTPP program is the largest and most comprehensive pavement performance database worldwide (LTPP 2022). The LTPP database published in August 2022 (Standard Data Release 36) is collected for training the DL model. Specifically, 4880 sets of data are collected from 63 pavement sections in the General Pavement Studies (GPS) program, including GPS-1, GPS-2, and GPS-6, and the Specific Pavement Studies (SPS) program, including SPS-1, SPS-3, SPS-5, and SPS-8 test sections, respectively.

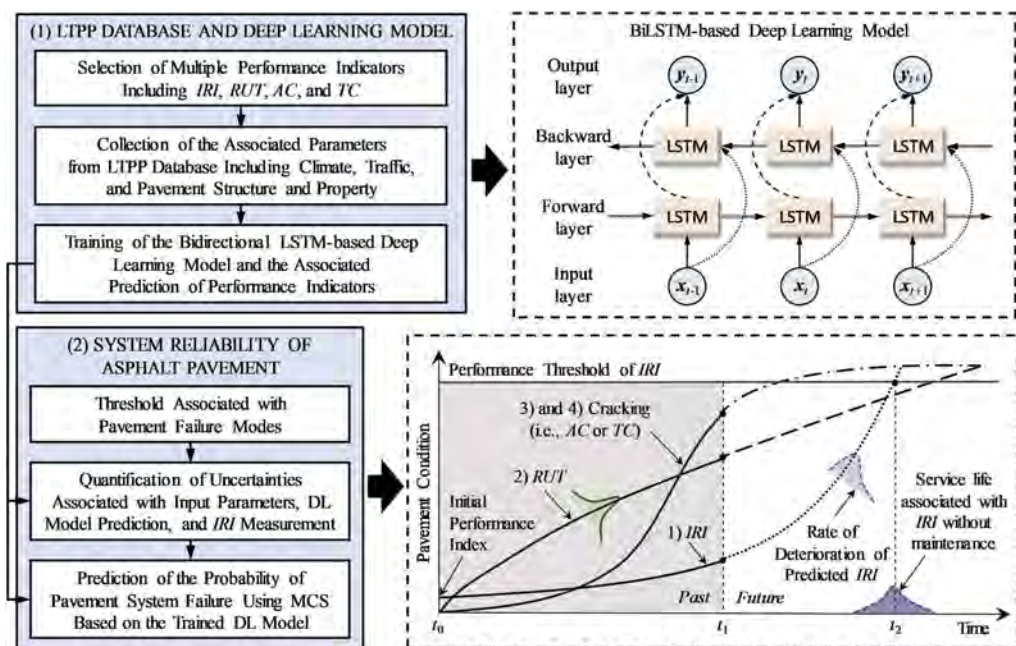

Figure 1. Flowchart of system reliability estimation of asphalt pavement using deep learning model.

Four performance indicators used for evaluating the functional adequacy and structural condition of asphalt pavement, including *IRI*, *RUT*, *AC*, and *TC*, are selected as the output of the DL model. For the input, the selected fourteen parameters are as follows (FHWA 2017):

- Climate parameters including (a) Hum_{max} and Hum_{min} : average of daily maximum and minimum relative humidity for the month, respectively (%); (b) *Precip*: total monthly precipitation (mm); (c) *Snow*: monthly total snowfall (mm); (d) *Temp*: average of daily mean air temperatures for the month (degree Celsius); (e) *FI*: monthly freezing index; (f) *FT*: monthly freeze thaw (days); and (g) *Wind*: average of daily mean wind speed for the month (m/s);
- Traffic parameters including (a) *kESAL* and (b) *AADT*: annual equivalent single axle loads in thousands and average daily number of trucks in the LTPP lane, respectively;
- Pavement property parameters including (a) *Age*: time since the initial construction (years) and (b) *DFL*: deflection response of pavement to a load of known magnitude (μm); and
- Pavement structural parameters including (a) H_{asp} and (b) H_{base} : thickness of asphalt layer and base & subbase layers, respectively (cm).

2.3 Deep learning model

Deep learning is able to deal with large datasets by automatically and efficiently figuring out the complex relationship between inputs and outputs (Chollet 2021). The deep learning model consisting of BiLSTM neural networks was constructed, as shown in Figure 2, to predict the performance indicators of asphalt pavement based on the associated operating conditions (i.e., climate, traffic, and pavement property and structure). Specifically, the model contains an input sequence layer, two BiLSTM layers, three fully connected layers, two dropout layers, and a regression output layer. In total $N = 4880$ datasets, 70% and 30% are used as training and test data, respectively. Figure 3 shows the comparison between the predicted and measured performance indicators for training and test data, respectively. The coefficient of determination (R^2) values for all indicators are larger than those of distress prediction equations presented in the MEPDG (AASHTO 2020).

Figure 2. The structure diagram of the DL model based on BiLSTM.

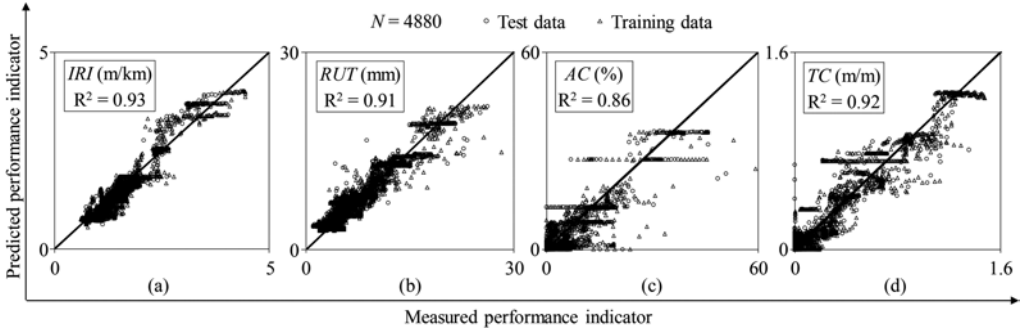

Figure 3. Training results of (a) *IRI*, (b) *RUT*, (c) *AC*, and (d) *TC* using the DL model.

2.4 System reliability analysis using DL model

MCS is adopted to compute the system reliability, as:

$$Pr_{r, sys}(t) = E \left\{ I \left[\min_i g_i(X_i) \right] \right\} = \frac{\sum_{j=1}^{N_{simu}} I \left[\min_i g_i(X_{ij}) \right]}{N_{simu}} \quad (1)$$

in which

$$g_1(X_1) = Thres_1 - [DL_1(X_{input}) + \varepsilon_{DL,1} + \varepsilon_{meas}(IRI)], i = 1 \quad (2)$$

$$g_i(X_i) = Thres_i - [DL_i(X_{input}) + \varepsilon_{DL,i}], i = 2, 3, \text{ and } 4 \quad (3)$$

where $E\{\cdot\}$ = expected value, $I[\Delta]$ = indicator function of Δ defined as $I[\Delta] = 1$ at $\Delta > 0$ and $I[\Delta] = 0$ at $\Delta \leq 0$, \min = finding the minimum elements of an array, $i = 1$ to 4 denote the four failure modes associated with the *IRI*, *RUT*, *AC*, and *TC*, respectively, g_i = individual limit state functions (LSF) of i , vector $X_{ij} = j$ -th sample value of vector X_i in the total number of simulations N_{simu} , $Thres_i$ = threshold of indicator i , DL_i = indicator i predicted by the DL model, $X_{input} = (X_1, X_2, \dots, X_{14})^T$ = variable vector as illustrated in Section 2.2, $\varepsilon_{DL,i}$ = DL model error associated with the prediction of indicator i , and $\varepsilon_{meas}(IRI)$ = *IRI* measurement error.

3 CASE STUDY

3.1 Input parameters for DL model

The proposed system reliability estimation methodology is applied to two existing LTPP asphalt pavement sections ID 42-B340 in Pennsylvania and ID 12-0112 in Florida, respectively. The

parameters (i.e., mean and standard deviation (SD)) associated with the variables for the DL model prediction and system reliability calculation are those indicated in Xin (2021).

3.2 Time-variant system reliability using DL model

Figure 4 shows the calculated system reliability for pavement section (a) ID 42-B340 in Pennsylvania and (b) ID 12-0112 in Florida versus time using Equation 1. The threshold associated with the system reliability is 75%. It can be seen that the system reliability of pavement sections ID 42-B340 and ID 12-0112 reaches the threshold at approximately 8.3 and 7.3 years, respectively, indicating that appropriate preventive maintenance actions should be scheduled in advance to postpone the rehabilitation or reconstruction of the corresponding pavement.

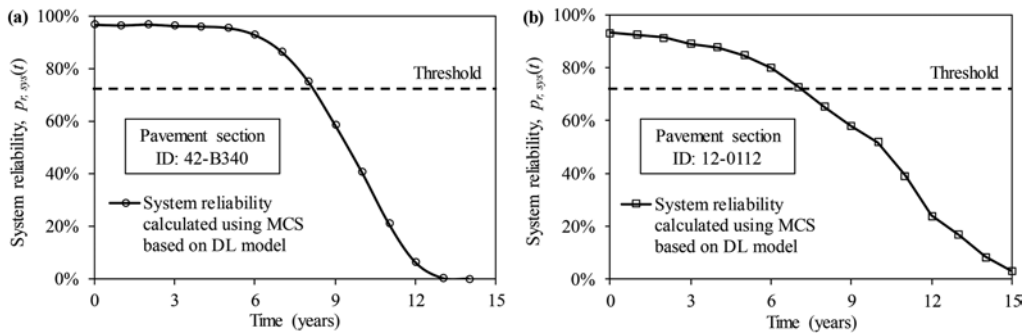

Figure 4. Time-variant system reliability of asphalt pavement section (a) ID 42-B340 and (b) ID 12-0112.

4 CONCLUSIONS

A novel deep learning model is proposed in this paper to realize the proper predictions associated with asphalt pavement performance indicators. The model is built based on the bidirectional long short-term memory neural networks and is trained with high predictive accuracy using the collected LTPP database.

Based on the trained model, the life-cycle system reliability analysis method is presented considering the four correlated failure modes, the associated operating conditions, DL model error, and measurement uncertainty of the asphalt pavement using MCS.

Traffic, climate, and pavement structure and property have significant effects on the life-cycle performance of the asphalt pavement, which should be taken into account for the decision-making on optimum M&R strategies.

Climate change impact on the integrity of structures and infrastructure in mountainous or hilly areas

National Technical University, Athens, Greece

D.M. Frangopol

Lehigh University, Pennsylvania, USA

ABSTRACT: Climate Change (CC) includes both global warming driven by human-induced emissions of greenhouse gases and the resulting large-scale shifts in weather patterns. Although there have been previous periods of CC, since the mid-20th century humans have had an unprecedented impact on Earth's climate system and have caused changes on a global scale. One of the most important issues of the complex phenomenon of CC is the fact that the higher temperatures are increasing the rates of evaporation, causing more weather-related extreme incidents, such as intense storms and heavy rainfalls. Since the frequency, duration and intensity of the rainfalls are related to the instability and/or the erosion of a natural or an artificial soil slope, it becomes evident that the integrity of any structure or infrastructure located on a mountainous or a hilly region may be directly or indirectly affected by the CC during its lifetime. Under this perspective, the current paper focuses on the potential impact of CC on the instability and/or the erosion of natural and artificial soil slopes at mountainous or hilly areas, and subsequently on the integrity of the structures and infrastructure in these areas. The results illustrate that in these specific problems of geotechnical engineering (i.e., slope instability and erosion) the impact of CC may be either detrimental or beneficial, depending on the prevailing circumstances and local site conditions. Accordingly, geo-scientists and especially geotechnical engineers should collect all the required data (i.e., topographical, geological, hydro-geological, geotechnical, and seismological), assess their potential variation over time, and examine each potentially unstable area on a case-by-case basis.

1 INTRODUCTION

The over-increasing need for sufficient and uninterrupted energy production and transmission has led to the further development (i.e., design, construction and operation) of Critical Energy Structures (CESs) and Infrastructure (CEI), worldwide. The term “Critical Energy Structures” describes structures, such as onshore or offshore wind turbines and offshore fixed platforms, which have rather limited dimensions. On the other hand, “Critical Energy Infrastructure” is mainly the large-scale high-pressure gas or -in the near future- hydrogen pipelines, as well as the power transmission cables, which extend for hundreds to thousands of kilometers onshore and/or offshore. Such structures and infrastructure are extremely expensive engineering projects of paramount importance, directly as a capital asset and indirectly as an essential element, that contribute to a productive economy and ensure energy production, transmission and security. Nevertheless, CESs and CEI often face various challenges that depend on the ground/seabed characteristics and the potential geohazards of the area under consideration.

The instability of natural slopes (i.e., landslides) can be considered as one of the most unpredictable and destructive onshore and offshore geohazards with significant consequences on the structural performance of adjacent or crossing structures and lifelines, on the regional and national/

international economy, as well as on human losses (Cruden and Varnes, 1996). A landslide constitutes a natural geological activity triggered by seismic and other dynamic loads (if any), groundwater table fluctuation, soil erosion and/or other factors. It is highlighted that in mountainous and hilly areas, landslides triggered by rainfalls are the most usual type of geohazard, leading to an annual average of approximately 1000 fatalities, as reported from the “EM-DAT” Database (Guha-Sapir et al., 2022).

Landslides can cause sudden or progressive displacements at the ground surface or at the seafloor and may result in failure of structures and infrastructure due to imposed External Loads (ELs), Permanent Ground Displacements (PGDs) and/or a combination of these actions. It is noted that the complete avoidance of potentially unstable slopes is sometimes technically and economically unfeasible. Indicatively, the European Gas Pipeline Incident Data Group (EGIG, 2015) has reported that the 85% of gas pipelines accidents due to geological reasons across Europe from 2004 to 2013 were related to landslides. Additionally, in the mountainous areas of Andes, almost 50% of CEI failures have been caused by landslides (Esford et al., 2004). Under this perspective, the realistic assessment of the potential geohazard of slope instability in conjunction with the resulting structural distress of Critical Energy Structures and Infrastructure constitutes an essential process during their design phase.

Although there have been previous periods of CC, the unprecedented impact of humans on Earth’s climate system in recent decades has caused a climate crisis, which has created an urgent and dangerous situation, capable of imposing a tremendous (direct or indirect) impact on the structural integrity of such Critical Energy Structures and Infrastructure worldwide. In general, CC involves both global warming driven by human-induced emissions of greenhouse gases, as well as the resulting large-scale and long-term shifts in weather patterns. More specifically, CC causes long-term shifts in the frequency, duration and intensity of rainfalls, a fact that is directly related to the groundwater table fluctuation and the soil erosion phenomena, and consequently, to the geohazard of slope instability. It has been reported that the intensity of precipitation extremes, such as heavy rainfalls, have been increased in the past 50 years, even for areas with a decrease in average precipitation levels, such as central Europe and the Mediterranean Region. However, according to Masson-Delmotte et al. (2021) heavy precipitation events are expected to occur more frequent as a direct consequence of CC.

It should be stressed that the European Commission underlines the emerged threat of CC on the structural performance of CESs and CEI, as a very crucial topic. In particular, considering that: (i) approximately 5% of the total population lives in areas susceptible to landslides, (ii) heavier precipitation due to CC could indirectly affect CESs and CEI that have been designed in the past and cross or are placed close to potentially unstable slopes, (iii) CESs and CEI are indirectly related to other social, economic and environmental factors, exacerbating risks to individual and household well-being and quality of life, and (iv) there are important knowledge and regulation gaps that need to be addressed for both national and cross-border uninterrupted energy production and supply, it becomes evident that the impact of CC on the structural behavior of CESs and CEI is of paramount important and it will undoubtedly have a substantial social, environmental and financial impact worldwide. Along these lines, the current paper aims to assess -utilizing simplified analytical methodologies- the impact of the anticipated CC on the geohazard of slope instability and the consequent threat on the integrity of (existing or future) Critical Energy Structures and Infrastructure.

2 PROBLEM DESCRIPTION

Slope instability constitutes a complex geohazard that mainly depends on physical processes and is usually assessed by means of the Factor of Safety (FS). The latter can be defined as the ratio of the resisting forces to the driving forces, under static or dynamic conditions. FS lower than one indicates an unstable slope and in this case the evaluation of ELs, PGDs and/or a combination of these actions is also required for the Soil Structure Interaction (SSI) or the Soil Infrastructure Interaction (SII) (Kramer, 1996). Several methods have gradually been developed for calculating the FS of a soil slope, such as limit equilibrium methods, infinite slope approach, numerical methodologies, and the more-computationally-efficient Artificial Intelligence methodologies. The most important parameters that dominate the resulting FS are related to: (a) the slope inclination and

the geomorphological characteristics of the area of interest, (b) the mechanical properties of the soil material(s) (i.e., soil cohesion and internal friction angle), as their values determine the shear strength and (c) the seismic and other dynamic loads (if any), as they can either reduce the shear strength or increase the shear stresses.

However, it is worth noting that potential groundwater flow plays a key role in the stability of soil slopes. An increase of the level of groundwater table, usually attributed to rainfalls, is the most common reason for slope failure, since it reduces the effective stresses of the soil slope and consequently, the corresponding FS. Figure 1 depicts that the frequency, duration and intensity of the rainfalls determine the ratio between: (a) evaporation - transpiration, (b) runoff, (c) infiltration – percolation and (d) root water uptake. The latter, in conjunction with the soil properties, determine the level of the groundwater table. The increased levels of precipitation may have triggered a slope failure 4 miles east of Oso, Washington, DC, USA, which occurred in 2014 and resulted in 43 fatalities (Henn et al., 2015). Precipitation could also trigger landslides destabilized by a previous event, e.g., an earthquake, as observed in the landslides triggered by a rainstorm after the Wenchuan earthquake (Tang et al., 2011).

Figure 1. The hydrological cycle and the main consequences of rainfall on soil slopes (adopted from Emadi-Tafti and Ataie-Ashtiani (2019)).

CC has various impacts on the weather and consequently on the aforementioned hydrological cycle. Several researchers have investigated the anticipated impacts of CC on hydrological processes (Green et al., 2011) and changes in the annual precipitation patterns (Kaźmierczak and Kotowski, 2014). Specifically, one of the most important issues of CC is the fact that the higher temperatures and greater wind velocities are increasing the rates of evaporation, causing more frequent and intense storms and heavy rainfalls, even in countries where such phenomena were very rare in recent history. In parallel, the high volume of rainfalls affects the hydraulic conductivity and moisture of the soil, and consequently, the water infiltration. Additionally, high temperatures constitute a direct threat for the vegetation and forestry, which are directly related to root water uptake. Finally, the resulting runoff constitutes the remaining rainfall volume. Hence, it is evident that the CC affects the hydrological cycle.

However, apart from the weather conditions (i.e., frequency, duration and intensity of rainfall and wind), the characteristics of the slope (i.e., slope inclination, soil properties, and vegetation cover and forestry) also play an important role on the ratio between the evaporation - transpiration, runoff and infiltration – percolation and they can be affected from the consequences of CC. Evidently, the runoff is directly related to the potential erosion parallel to the slope surface and the potential flooding phenomena downstream that will also cause a transversal erosion at the slope toe. Soil erosion phenomena may alter the geometric characteristics of the slope and affect

its stability. The infiltration - percolation is related to the level and the shape of the groundwater table, and subsequently to the slope instability.

According to Figure 2, the FS of a soil slope is strongly affected and gradually decreases with respect to time due to various factors, such as the weathering and the heavy rainfall, whereas the impact of the erosion at the slope toe is detrimental (Popescu, 2002). Due to CC, slope instabilities and landslides are expected to occur more frequently (Psarropoulos et al., 2022), as the frequency, duration and intensity of the rainfalls are undoubtedly related to the instability and/or the erosion of a natural soil slope. Hence, it becomes evident that the realistic quantification of CC effects on the average annual precipitation is a critical issue for slope stability. However, in order to investigate such complex phenomena, hydrological models combined with the aforementioned slope stability analysis methods have been developed to calculate the FS of a slope under such conditions (Crosta and Frattini, 2008).

Figure 2. Changes in the Factor of Safety with respect to time (modified from Popescu (2002)).

As it has already been described, the phenomenon of slope instability constitutes a severe threat for CESs and CEI due to the high frequency of landslide occurrence, combined with the fact that especially large-scale energy infrastructure will unavoidably cross several potentially unstable slopes. The excessive PGDs that could be generated due to a slope failure are considered the most critical type of loading for CEI, sine the resulting deformation, in terms of stresses/strains, could lead to failure due to tension or buckling, resulting in significant leaks, major environmental impacts and long periods of service disruption (Vasseghi et al., 2021). Figure 3a presents slope instabilities close to the routing of Trans Adriatic Pipeline (TAP) in central Albania, while Figure 3b displays soil erosion phenomena along the routing of TAP close to the Greek-Albanian borders.

Figure 3. (a) Slope instability phenomena and (b) soil erosion phenomena close to the routing of TAP (photos taken by P.N. Psarropoulos).

3 ANALYTICAL ASSESSMENT

Herein, a simplified approach considering a plane translational slide has been examined, aiming to facilitate the understanding of the impact of the groundwater table on the resulting FS of a soil slope. In general, during a typically infinite translational slide, the upper mass of soil or sediments moves along a planar surface parallel to the ground surface or seabed. The soil mass movement may be represented in a simplified manner by a rigid block of height z , sliding on an inclined planar surface of angle θ . In order to demonstrate the effect of the aforementioned parameters on the FS, a parametric study has been conducted considering two different cases: (a) soil slope without groundwater table, and (b) soil slope with an inclined groundwater table. The resulting Factors of Safety have been evaluated considering three cases regarding clay under drained and undrained conditions, respectively, and sand. The angle of friction, ϕ , has been chosen equal to 30° , whereas soil cohesion under drained and undrained conditions, c and c_u , respectively, have been set equal to 20 kPa. In all cases the unit weight, γ , has been set equal to 17 kN/m^3 , while two cases of z have been taken into account ($z = 5 \text{ m}$ and $z = 15 \text{ m}$).

Figure 4. Sketch of a planar translational slide without the presence of groundwater table.

Figure 4 depicts the infinite translational slide without the presence of groundwater table, whereas the associated FS is expressed by:

$$FS = \frac{c}{\cos^2 \theta} + \frac{z \cdot \gamma \cdot \tan \phi}{z \cdot \gamma \cdot \tan \theta} \quad (1)$$

Accordingly, Figure 5 displays the resulting FS by means of the slope inclination angle, θ , and slope height, z , for the three aforementioned cases. More specifically, results from Figure 5a reveal that FS is quite high for small values of slope inclination (i.e., $\theta < 10^\circ$), and subsequently it gradually decreases with the increase of the inclination. It is worth noticing that z has a marginal impact on FS. As shown in Figure 5b, cohesionless soil material has exhibited a different behavior, compared to the other two cases, since the corresponding FS has been remained unaffected from the change of z . Moreover, it can be clearly observed that FS reaches 1 (i.e., the critical FS) when slope inclination is equal to angle of internal friction (i.e., $\phi = \theta$). Figure 5c, where $\phi = 0^\circ$, demonstrates that FS depends on both the slope inclination, θ , and height, z . Particularly, the resulting FS is relatively low, compared Figures 5a and b, especially when z is high, even at low values of slope inclination. In general, it can be clearly seen the soil mechanical properties and slope inclination may have a detrimental impact on FS, since reducing c and/or ϕ or increasing the value of slope inclination can produce lower values of FS.

Figure 5. Variation of FS with respect to slope inclination, θ , without groundwater table for the three examined soil types.

Figure 6. Sketch of a planar translational slide with the presence of groundwater table.

Figure 6 presents an infinite planar translational slide with inclined groundwater table. Assuming that the unit weights of the soil above and below the groundwater table (bulk and saturated unit weights) are equal to γ , the weight W' of a submerged segment is:

$$W' = \gamma' \cdot \alpha \cdot z \quad (2)$$

where γ' is the effective unit weight, derived by subtracting the unit weight of water γ_w from γ ; φ = angle of internal friction; γ = unit weight. The resulting FS' is calculated in this case as follows:

$$FS' = \frac{\frac{c}{\cos^2 \theta} + (z \cdot \gamma' + z_w \cdot \gamma_w) \cdot \tan \varphi}{z \cdot \gamma \cdot \tan \theta} \quad (3)$$

A parametric study has been conducted for the same three characteristic cases, taking into account the existence of groundwater table up to the middle (i.e., $z_w = z/2$) and up to the top of the layer (i.e., $z_w = 0$), as well. Hence, Figure 7 depicts the variation of the FS by means of slope inclination, for two different values of z . More specifically, Figures 7a to c correspond to the special case where $z_w = z/2$ and it can be clearly seen that an increase of the slope inclination has yielded a substantial decrease of FS', while an unfavourable impact of the increase of slope height on FS' has been revealed. Comparing Figures 7a and b (corresponding to $z_w = z/2$) with Figures 7d and 8e (corresponding to $z_w = 0$), it is obvious that an increase of the level of groundwater table has a detrimental impact on FS', as it was expected.

It is worth noticing that in clayey materials under drained conditions and in sandy soil materials $FS' = 1$ occurs when θ is much lower than φ , compared to dry conditions. Nonetheless, it is highlighted that increasing the level of groundwater table has not affected the case of

clay under undrained conditions. It can be generally observed that the FS of a soil slope is considerably affected by the soil mechanical properties and slope inclination, regardless of the presence of groundwater table, since reducing c and/or ϕ or increasing the value of slope inclination can produce lower values of FS or FS'. Nonetheless, increasing the level of groundwater table results in lower values of FS'. Moreover, by comparing a clayey soil material under drained conditions with and without the presence of groundwater table, it can be noticed that the presence of water leads to a substantial decrease of the FS. Analogous behaviour can be observed for the case of cohesionless soil material, with the exception that the height z of sliding mass has no impact on FS.

Figure 7. Variation of FS' with respect to slope inclination, θ , with inclined groundwater table for the three examined soil types. Cases (a), (b), and (c) are associated with $z_w = z/2$, while cases (d), (e) and (f) are associated with $z_w = 0$.

4 CONCLUSIONS

The current study focuses on the potential impact of CC on the structural performance of CESs and CEI that are located in or crossing mountainous or hilly areas and are exposed to the geohazard of slope instability. Despite that CC is generally considered as a major threat (since it is usually related to destructive phenomena), the current study shows that in these specific problems of geotechnical engineering (i.e., slope instability and soil erosion) the impact of CC on CESs and CEI may be either detrimental or beneficial depending on the local site conditions and the prevailing circumstances.

Undoubtedly, CC leads to more intense (i.e., heavier), but shorter in duration and less frequent, rainfalls. Hence, on the one hand, runoff is increased and consequently floods downstream and transversal erosion at the slope toe are increased (reduced slope stability – detrimental to CESs and CEI). In addition, the increased runoff may lead to increased erosion along the slope, which can be beneficial or detrimental, since the erosion may decrease or increase the slope inclination, respectively, depending on the circumstances. On the other hand, CC leads to a lower level of groundwater table due to the relatively decreased infiltration (higher slope stability – beneficial to CESs and CEI). Therefore, geo-scientists and especially geotechnical engineers should collect all the required input data (i.e., topographical, geological, hydro-geological, geotechnical and seismological) in order to examine the impact of CC on each potentially unstable area and subsequently on the integrity of CESs and CEI on a case-by-case basis.

ABSTRACT: Bridge structures are exposed to several chronic and abrupt stressors, among which the combined effects of corrosion and earthquakes pose a major threat to their long-term safety. Probabilistic risk assessment frameworks that quantify and propagate uncertainties inherent to these phenomena are necessary to mitigate this threat. This paper proposes a dynamic Bayesian network for state-dependent seismic fragility functions, capturing corrosion and seismic effects over time. Markovian transitions among deterioration states for different bridge components are developed, combining chloride diffusion and corrosion propagation models with non-stationary Gamma processes. State-dependent fragility curves are derived based on non-linear dynamic time-history analyses given possible degradation configurations of the structure, accounting for uncertainties in material, geometry, and deterioration parameters. Record-to-record variability is captured using synthetic ground motions. Results on a 4-span Gerber bridge showcase the suitability of the framework for describing life-cycle fragility, and its capacity for embedding in advanced algorithmic decision-making workflows is discussed.

1 INTRODUCTION

Bridges are infrastructure constituents of key socioeconomic importance, supporting vital road, rail, and pedestrian transportation systems. During their life-time, these structures must endure several continuous and sudden exogenous stressors.

Depending on the construction materials and environmental exposure, deterioration phenomena, such as corrosion, can have severe safety-reducing effects that increase over time (Vu & Stewart 1998). These become particularly critical when combined with extreme event hazards, such as those manifested in seismic-prone regions (Choe et al. 2008, Cui et al. 2018, Ghosh & Padgett 2010, Shekhar & Ghosh 2021).

Over the past century, the bridge construction sector has greatly focused on reinforced concrete designs due to material availability, cost-effectiveness, and structural performance considerations. A major deterioration factor for these structures, many of which are currently approaching or have well exceeded their design life, is corrosion of steel rebars (Bertolini et al. 2005), which exacerbates typical structural weaknesses against seismic loads. Besides strength and ductility reduction for the main concrete members due to rebar mass losses, corrosion also affects the performance of smaller, yet critical, bridge compartments, such as steel bearings, e.g. through plate thickness reduction, interlocking of sliding surfaces, and bolt failures (Mander et al. 1996). As such, bridges are heterogeneous time-dependent systems, where local component dynamics interact to eventually define global systemic behaviors and risks over the entire life-cycle. Numerous studies have dealt with the quantification of seismic safety losses deteriorating reinforced concrete bridges (Choe et al. 2008, Cui et al. 2018), also explicitly considering their multi-component character (Ghosh & Padgett 2010, Shekhar & Ghosh 2021).

Properly assessing structural safety losses is prerequisite for our ability to efficiently maintain the massive stock of aging concrete bridges, which is, in turn, paramount both for

minimizing the use of concrete in construction, thus curbing its major environmental impact, and for streamlining the immense economic needs of structural interventions. In that sense, managing structural integrity of existing bridges, requires not only at modeling of the aforementioned mechanical deterioration phenomena and their uncertainties, but also making these integrable with decision analysis frameworks.

In past years, the field of decision-making under uncertainties for existing structures has focused on coupling stochastic deterioration models, Bayesian decision principles, and advanced algorithmic procedures. Given the complexity of inspection and maintenance planning, featuring numerous possible actions in highly probabilistic environments, the problem has been shown to be efficiently defined within the global optimization framework of partially observable Markov decision processes (Andriotis & Papakonstantinou 2019, Morato et al. 2022). At the core of this formulation is expressing the deteriorating environment as a Dynamic Bayesian Network (DBN), which allows for efficient uncertainty propagation and inference over multiple time steps.

To address this need, this paper proposes a DBN approach allowing for updatable state-dependent seismic fragility functions, capturing long-term corrosion and seismic effects over time. The framework is applied to a case study bridge, modeled as a multi-component system, whose components are columns (COL), high type fixed bearings (HTFB), high type expansion bearings (HTEB), and low type fixed bearings (LTFB). In Section 2, the entire approach is described. First, the DBN structure is presented as well as the states which characterize it, namely the Corrosion Deterioration States (CDSs) and Seismic Damage States (SDSs). Then, the methodologies for determining both the conditional probabilities for Markovian transition among different corrosion damage states and the state-dependent seismic fragility curves are described. Section 3 is devoted to the case study bridge description to which the approach is applied. Then, in Section 4, the chloride corrosion probabilities over the lifetime of the structure are quantified and presented, as well as the state-dependent fragility curves, and the longitudinal effects of corrosion on the seismic fragility of column components. Finally, in Section 5, the main findings are summarized, underlining the suitability of the framework for capturing life-cycle fragility, as well as for being integrated with algorithmic decision-making workflows towards enhanced structural safety.

2 METHODOLOGY

2.1 DBN for life-cycle seismic fragility of deteriorating bridges

Seismic fragility functions represent the probability of a structure exceeding a seismic damage state (SDS), which quantifies structural damage in a discrete space in terms of an Engineering Demand Parameter (EDP), given an intensity measure (IM) of seismic action. As discussed in the previous section, seismic fragility is expected to increase over time due to structural deterioration for aging bridges. Therefore, encoding the corrosion intensity in a discrete space through the vector of corrosion deterioration state (CDS) of the system components, and the structural damage of those through the vector of seismic damage state (SDS), this probability can be expressed as:

$$P_{SDS,t} = P(SDS_t \geq s | IM_{0:t}, CDS_{0:t}, SDS_{0:t-1}) \quad (1)$$

where, without loss of generality, IM can also refer to vectors.

In this study, as an IM, the Peak Ground Acceleration (PGA) of the ground motion is used. For CDSs, rebars/bolts mass loss, M_{loss} [%], steel plates thickness reduction, PTR [mm], and the additive coefficient of friction k_{corr} [-], accounting for the interlocking effects due corrosion for expansion bearings, are used. The discretization and value ranges of these quantities are given in Table 1 for each component type, i.e. the columns component (CDS_{COL}), and the bearings component (CDS_{BEA}). SDSs for each component are defined through lognormal distribution of EDPs according to (Ghosh & Padgett 2010), with respective thresholds shown in Table 2, for each component type. The inference of Eq. (1) requires, in general, the use of a large number of analyses, that must combine the effects of corrosion and seismic action over the structural lifetime. To solve this problem, a Dynamic Bayesian Network (DBN) for quantifying the risk of aging bridges over their life-cycle is here developed and shown in Figure 1. A DBN is a directed acyclic graphical model that is particularly suitable for modeling

temporal patterns affected by uncertainties and can be used to easily solve inference problems. In such a model, variables are introduced through nodes, while conditional probabilities between these are represented by directed links. This way, it is possible to decompose the entire problem into smaller, easier-to-compute components by evaluating each probabilistic dependency with independent analyses.

The time-dependent nature of the seismic risk for aging structures is dynamically described through time-slices connected by conditional probabilities among CDS nodes, for which the Markovian assumption is considered. This way, CDS at time step $t+1$ depends only on the CDS in slice t :

$$P_{CDS,t} = P(CDS_0) \prod_0^{t-1} P(CDS_{\tau+1}|CDS_{\tau}) \quad (2)$$

To complete the description of the probabilistic graphical model, the following transitions between variables are introduced: the Markovian transition that describes the probability of having a corrosion state $CDS=j$ at time $t+1$, given the corrosion state $CDS=i$ at the previous time step t ; and the state-dependent and time-invariant fragility functions, describing the probability of the bridge reaching a seismic damage state SDS, given the IM and the corrosion deterioration state CDS. It is worth noting that, as CDSs are discrete and the corrosion phenomenon is time-dependent, Markovian transitions are described by non-stationary matrices, while fragilities are continuous functions since the IM variable is not subject to discretization. In addition, Markovian transitions between SDS nodes over time may be introduced to consider that the resulting structural damage carries over to the next time step if no repair action is not taken.

Table 1. Corrosion Deterioration States.

CDS		0	1	2	3
Component	Parameter	LB-UB	LB-UB	LB-UB	LB-UB
Columns	M_{loss} [%]	0-0	0-15	15-30	30-45
Bearings	M_{loss} [%]	0-0	0-15	15-30	30-45
Bearings	PTR [mm]	0-0	0-3.5	3.5-5.1	5.1-6.5
Bearings	k_{corr} [-]	0-0	0-0.35	0.35-0.64	0.64-0.92

* M_{loss} = rebars/bolts mass lost, PTR = plates thickness reduction, k_{corr} = additive coefficient of friction for expansion bearings.

2.2 Non-stationary transition for corrosion initiation and propagation

Non-stationary transitions among CDSs are calculated through a probabilistic analytical assessment of the rebars/bolts mass loss, M_{loss} [%], over the life-time of the structure. The other corrosion parameters, i.e., PTR [mm] and k_{corr} , are assumed to follow the same transitions in accordance with the CDSs defined in Table 1. In addition, the transition for corrosion initiation and propagation are calculated separately to account for the two-phase nature of

Table 2. Probabilistic seismic damage states thresholds.

Component	EDP	Slight		Moderate		Extensive		Complete	
		M	D	M	D	M	D	M	D
COL	Curvature ductility [-]	1.29	0.59	2.1	0.51	3.52	0.64	5.24	0.65
HTEB-L	Displacement [mm]	37.4	0.6	104.2	0.55	136.1	0.59	187	0.65
HTEB-T, HTEB, LTFB	Displacement [mm]	6	0.25	20	0.25	40	0.47	187	0.65

* M = median of the lognormal distribution, D = Dispersion of the lognormal distribution, L = Longitudinal direction, T = Transverse direction.

the phenomenon. Chloride corrosion occurs when the chloride content at the depth of the bars, C , exceeds the critical threshold, C_{cr} , and thus destroys the protective film of the reinforcing bars, exposing them to aggressive agents. Chloride penetration into the concrete volume is captured by Fick's second law, under the assumption of constant chloride content at the outer surface (Choe et al. 2008, Cui et al. 2018, Ghosh and Padgett 2010, Shekhar & Ghosh 2021), C_s , and considering the diffusion coefficient, D_c , through the model proposed in (fib 2006). The time to corrosion initiation, T_{corr} [years], which defines the transition from CDS=0 to CDS=1, is thus determined by discretizing the structure life-time in yearly time-slices and determining the first slice when $C(x,t) > C_{cr}$.

Corrosion propagation over time is a phenomenon governed by environmental and concrete parameters and is strongly characterized by aleatoric uncertainties. To capture its randomness, the phenomenon is modeled through a Gamma process, in which the mean annual increase in uniform bar penetration is calculated with the model proposed by (Vu & Stewart 1998) and considering a CoV of 0.5 (fib 2006). To calculate the mass loss for steel rebars/bolts, which defines the CDS, a corrosion morphology model must be introduced. In this study, the model proposed by (Val & Melchers 1997), which relates the maximum penetration in the rebar with the mass lost through the pitting factor R (i.e., ratio between maximum and uniform penetration) is adopted. Furthermore, the pitting factor is considered as a random variable to account for the randomness of the corrosion morphology, following the probability distribution suggested in (Stewart & Al-Harthy 2008). The corrosion initiation time, T_{corr} [years], is also required in the propagation model, thus, the statistics obtained through the initiation model are used to consider its variability. Therefore, changes in CDSs are evaluated for each time step, t , by calculating the annual increase in rebar/bolt mass losses.

Non-stationary transitions for both the initiation and propagation phases represents the conditional probability of having CDS= j at time $t+1$, given that CDS= i at time-slice t . This probability is estimated as:

$$P(\text{CDS}_{t+1} = j | \text{CDS}_t = i) = \frac{\#(\text{CDS}_{t+1} = j \cap \text{CDS}_t = i)}{\#(\text{CDS}_t = i)} \quad (3)$$

For this study a sample size of 10^6 Monte Carlo simulations has been observed to be sufficient. More details on statistical properties adopted in this study for the random variables are given in Section 3.

2.3 State-dependent fragility curves

The state-dependent and time-invariant fragility functions are estimated by comparing probabilistic demand parameters and capacity limit states for structural components. Demand parameters for structural components, are determined using nonlinear dynamic analysis, and a suite of synthetic ground motions to account for the record-to-record variability (Vlachos et al. 2018). To account for uncertainties in materials, construction details, model, and seismic demand, 25 nominally identical but statistically different Finite Element (FE) models of bridges were considered, for which 250 synthetic ground motions were applied, resulting in a sample size of 6250 demand parameters. Three-dimensional FE models were set up using OpenSees (McKenna 2011). The non-linear behavior of structural components is taken into

account for those considered as most vulnerable with respect to seismic and deterioration phenomena, i.e., COL, HTFB, HTEB, LTFB. For each structural component, 50 capacity values were sampled as per Table 2, and compared with the 6250 demand parameters, resulting in a total of 312500 SDS labels for component as a function of the IM.

This dataset was used for multinomial logistic regression, thus allowing the prediction of the probability of belonging to a given SDS as a function of IM through the softmax function (Andriotis et al. 2018). Therefore, the fragility for a limit state $SDS=i$ is obtained through sum of the softmax functions related to the SDSs $\geq i$:

$$P(SDS_i \geq i | IM, CDS) = \frac{\sum_{j=i}^J e^{\beta_{0,j} + \beta_{1,j} \ln(IM)}}{\sum_{j=0}^J e^{\beta_{0,j} + \beta_{1,j} \ln(IM)}} \quad (4)$$

where J is the number of SDSs defined in Table 2, plus one, to consider the possibility of not activating any damage state. For the choice of multinomial logistic regression compared to other methodologies to define fragility functions the interested reader is referred to (Yi et al. 2022).

2.4 Corrosion modeling of structural components

The non-linear behavior of columns due to steel reinforcement corrosion has been considered by reducing as a function of M_{loss} the (i) reinforcement strength; (ii) concrete cover strength and stiffness; and (iii) concrete core confinement. Steel rebar and bolt yielding strengths have been reduced according to the degradation law for uniform and pitting corroded rebars proposed in (Imperatore et al. 2017). Note that the morphological nature of the corrosion is taken into account by considering uniform corrosion law if pitting factor R is lower than 4, and pitting corrosion law if R is higher than 4, thus identifying the type of corrosion as suggested in (Bertolini et al. 2005).

Concrete cover cracking following the expansion of the oxides produced by the corrosion process is accounted as proposed in (Coronelli & Gambarova 2004), and evaluating the average crack opening due to corrosion oxides expansion with the model proposed by (Vidal et al. 2004). In (Coronelli & Gambarova 2004), it is also suggested to consider the concrete cover stiffness reduction, which is accounted in this work in a simplified but safety-aware way, by neglecting the presence of the concrete cover upon exceedance of an average crack width of 1mm. Confinement losses of the concrete core, evaluated as proposed in (Mander et al. 1988), are accounted reducing the yielding strength of the stirrups. Bearings modeling approaches are based on the extensive study by (Mander et al. 1996), in which the experimental behavior of several types of steel bearings is compared with analytical methods, and in which valuable suggestions for the finite element modeling are reported. Following this approach, the mechanical behavior of these components is studied and modeled separately, with regard to the longitudinal and transverse direction of the bridge. For these components, the failure modes considered, as well as the analytical approaches for estimating the ultimate strength, even in the presence of corrosion, are referred to (Mander et al. 1996, Shekhar & Ghosh 2021).

3 CASE STUDY BRIDGE

The methodology described in the previous section is applied to an archetype 4-span bridge, representative of a wide range of seismic-vulnerable and deterioration-sensitive existing reinforced concrete bridges, present in infrastructure networks. The main geometrical features and finite element modeling choices are summarized in Figure 2. The deck has six prestressed I-beams, 1.5 m high, and presents two Gerber spans between half-joints. The column piers have a double circular cross-section of 1.3m diameter. Seismically vulnerable features of the bridge include the poor detailing of the columns as longitudinal reinforcement ratio equals 1% and circular stirrup spacing of 250mm, without any additional confinement in the dissipative zone.

For columns, nonlinear beam-column elements are used with appropriate (un)confined concrete and steel properties in OpenSees. The structural component is discretized along the height into three distinct elements. This way, since wide value ranges for CDSs are considered,

Figure 2. The studied 4-span Gerber bridge with respective geometrical and FE modeling features.

as shown in Table 1, the chance to have different corrosion intensity (M_{loss}) within the same CDS along the height of the column is accounted, thus the possibility of plastic hinges in zones away from the column base due to corrosion is captured (Yuan et al. 2017). The behavior of the bearings is modeled through friction and hysteretic links in the direction where displacements are constrained, and friction links only in the longitudinal direction for HTEB. Pile foundations are modeled using soil-foundation springs with linear behavior, abutments are modeled with linear translational springs, considering both passive and active stiffnesses. Abutment-deck gaps are modeled through gap elements.

Following the definitions of (Duracrete 2000), environmental effects of both “splash” zone, representative of the use of de-icing salts, and “atmospheric zone” were compared. Moreover, “humid” exposure is considered. For the evaluation of CDSs transitions, the following random variables are assumed for components’ materials and geometry: a lognormal distribution with mean 30 mm and CoV of 20% for the concrete cover depth; a discrete uniform distribution between [0.4,0.45,0.50] for the water-cement ratio; a normal distribution with mean 293° K and CoV of 2% for the actual temperature; and a Gumbel distribution with characteristics defined in (Stewart & Al-Harthy 2008) for the pitting factor. In addition, the other random variables in the chloride propagation model are assumed according to the values suggested in (Duracrete 2000, fib 2006, Choe et al. 2008). For the bridge FE model, the following random variables are considered for material properties: a normal distribution with a mean 43 MPa and CoV of 20% for the concrete mean cylindrical compressive strength; a lognormal distribution with mean 520 MPa and CoV of 10% for the steel yielding strength. The other material properties such as ultimate strain for (un)confined concrete, and steel stiffnesses, are adopted as suggested in (Cui et al. 2018). Regarding values for random variables related to others modeling parameters, reference is made to (Nielson & DesRoches 2007).

4 RESULTS

In this section, the built model is applied for assessing the state-dependent fragility of the studied bridge. In Figure 3, the CDS probabilities, P_{CDS} , for structural components over the structural lifetime, relatively to both “splash” and “atmospheric” zones, are shown; these are generated by multiplying the observed non-stationary transitions by Eq (2). As expected, a higher probability of corrosion activation and propagation for the “splash” zone is found, as it is representative of a more chloride-aggressive environment. Environmental effects resulted in the following CDS probabilities after 100 years for the “splash” zone: $P_{CDS=0} = 0.0289$, $P_{CDS=1} = 0.2342$, $P_{CDS=2} = 0.2374$, $P_{CDS=3} = 0.4995$; and on the other hand, for the “atmospheric” zone, the following CDS probabilities, P_{CDS} , after 100 years are found: $P_{CDS=0} = 0.9726$, $P_{CDS=1} = 0.0124$, $P_{CDS=2} = 0.0064$, $P_{CDS=3} = 0.0085$. The results of seismic nonlinear dynamic analyses for column components are presented with respect to 4 corrosion scenarios, i.e., $DCS_{COL} = 0$ & $DCS_{BEA} = 0$, $DCS_{COL} = 1$ & $DCS_{BEA} = 0$, $DCS_{COL} = 2$ & $DCS_{BEA} = 0$, $DCS_{COL} = 3$ & $DCS_{BEA} = 0$. In Figure 4 the respective state-dependent fragility curves for column components are reported, thus showing the corrosion effects on their seismic safety.

The longitudinal effects of columns corrosion for their fragility for both “splash” and “atmospheric” are shown in Figure 5; these are obtained by combining the above results on non-stationary

Figure 3. Probability for corrosion deterioration states (P_{CDS}) of structural components over their lifetime.

CDS probability and state-dependent fragilities through the weighted sum of the logistic functions based on P_{CDS} . This way, the suitability of the method for predicting time-varying fragility effects due to exposure to chloride-aggressive environments over the structural life is highlighted.

5 CONCLUSIONS

In this paper, a dynamic Bayesian network for life-cycle seismic fragility assessment of aging bridges is developed. The methodology is applied to a 4-span Gerber bridge case study, modeled as a multi-component structural system, with components referring to different columns and bearing types, to properly define seismic damage state characteristics under corrosion. Non-stationary Markovian transitions among deterioration states of the structural components are estimated through Monte Carlo simulation, and based on available probabilistic models for corrosion initiation and propagation. The seismic fragility with respect to five states of seismic damage is learned through multinomial logistic regression based on the results of nonlinear dynamic analyses, in which uncertainties in materials, geometry, modeling, seismic action and corrosion process are accounted. The results confirm the sensitivity of seismic responses to corrosion effects, and display how different aggressive environments can change the seismic safety of the bridge

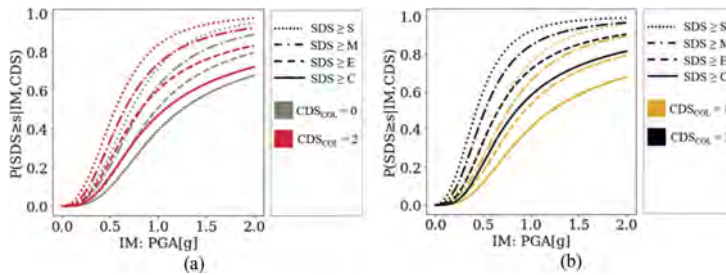

Figure 4. State-dependent fragility curves for the 4-span bridge columns. a) Comparison between scenarios $CDS_{COL} = 0$ and $CDS_{COL} = 2$; b) Comparison between scenarios $CDS_{COL} = 1$ and $CDS_{COL} = 3$.

components over time. The proposed approach is an important step towards effective and flexible assessment and management of aging bridges structures. The DBN structure makes it possible to add new variables in the probabilistic graph without affecting those presented here, as well as to lend itself to advanced decision-support systems relying on Markov processes which can be consistently to the derived transition probabilities. Along these lines, possible extensions include, among others, consideration of residual structural capacity in the damage state definition, coupling of component limit states with non-seismic loads, and incorporation of action and observation variables for fragility updates based on inspection and maintenance outcomes.

Bolt axial force detection using deep learning based on vision methods

Y. Chen, J. Lai, G. Hayashi & T. Yamaguchi
Osaka Metropolitan University, Osaka, Japan

ABSTRACT: Previous studies have found that high-strength bolt axial force of many in-service bridges decreased by 10%–20% from the design bolt axial force. One of the reasons is that the bolts cannot be tensioned to the design axial force owing to various difficult construction conditions and errors. Appropriate control of the axial force while fastening the bolts is important. Contact methods using ultrasonic testing and eddy currents have been employed to detect bolt axial force. This paper proposes a non-contact vision-based bolt axial force detection method using deep learning. We focus on the relative deformation feature of the bolt head inscriptions and train the neural network via regression method. The training results indicate that even when the image size is reduced to 448 pixels, it was able to obtain correct results for axial force detection for the type of bolt that was used to train the model.

1 INTRODUCTION

High-strength friction bolted joints (hereafter referred to as friction joints) are often used in the field joints of steel bridges (AASHTO, 2020; Eurocode3, 2005; Japan Road Association (JRA), 2017). A prior study (Iida et al., 2021) investigated the residual axial force of high-strength bolts after friction joints have been in service for several years. The results showed that the residual axial force of many bolts was 10%–20% lower than the design axial force, irrespective of the service life of the friction joints and erection conditions of the steel bridges. This disparity was attributed to variations in the torque coefficients of bolts in situ joints and difficulties in controlling the construction quality (Iida et al., 2021, 2022).

Given that the residual bolt axial force may be lower than the designed axial force owing to limited control of the axial force during fastening, it is crucial to ensure the appropriate bolt axial force in the initial stage.

Among the contact methods to detect the bolt axial force, a novel method to measure axial force by using the vibration of bolts has been reported (Toh et al., 2019). An axial force evaluation method using eddy current has also been proposed (Akutsu et al., 2022). Further, (Hirao et al., 2022) proposed an ultrasonic bolt axial force evaluation method using machine learning based on characteristic signals to detect the bolt axial force. However, considering the construction conditions in situ, determining the axial force using an axial force meter (ultrasonic or load cell type) or percussion test on-site would be difficult (e.g., in case of on-site construction in aerial work platforms). Considering the current aging population and decreasing number of engineers, developing a non-contact method to control bolt axial forces is necessary.

Convolutional neural network (CNN)-based methods using bolt head photographs have been explored for non-contact axial force control since 2012. (Huynh et al., 2019; Ramana et al., 2019) proposed CNN-based methods for determining whether a bolt is tight based on the bolt diameter and exposed shaft length. (Zhao et al., 2019) studied the effects of aspects such as angle and exposure associated with the bolt head photographs, which are used as

Figure 1. Experimental setup to measure actual bolt axial force and record the picture of bolt head.

training data for a CNN, on the recognition rate. The results of the aforementioned studies have high potential applicability in controlling bolt tension by using photographs of the bolt heads; thus, CNNs may be used to realize the management of bolt axial forces in situ.

Bolt recognition generally employs the shape of the bolt as a feature for classification analysis; there are no rigorous requirements concerning the accuracy of the image. In this study, we developed a method to extract the relative deformation of bolt head inscriptions to detect bolt axial force by training the neural network with regression. Because of the need to observe even small deformations, it demands relatively large image sizes. We investigated the possibility of managing bolt axial forces based on photographs of bolt heads by using CNNs and high-strength hexagonal bolts. Additionally, we investigated the practicality of the method by fully adapting the specifications, such as the brightness, resolution, and focal length, of the photographs to an in-situ construction environment.

2 EXPERIMENT

2.1 Set up

Figure 1 shows that a 500 kN hydraulic jack (hand pump) was used to apply the bolt axial force, while a load cell and data logger (TDS-630) were used to measure the true bolt axial force, which was recorded in the computer. Simultaneously, the bolt head picture was taken by a digital single-lens reflex camera (Sony $\alpha 1$). Both the camera and data logger were set to record (take pictures) data at 2 s. Table 1 shows the detailed settings of the device.

Table 1. Device and parameter settings.

Name	Parameter
Data Logger	TDS-630
Measurement interval	2 s
Load speed	2 kN/1 s
Camera	Sony $\alpha 1$
Lens	FE 24-70 mm F2.8 GM II
F-stop	f/2.8
Exposure time	1/80 s
ISO	200
Focal length	70 mm
Resolution	350 DPI

2.2 Dataset and case

Considering the different surface properties of each bolt, 12 bolts were prepared for this study. We took 200 pictures of each bolt and augmented them to 1,000. A picture was taken at 5 kN intervals, and when the load reached approximately 106 kN, the bolts were unloaded to 10 kN.

Owing to the different traits of the bolt head surface, two series of cases were established in this study to discuss the qualities needed to detect the bolt axial forces. To discuss the effects of the input image size on the training accuracy, the image size was set as a parameter as shown in Table 2.

The valid dataset has a similar experiment environment as the training data and uses similar bolt series, while the test dataset uses completely different bolts and experiments at the real bolted joint.

Table 2. Discussion case and its parameters.

Series	Total number of bolt	Inputs size	Number of input picture		
			Train	Valid	Test
One-bolt	1	1120 × 1120 672 × 672	1600	400	400
Multi-bolt	12	448 × 448 224 × 224	8000	2000	2000

2.3 Hardware and software configurations

Training deep learning networks (especially using high-resolution images) requires ample computing power. A Dell 7910 workstation was used for training the model. The workstation featured an Nvidia RTX A4000 (16 GB GDDR6 GPU memory) and 256 GB of RAM. The model training was based on PyTorch, CUDA, and cuDNN.

3 CONVOLUTIONAL NEURAL NETWORK

Evidently, the deeper the neural network, the harder it is to train. Deeper networks can cause vanishing and exploding gradient problems. To avoid such problems, we used ResNet-50 in this study (He et al., 2016) as the base framework for the network architecture. This framework introduces a residual block that could skip some layers to connect the activations of one layer to other layers as expressed in $y = \mathcal{F}(x, \{W_i\}) + x$. As shown in Figure 2, the output of the network used logistic regression analysis, wherein the output class was 1 for the speculative axial force of the bolt. The loss function (MSE loss) and sigmoid function were used in the output regression layer. Stochastic gradient descent (SGD) was used in the optimizer. The hyperparameters of the optimizer and dropout layer are shown in Table 3.

When high-strength bolts are subjected to axial force, the bolt heads deform to a concave shape, and the relative positions of bolt head inscriptions change. The input images were converted from 24-bit color to 8-bit grayscale format. This grayscale value matrix was read, and a convolution layer was used to extract the features. A convolution kernel (filter) was used as a bias (W_i). The extracted data was processed by a pooling layer to perform maximum or average processing as shown in Figure 3. The training was then completed by iteratively computing the feature values to obtain the best bias.

4 DATA PREPROCESSING

4.1 Data augmentation

The original input images were randomly augmented nine times using one of the following augmentation algorithms: additive Gaussian noise, add (adds a value to all pixels in an image),

Table 3. Hyperparameters of training.

Hyperparameters	Value
Optimizer	SGD
Learning rate	0.001
Momentum	0.9
Dropout	0, 0.25, 0.5, 0.8
Loss Function	MSELoss
Full Connection Layer	1, 2, 3
Epoch	500

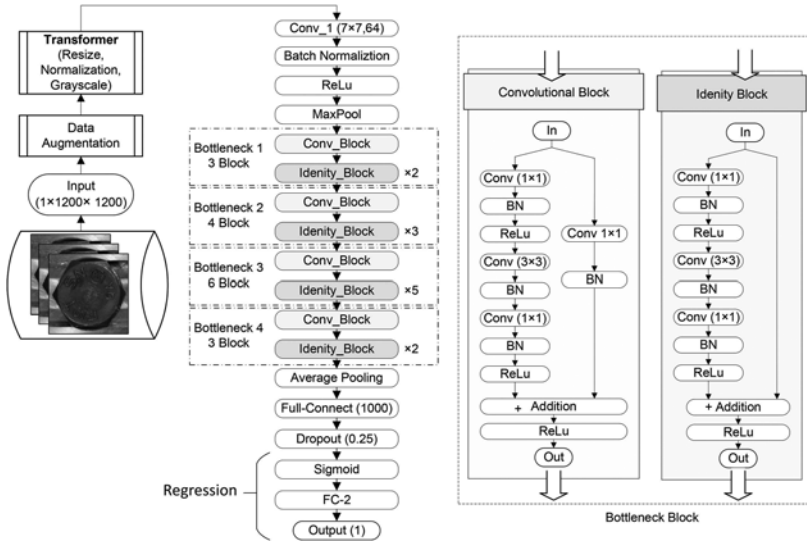

Figure 2. CNN architecture based on resNet50, and the residual block.

Figure 3. Extraction of bolt head features and setting of bias.

multiply (multiplies all pixels in an image using a specific value), edge detection (detects all edges in an image), contrast normalization, and sharpen. Figure 4 shows the original input image and that augmented using the additive Gaussian noise and sharpen algorithms.

4.2 Transformer

All the images were treated using grayscale processing, so the input layer of the network was set to 1. To study the effect of the image size on the prediction accuracy, the input images were resized to 1,120 (0.0029 mm/pixel), 672 (0.048 mm/pixel), 448 (0.073 mm/pixel), and 224 (0.15 mm/pixel) pixels.

Figure 4. Input picture (Augmented using additive Gaussian noise, sharpening).

5 RESULTS

5.1 Performance measures

In this study, we used the mean squared error (MSE), root mean squared logarithmic error (RMSE), mean absolute error (MAE), and coefficient of determination (R^2) to evaluate the regression model.

The MSE represents the average of the squared difference between the original and predicted values in the data set. It is used to measure the variance of the residuals.

$$\text{MSE} = \frac{1}{N} \sum_{i=1}^N (y_i - \hat{y}_i)^2 \quad (1)$$

RMSE is the square root of the MSE. It is used to measure the standard deviation of the residuals.

$$\text{RMSE} = \sqrt{\frac{1}{N} \sum_{i=1}^N (y_i - \hat{y}_i)^2} \quad (2)$$

The MAE represents the average of the absolute difference between the actual and predicted values in the result. It is used to measure the average of the residuals in the result.

$$\text{MAE} = \frac{1}{N} \sum_{i=1}^N |y_i - \hat{y}_i| \quad (3)$$

R^2 represents the proportion of the variance in the dependent variables, which is explained by the regression model:

$$R^2 = 1 - \frac{\sum_{i=1}^N (y_i - \hat{y}_i)^2}{\sum_{i=1}^N (y_i - \bar{y})^2} \quad (4)$$

Where y_i is the actual value and \hat{y}_i the predicted value. \bar{y} is the mean value of the actual dataset.

5.2 Impact of input image size on accuracy

Figure 5 shows the R-squared test result of the one-bolt and multi-bolt series. For the one-bolt series, the size of the input image does not greatly influence the verification result. However, when the training data has 10 different bolts and the input image is reduced to 224 (0.15 mm/pixel), the R-squared (accuracy) of the validation results drops dramatically to around 0.5. This is so because when there are multiple bolts, the amount of features to be extracted is more than that of a single bolt.

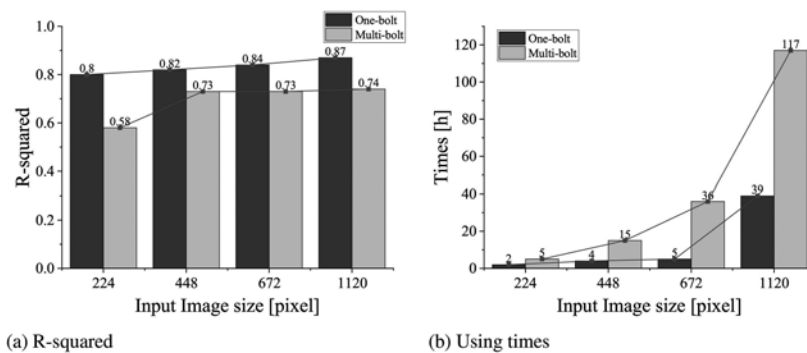

Figure 5. The R-squared and time test result of one-bolt series and multi-bolt series.

Additionally, the time required for each series of calculations is shown in the figure. When the training data reaches 8,000 images (multiple bolts), it takes 117 hours to train a set of high-resolution images (size 1,120, 0.029 *mm/pixel*) and 15 hours to train images of size 448 (0.073 *mm/pixel*) that have a small R-squared (accuracy) difference. Considering the computational cost and feasibility of the application for real-time bolt axial force detection, sizes 448 or 672 are the recommended image sizes. The image size here is the image that contains exactly the entire bolt head.

5.3 Validation results

The relationship between the prediction and label data of the one-bolt and multi-bolt series is shown in Figure 6. Regarding the validation dataset, most of the predictions were accurate. In case of valid multiple bolts, the detected bolt axial force has a large variate. It is assumed that because each bolt head has a different shape, the network detects the bolt head features incorrectly.

Table 4 shows the total validation result of the one-bolt and multi-bolt series. Dropout is a regularization technique used to reduce overfitting in neural networks by randomly setting a fraction of the input units to 0 during training. The greater the dropout parameter, the better would be the obtained results. Even when the parameter was 0.8, the training results indicate remarkable performance. The amount of features needed to train a network using the bolt heads is not as large as expected, and this task does not require particularly high-pixel images.

On the test dataset, an R^2 value of only 0.48 is attained, indicating that this network could not detect bolt axial force in diverse environments with different bolts. The surface traits of each bolt head varied and the relative positions of the head inscriptions were inconsistent, thereby resulting in the inability of the network to obtain the required amount of features. Since the training data had been greatly augmented, the input images were grayscale, and the images were cropped to include only the bolt head during training, it can be concluded that environmental factors hardly affect the model performance.

5.4 Training loss

Figure 7 shows the relationship between total loss and epoch (a is case 5 and b is case 10). Most cases converge to 0 loss at approximately 250 epochs. The training was suspended after reaching approximately 500 epochs. Although the validation loss fluctuated slightly between 250 and 500 epochs, no overfitting occurred.

6 CONCLUSIONS

This study used a modified ResNet-based neural network to detect the bolt axial force using bolt head images. When the bolt was subjected to an axial force, the head of the bolt deformed into a concave shape, and the axial force of the bolt was detected by determining the relative

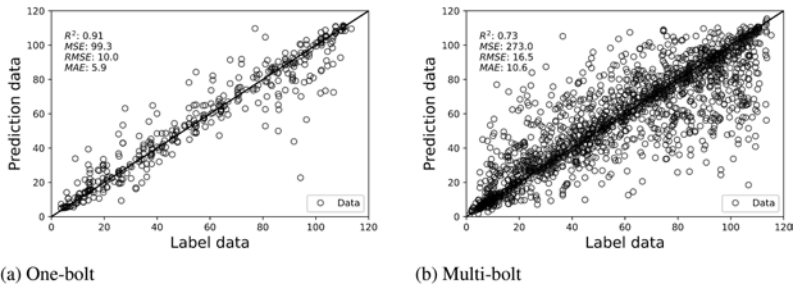

Figure 6. Relationship between prediction and label data.

3	one	672	1	0	208	14.4	8.9	0.84
4	one	1120	1	0	146.34	12.1	6.92	0.87
5	one	448	1	0.8	134.74	11.6	7.13	0.88
6	one	448	3	0	135	11.8	7.86	0.87
7	one	448	3	0.25	131	11.4	7.06	0.88
8	one	448	3	0.5	124.6	11.4	7.06	0.89
9	one	448	3	0.8	99.2	9.96	5.88	0.91
10	Multi	224	3	0.8	352.31	26.23	14.2	0.58
11	Multi	448	3	0.8	273.01	16.52	10.57	0.73
12	Multi	672	3	0.8	251.15	15.34	10.25	0.73
13	Multi	1120	3	0.8	246.2	15.1	9.83	0.74
14	Test-multi	448	3	0.8	614.55	25.75	18.32	0.48

Figure 7. Total loss under different cases.

change in the features of the bolt head. The network included a dropout layer to prevent overfitting and a modified output full connection layer; further, the activated function changed network to the regression method.

- When the input image size was reduced from 1120×1120 (0.029 mm/pixel) to 448×448 pixels (0.073 mm/pixel), the validation results converged and did not change considerably. Even when the image size was reduced to 448 pixels, the proposed model was able to obtain correct results for axial force detection, with an R-squared value of 0.91 and a mean absolute error of 5.8 kN. Considering the computational cost and feasibility of the application

of this method for real-time bolt axial force detection, 448 or 672 pixels are the recommended image sizes. The images used in this study were of the entire bolt heads.

- The dropout layer plays an important role in optimizing the training results; even when the dropout parameter was set to 0.8, the model obtained good training results. The number of features needed to train the network using the bolt head images was not as large as expected.
- Although good results on the validation set were obtained using this model, the network did not perform suitably on the test set. Further research must be conducted to overcome the variations in the number of features corresponding to the different types of bolts.

ABSTRACT: We have developed a system that inspects the entire circumference of tube-to-tube sheet welds using phased array ultrasonic testing for manufacturing of heat exchangers. Therefore, a huge number of images were generated during the inspection. In the past, inspectors made visual judgments based on these images, but due to the long inspection period, it was difficult to inspect all of them. As a solution to this problem, we have developed a system that automatically detects flaws in weld. In constructing the flaw detection system, image processing, AE (Autoencoder), and CNN (Convolutional Neural Network) were examined, but individual judgment accuracy was not sufficient. Therefore, an ensemble method was applied. In the proposed method, the reliability of each discriminator was calculated for each image to be evaluated, and the presence or absence of flaws was finally determined according to the reliability. It was confirmed that the accuracy was improved by applying this flaw detection system.

1 INTRODUCTION

As an inspection method for tube-to-tubesheet weld in multitube heat exchangers, phased array ultrasonic testing (PAUT) is used to detect flaws, such as welding defects and cracks, and measure the weld metal height and to verify integrity and conformity to design dimensions (Abe et al. 2017, Shinoda et al. 2019). Flaw detection data were used to generate 360 flaw detection images per tube, and then a system was put into practical use that judges the presence/absence of flaws by using deep learning AI technology (Abe et al. 2022). In this paper, we describe the improvement of the reliability calculation method for classifiers.

2 PHASED ARRAY ULTRASONIC TESTING SYSTEM

An instrument equipped with an array probe is inserted into a tube and propagates ultrasonic waves from the tube inside to inspect all 360 degrees of the tube's circumference at the tube-to-tubesheet weld, at 1-degree intervals. Using multiple array probes based on the tube diameter, linear and sector scans are performed by electronic scanning, improving the flaw detection accuracy. As a guide, the inspection time is 1 minute or less per tube, with some additional time for repositioning the PAUT device.

3 FLAW DETECTION IMAGE

Figure 1 shows the flaw detection image data of the tube sheet welding specimen. The specimen has an artificial hole with a diameter of 1 mm (flat-bottomed hole, FBH) in a direction parallel to the tubesheet surface and perpendicular to the tube axis. The top center image shows the linear scan results, and the top left and right images show the sector scan results from the tube end and root sides of the array, respectively. The bottom image shows the whole circumference, called the C-scope, obtained by turning the array probe 360 degrees, and the detection data for the FBH is displayed in the band indicating the weld joint. As shown in the segment circled in red in Figure 1, the FBH is clearly detected. A similar flaw detection result was obtained for another test specimen with an artificial hole in a direction oblique to the tubesheet surface and parallel to the tube axis. If the weld height is insufficient, the band indicating the weld is narrower. If there is a defect in the weld, a reflection echo will appear. And so, the integrity of the weld can be clearly confirmed.

Figure 1. Screen displaying scan results for FBH.

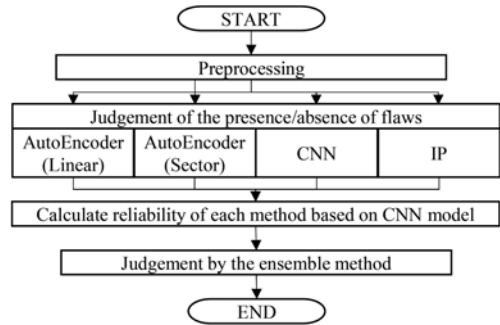

Figure 2. Judgement flow for PAUT of tube-to-tubesheet weld joint.

4 FLAW DETECTION SYSTEM

The flaw positions, weld metal heights, shapes and sizes of reflection echoes, and other parameters may vary in complicated ways in flaw detection images depending on the welding conditions of the tube-to-tubesheet weld, contact conditions of the array probe, and other factors, even if the thicknesses and diameters of tubes are the same. The proposed decision support system provides an integrated optimal solution to each problem by combining multiple judgment methods in order to improve the accuracy in judging the presence/absence of flaws while taking these variations into account.

4.1 Judgement system

Figure 2 shows the judgement flow for the present system. YOLO, Convolutional Neural Network (CNN), and Auto Encoder (AE), which are all classified as deep learning approaches, were adopted (Hinton et al. 2006, Krizhevsky et al. 2012, Rendon et al. 2016, Wen et al. 2016, Zhao et al. 2017). In this system, the detection images were preprocessed to use as input data for the judgement system. At first, the flaw detection area was extracted by YOLO. The presence/absence of flaws was judged by using image processing (IP), image classification using CNN, and image restoration using AE on the preprocessed flaw detection images. The probability of being correct was calculated for each judgment method with the reliability level by CNN. Finally, an ensemble judgment was made based on the judgment results and reliability for each method, and the final judgment result was output. Each system is described in detail below.

4.2 Preprocessing: Extraction of the judgment area by YOLO

In order to judge only the tube-to-tubesheet weld in the flaw detection image, the judgment area was extracted using the YOLO object detection method. The extracted area is surrounded by

a black dashed line and contains the tube-to-tubesheet weld, targeting (1) to (4) in Figure 3(a), which are echoes reflected from the periphery (tube surfaces at the tube end and root sides) of the tube-to-tubesheet weld (bottom echoes). The above area was annotated to learn the coordinate information as training data, and the area detection model shown in Figure 3(b) was created.

Figure 3. Detection area and extraction result by YOLO.

4.3 Judgment by IP

IP is a method of distinguishing pixel values of images based on a pre-set threshold. In the case of judging the presence/absence of flaws in flaw detection images by IP, the detection area was first extracted using YOLO, and a flaw was then judged to be present if there was more than a certain number of pixel values with levels greater than the threshold among all the pixels in the area, excluding bottom echoes.

4.4 Judgment by image classification using CNN

CNN is highly accurate as a method of image classification, and it extracts and classifies image feature values. In the case of judging the presence/absence of flaws in flaw detection images by CNN, the detection area was first extracted using YOLO, and then the images were classified into 2 groups (with flaws and without flaws) based on the results of learning images with flaws and images without flaws.

4.5 Judgment by image restoration using AE

AE is an unsupervised learning technique, and it has the advantage of being able to learn with only normal data. In the case of judging the presence/absence of flaws in flaw detection images by AE, the detection area was first extracted using YOLO, and then the difference in pixel value at the flaw position was used as the judgment index. It was judged that there was a flaw if the difference in the pixel value was greater than a certain value and that there was not a flaw if the value was less than a certain value.

4.6 Judgment results by each judgment method

Table 1 shows the results of judging 16,920 test images, including 762 images with flaws, using the IP, CNN, and AE methods (Shinoda et al. 2022). The test images were randomly extracted from flaw detection data of actual equipment. Accuracy represents the probability of correctly classifying the presence/absence of flaws in all the images. Precision represents the probability of including the actual images with flaws in the results predicted to include flaws. Recall represents the probability of correctly judging the images with flaws and it's an indicator of the oversight. Finally, specificity represents the probability of correctly judging the images without flaws and it's an indicator of the over-detection.

Because of the focus on increasing Recall accuracy to reduce the number of flaw images that were not detected, Precision accuracy was also proportionally reduced. In addition, some of the images that were classified correctly or incorrectly differed depending on the method. For example, images incorrectly judged by CNN, which had the highest recall among the individual methods, were sometimes judged correctly by IP and AE. Therefore, the reliability and ensemble judgments were adopted.

Table 1. Judgment results by each method.

Method	Accuracy (%)	Precision (%)	Recall (%)	Specificity (%)
IP	98.4	74.0	98.4	98.4
CNN	94.0	42.6	99.6	93.7
AE	98.3	73.8	97.2	98.4

4.7 Reliability judgment

To determine the reliability of each method, we prepared data of correct and incorrect images judged by each method. These images were used as training data of a newly constructed CNN model. The output value from the model was then defined as the reliability of each method. Specifically, its output value is given a numerical value between 0 and 1 as the probability that each method is correct. The reliability of each image was calculated for each judgment method as input the images of flaws from which the judgment area was extracted by YOLO. If the image is similar to an image that was previously correct, the reliability is given a value close to 1. If the image is similar to an image that was previously incorrect, the reliability is given a value close to 0.

It takes time to calculate the weight for each image, but it is possible to make more precise judgments because it is determined based on past results.

4.8 Ensemble judgment

Ensemble judgments were made based on the sum (y) of the products of the judgment results (x_i) and reliability (r_i) for each judgment method, as shown in the equation below. The ensemble judgment result was deemed to be the final judgment result: $y > 0$ for images with flaws; $y < 0$ for images without flaws; $y = 0$ for not determinable. It represents a comprehensive judgment result that appropriately takes into consideration the judgment results of each method according to their reliability based on the flaw detection image.

$$y = \sum x_i r_i \quad (1)$$

where x_i is the judgment result for each method (with a flaw, 1; without a flaw, -1) and r_i is the reliability for each method (real number from 0 to 1).

Table 2 shows the results of an ensemble judgment for the 16,920 test images used in Section 4.6. Although there was 1 undetected image among the 762 images with flaws, the judgement accuracy was improved for every index compared with the results for each of the individual judgment methods, and it was possible to reduce not only the undetected images with flaws but also the erroneously detected images without flaws.

Table 2. Judgment results by ensemble system.

Method	Accuracy (%)	Precision (%)	Recall (%)	Specificity (%)
Ensemble	99.4	88.6	99.9	99.4

5 VERIFICATION ON THE ACTUAL EQUIPMENT

5.1 Verification on the actual equipment

Table 3 shows the results of judging 36,723 test images, including 11,896 images with flaws. Those data were different from the data of the previous chapter. In this case, the size of tube is bigger than previous one and another condition is also different. Thus, AE for judgement and CNN for reliability was learned the data form this equipment. Since this tube-to-tubeseet was in service, the inner surface has some corrosion. From this thing, the obtain data has some noise. Then, the accuracy was lower than the result of the previous one.

Table 3. Judgment results by each method and ensemble system.

Method	Accuracy (%)	Precision (%)	Recall (%)	Specificity (%)
IP	60.9	59.2	92.0	23.0
AE(Linear)	77.1	89.6	66.0	90.7
AE(Sector)	52.3	56.5	56.6	47.1
Ensemble	76.3	76.2	82.6	68.7

From this result, it's confirmed the accuracy of ensemble system lower than accuracy of the AE used linear image. So, the reliability of each test data was confirmed. Tables 4, 5 and 6 show the relationship of the correct/incorrect and the reliability for each image. In those table, the reliability was divided two categories, less than 0.5 or more.

Table 4. The relationship of the correct/incorrect and the reliability for IP.

Status	Reliability < 0.5	Reliability >= 0.5	Accuracy (%)
Incorrect	10,606	3,764	73.8
Correct	6,853	15,500	69.3

Table 5. The relationship of the correct/incorrect and the reliability for AE used linear image.

Status	Reliability < 0.5	Reliability >= 0.5	Accuracy (%)
Incorrect	6,587	1,807	78.5
Correct	9,930	18,399	64.9

Table 6. The relationship of the correct/incorrect and the reliability for AE used sector image.

Status	Reliability < 0.5	Reliability >= 0.5	Accuracy (%)
Incorrect	9,626	7,880	55.0
Correct	6,557	12,660	65.9

From those results, it was confirmed the accuracy of reliability is less than 80%, especially, the accuracy for AE used sector image are less than 70%. It means correlation between correctness and reliability was low.

5.2 Improve the reliability calculation method

In this section, the image to calculate the reliability was changed to composite image. Composite image was made from linear and sector images. The value of each pixel of composite image is max value of those three images. By using composite image, it is expected the accuracy of reliability is improved.

Figure 4. Composite image.

Tables 7, 8 and 9 show the relationship of the correct/incorrect and the reliability for each image when use the composite image using same data with Section 5.1.

Table 7. The relationship of the correct/incorrect and the reliability for IP.

Status	Reliability < 0.5	Reliability >= 0.5	Accuracy (%)
Incorrect	12,240	2,130	85.2
Correct	4,128	18,225	81.5

Table 8. The relationship of the correct/incorrect and the reliability for AE used linear image.

Status	Reliability < 0.5	Reliability >= 0.5	Accuracy (%)
Incorrect	7,605	789	90.6
Correct	5,837	22,492	79.4

Table 9. The relationship of the correct/incorrect and the reliability for AE used sector image.

Status	Reliability < 0.5	Reliability >= 0.5	Accuracy (%)
Incorrect	13,767	3,739	78.6
Correct	4,394	14,823	77.1

From those results, it was confirmed the accuracy was of reliability was improved to more than 77%.

Table 10 shows the results of same data with section 5.1.

Table 10. Judgment results by improved ensemble system.

Method	Accuracy (%)	Precision (%)	Recall (%)	Specificity (%)
Ensemble	85.8	85.8	88.9	82.0

From Table 10, it is confirmed the accuracy of ensemble system and other parameter were improved more than 10% compare with the result of section 5.1. Thus, it is concluded the ensemble method that using composite image is efficient.

6 CONCLUSION

A PAUT testing device for the tube-to-tubesheet weld in multi-tube heat exchangers and a flaw detection system that automatically judges acquired flaw detection data for the presence/absence of flaws were previously developed. By improving the reliability calculation method, the system represents a highly accurate judgement method, as it reduces the undetected images with flaws and erroneously detected images without flaws in flaw detection images. A method to prevent unacceptable welds from being missed was established, this reduced the judgment time by at least 75%, compared with judging all flaw detection images visually, and enabled practical use as a total number inspection for tube-to tubesheet weld.

Innovative methods for the inspection of hydraulic structures

A. Seiffert & J. Bödefeld

Federal Waterways Engineering and Research Institute, Karlsruhe, Germany

ABSTRACT: For many years, inspections of hydraulic structures have been carried out in the same way using analogue methods. However, the challenges associated with such inspections are increasing. Making greater use of digital technologies during inspections could help to manage these challenges. The Federal Waterways Engineering and Research Institute therefore conducted a systematic study to determine to what extent innovative methods, such as UAS, laser scanning and multibeam sonar can support hydraulic structure inspections.

1 INTRODUCTION

Regular inspections of the hydraulic structures on Germany's federal waterways are indispensable to ensure the safe, economical and sustainable operation of the infrastructure. Inspections of hydraulic structures are carried out at least every six years. The associated expenses are not negligible as each inspection requires that the structure is drained of water. An ageing infrastructure, the often large dimensions of hydraulic structures and the multitude of damage mechanisms place higher requirements on inspection staff. As it is not always possible to bypass hydraulic structures in the network of waterways, it would be desirable to shorten inspection times while ensuring at least the same level of inspection quality. Advances in digitisation with high-resolution sensors, powerful storage media and intelligent machine learning algorithms could provide opportunities for increasing efficiency. While innovative structural inspection methods have already been tested successfully in pilot projects, a systematic overview of the potential offered by such methods in the inspection of hydraulic structures in particular is still lacking.

With this background in mind, the Federal Waterways Engineering and Research Institute carried out the research project 'Innovative methods for structural condition assessment' in cooperation with the Geodetic Institute of RWTH Aachen University. The starting point for the project was a systematic documentation of the inspection process to identify optimisation opportunities. This documentation was used to select innovative methods that could potentially support the inspection of hydraulic structures. The methods were tested on a drained and on a flooded navigation lock. The tests comprised carrier platforms (unmanned aerial system and remotely operated underwater vehicle); measuring instruments (laser scanner, hand-held scanner, thermal imaging camera and multibeam sonar) and evaluation methods (photogrammetry and machine learning). All these methods were systematically assessed for their user-friendliness and the quality of data provided. Based on the results, a recommendation for the use of innovative methods for the inspection of hydraulic structures was prepared.

2 CONVENTIONAL INSPECTION OF HYDRAULIC STRUCTURES

The research project began by analysing current approaches to inspections of hydraulic structures, i.e. the conventional methods applied. This analysis served as the starting point for

identifying suitable innovative inspection methods and consisted of two parts: an analysis of existing regulations for structural inspections, and participation in two inspections. Administrative Regulation VV-WSV 2101 of the German Federal Waterways and Shipping Administration (WSV) on the inspection of structures (Federal Ministry for Digital and Transport 2022) is the basic regulation governing the inspection of structures falling within the competence of the WSV. According to this regulation, the ‘condition at the time of inspection has to be assessed and documented, and on this basis the necessary action has to be taken without delay’. To this end, assets with a particularly high potential risk and level of complexity, e.g. weirs and navigation locks, must be drained of water and inspected at least every six years.

Participation during the research project in the inspections of a weir and a navigation lock resulted in the identification of two distinct groups of inspection aids. On the one hand, smaller aids such as digital cameras, notepads, spray paint, torches, crack templates and hammers were used to determine and document damage. On the other hand, larger aids and tools were employed to facilitate access to the structures, e.g. ladders, cherry pickers, lifting platforms, work baskets and platforms and various types of scaffolding. Additional measuring instruments such as rebar detectors were used to examine damage in specific cases, but not routinely. The digital camera was therefore the only digital method used as a standard procedure in the inspections attended. The inspection process observed for the structures was documented to evaluate which innovative methods can be integrated into this process. Four process steps were identified as essential to meeting the inspection objectives. In chronological order these are: identifying anomalies e.g. deviations from the target condition; detecting damage; assessment of damage and damage documentation. Each step is characterised by different data collection requirements. Identifying deviations from the target condition is essential for the subsequent steps and thus the focus of the following field tests.

3 SELECTION OF INNOVATIVE METHODS

A literature review was conducted to select suitable innovative methods for the inspection of hydraulic structures. This review resulted in a list of innovative methods that are suitable for purpose. Given the fixed project period, only a limited number of methods could be evaluated. The selection criteria were, first, the assumed direct benefit of the method for the inspection work and, second, the assumed expense for testing the method. The methods selected for the drained lock were unmanned aircraft (drone), terrestrial laser, thermography, hand-held triangulation scanner, photogrammetry and damage detection using machine learning. The drone and terrestrial laser were selected because, according to the literature, both systems are capable of capturing high-resolution images of areas above water level in a relatively short period of time. The combination of an aerial system with the photogrammetric method has the advantage of providing a textured model (Nooralishahi et al. (2021), Hubbard and Hubbard (2020), Holst et al. (2016)) while the strength of the terrestrial laser lies in the accuracy of size determination (Truong-Hong & Laefer (2014), Anil et al. (2013), Mischo et al. (2019)). Thermography was considered to be a useful supplement as, in contrast to these two methods, it holds greater potential for the detection of cavities and voids (Mold et al. (2020), Rocha et al. (2018)). The main advantage of the hand-held triangulation scanner is probably its ability to make three-dimensional measurements of damages or structural components (Kus et al. (2009), Fuentes et al. (2007)). Image-based detection of damages using machine learning was selected for the project as it seems a suitable method for the efficient evaluation of large data volumes in particular (Morgenthal et al. (2021), Dais et al. (2021), Blut et al. (2021)).

The remotely operated vehicle (ROV), imaging sonar and echo sounder were tested on the flooded structure. The remotely operated underwater vehicle can prove an efficient solution for visual inspections of individual areas (Sugimoto et al. (2017), António Neves Lousada et al. (2021)). In addition, it can be equipped with an imaging sonar so that this method can also be tested without significant additional cost. In contrast, the use of an echo sounder appeared to be a suitable method for the efficient surveying of large areas and subsequent modelling. It was therefore considered a useful addition to the ROV (Moisan et al. (2018), Holste et al. (2019), Müller-Braune (2022)).

4 FIELD TESTS

The north chamber of the Sülfeld navigation lock was used as a test object for the tests carried out both underwater and above water. This particular test object was chosen because it is possible to drain the lock, the scheduled time of drainage aligned well with the project schedule, and there are various types of damage in the lock. The lock is located on the Mittelland Canal near the German city of Wolfsburg. Of its two chambers, the north chamber was used for the field tests because it is older and in poorer condition. The chamber was built in 1938 using concrete gravity walls with a suspended floor. An assessment in May 2021, prior to the construction inspections, rated the lock's condition at the poorest level of 4. The field tests comprised only the lock chamber and the gates of the facility, as these are decisive for its functioning. Four chamber blocks, each 12 m long, were selected for the manual mapping of damages. This was done in a conventional way, e.g. by marking and measuring the damaged areas followed by photo documentation. The comparative data thus collected are used to evaluate the detection capability of the innovative methods.

Table 1. Tested methods.

Method	Model	Area	Result
Unmanned aerial system (UAS)	Matrice M300, Sony Alpha 7 RII, Sony RX0II	Chamber	Images, 3D surface model
	Elios, 1/2,3" CMOS, Lepton 3.5 FLIR	Culvert	
Terrestrial laser	Leica-P30	Chamber	Point cloud
Hand-held triangulation scanner	Artec MHT	Specific damages	Point cloud
Thermal imaging camera	FLIR T660	Specific damages	Thermal images
Remotely operated vehicle (ROV)	Blueprint Oculus Multibeam Sonars - M1200D	Chamber Specific damages	Videos, sonar images
Multibeam sonar	Multibeam Teledyne SeaBat T50-P	Chamber	Point cloud

Table 1 shows the tested methods. Drone-based inspection and recording of the lock chamber's condition was carried out with the unmanned aircraft system (UAS) Matrice M300. The UAS was manually piloted without pre-programmed flight routes. It recorded the condition of the entire lock chamber including the gates. The chamber walls and the gates were surveyed from a distance of around 3 m while a shorter distance of around 1.5 m was used for the four chamber blocks where damages were documented. An image overlap of 60–70% was used so that the images could be put together by means of photogrammetry to obtain a textured 3D surface model of the lock chamber. In addition, the images were used to evaluate the capability of detecting damage automatically using machine learning methods. A UAS specifically designed for indoor inspections – the Elios model from Flyability – was used to survey the culvert at the upper lock head. This UAS is protected by a cage and is therefore collision tolerant. Similarly to outdoor applications, data are collected as raster images with an overlap of 60–70% and at a distance from the wall of around 50 cm. In this way, the ceiling and the walls of the culvert were mapped. The Leica-P30 panorama scanner was used as the model for terrestrial laser scanning. The entire lock chamber was surveyed from several locations at 10 m distance with an approximate effective ground resolution of 1 cm. The four chamber blocks in which damages were mapped were surveyed at a higher resolution of around 0.5 mm, which corresponds to the UAS's resolution. A FLIR T660 thermal imaging camera was used to test the potential of thermography for identifying cavities and delaminations. As

the literature reviewed contained a reference to the potential suitability of thermography, thermal imaging was carried out on the chamber wall approximately one hour after direct solar radiation. A suspected cavity was checked by tapping the potentially damaged area. The Artec MHT hand-held triangulation scanner was tested by performing three-dimensional scanning of specific damages, such as cracks and spalling in the chamber walls. The tests mainly focused on user experience for the inspection staff, which is why the responsible staff conducted the tests.

The unmanned underwater vehicle and the multibeam sonar were deployed in the flooded lock. The remotely operated vehicle (ROV) was used to detect specific areas of damage. Its equipment comprised an RGB camera and an imaging sonar. The multibeam sonar, on the other hand, was used to survey the entire lock chamber and generate a 3D surface model. The ROV used was the DeepTrekker Revolution with an integrated Blueprint Oculus M1200D multibeam imaging sonar. The south chamber blocks 3 and 12 were inspected because damages had been mapped there and were greater in number than in the north blocks. First, the ROV was positioned at different depths, in each case at 2 m distance from the chamber wall, and the sonar collected images from various angles. Subsequently, the wall section was surveyed horizontally at different depths and at a distance of around 1/2 m to produce video recordings. An underwater surveying system comprising a boat, a Teledyne SeaBat T50-P multibeam sonar and a tachymeter was used to obtain a complete survey of the chamber. This enabled the entire lock chamber, i.e. the walls, the floor and the gates, to be surveyed.

5 RESULTS OF THE FIELD TESTS

To evaluate the diagnostic capability of the innovative methods for damage detection, the generated images were compared with the results of manual damage mapping. Cracks were the prominent damage pattern found in the chamber blocks and were therefore used as the criterion for assessing detection capability. The evaluation revealed that around 80% of the cracks identified by manual damage mapping could be detected on the laser scanning images. The images generated by the UAS had the second-best recognition rate with around 70% of the cracks being detected on them. By contrast, automatic damage detection applied to the UAS images was unsatisfactory with a recognition rate of only around 10%. Underwater methods as well only yielded unsatisfactory results regarding crack detection. Around 10% of the cracks were visible on the ROV images, whereas the images derived from echo sounding showed no cracks at all. Further investigations are required for both methods to enable an appropriate assessment of their reliability. Using thermography to detect cavities showed the potential of this method which should also be investigated in a more detailed study.

The hand-held triangulation scanner was the only method that proved to be of little practical use, especially in comparison to its benefit. The results were therefore not analysed in detail. The experience gathered in the project has been documented in a decision matrix to support potential users of innovative methods in the selection of a suitable method. Table 2 shows the resulting matrix: it contains an estimate of the maximum resolution and 3D accuracy attained in the project, the time needed for data collection and the cost of the methods. It should be noted that these data reflect the experience gathered in the project; they show trends but do not provide a sufficient basis for generally applicable statements. This applies in particular to the resolution and accuracy indicated, which depend on the sensor used, the working distance and other factors such as the georeferencing accuracy. As a result, the values indicated in the table are qualitative, with + representing a low, and +++ representing a high value. As is evident from the project findings, the highest resolution can be attained with the hand-held triangulation scanner. Next in the ranking are the UAS and the terrestrial laser scanner, both of which were also able to detect damage in the sub-millimetre range in the project.

In contrast, active thermography and multibeam echo sounding only detected damages at a scale of several centimetres. No reliable information on the resolution obtained with the ROV is available from the project. The 3D accuracy that can be achieved is only indicated in the matrix for those methods that are capable of generating a 3D model, i.e. UAS with

Table 2. Decision matrix.

Method	Max. resolution	3D accuracy	Time for data collection	Cost	Use cases								
					1	2	3	4	5	6	7	8	
Unmanned aerial system (UAS)	++	+	1 day for 6 chamber blocks*	++	x	x	x	x					
Indoor-UAS	++		½ day for 1 culvert*	++		x	x						
Terrestrial laser	++	++	2 days for 1 chamber block*	++	x	x			x	x			
Thermal imaging camera	+		½ day for 1 chamber block*	++								x	
Hand-held triangulation scanner	+++	+++	10 min for 1 m ² *	++				x		x			
Multibeam sonar	+	+	½ day for chamber block*	+	x						x	x	
Remotely operated vehicle (ROV)	n. s.		2 hours for chamber block*	++			x	x					x

* Reference: Sülfeld lock; chamber: 6,000 m²; chamber block: 160 m²; culvert: 150 m².

Use cases:

- 1: 3D model
- 2: Detection of damage
- 3: Visual identification of damage
- 4: Measurement of damage
- 5: Detection and measurement of spalling
- 6: Deformation measurement
- 7: Detection of voids
- 8: Identification of baffles

orthophotography, terrestrial laser scanner, hand-held triangulation scanner and multibeam sonar. Again, the best results in the sub-millimetre range were obtained with the hand-held scanner; the accuracy of other surveying methods was in the centimetre range. The time needed to collect data indicated in the matrix relates to the dimensions of the test object, i.e. the north chamber of the Sülfeld ship lock. In this case, thermography and multibeam sonar are the fastest methods while the survey with the hand-held triangulation scanner was most time-consuming. In view of the multitude of available sensors and system providers, the cost of each method is also stated in qualitative terms: + represents a minor and +++ a major cost advantage. The project showed that the multibeam sonar has a minor cost advantage while the UAS and hand-held triangulation scanner were associated with a major cost advantage.

6 CONCLUSIONS

There are many opportunities for continuing the research work. For example, the object studied could be altered, additional methods investigated and the findings transferred for practical use. Altering the object would include in particular changing the damage features (limited to cracks in this research project), and the type of object studied (a navigation lock in this project). Moreover, the project focused on recording the current condition of the structure. However, it can be assumed that, because of their standardised recording technology, digital methods are most effective when they are used more frequently, i.e. for recurrent inspections of structures. This would help to obtain more detailed knowledge about damage development, which would be useful for its assessment. The terrestrial laser scanner with a camera is another innovative method that should be taken into consideration as it can generate highly accurate textured images. Including this method in the scope of further research would therefore be highly interesting, in particular because the terrestrial laser scanner was used with positive results in the navigation lock. The additional use of a laser line scanner for underwater

investigations might be promising as it would probably provide a higher resolution than the multibeam sonar. Last but not least, it is important to remain focused on transferring the lessons learned into practice. It should be specified, for example, how innovative methods can be integrated in structural inspection processes, not only in respect of data collection but also for the evaluation and assessment of data.

Behaviour of corroded bridge bearing and full-bridge modeling

A. Hiraoka, G. Hayashi & T. Yamaguchi

Osaka Metropolitan University, Osaka, Japan

ABSTRACT: Corrosion of bridge bearings can cause fatigue cracking from welds at the edge of the bottom plate. It is important that assessment of the condition of the bridge bearing for determining the soundness and load-bearing capacity of the bridge. In this study, the relationship between corrosion level and bearing function is clarified by FE analysis using a detailed bearing model. The behavior of bearing is applied to the full-bridge model as spring properties to study the differences in bridge response due to bearing corrosion. The analysis is targeted at corrosion on the contact surface of the spherical bearing (BP-A), which is in the largest number of steel bearings in service. Analysis of the corroded bearing showed that if the friction coefficients of the contact surfaces were increased, the bearing could not follow the displacement of the girder and rotated in the opposite direction to that of the intact bearing. The increased friction coefficient may cause fatigue cracks due to the increased compressive stress at the sole plate edge. Furthermore, this paper presents a cost-effective modelling of the bearing behaviour by representing it with two-directional and rotational springs and proposing spring constants and mounting positions according to the degree of corrosion.

1 INTRODUCTION

Bearings are installed at the contact point between a superstructure and substructure. Bearings are necessary to transmit the loads acting on the superstructure to the substructure and to follow the horizontal and rotational displacements of the superstructure smoothly (Japan Road Association, 2019:). However, bearings are installed in narrow spaces, such as those between the bridge girder ends and abutments, and leakage occurs from the upper expansion joints. This results in several reports of corrosion damage to steel bearings and anchor bolts (Brinckerhoff, 1992:), which may cause fatigue cracks near the sole plate at the girder ends owing to the decrease in bearing function. Consequently, several studies have been conducted on the effects of corrosion damage on the functions of steel bearings. (Fan, 2015; Kamaitis, 2001:)

Studies on the decrease in bearing function due to corrosion have focused on the BP-A bearing, which is the most used steel bearing in Japan. The BP-A bearing consists of a bearing plate (BP) with vertical force support, horizontal movement, and rotation functions (Japan Road Association, 2019:). There is a sliding motion of the horizontal contact surface between the upper shoe and BP, which performs the horizontal deformation function, whereas the spherical contact surface between the BP and lower shoe performs the rotational function. However, corrosion of the contact surfaces of BP-A bearings has been reported in several cases. Because of this corrosion, BP-A bearings cannot follow the displacements of the superstructure, resulting in horizontal forces that were not considered in the design (Niwa, 2018:). This leads to a concentration of compressive stress at the weld at the end of the sole plate in the lower flange, which causes fatigue cracks (Yamamura, 2010:). 6. These studies were conducted on after-service BP-A bearings. Few studies have focused

Figure 1. Examples of damage in hinge bearings.

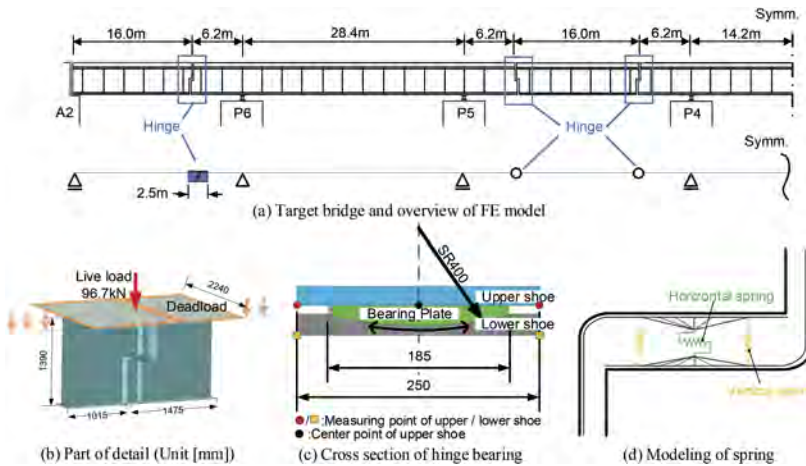

Figure 2. Actual target bridge and analysis model.

Table 1. Material properties.

Bearing plate	100	0.3	–

on the in-service corrosion levels, and the effect of the resulting changes in behaviour on the horizontal forces should be investigated.

A bridge type with BP-A bearings and a high likelihood of bridge collapse owing to fatigue cracks is the cantilever-suspended girder bridge. These bridges have continuous girders with intermediate hinges to increase the span length. However, corrosion at the intermediate hinge bearing (hereafter, hinge) is often reported because of leakage from the expansion joint installed above. As a consequence, fatigue cracks in the girders are often reported around the hinge (Figure-1). However, the relationship between bearing corrosion and fatigue crack initiation is unclear.

In addition, few studies have examined the effects on the entire bridge depending on the degree of corrosion of the bearings. In the overall bridge model, the corroded bearings are mostly modelled with either simple springs or perfect adherence. There has been no investigation into whether this model reproduces the corroded bearing behaviour.

In this study, the relationship between the hinge corrosion level and fatigue cracks in the surrounding members was clarified. In addition, a model using springs that can reproduce the behaviour of a corroded hinge was investigated.

2 ANALYSIS MODEL

The actual target bridge, which was completed in 1959, is a cantilever–suspended non-synthetic girder bridge with seven spans, including suspended-span and cantilever-girder lengths of 16.0 m and 40.8 m (6.2 m + 28.4 m + 6.2 m), respectively. Because the target bridge is symmetrical, its general drawing is presented from the A2 abutment to its centre, as illustrated in Figure-2. In the analysis model, a symmetry condition was provided in the centre, and a 1/2 model was created. In this study, only one main girder was modelled because the focus was on the effect of corrosion at the hinge on the local response. To focus on the hinge of the end-suspension girder, only the area surrounding the hinge was modelled in detail, as shown in Figure-2(a) and (b).

Table 2. Vertical and horizontal spring constant.

Case		Case-0.05		Case-0.4

Vertical disp.[mm]	Upper	-7.41	-7.48	-7.26	-7.26
	Lower	-7.61	-7.23	-7.46	-7.15
	Difference	0.20	-0.25	0.19	-0.11
Vertical spring constant [N/mm]		109578.3	90311.2	110770.8	187441.2
Horizontal relative displacement [mm]		0.514		0.037	
Horizontal spring constant [N/mm]		2178.3		229474.9	

To clarify the behaviour of the hinge during corrosion, the bearing was modelled in detail, and an FE analysis was performed with the friction coefficient of the contact surface as a parameter. Using the results of this study, a model of the corroded bearing using spring elements was investigated, and a model is proposed that gives similar results to the detailed model. The general-purpose FEM software Abaqus/Standard 2022 was used for analysis. The detailed model, spring model, and loading conditions are described below:

2.1 Detailed model

In the detailed model, the hinge was modelled using an eight-node solid element. A cross-sectional view of the hinge is shown in Figure-2(c). Because detailed drawings of the hinge were not available, the radius of curvature was set to ensure a contact area that satisfied the allowable bearing stress required in the design.

The webs and flanges around the hinge were modelled using four-node reduced-integral shell elements, whereas the girders outside the shell element parts were modelled with two-node beam elements. The area to be modelled with shell elements was between the vertical stiffeners. This is the area where stress fluctuations are eliminated, which was determined in a preliminary analysis. The coupling condition between the girder of the beam elements and the shell element is a rigid coupling with a multi-point restraint. The element sizes were set to 5 mm × 5 mm for the hinge, 30 mm × 30 mm for the girder of the shell, and 100 mm × 100 mm for the girder of the beam. Table-1 presents the properties of the materials used in this study. In this analysis, the corrosion level at the bearing contact surface was determined by varying the friction coefficient. Three corrosion levels were considered. The friction coefficients were set to 0.05 for the intact condition and 0.4 for a corroded surface in service. The case of shared nodes of the contact surface was also investigated, assuming a complete fixing.

2.2 Spring model

A model with springs that can reproduce the behaviour of corroded bearings was obtained using the detailed bearing model studied above. The bearings exhibited rotational behaviour

Figure 3. Vertical displacement at the underside of the lower flange just below the hinge centre point.

perpendicular to the bridge axis, horizontal displacement in the direction of the bridge axis, and vertical displacement. Thus, three springs were installed in two directions, and their spring constants were varied to represent the behaviour of different degrees of corrosion. The spring installation method is illustrated in Figure-2(d). In this model, the reference points were set at the top surface of the upper flange in the main cantilever span and the bottom surface of the lower flange in the suspended span of the notch. These sets were joined to two nodes placed in the middle of the upper and lower notch surfaces. A horizontal spring was introduced between the two nodes. Here, the range of the flange to the connection is the same as the contact surface between the flange and the upper or lower shoes in the detailed model.

Vertical springs were introduced between the two nodes located on the boundary line with shoes in the flanges. The nodes were joined to the boundary line. The calculation of the vertical and horizontal spring constants was based on the results of the study of different friction coefficients in the detailed bearing model. The calculation method is described as follows:

2.2.1 Vertical and horizontal spring constant

To calculate the spring constant, the frictional force on the spherical contact surface that resists the behaviour was calculated. The frictional force was calculated as the total contact pressure on the contact surface multiplied by the friction coefficient. This frictional force, divided by the vertical and horizontal displacement of the hinge, was used as the spring constants.

The vertical displacement of the hinge required to calculate the vertical spring was determined by subtract the vertical displacement of the measuring point of the lower shoe from that of the upper shoe. This value was calculated for each edge of the point.

The horizontal displacement required for the calculation of the horizontal spring constant was defined as the relative displacement between the centre point of the BP and the lower shoe on the contact surface. Table-2 lists the values used in the calculations and the obtained vertical and horizontal spring constants.

2.3 Loading method

Subsequently, the loading conditions are discussed. The dead loads were introduced as distributed loads on the entire top surface of the slab in the detailed section and on the beam elements in the beam element section. To calculate the live load, a preliminary analysis was carried out assuming that a carriage with a wheel load (front axle weight: 12.5 t, rear axle weight: 12.5 t) equivalent to the design live load specified in the Specification for Highway Bridges was running in the centre of one side of the two-lane road. From the results, the load on a main girder, where most of the loads are distributed, is placed as a concentrated load (96.7 kN) directly above the hinge. The loading steps were as follows: dead loads were introduced in Step 1 and live loads were loaded in Step 2.

3 ANALYSIS RESULTS OF DETAILED MODEL

3.1 Vertical displacement

The vertical displacement at the underside of the lower flange just below the hinge centre point is indicated by the solid line in Figure-3. The vertical deflections at the final loading

stage are 5.84 mm for Case-0.05, 5.73 mm for Case-0.4, and 5.64 mm for Case-Fixed. This indicates that the deflection tends to decrease as the degree of corrosion increases. However, the differences between the cases are very small, with an error between Case-0.05 and Case-Fixed of only 3.5%. This indicates that the corrosion occurring at the hinge had a small effect on the overall bridge response.

3.2 Principal stress distributions

We focus on the principal stress distribution around the hinge in the final loading phase. The maximum principal stress distribution on web is shown in Figure-4(a). As can be observed, a tensile stress of approximately 70 N/mm² occurs at the notch on the cantilever-girder, which is considered the starting point for fatigue cracks. However, the stress levels at this location did not differ between the cases and remained constant. This is attributed to the web on the cantilever-girder side, which restrains the downward vertical displacement of the flange at the hinge. Because the vertical displacements described in Section 3-1 exhibit small differences between the cases, the stress levels are also expected to have small differences. The direction of the principal stresses was found to be 45° to the bridge axis at the notch on the cantilever-girder. This indicates that the direction of the principal stress is in the direction of the fatigue crack extension in the notch. In conclusion, the tensile stresses occurring in the notches are dependent on their shape, and the influence of corrosion is considered to be small.

Figure 4. Maximum principal stress in the web.

The minimum principal stress distribution in the web is shown in Figure-5(a). High compressive stresses of approximately 70 and 130 N/mm² occur in Case-0.04 and Case-Fixed, but they are of approximately 30 N/mm² in Case-0.05, near the edge of lower shoe on cantilever-girder. From the vertical displacement of the hinge shown in Figure-6, it is considered that in Case-0.4 and Case-Fixed, the bearing cannot follow the displacement of the girder owing to the large friction coefficient at the contact surface, and the bearing rotates around the end of the cantilever-girder side. The results indicate that fatigue cracks may extend from the flange at the bearing end to the web as the degree of corrosion increases.

4 ANALYSIS RESULTS OF SPRING MODEL

The analytical results of the spring model were compared with the results of the detailed model, and the reproducibility of the spring model was discussed.

4.1 Vertical displacement

The vertical displacement at the lowest point of the web, just below the hinge centre point, is indicated by the dotted line in Figure-2. The vertical deflection at the final load stage is 5.78 mm for Case-0.05, 5.72 mm for Case-0.4, and 5.55 mm for Case-Fixed, which is smaller than that in the detailed model. However, the errors are small, at approximately 1%, 0.2%, and 1.6%, respectively, and the error between Case-0.05 and Case-Fixed is 4.1%, which is approximately equal to the 3.5% error in the detailed model. Thus, it is considered that the spring model reproduces the vertical displacement of the bridge during corrosion.

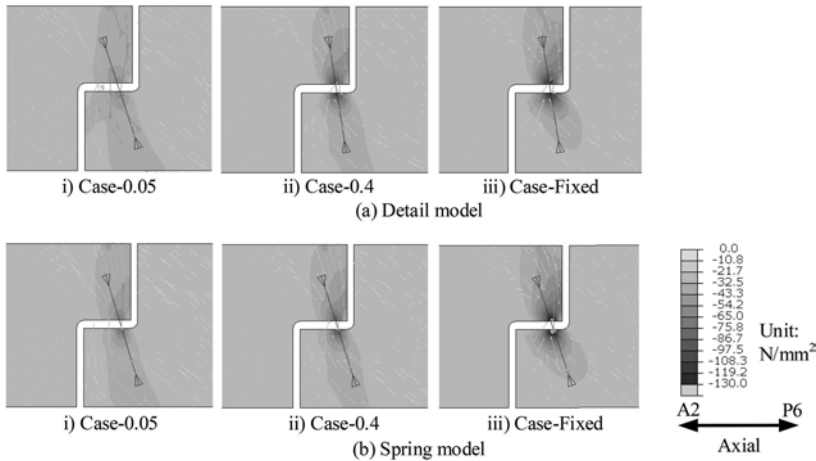

Figure 5. Minimum principal stress in the web.

Figure 6. Vertical displacement of the hinge.

4.2 Principal stress distributions

We focus on the principal stress distribution around the hinge in the final loading phase. The maximum principal stress distribution in the web is shown in Figure-4(b). The maximum principal stress distribution in the notch on the side of the cantilever girder was similar to that of the detailed model in terms of the stress degree, area, and principal stress direction. The tensile stress at the upper shoe end of the web on the suspension girder side is approximately 120 N/mm², that is, 1.6 times higher than that in the detailed model. This occurs because of the large vertical spring constant, which significantly influences the stress level in this area. The hinge is displaced in the vertical direction owing to elastic deformation even when the contact surface is fixed; however, the spring model does not take this effect into account.

Next, focusing on the minimum principal stress distribution in the web shown in Figure-5(b), it can be observed that the large minimum principal stresses occurring the edge of lower shoe on cantilever-girder are larger than those in the detailed model. In Case-0.05 and Case-Fixed, the compressive stress was approximately twice as high. In the detailed model, the flange is gently deformed as the bearing is elastically deformed, whereas in the spring model, the flange is rigidly coupled to the spring introduction node. Thus, the flange deformation is greater in the spring introduction and non-spring introduction areas. This is thought to increase the compressive stress generated.

5 CONCLUSIONS

In this study, an FE analysis was used to determine the effect of changes in the coefficient of friction, which simulates the effects of the corrosion level of the hinge bearing in the form of a BP-A bearing on the vertical deflection, which is one of the overall bridge responses, and on the principal stresses in the surrounding members. In addition, we developed a modelling method using springs to reproduce those effects. The following conclusions were drawn:

- Although the vertical deflection decreased as the degree of corrosion on the hinge contact surface increased, the error between Case-0.05 and Case-Fixed was small (3.5%), indicating that the influence of corrosion was small.
- On the web of the cantilever-girder, a maximum principal stress of approximately 70 N/mm² occurred at the notch, which was the starting point for fatigue cracks. However, the stress level did not vary with the degree of corrosion. This is attributed to the web on the cantilever-girder side restraining the downward vertical displacement of the flange at the hinge.
- In Case-0.4 and Case-Fixed under corrosion, the compressive stresses at the web of the cantilever-girder were found to be 3.5 and 5 times higher than those in Case-0.05, respectively. This is due to the fact that the bearing rotates around the end of the cantilever-girder side because the friction coefficient at the contact surface is too large to follow the displacement of the girder.
- In the spring model, the vertical deflection had a maximum error of 1.6% compared to that in the detailed model, which can be considered highly reproducible.
- In the spring model, focusing on the maximum principal stresses occurring in the notch of the cantilever-girder's web, it was found that the principal stress degree and its directions at the notch, where fatigue cracks start, could be reproduced almost as well as in the detailed model.
- In the spring model, the maximum principal stress distribution at the upper shoe end of the suspension girder's web of Case-Fixed was found to be approximately 1.6 times higher than that in the detailed model. This is because the vertical spring constant in the spring model does not consider the elastic deformation of the hinge.

Damage identification of corroded arch bridge using vibration characteristics and rotational angle

K. Akahoshi, G. Hayashi, Y. Chen & T. Yamaguchi

Department of Civil Engineering, Osaka Metropolitan University, Osaka, Japan

ABSTRACT: Identifying the number and location of damage is an important issue in the vibration health monitoring of bridges. This study aimed to improve the accuracy of damage detection using the natural frequencies utilized in conventional monitoring and the rotational angle of the bridge in the transverse direction. An analytical model was constructed based on a reduced arch model developed by the laboratory group. Damage in the hanger members, stiffening girders, and cross girders of the analytical model was investigated with reference to the corrosion reported for real arch bridges. Two selections were obtained from this damage, and the damage was modeled. Eigenvalue and static analyses were then carried out to investigate the accuracy of damage type and damage location detection based on the natural frequency and rotation displacement changes caused by each damage pattern. The results showed that the natural frequencies of damage at the location where the mode shape is predominant change significantly, and that the natural frequencies that change for each damaged member are different. It was also found that the damage that could not be identified by natural frequencies alone could be detected using the angle of rotation. These results indicate the possibility of classifying damage locations and types when there is more than one type of damage.

1 INTRODUCTION

In Japan, the number of bridges significantly increased during the periods of high economic growth. Consequently, the number of bridges that are 50 or more years is increasing rapidly. Therefore, it is important that these bridges be inspected and repaired. The current inspection methods are mainly visual inspections that require engineers to visit the site. This method is inefficient, and the inspection results are subjective. Therefore, structural health monitoring has attracted attention as an alternative to visual inspection. In particular, vibration-based structural health monitoring (VSHM) is being utilized because the damage and deterioration that are difficult to observe are more likely to appear in vibration characteristics. Once a damage detection method for vibration health monitoring is established, the damage can be detected simply by installing sensors on-site and analyzing the data obtained. Therefore, many studies are being undertaken from various perspectives to improve the accuracy of vibration health monitoring.

Numerous parameters are currently being considered for damage detection. For example, (Morichika et al., 2021) studied the displacement as a bridge response, whereas (Zhou et al., 2022) used mode shapes and natural frequencies to determine the amount of change in values when a real bridge is damaged. (Mustafa et al., 2018) proposed a damping-based damage detection method. (Moughty and Casas, 2017) compared the most detectable energy-based parameters. More recently, parameter identification procedures have been black-boxed and anomaly detection based on acceleration waveforms has also been performed (Shang et al., 2022). Although all the parameters have the potential to detect damage, the relationship between the parameters and damage has not been clarified. In this study, the goal was to detect multiple damages. (Lee et al., 2014) stated that by placing sensors at the damage location, it is possible to detect multiple damages without prior data. However, the possibility of detection depends on the location of the sensor. Therefore, in this study, a single measurement position was selected, and the effect of

damage on the overall response of the bridge was investigated. Based on the above, the parameters that have the potential for multiple damage detection were selected after confirming the effect of each damage on the parameters, and the possibility of detecting them was shown.

The studied bridges were arch bridges. Examples of arch bridge accidents include the Nanfangao Straddling Port Bridge collapse in Taiwan in 2019, and the Rokujutani Water Environment collapse in Japan in 2021. Both were caused by corrosion and rupture of the hangers. Although many studies have been conducted on arch bridges (Wang and Su, 2021), (Maes et al., 2022), the effects of damage at each position of each member have not been clarified. Therefore, this study clarified the effects of damage on the parameters based on the FEM analysis of a steel arch bridge model and showed the possibility of multiple damage detection.

2 FEM ANALYSIS

2.1 Subject bridge

Figure 1 shows the overall view of the bridge model and the number of the damage to be considered (member name + 'a' or 'b' side + damage number). The damage is described in detail in Section 2.5. The model is a 1/15 scale model of a 750 m long Langer arch bridge. The model bridge is a steel arch bridge with a total length of 5000 mm, width of 567 mm, and height of 893 mm. The bridge is composed of arch ribs, stiffening girders, cross girders, hangers, and gusset plates. The steel used was SS400 (JIS G 3101). SS400 has a tensile strength of 400-510 N/mm² and a yield point of 245 N/mm² or more up to a thickness of 16mm. Hangers and arch ribs were connected to the stiffening girders with M10 bolts via gusset plates. The cross-sectional shapes of the members are presented in Table 1.

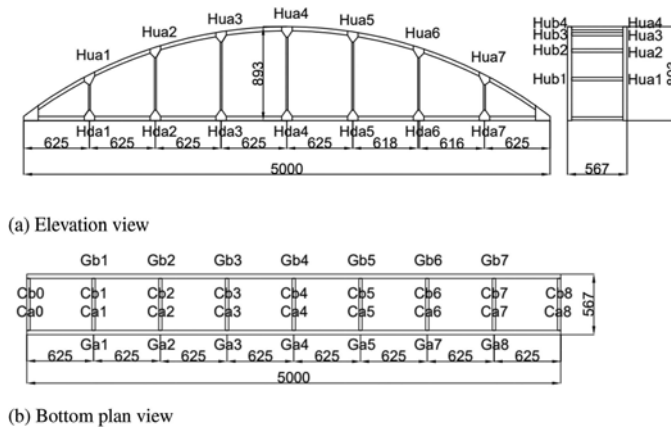

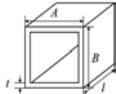

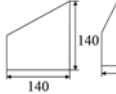

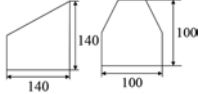

Figure 1. Overall view.

2.2 Analysis model

In this study, to perform damage detection using a simplified model, the entire arch bridge was modeled as a beam element. Figure 2 shows a general view of the analytical model. Each number corresponds to the damage number in Damage Figure 1. The finite analysis software Abaqus/Standard 2022 was used. The overall stiffness was 200000 N/mm², Poisson's ratio was 0.3, density was 77 kN/m³, and total weight was 65 kg. The gusset plates of hangers were represented by increasing the cross section of the beam elements in that area. The stiffness was modified such that the gussets connecting the stiffening girders and arch ribs were taken into account. The gusseted girders were rigidly connected to each other by gusset welds; therefore, the entire bridge was considered to be a single member in the analytical model. In this model, the arch ribs and stiffening girders were divided into 250 sections, the transverse girders into

30 sections, the suspension members into 20 to 40 sections depending on their length, and the damaged sections into 3 sections. The boundary conditions were roller supports at two of the four corners and pin supports at the remaining corners. In Figure 2, the boundary condition is shown only at a point in the foreground.

Table 1. Analysis model.

Element	Size ($A \times B \times t \times l$) (mm)	Cross section
Stiffening girder	$40 \times 40 \times 1.6 \times 5000$	l : Length of damage
Arch rib	$40 \times 40 \times 2.0 \times 5000$	
Cross girder	$30 \times 30 \times 1.6 \times 487$	
Hanger	$16(A) \times 4.5(t)$	
Gusset	$t = 3$	

Figure 2. Analysis model.

2.3 Analysis outline

Eigenvalue and static analyses were performed. Eigenvalue analysis was performed at the maximum frequency of 100 Hz. For static analysis, a concentrated load of 20 kg was applied. The positions and directions are shown in Figure 2.

2.4 Parameters

The rotational angle (rotational displacement in the analysis) and natural frequencies, which can be measured with a quartz triaxial accelerometer, were selected as those that can be easily measured on an actual bridge. The measurement points in the analysis were the loading positions shown in Figure 2. As shown in Figure 2, there are rotational displacements in the x-, y-, and z-directions, clockwise about the axes. The natural frequencies of the modes could be measured up to the third bending mode.

2.5 Damages

The damage was assumed to be localized corrosion of the hanger and internal corrosion at each point of the cross girder and stiffening girder. In these places, the damage is difficult to

confirm, in accordance with the report on the falling-arch bridge accident mentioned earlier and the periodic inspection guidelines for road bridges. Figure 1 shows the damage locations and numbers. Each damage was modeled by making the cross section of the damaged section deficient. Damage levels consisting of 25%, 50%, and 75% reductions in the plate thickness were assumed. The analysis cases are listed in Table 2. First, three analyses were conducted for each of the three damage levels, as shown in Figure 1, for a single damage location. Next, 10 locations were selected such that each member had three or four damage levels, and two damage levels were selected from the 10 locations. The degree of damage was set to nine levels such that each member had three levels of damage.

Table 2. Analysis case.

	Damage type	combination	degree	case
Singledamage	60	60	3	180
Double damage	10	78	Damage1:3 Damage2:3 3×3=9	708

3 ANALYSIS RESULTS

To determine the effect of each damage on the parameters, we first considered the case of a single damage.

3.1 Natural frequency

Figure 3 shows the horizontal and bending mode shapes obtained from this analysis. Although the mode shapes were not used as parameters, a comparison of the natural frequencies showed that they are based on mode shapes. We obtained the first and second horizontal modes, first and second torsional modes, and first, second, and third bending modes, with the third bending mode as the maximum frequency. Next, considering the change in natural frequencies when each type of damage occurs, it was found that for each member, there was a natural frequency that tended to change when the member was damaged. Cross girders had first and second horizontal modes, and the hangers had first and second bending modes. No independent natural frequencies were observed for the stiffening girders; however, the bending mode showed a greater change than that in the other members.

Figure 4 shows the change in natural frequencies of the (a) first horizontal mode, (b) second horizontal mode, (c) first bending mode, (d) second bending mode, and (e) third bending mode when each damage occurred. The horizontal axis represents the damage number shown in Figure 1 and 2, which indicates the location of the damage. The plot line is different for each damaged member, and the shape of each member is shown in the legend. The vertical axis represents the difference in vibration frequencies between the healthy and damaged members. First, as shown in (a), we can see that the change is larger when the cross-girder is damaged. Damage numbers 0 and 8 are particularly significant, and the mode shape is that of the girder with 0 and 8 as nodes, indicating that the oscillation in this mode depends significantly on the stiffness of the girder. The mode shapes of the girders at other damage numbers also changed more than those of the other members. Overall, the contribution of transverse girders to this mode was high. Similarly, as shown in (b), the dominant position is different from that of the first mode, and the damage numbers 1, 2, 6, and 7 are dominant. In the second bending mode shown in (c), the hanger mode is dominant in both the upper and lower modes. Damage number 4 is dominant, but the mode shape shows that the node is located at the center of the span. This mode is highly dependent on the stiffness of the suspension. As shown in (d), the change in the mode shape is also significant when the hanger is damaged, but the effect of the damage to the stiffening girder is slight. As shown in (e), the change in both the stiffening girder and hanger is significant, but the mode shape oscillates when the dominant part is a node.

From the above, it can be said that each member has a dominant mode and the change is the greatest at the nodal point. In addition, because there are two dominant frequencies for the cross girder and hanger, and because the dominant feature values are opposite, the two frequencies can be used together to facilitate classification. In terms of damage detection, it is possible to determine the damaged member; however, considering the symmetry and the fact that the values are the same on the a and b sides, other indices are necessary.

Figure 3. Mode shapes.

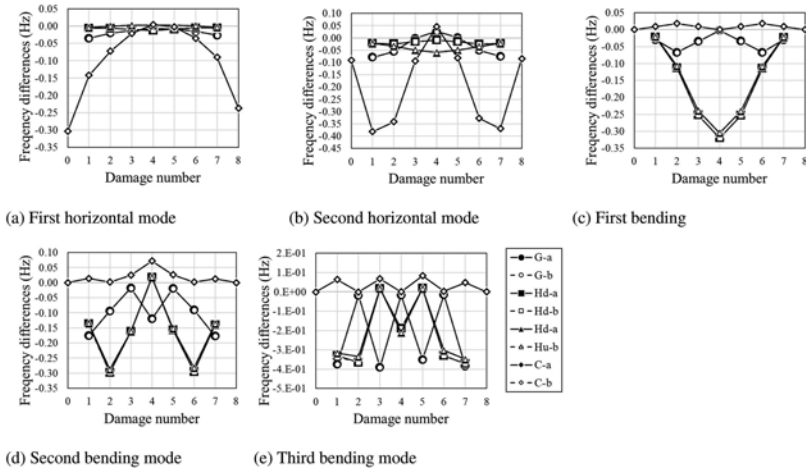

Figure 4. Relationship between damaged areas and natural frequencies.

3.2 Rotational displacement

Similarly, Figure 5 shows a comparison of the rotational displacement values along the vertical axes. The x-, y-, and z-axes are used as the centers of rotation in (a), (b), and (c), respectively. As shown in (a), the difference between the a and b sides, which did not appear in the other parameters, is evident. This is because the center rotates in the direction of the damage. The rotation angle in the x-direction coincides with the change in displacement, indicating that the rotation angle also increases as the load-bearing capacity decreases. As depicted in (b), the differences between the left and right sides and between the a and b sides are significant. The reason for the large difference between the left and right sides of the stiffening girders is considered to be the roller support provided to stiffening girder number 8, which reduces the damage effect. The large influence of the hanger, which rotates in the opposite direction of the corrosion, is shown in (c). The z-axis can be used to distinguish between the left and right sides. The above results indicate that the rotational displacement is used to determine whether the damage is in the degree position, because it is tilted toward the direction of the damage. Rotational displacement can be used as an indicator to determine the position of the damage level.

Figure 5. Relationship between damaged areas and rotational displacement.

3.3 Difference by damage level

Figure 6 shows a three-dimensional space in which the dominant mode for each material is selected. The origin indicates the healthy state. Part (a) in of the figure shows the natural frequency parameters, which are the most likely to detect damage, for three different degrees of damage. Only the damage from 1 to 4 on the a side is considered. Because there is little difference between the top and bottom of the suspension, only damage on the bottom side is represented. The values for different damage levels are plotted as ●-25%, + -50%, and ◊-75%, and a straight line connecting the 75% damage level and the healthy level is also drawn. The change in the degree of damage appears almost on a straight line.

However, a closer look reveals that this change appears on a curve that is very close to a straight line.

Part (b) shows the difference when the damage degree of Ha3, which varies greatly, is finely changed. The change in value appears in the form of a certain curve. The numbers next to the plot indicate the plate thickness. Considering the equation of motion, the natural frequency can be expressed as the square root of stiffness and mass. When the damaged stiffness changes in stages, the natural frequency can be expressed as a function of stiffness. Therefore, the change in the damage phase can be considered to be quadratic.

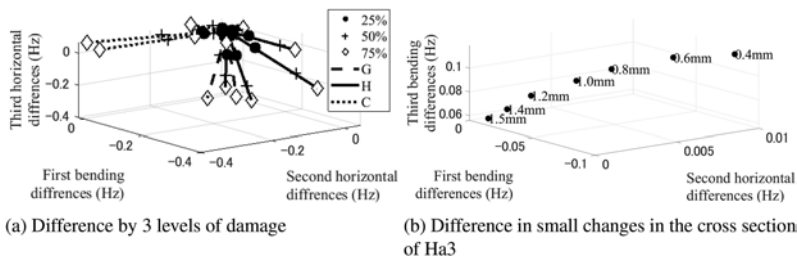

Figure 6. Difference in natural frequencies of the three modes at varying degrees of damage.

3.4 Multiple damage

The change in the values in the case of multiple damages was considered. The dominant frequencies in each member are considered to be the second horizontal mode, the first bending mode, and the third bending mode. As shown in Figure 7 (a), the horizontal axis is the second horizontal mode and the vertical axis is the second bending mode; as depicted in (b), the horizontal axis is the first bending mode and the vertical axis is the third bending mode; and, as shown in (c), the horizontal axis is the second bending mode and the vertical axis is the third bending mode. The shape of each plot depends on the combination of members, as shown in the legend. Among the analyzed cases, only the cases related to suspension members are shown. For example, the triangles represent damage to the hangers and stiffening girder, which indicates that the damage can be plotted as a single overlaid damage, and that there is cohesiveness among the damaged components. Damage that is difficult to classify in (a) can be classified to a certain extent in (b) and (c). However, as shown in Figure 4, it is difficult to distinguish stiffening girders from hangers.

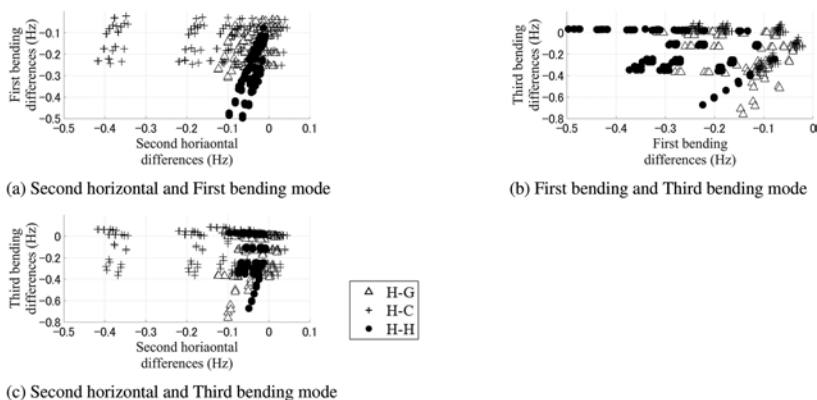

Figure 7. Multiple damage using two natural frequencies.

Figure 8. Multiple damage using three natural frequencies.

Based on the above, multiple damage values are plotted in a three-dimensional space with three modes along the axes (Figure 8), where the x-axis represents the second horizontal mode, the y-axis represents the first bending mode, and the z-axis represents the third bending mode. The shapes of the plots are different for each combination of members, as shown in Figure 7. This figure shows that the damage is grouped by shape, and that it is possible to distinguish the damaged components. In addition, for each damage combination, a plane appears on which the curves described in Section 3.3 are added, and the different damage stages are indicated on the plane. By looking at the plotted locations, it is possible to understand the damaged member and location of the damage to some extent.

By examining these planes and plotted locations, the damaged member and location of the damage can be determined to some extent. Furthermore, the location of the damage within the same member can be determined more accurately by comparing the values of the two dominant frequencies for each member, as described in Section 3.1. Furthermore, as described in Section 3.2, the rotational displacement can be used to identify damage on the left or right side, or on the a or b side. The combination of rotational displacement and natural frequency can be used for more accurate damage detection for stiffening girders and damage locations that are difficult to detect on only one side of the girder, and it is also possible to determine whether the damage is single or multiple. For example, if the eigenvalues are calculated in advance using an analytical model, the location of the damaged member can be plotted in space, as shown in Figure 8, and the detailed location can be found by examining the two frequencies and rotational displacements at which the damaged member is dominant.

4 CONCLUSION

In this study, we confirmed how the damaged member and its location affect the parameters for damage detection and then examined how the parameters should be appropriately used for multiple damage detection. The conclusions are as follows.

- The influence of each damage on rotation angle and natural frequency is based on its shape, and the nodal point is dominant in taking that shape. Thus, there is a dominant mode in the natural frequency for each member.
- As certain curves appear when the degree of damage is varied, it is possible to predict the values for other degrees of damage if some values are obtained in advance.
- The damaged member can be identified based on the significant change in natural frequency, and its location can be determined from the natural frequency and rotation angle that prevail when the member is damaged. Using this method, there is a possibility of multiple damage detection.

Additional issues include determining the actual number of damages that can be detected using machine learning, and to what extent the trends in this study will be apparent when the actual values are measured. In addition, damage detection requires the prediction of the values in advance, and the model must be effectively updated to predict the values with good accuracy.

ABSTRACT: Visual inspection of bridges is important to maintain the sustainability of civil infrastructure. A hammering test is one of the non-destructive and verified methods used for this purpose, by which an expert inspector identifies spalling inside a concrete structure. The reliability of this method depends on the technique of the inspector. However, Japan society faces the problem of a scarcity of labor across all fields. Because of this, there are few training opportunities for new inspectors to learn the technique. This study aims to identify spalling concrete by using an autoencoder, instead of professional inspectors. First, a spalled concrete specimen was used to record the hammering sounds. The experimental method and a comparison of frequency spectra at each level of damage were described. Next, the autoencoder was applied to identify spalling concrete, and a comparison of the identification precision at each damage level was conducted. The results of the analysis show that spalling concrete can be identified by autoencoder to a concrete thickness of less than 30 mm.

1 INTRODUCTION

In Japan, civil infrastructure works, such as bridges, are needed for a sustainable society. To maintain vital bridge infrastructure, visual inspection is typically needed every 5 years per Japanese government policy. A hammering test is one of the most reliable, non-destructive methods used by expert inspectors to identify spalling inside of concrete. A weakness of this method, however, is that it relies on the technical expertise of inspectors. Exacerbating this, Japan faces a social problem of scarce labor across all fields due to a low birthrate and a retired labor demographic. Added to this are Japanese social goals of changing working culture to balance work and life. To resolve these problems, the Japanese government aims to realize a Society 5.0 era in which cyberspace and physical space are highly integrated. For example, the Ministry of Land, Infrastructure, Transport and Tourism plans to change working life and improve production efficiency through i-Construction.

Towards these efforts, this study aims to identify spalling concrete by using an autoencoder instead of professional inspectors. For this work, an autoencoder was developed using a neural network for the reconstruction of input data by compressing dimensional algorithms. For the experimental portion of the study, a spalling concrete specimen was first produced for the hammering test. The size of this specimen was $1500 \times 1200 \times 600$ (mm). The test was run by hammering the center point of each 50 mm mesh about 10 times, while collecting the frequency spectra of each damage area. Next, an autoencoder was used to identify spalling concrete for damaged or non-damaged specimens. Input and output data represented the damage level feature of each frequency spectrum between 10 Hz until 10,000 Hz. The autoencoder output data was reconstructed using the input data. When the correct model was used, the input value should be the

same as the output data. If the output value is different from the input value, this indicates spalling concrete (a damage condition). This different value is quantified as the reconstruction error (the mean squared error). A real bridge world does not provide the damaged concrete condition for autoencoder model learning, because when a damaged concrete condition is found, the bridge manager needs to repair it. Because of this, non-damaged data is used for autoencoder model learning. A comparison of the precision of identification of each damage level is described. The damage level is fundamentally based on the thickness of the covering concrete and the size of the spalling material. Finally, this study found the optimal parameters to identify spalling concrete by autoencoder as a thickness of covering concrete of less than 30 mm.

2 OUTLINE OF A HAMMERING TEST

A hammering test is a concrete bridge inspection method that detects the presence or absence of a damage condition from differences in the hammering sound (MLIT 2016). Types of damage conditions include spalling due to the cracks and corrosion of reinforcing bars in the concrete and poor adhesion of cement. In the hammering test shown in Figure 1, a hammering sound is used by an expert inspector to judge the concrete damage level. If the hammering sound is clear and dry, spalling is not indicated, and if the sound is dull, spalling is indicated. Spalling concrete needs to be repaired immediately when detected by the hammering sound. In addition, deterioration aging and leaking rainwater may cause internal abnormalities that cannot be seen. These areas of damage must also be removed because they affect the safety of the structure and the aesthetic appearance of the outer wall.

The hammering test is also a standard inspection method in the road bridge inspection guidelines for detecting the spalling of concrete, loose bolts, damage to repair/reinforcing materials, and abnormalities in anchorages (MLIT 2019).

However, a hammering test is based on the subjective senses (hearing) of the inspector to detect the presence or absence of a damage from the different hammering sounds. Therefore, the inspector's experience and skill are required, and the inspection results may differ depending on the inspector. Furthermore, there are cases in which even an expert engineer cannot clearly judge the damaged conditions by hearing. Finally, with this method there is no objective assignment of value for the level of damaged and undamaged conditions. Because the data is subjective and qualitative based on the hearing of the inspector, it is impossible to continuously store bridge damage assessment data and evaluation.

Recently, the Japanese government recommended changing society's working style in an initiative called Society 5.0. To meet this goal and increase production efficiency, infrastructure damage inspection should become more automated by robots. To automate the bridge inspections, the hammering test first needs to be quantified.

3 TEST SPECIMENS AND EXPERIMENTAL METHODS

3.1 *Design of the damaged test specimens*

This study aims to clarify how to identify real-world hammering sounds by autoencoder. For this, we used a spalling concrete specimen with known characteristics, such as the thickness of concrete cover, and damage condition, such as the length, thickness, and location of spalling.

Figure 1. Example of a hammering test at spalling concrete in a damaged specimen.

The spalling concrete specimen's properties are shown in Figure 2 and Table 1. The size of the spalling concrete specimen is $1500 \times 600 \times 1200$ mm with locations of spalling damage shown in Figure 3. The damage locations were determined by the air gap located inside existing spalling concrete, referred to as the spalling material. The air gap was represented by NR sponge rubber. The specimen was set up with concrete spalling on each side of the specimen. A wide specimen was utilized (600 mm) so that locations of damage did not affect the hammering sound or vibration on each side. Table 1 shows the material specimen, where the spalling material used was NR sponge rubber. The planar shape of the spalling material was a square, with sides of 100 mm, 150 mm, and 200 mm. The thickness of the spalling concrete material was 5 mm, 10 mm, and 20 mm. The thickness of the covering concrete was 30 mm, 60 mm, 90 mm, and 150 mm.

The main factor which ordinarily causes spalling in concrete is the expansion due to rebar corrosion in concrete. In this study, the thickness of covering concrete was determined by the minimum thickness based on road bridge specifications (Japan Road Association 2019). A thickness of 30 mm was set from the minimum cover of reinforcing bars in the beam. A thickness of 60 mm was set from the minimum cover to prevent corrosion of steel materials in areas affected by chloride induced deterioration damage (countermeasure categories II and III). Similarly, a thickness of 90 mm was set from the minimum cover to prevent corrosion of steel materials in areas where the effects of chloride induced deterioration are severe (countermeasure category S). In addition, a thickness of 150 mm was set for cases where the spalling concrete occurs along the main rebar.

Figure 3. Location of damaged areas (spalling concrete).

3.2 Experimental method and conditions

In this study, a hammering sound was recorded through an audio interface using a condenser microphone. The hammering point was the center of a 50 mm square mesh in each spalling concrete specimen. The method of evaluating the hammering sound data used the average spectrum of ten hammering sounds per mesh.

The main part of the hammering sound was processed by a computer program from the input time-sound pressure signal. Device details and specification are provided in Figure 4 and Table 2. The recording conditions are presented in Table 3. Recording time was 100 msec, which includes 3 msec before the peak amplitude and 97 msec after the peak. A time of 97 msec was enough to converge amplitude waves, as shown in Figure 5. Sampling frequency was 44,100 Hz, based on the audible frequency band. Generally, the audible frequency band of a healthy young person is between 20 Hz to 20,000 Hz (MOE 2019). In addition, in order to record and quantify sound waves, which are continuous signals, it is necessary to collect (sampling and quantizing) discrete signals by measuring the sound waves at regular intervals.

At this time, sound waves with a frequency higher than the Nyquist frequency (a frequency equivalent to 1/2 of the sampling frequency) cause a phenomenon of aliasing when sampling, and are not faithfully reproduced as the original signal during playback (sampling theorem). Therefore, in order to record sound waves up to 20,000 Hz, which is the limit of human hearing, it is necessary to record at a sampling frequency of 40,000 Hz or higher, which is twice the Nyquist frequency. From this, we recorded the hammering sound at 44.1 kHz, which is more than 40,000 Hz, is widely used for general application, and is compatible with the audio interface used in this research. The sound pressure of the hammering sound input from the microphone varies greatly depending on the strength of the hammering, the distance between the hammering position and the microphone, and the input sensitivity of the audio interface. Because the hammering test is performed manually, it is not always possible to hammer with the same strength. Additionally, this research assumes that the hammering sound is input by holding a condenser microphone in the hand opposite to the hand holding the hammer, so the distance between the hammering position and the microphone is not constant. Therefore, to reduce the differences in sound pressure caused by these factors, all hammering sound data were divided by the maximum amplitude of each hammering sound data, with the maximum amplitude of “1” used for normalization.

Figure 4. Setup of the sound recording devices.

Table 2. Sound recording device details.

Device name	Type	Detail	
Unidirectional microphone	SYNCO Mic-D2	Frequency Response	20 Hz – 20 kHz
		Sensitivity	-32 dB ± 3 dB
		Max. Input SPL	130 dB
		Signal to Noise Ratio	80 dB
		Dynamic Range	117 dB
Audio interface	behringer U-PHORIA UMC202HD	Frequency response	10 Hz – 60 kHz
		Impedance	3kΩ
		Max. input level	-4 dBu
		Supported sample rates	44.1/48/88.2/96/176.4/192 kHz

3.3 Comparison of spectra for each damage level

To confirm only the effect of the “thickness of covering concrete” on the frequency spectrum of the hammering sound for spalling concrete, we compared spalling conditions that had the same shape and thickness of spalling material. Figure 6 shows the frequency spectrum of the non-damaged part of the specimen and the frequency spectrum used for the study of the “thickness of covering concrete” of the spalling. The spalling conditions filled in with the same color in the “No.” column have the same spalling shape and thickness. In Figure 6, the frequency spectrum of the defective part of the specimen shows a different outline than the frequency spectrum of the sound part of the specimen when the thickness of covering concrete was shallower (the length of one side of the spalling was larger). In particular, there was a noticeable difference between the spectra No. 20 and No. 21. Spectra No. 11, No. 12, No. 28, No. 49 and No. 29 were similar to the frequency spectrum of the healthy part of the specimen, as the thickness of covering concrete was larger. The above results show that identification of spalling concrete is easier with a thinner thickness of covering concrete.

We further examined the effect of the size of the spalling concrete. By comparing the difference in the frequency spectrum depending on the condition of the spalling material, it was found that the effect of the thickness of the spalling material on the frequency spectrum was less pronounced.

The “thickness of covering concrete” and “size of the spalling material” represent most of the differences in the frequency spectrum. This is likely due to the fact that only the spalling concrete vibrates with hammering, and the impact force is not transmitted beyond a certain thickness depth.

Therefore, the examination of the applicability of the autoencoder to the hammering test in this study was conducted for the “thickness of covering concrete” and “size of the spalling material”.

4 APPLICATION OF AUTOENCODER FOR DETECTING SPALLING CONCRETE

4.1 Outline of an autoencoder

An autoencoder (Geoffrey E. 2006) is a type of neural network for the reconstruction of input data by compressing dimensional algorithms. This model is shown in Figure 7.

In neural networks, the expressive power of the network is usually enhanced by setting more neurons in the hidden layer than in the input and output layers. On the other hand, an autoencoder constructs a neural network by reducing the number of neurons in the hidden layer relative to the input and output layers. When it is learning in this state, the input data were compressed between the input layer and the hidden layer, and restored between the hidden layer and the output layer. This compression process is called encoding, and the reconstruction process is called decoding. By training the input layer and the output layer with the same data, a generative model that can reconstruct the input data in the output layer can be decoded. If the input value is equal to the output value, it can be determined that the data compressed by the middle (hidden) layer represents the features of the data. This type of autoencoder algorithm is called dimensionality reduction.

4.2 Application of an autoencoder for detecting spalling concrete

Anomaly detection through dimensionality reduction is based on the premise that it is possible to transfer the dimensionality-reduced feature values to a space in which normal data and abnormal data are distributed in separate regions (Chandola 2009).

In this study, the hammering sound data have values in each frequency band, with generally hundreds to thousands of feature values. However, bridge inspection engineers can identify anomalies despite hearing thousands of feature values. In other words, the sound can be classified as normal and abnormal values based on reducing the data to a low-dimensional vector, removing thousands of redundant feature values. Therefore, in this research, we attempted anomaly detection by dimensionality reduction using an autoencoder.

When the autoencoder is trained only on normal data, the trained model becomes a generative model that reproduces normal data from the input data. When abnormal data are input to this model, the autoencoder performs fragile reconstruction because it has not learned the abnormal data, and outputs features close to normal data. Here, the mean squared error (MSE) of the input and the output is the error of reconstruction. MSE is a minimum value if input data are normal. This means the input and output data are roughly equal. On the other hand, MSE is a maximum value if input data are abnormal. This means the input and output data are quite different values. In this study, the autoencoder can identify hammering sound differences due to setting a threshold value for the MSE (reconstruction error).

Figure 6. List of frequency spectrum for spalling concrete damage areas by the “thickness of covering concrete” and size of spalling condition.

4.3 Results of identifying spalling concrete using damaged specimens

Hammering sound data were recording from a point at each 50 mm mesh in the damaged specimen, as shown in Figure 3. In this figure, “d” is thickness of the covering concrete and “t” is the thickness of the spalling material. The center of each mesh was hammered 10 times. The

Figure 7. Model of an autoencoder.

parameters of the hammering sound data are shown in Table 4. The parameters of the autoencoder for identifying the hammering sound are shown in Table 5.

The results of identifying spalling concrete by autoencoder are shown in Figure 8 (the training data set is sample1). The identification results in Figure 8 are represented by the MSE value (reconstruction error) for each mesh as detected by the autoencoder. A threshold value of reconstruction error for identifying normal and abnormal was set to “10”. The areas marked in red in Figure 8 are the areas identified as abnormal.

As a result, spalling concrete could be identified with any learning data set (sample 1 to sample 3). The spalling concrete was identified with thicknesses of covering concrete less than 30 mm and length of a spalling material more than 150 mm.

However, the autoencoder couldn't identify spalling concrete at thicknesses of covering concrete of more than 60 mm. This is because the frequency spectrum of hammering becomes similar with a deeper thickness of covering concrete or a smaller area of spalling, which results in a reconstruction error value too small for detection through the autoencoder method in this study.

The above results determine that the applicable range of hammering sound identification by autoencoder for these trials is at thicknesses of covering concrete of less than 30 mm and a spalling size of more than 150 mm × 150 mm.

Table 4. Outline of the hammering sound data for inspection of the damaged specimen.

Number of learning data	normal (non-damaged) hammering sound 10 times by repeating (3 patterns: sample 1, sample 2, sample 3)
Number of test data	1040 (normal 864, abnormal 176)
Range of frequency	0-10,000 Hz
Resolution of frequency	10 Hz
Number of features	1000

5 CONCLUSIONS

In this paper, we attempted to identify spalling concrete by autoencoder. A spalling concrete specimen was made $1500 \times 600 \times 1200$ mm in size, and hammering sound data were recorded as training datasets. Recorded sound data were converted to frequency spectra for each sample point. Then, the data features for each damage level were described by a comparison of frequency spectra. Autoencoder learned by using non-damaged hammering sound data. If output data were different from input data, spalling concrete could be detected due to reconstruction error value (the mean squared error), with a threshold value for identifying damage condition set to a reconstruction error of 10. In this research, the autoencoder could identify damage conditions for a thickness of covering concrete less than 30 mm and a spalling size of more than $150 \text{ mm} \times 150 \text{ mm}$. In the future, methods are needed to identify damage at deeper thicknesses of covering concrete.

ACKNOWLEDGEMENTS

This paper would not have been possible without the contributions of many Fukushima college students and civil engineers. We would like to thank the FUJI P.S CORPORATION for making the specimen. We also summarized a part of Mr. Yasutaka BABA's advanced course thesis at Fukushima college in this paper.

ABSTRACT: In recent years, the structural integrity of social infrastructures has become a concern as they age, and how to efficiently and accurately assess their structural integrity is important in developing maintenance management plans. In this study, we aim to save time and labor by automating the evaluation of corrosion progress using machine learning. Specifically, we will investigate whether it is possible to detect corrosion based on deep learning using images of monorail bridges taken from an on-board camera, and then evaluate the progress of corrosion using images taken at the different inspection time.

1 INTRODUCTION

In recent years, the structural integrity of aging and unsafe social infrastructure has become a major concern, and how to assess structural integrity effectively and accurately has become an essential part of maintenance planning. 2015 saw the revision of Japan's Road Act, which requires that bridges with a span of 2.0 m or more be visually inspected in close quarters once every 5 years. The new law requires a close visual inspection once every 5 years for bridges with a span of 2m or more. Currently, these bridges are visually inspected by specialized engineers. However, in anticipation of a future shortage of engineers due to a declining population, it is important to establish a labor-saving system for inspections while assuring the accuracy of inspections by skilled engineers.

In a previous study by Nakamura et al. 2021, a learning model for a corrosion detector of steel bridges using CNN as a machine learning method was constructed using photos of the condition of road bridge inspection results conducted by Fukushima Prefecture as training data. The learning model was constructed using the cross-validation method and the results of a field survey of actual bridges in the Kitakata area as test data to evaluate generalization performance. However, no progress evaluation was conducted, and we believe that the model is not suitable for judging the priority of repair locations. In this study, we aim to save time and labor by automating the evaluation of corrosion progress using machine learning. Specifically, we will investigate whether it is possible to detect corrosion based on deep learning using images of monorail bridges taken from an on-board camera, and then evaluate the progress of corrosion using images taken before and after the progress of corrosion.

2 SYSTEM FLOWCHART

Figure 1 shows the two-stage evaluation system flow including object detection (YOLOv5) and additive mixture of color method in this study. First, YOLOv5, which was trained using teacher data, is used to detect corroded areas in the 2021 image, and a rectangle is displayed in the corroded area. The images with corroded areas are narrowed down to those with a uniform angle of view between the images captured in 2020 and 2021. After that, the additive mixture of color method is applied to evaluate whether the corrosion has progressed.

Figure 1. System overview.

2.1 YOLOv5

The structural surface damage screening technology in this study is based on general object detection using deep learning, and YOLO is used as the detection method. The most important feature of YOLO in object detection is that it extracts candidate regions of the target object and simultaneously calculates the class probability of those candidate regions in a single guess. This allows for very fast and real-time object detection, even for video images. YOLO is one of the fastest general object detection systems proposed so far, but YOLOv2 and YOLOv5 have also been more accurate detection tools. These, like YOLO, are offered as part of Darknet. In this study, the fastest detection method, YOLOv5, is used; the inference flow of the YOLO system is shown below. The network structure of YOLOv5 used in this study is shown in Figure 4, and is roughly divided into three parts: Backbone, Neck, and Head. Backbone creates feature maps for each image through convolutional operations. In Figure 2, CBL refers to Conv2D, BatchNormal, and LeakyRELU. CSPNet (Cross Stage Partial Network, Wang et al. 2020) is used for feature extraction by performing convolution on a portion of the feature map and concatenating the remaining portions. By adjusting the width and depth of the BottleneckCSP, there are four weights of the learned model in YOLOv5: s , m , l , and x . The weights of the learned model are then used as the weights of the SSP (Spatial Space Profiler). Then, in the SPP (Spatial Pyramid Pooling, He et al. 2014) layer, the extracted features are changed into fixed-length feature vectors for each candidate region. Next, Neck is a layer that combines the feature maps generated by Backbone, where PANet (Path Aggregation Network, Liu et al. 2018) and FPN (Feathre Pyramid Network, Lin et al. 2017) based on Mask R-CNN proposed by He et al. 2017 are used. A bottom-up feature pyramid structure based on PANet (Path Aggregation Network) and FPN (Feathre Pyramid Network) is employed. This enables recognition of objects of different scales. Finally, the Head uses the feature map generated by the Neck to make predictions about the coordinates and class of the box. In YOLOv5, the confidence for the candidate region is calculated as follows.

$$GloU = \frac{|A \cap B|}{|A \cup B|} - \frac{\left| \frac{C}{(A \cup B)} \right|}{|C|} \quad (1)$$

$$LGIoU = 1 - GIoU \quad (2)$$

GIoU Loss (Generalized IoU Loss, Rezatofighi et al. 2019) is employed as the loss function; GIoU makes it possible to quantify how far apart the two regions are when the two bounding boxes do not overlap at all. The GIoU is calculated as follows using the product and sum of the two regions plus the smallest and identically shaped region surrounding the two regions. Note that GIoU Loss is calculated by subtracting GIoU from 1.

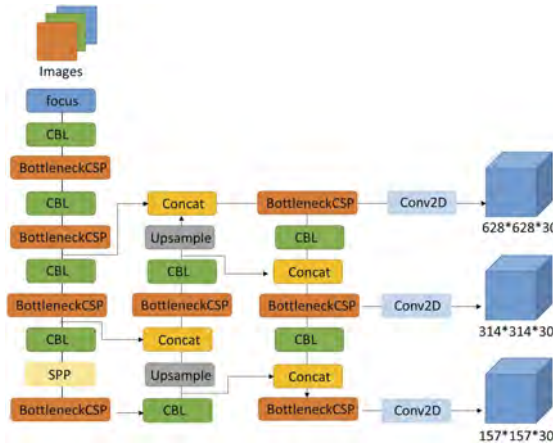

Figure 2. The architecture of YOLOv5.

2.2 Additive mixture of color method

Figures 3 and 4 illustrate the concept of additive mixture of color and the specific additive mixture of color process used in this study. The values in both images represent the RGB value of each pixel. Additive mixture of color is a method of adding colors using the three primary colors of light (Figure 3). The three primary colors of light are red, green, and blue, and various colors can be created from these three colors. As shown in Figure 4, mixing red and cyan produces a whitish color. In this case, the image before corrosion is converted to a red scale without the green and blue information, and the image after corrosion is converted to a cyan scale without the red information. In other words, by adding both images together, changes before and after corrosion can be indicated by colors such as white, black, red, and cyan. As a specific example, as shown in the first line of Figure 4, the RGB values before and after corrosion progress are both black (0, 0, 0), so the color of the areas with no change before and after corrosion progress is close to black (0, 0, 0) in the additive color mixture result. In addition, the area where the bridge was stained in the previous year and the stain disappeared this year is cyan (0,255,255), as shown in the second line from the top in Figure 4. Similarly, areas where there was no corrosion but corrosion has progressed are closer to red (255,0,0), as shown in the third line from the top in Figure 4. Finally, if there is no change before and after corrosion, as in the case of black, the color is closer to white (255,255,255) in the result of additive mixing, as in the fourth line from the top of Figure 4. In other words, areas that remain unchanged before and after the corrosion process return to their original color, while areas that have changed are displayed in cyan or red. Based on the above, as shown in the lower part of Figure 4, the additive mixture of color method can be used to identify only the areas where corrosion has progressed. However, it is assumed that the angle of view is the same for both images. In Figure 4, assuming no development, the same image is converted to red and cyan scales and then subjected to additive mixture of color.

Figure 3. The three primary colors of light.

Figure 4. Additive mixture of color method.

3 CORROSION DETECTION BY YOLOV5

In order to perform object detection, it is necessary to learn information about corrosion in images. This requires the creation of an image and metadata associated with the image. This process is called annotation. In this study, since the corrosion in the image is the detection area, the coordinates are used as metadata. Labelling, an annotation tool, is used to annotate the detection images used as training data. The image of the corroded area is generated as metadata for the training data. The data utilized in the demonstration experiment consisted of 2,282 images taken by engineers. In this study, we limited the annotation to images with corroded areas out of the images taken in 2020. This study adapts the general object detection technique YOLOv5. In this study, we used YOLOv5m, which is a heavy processing and has good accuracy. From the above data, YOLO was used on 376 pieces of training data and 36 pieces of validation data to train and detect corroded areas. The batch size was set to 8 and the number of epochs to 1000. In this study, the probability of detecting corrosion was calculated using the confidence level, which is one of the indices for object detection. The threshold of detection probability was set at 0.40.

Figure 5 shows the training loss, precision and recall when trained. Each figure are stopped in the middle because the early stopping function, which stops overlearning, is activated in each case. Overlearning is a phenomenon in which excessive adaptation occurs only to the training data. The loss shows that learning is progressing well, since it is getting smaller as the number of epochs increases. Finally, the loss is 0.0427, the fit is 0.709, and the recall is 0.545.

Corrosion was detected in 107 images from 570 images captured in 2020, and in all 32 images that were judged to be corroded by the technicians. The average confidence level was about 0.6, and there were no false positives. The example of detection results is shown in Figure 6.

Figure 5. Training procedure.

Figure 6. Example of corrosion detection results.

4 CORROSION PROPAGATION DETECTION BY ADDITIVE MIXTURE OF COLOR MEDHOD

Of the 107 images in which corrosion was detected, 32 images showed progressive corrosion, and a comparison of the images in 2020 and the images in 2021 shows that the corrosion has spread. The examples of corrosion propagation results by Additive mixture of color method is

Figure 7. Examples of corrosion propagation results.

indicated in Figure 7. As shown in this figure, it is found that the corrosion progression area was detected correctly.

However, as shown in the black box on the right side of Figure 8, false positives were observed in some areas. It is considered to be due to the misalignment of the camera mounted on the inspection vehicle caused by the vibration of the bridge during the shooting.

Figure 8. Example of false detection for corrosion results.

5 CONCLUSIONS

The purpose of this study was to develop a system that can detect structural surface damage with high accuracy and speed using visual damage inspection results, and a system to evaluate the progress of damage using the additive mixture of color method. In addition to the detection technique using YOLO, which is capable of high-speed processing of large-area and large-volume images, the three primary colors of light We aimed to improve the accuracy of damage detection and progress evaluation by adapting additive mixture of color using. At YOLO, the lack of the detection of corrosion is close to zero, which is the standard, and we were able to achieve this with the data currently in our possession. At additive mixture of color, we confirmed that the corrosion progresses could be detected only when the angle of view is uniform. In the future, we plan to research methods to unify the angle of view, which is a condition for applying additive mixture of color.

Development of a cable inspection robot for cable-stayed bridges

K. Kawamura & W. Zheng

Yamaguchi University, Ube, Yamaguchi, Japan

M. Shiozaki

Sumitomo Mitsui Construction, Chuo-ku, Tokyo, Japan

ABSTRACT: The authors have developed a cable inspection robot for the cable-stayed bridges (CSBs). The robot is possible to photograph the entire circumference of the CSB cable surface with several cameras while moving up and down along the cable, and then creating an image development diagram of the CSB cable surface from the video. By utilizing an image development diagram, it is possible to confirm the position and the shape of damage to the cable, which can be difficult to grasp using video only.

1 INTRODUCTION

The number of the cable-stayed bridges (CSBs) in Japan is 319 as of March 2021 (MLIT 2021) and the need for maintenance is increasing. The cable inspection of CSBs is either conducted visually on aerial work platforms or carried out by inspectors with special altitude technology. However, these inspection methods are problematic in that there is a limit to the inspection height, and there is a problem that the work must be carried out at the height which is dangerous for the inspector. Consequently, the study on developing CSB cable inspection robot is being done in Japan. In terms of existing studies, the cable inspection robots have been developed by Chodai Corporation (Chodai co., Ltd. 2017) and Nishimatsu Construction Corporation (Nishimatsu Construction co., Ltd. 2022) in addition to the robot used in this study (Kawamura et al. 2016, 2017, 2021).

The authors have developed a cable inspection robot for the CSBs. The robot is possible to photograph the entire circumference of the CSB cable surface with several cameras while moving up and down along the cable, and then creating an image development diagram of the CSB cable surface from the video. By utilizing an image development diagram, it is possible to confirm the position and the shape of damage to the cable, which can be difficult to grasp using video only.

The robot is able to automatically synchronize the start time of each mounted camera to avoid timing errors in order to make an image development diagram. Specifically, by making a majority of red LEDs set in the inspection robot flash synchronously in time with each camera, the flicker can be confirmed to be within the processing range of the image development diagram of the inspection robot. In addition, the initial illumination of the red LED is automatically detected within the photographic image, and the photographic image synchronization of each camera is executed. However, due to the existence of pixels similar in red color to that of the LEDs, it is possible to perform a false identification, leading to unwanted synchronizations. Therefore, a method was proposed to install the red LEDs on green base plates in order to perform the detection with fewer similar color pixels in the shooting area. In addition, Yolov5 (Glenn, 2020), a deep learning model used for object detection, was used in the automatic detection. The paper outlines a method to make an image development diagram in the following chapters.

2 INSPECTION METHOD OF CSB INSPECTION ROBOT

2.1 Introduction

This chapter describes the CSB cable inspection robot developed by the authors. The robot is to photograph the cable surface with the robot and make the image development diagram of the cable surface from the produced video. Figures 1 and 2 show a diagram of the CSB and a photo of the robot installed on a cable. At point A in Figure 1, video photography is started manually. After the robot rises to point B, the red LEDs in the robot flashes and returns to point A. The image development diagram is made using the video taken during the descent from location B to A.

Figure 1. Schematic image of a bridge by the cable-stayed bridge cable inspection robot.

Figure 2. Photograph of cable-stayed bridge cable inspection robot.

2.2 Component of the cable-stayed bridge cable inspection robot

As shown in Figure 2, the robot is composed of three units: a photography unit, an elevation unit (UAV), and the image development diagram software. The elevation unit is used to raise the photography unit, detaching from the photography unit after reaching the destination so as not to interfere with photography. Inside the photography unit, six cameras are mounted so that the entire surface of a cable can be photographed at a single elevation. In addition, the descent speed mechanism keeps the descent speed of the photography unit stable, while a separate device records the distance (mm) in which the photography unit has moved in relation to the cable as well as the angle of rotation. The amount of movement recorded by this measuring device is then used when creating an image development diagram.

2.3 Image deployment diagram production

The processing of image development diagram software can be divided into the following seven steps.

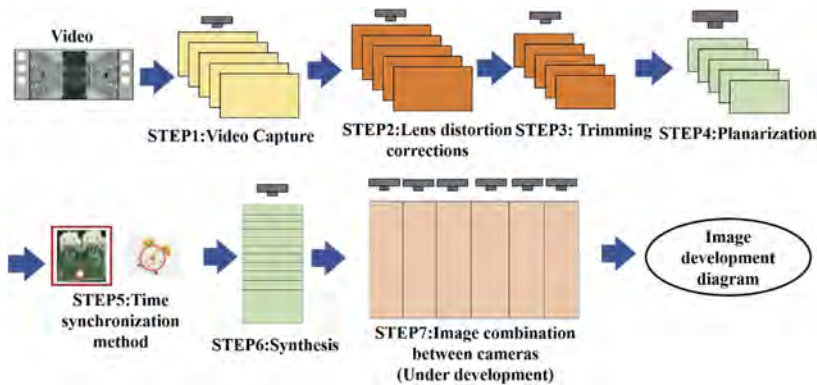

Figure 3. Flow of image deployment diagram production.

STEP 1: Video Capture. PNG files are generated for each video frame from the video taken by the photography unit.

STEP 2: Lens distortion correction. Lens distortion correction is then performed on all captured images generated in STEP 1.

STEP 3: Trimming. After lens distortion correction, the area where the cable is projected is cropped off. The crop range is specified using the first captured image and applied uniformly to the remaining images.

STEP 4: Planarization. This step makes a planarized image for the surface of the cable.

STEP 5: Time synchronization method. It is necessary to synchronize the start time of the image development diagram making process for each of the six cameras mounted on the robot. Therefore, a number of green bases equipped with red LEDs are installed inside the robot. The configuration condition is that all cameras can detect any kind of red LEDs, which are set to light up at the same time as the start of the image development diagram. Thus, in order to grasp the start time of the image development diagram process, it is necessary to correctly obtain the frame number for when the red LEDs begin flashing. The next chapter describes the LED detection process.

STEP 6: Synthesis. Using the movement data recorded during photography, the images made in STEP 4 are then combined into a single synthesized image of the cable surface.

STEP 7: Image combination between cameras. Since STEPS 1~5 occur for all six cameras on the photography unit, a detailed image of the entire circumference of the cable surface can be generated by further combining all of the continuous images made during STEP 5.

3 TIME SYNCHRONIZATION METHOD

3.1 Introduction

This chapter describes the time synchronization method for making an image development diagram. Specifically, a method for automatically detecting the flash of the red LEDs from captured video was adopted in order to synchronize six cameras installed on the robot.

3.2 Necessity of LED detection

During STEP 5 of the image development process mentioned in 2.4, it is necessary to synchronize the start time of the image development diagram making process for each of the six

cameras mounted on the robot. Therefore, a number of green bases equipped with red LEDs are installed inside the robot. Figures 3 and 4 respectively show photos taken inside the robot and the enlarged area of the green bases equipped with red LEDs. The configuration condition is that all cameras can detect any kind of red LEDs, which are set to light up at the same time as the start of the image development diagram. Thus, in order to grasp the start time of the image development diagram process, it is necessary to correctly obtain the frame number for when the red LEDs begin flashing.

Figure 4. Interior of cable-stayed bridge cable inspection robot.

Figure 5. Enlarged image of a green base.

3.3 Method of LEDs detection

The robot unifies the start time of image development by detecting whether the red LEDs on the green bases are lit at the same time. The goal is to automatically detect the lighting of red LED from the video taken by the cameras mounted on the robot; the illumination of the red LEDs is detected only after the green base with fewer similar pixels is detected in the captured image, thereby reducing the possibility of false detection. In addition, the CSB cable inspection robot will experience vibration during lifting and lowering, resulting in the position of green bases and red LEDs on an image not being set correctly. For this reason, yolov5 (Glenn, et al. 2020) that deep learning object detection algorithm proposed in 2020 was employed to accurately track the detection of green bases in video. The specific detection methods of green bases and red LEDs will be described in the next section.

3.4 LED detection process

Processing of the red LEDs lighting detection algorithm that is performed on every camera is divided into the following four steps. Figure 6 shows the flow of the detection algorithm and summarizes the details of each step.

STEP 1: The video is read frame by frame.

STEP 2: Use Yolov5 to get information about the range of the exploration rectangle containing the green base and judge whether the base exists. The information of exploration rectangle contains the xy coordinates of the center corner of the rectangle, as well as its length and width.

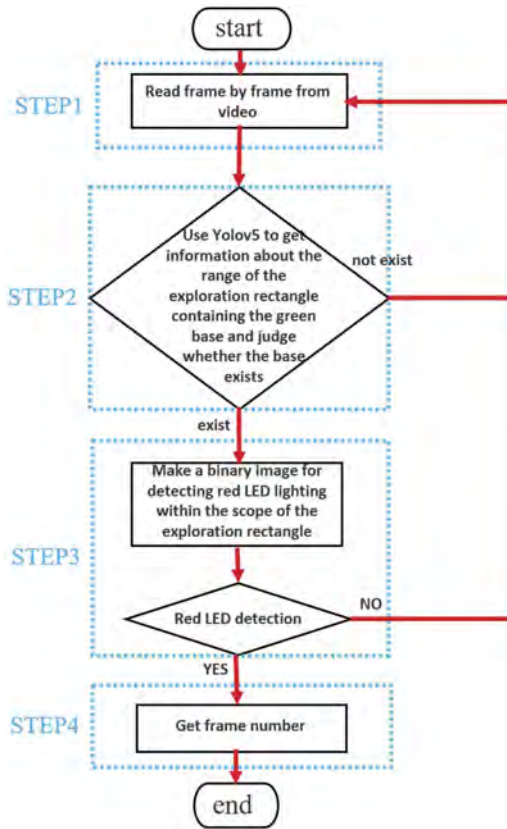

Figure 6. LED Detection Algorithm Flow Chart.

STEP 3: This step involves detecting the illumination of red LEDs within the search rectangle obtained in STEP 2, and the color representation of the image pixels value is converted from RGB format to HSV (Hue, Saturation, Value) format (Hideaki, S. & Takashi, O. 2017), also referred to as Hexcone Model. The color parameters in this model are hue, saturation and brightness respectively. RGB format is typically used for pixel values, but because it is difficult to specify the range of specific colors with RGB, this study used HSV format instead to intuitively show the brightness, hue, and saturation of visualized images. First, the pixel value (HSV) of the rectangular frame's xy coordinates are binarized according to the following Equation 1:

$$I(x, y) = \begin{cases} 255, & (0, 43, 46) \leq h(x, y) \leq (10, 255, 255) \\ 0, & \text{otherwise} \end{cases} \quad (1)$$

A threshold for separating red LED light from other pixel values within a predetermined HSV range is set, with pixels falling within this range designated as 255 (white) and those outside the range as 0 (black). In this way, targeted sections of the image are converted into 255 pixels by Formula 1 and identified as red. The range of red HSV values used in Formula was determined in advance by the authors through image analysis of the red LED lights. If the sum of pixel values in the exploration rectangular for the binary image is more than 1, it is assumed that the red LEDs are lit and the algorithm proceeds to STEP 4. When a pixel is determined as red by Formula 1 its pixel value will be 255, and the sum of pixel values in the search rectangular box is 255. In other words, if there is even one red pixel in the exploration rectangular, it treats the red LEDs as lit.

Figure 7. On-site verification of the cable inspection robot.

Figure 8. Appearance of Bridge M1 inspected by the cable inspection robot.

Figure 9. The shooting distance of the cable inspection robot on the cable.

On the other hand, if the sum of pixel values in the exploration rectangle is 0, it is judged that the red LEDs are not lit and will return to STEP 1.

STEP 4: In the event STEP 3 determines that the red LEDs are lit, the frame number of the image is obtained and the algorithm terminates.

4 APPLICATION OF THE INSPECTION ROBOT TO AN EXISTING BRIDGE

The robot was applied to the existing bridge (Bridge A1) in order to verify the ability of the shooting and the accuracy of the image development diagram. Figures 7 and 8 are the scene of

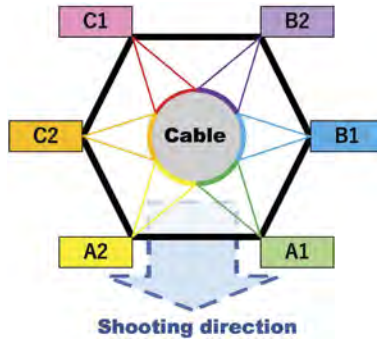

Figure 10. Camera placement in the robot.

Figure 11. Image development diagram at 67~70m of the cable S1.

Figure 12. Image development diagram at 64~67m of the cable S1.

Figure 13. Image development diagram at 61~64m of the cable S1.

on-site verification. Figure 7 is a scene where the robot is attached to the cable. Figure 8 shows the appearance of Bridge M1. As shown in Figure 9, there are 4 cables on one side of the bridge, which shows the shooting distance of the cable inspection robot on each cable. S1, S2, S3 and S4 are ID of each cable. The total lengths are 86m, 67m, 48m, 30m. The shooting distance are 70m, 52m, 36m, 21m, respectively. Then, Figure 10 illustrates the camera placement in the robot and the shooting direction. A1,A2,B1,B2,C1 and C1 are ID of each camera.

Figures 11 to 13 are the part of the image development diagram of cable S1 as an example to illustrate the accuracy of the image development diagram. The A1 to C2 in Figures 11 to 13 are correspond the camera ID in Figure 10. As shown in Figures 11 to 13, within the range of 64~70m of the cable S1, the images taken by each camera were well combined. However, the region in the red box in Figure 13 is slightly misaligned due to that there was unevenness at the joint of the cable.

5 CONCLUSIONS

This study describes the cable inspection robot for CBSs developed by the authors and explains in detail the entire process of making the image deployment diagram and the operation process of time synchronization method. Then, the robot is verified for an existing bridge. As a result, the robot is suitable for practical application.

Application of cluster analysis and Markov chain model for network-level highway infrastructure management

A. Amir & M. Henry

Shibaura Institute of Technology, Kotou-ku, Tokyo, Japan

ABSTRACT: Khyber Pakhtunkhwa province, Pakistan's third-largest provincial economy, is totally dependent on road transport. To upkeep the highway infrastructure in good condition, an effective, efficient, economical, and sustainable management technique needs to be devised. The pavement deterioration prediction is a vital element for an efficient pavement management system that can help the road authorities in determining the appropriate maintenance technique. The research aimed to develop the pavement deterioration prediction model at the network-level using Markov Chain. However, at the network-level, the road characteristics are not uniform due to which it is difficult to classify the road sections into families for applying Markov Chain. Thus, first Agglomerative Cluster Analysis was applied to define pavement families with similar characteristics. Then, the deterioration prediction models were developed for pavement families using Markov Chain. The combination of AHC with Markov Chain found was found an effective technique for pavement deterioration models at the network-level.

1 INTRODUCTION

The deterioration of road pavement results from the damaging effect of traffic loading, environmental conditions, age, and other associated factors greatly affects safety, serviceability, and riding quality. The maintenance management of deteriorated pavements poses a great challenge to engineers due to the random nature of the deterioration process and the complex relationship between pavement characteristics or variables (Surendrakumar et. al., 2013). Due to the uncertainty in the pavement deterioration process, the Pavement Maintenance Management System (PMMS) is becoming increasingly more complex. The PMMS is separated into two general levels: network level and project level (Smith et. al., 2001). The network level management system deals with the entire pavement network and involves high-level decisions related to network-wide planning for budget optimization, whereas the project level deals with smaller sections within the network and is generally involved with the decisions relating to condition, Maintenance Rehabilitation, and Reconstruction (MR&R) assignment and unit cost. According to the AASHTO guideline for the pavement management system, the approaches for the pavement management system can either be top-down by dealing with the network level first or can be bottom-up by dealing with the project level decision first depending upon data amount (Coree et. al., 1990).

The provincial highways road network of Khyber Pakhtunkhwa province of Pakistan consists of 3000 km of asphaltic pavements but, according to a report published by Asian Development Bank (ADB), only 27.7% of provincial highways are in fair to good condition while the rest are in poor conditions (ADB, 2018). The main element which contributes to the maintenance backlog is the absence of an effective maintenance plan to correlate the data for the development of the maintenance plan (Amir et. al., 2022). The research aimed to utilize the existing provincial highway network data of Khyber Pakhtunkhwa for network-level planning. Budget planning at the network level is complex due to the irregular behavior of pavement deterioration. However, the prediction for future repair demands of the road infrastructure at

the network level can be helpful for budget planning. The estimation of the repair demands, and life cycle cost is normally determined by deterioration models (Jiang et. al., 2000). These models can be deterministic or probabilistic (stochastic). The prediction models developed by deterministic and stochastic approaches differ in concept, formulation, and output format (Li. N et. al., 1996). There are many deterministic models developed for regional or local Pavement Management Systems, such as traffic-related models, time-related models, interactive-time-related models, and generalized models (Md. Sohail, 2015). However, by using the deterministic approaches, the developed model cannot explain some problems, such as in quantifying the parameters that are the main reason for pavement deterioration, the unpredictability of traffic loading and environmental conditions, and especially the bias when performing the subjective evaluations of pavement condition (Li et al.,1997). In recent years, pavement engineers and researchers have paid considerable attention to stochastic models. A stochastic model was developed for pavement deterioration represented by the Markov transition process (Li. et al., 1997). Dynamic programming combined with the Markov process produces optimal budget requirements for the given analysis period (Butt et al., 1994). Wang et al. developed the Markov transition probability model by using the pavement historical data for the categorized highway for the Arizona Department of Transportation (Wang et al., 1995). Butt et al. presented the approach for budget optimization based on the pavement deterioration model by utilizing the Markov process for the airport pavement network. The pavement sections were classified into families based on surface type, traffic, maximum deflection, etc., and then the Markov prediction model for each family was developed (Butt et al., 1994).

In this research, first, Agglomerative Hierarchical Cluster Analysis was carried out on the provincial road network data to identify different families of pavement sections with similar characteristics. Then, the Markov prediction model was developed for each pavement family to find the deterioration progress for the next ten years.

2 METHODOLOGY

The overall flow chart of the research study is shown in Figure 1. The pavement characteristics data of the provincial highway network of Khyber Pakhtunkhwa, which were collected from the Communication and Works (C&W) Department, Peshawar, Pakistan, were used in the research. The data comprised 18 characteristics of bituminous pavements with various ages of pavements ranging from 1-6 years old road.

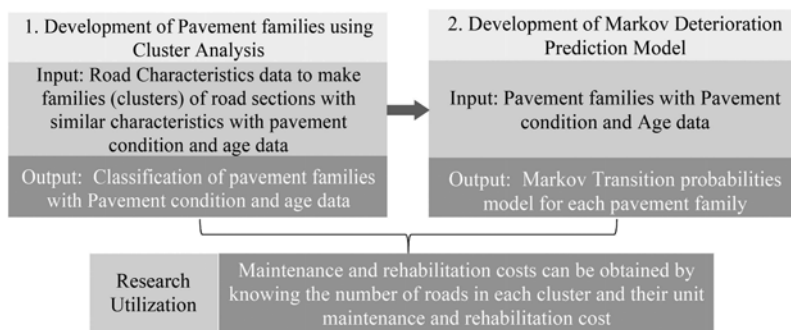

Figure 1. Methodology flow chart.

2.1 Cluster analysis

The first step of the research was to group the road sections having similar characteristics. Therefore, the Agglomerative Hierarchical Cluster Analysis was done to make the clusters or families of road sections that have similar characteristics.

Agglomerative Hierarchical Cluster Analysis, the most common type of hierarchical clustering, is an unsupervised machine-learning technique that sequentially groups objects into clusters based on similarities between the characteristics of objects (Murtagh et al., 2012). This technique was used in this research because it is a bottom-up approach that starts from the smaller clusters and is then combined to form the bigger clusters based on similarities. The analysis was carried out in an open-source statistical analysis software R (R Core Team, 2022) following the guidelines provided by Kassambara (2017).

In this research, the features for the cluster analysis were the road characteristics, such as traffic loading, cross and longitudinal drainage condition, the importance of the road, and pavement terrain (the full list of variables is shown in the results). All the features were converted into nominal data for performing cluster analysis. Different hierarchical trees, or dendrograms, were constructed with different distance methods. The dendrogram with Generalize Distance Measures (GDM) and the Mcquitty linkage function was selected because the numbers of data in the clusters were sufficient for the calculation of the probability matrix for the Markov model. However, the correlation coefficients between the generalized distance matrices and their respective cophenetic distance matrices were only the second highest among the linkage functions tested.

2.2 Development of Markov prediction model

The next step of the research was to develop a Markov Chain prediction model for each group of road section families. Markov's property is satisfied by stochastic processes where future states are determined by their present state instead of their past state. Hence, it means that the present state is the cumulative result of all past states (Surendrakumar et. al., 2013). So, the Markov transition matrix is the stationary stochastic matrix, and the matrix describing the initial condition of the system is the initial probability distribution matrix. The combination of both matrices is used for defining the deterioration processes. Hence the entire process consists of two steps: first, to develop the defined size of the transitional matrix, and second, the initial transition matrix and current conditions are multiplied to get the future conditions.

In deterioration modeling, the model elements change randomly with the progression of time. Hence, in the case of pavement deterioration, it is assumed that the pavement starts its life in nearly good condition and then undergoes a series of duty cycles that deteriorate its condition. In this research, the pavement states are expressed in terms of three pavement conditions - good, fair, and bad as defined in data obtained by the department as shown in Table 1. Thus, three 3x3 transition probability matrices were developed.

Table 1. Description of pavement condition.

Pavement Condition	IRI	Speed (kph)	Area Damaged (%)
Bad	7-10	25-40	10-25
Fair	4-6	40-60	5-10
Good	0-4	Over 60	-

2.3 Transition probability matrix

The first step of the Markov chain is to predict the transition probabilities in different states. For this purpose, the historical condition data were analyzed to get the transition matrix for each family. The initial data consisted of the pavement condition data in the year 2021 and the year of last rehabilitation or the year of construction, from which the age of the pavement was calculated for every road section. It was assumed that the road condition was good in the year of rehabilitation or construction, and no major maintenance treatment was performed during the pavement life. From this data, the pavement conditions in transition years were established, and subsequently, the probability and percentage in each condition were calculated. A sampling of the three pavement condition states data for Cluster 1 are shown in Table 2, which were used for the calculation of the initial transition matrix for Markov Chain prediction for future years.

2.4 Markov chain prediction

The Markov chain's initial step is to determine transition probability. If $\{X_n, n=0,1,2,\dots\}$ is the Markov chain, and $X_n=i_n$ represents that the procedure is cited in pavement condition (i) and at year n, then the conditional probability $P_{ij}(n,n+1)$ is called one-step transition probability from any specific pavement condition state (i) to a one-step lower pavement condition state (j) at the year n:

$$P_{ij}(n, n + 1) = P[X_{n+1} = j | X_n = i_n], n = 0, 1 \dots \quad (1)$$

Thus, according to the Markov chain process, the probability of transition from any specific pavement condition (i) to an immediate future pavement condition (j), given all previous pavement conditions and the current condition (j), is distinct from the previous conditions (states) and dependent only on the current condition (j) (Ahmed et. al., 2019) It means that the transition probabilities are assumed to be stationary or unchanged over the time period of interest and independent of how the current state was reached. The probability P_{ij} symbolizes the likelihood that the procedure will create a change to status (i), given that presently the method is status (j) as represented by the equation below:

$$P_{ij} \geq 0, \sum_{i=0}^n P_{ij} = 1, j = 0, 1, \dots \dots \quad (2)$$

Similarly for the transition matrix having P_{ij} , then the probabilities will be:

$$P = \begin{pmatrix} P_{00} & P_{10} & \dots \\ P_{01} & P_{11} & \dots \\ \cdot & \cdot & \dots \end{pmatrix} \quad (3)$$

However, the transition probabilities are represented as:

$$P_{00} = 1 - \alpha, P_{10} = \alpha, P_{11} = 1 - \beta \text{ and } P_{01} = \beta \quad (4)$$

Then after a single time interval, the probability transition matrix is specified by:

$$P = \begin{pmatrix} 1 - \alpha & \beta \\ \alpha & 1 - \beta \end{pmatrix} \quad (5)$$

Where α and β are possible values of probability.

The transition probability P_{ij} was determined for each of the three pavement states, from Equation 2 where n_{ij} represents the transition number as of state i (initial state) towards state j (next level deterioration state) in a specific time and n_i signifies the overall component number in state i before transition.

3 RESULTS AND DISCUSSIONS

3.1 Classification of the road families

The result of the cluster analysis is shown in Figure 2. The cutting of the tree was done at a specific height so that each cluster should contain the maximum number of road sections with similar characteristics or features. Hence, five clusters were obtained in total, but only three clusters were selected for building the deterioration model with Markov chain because they contained a sufficient number of pavement age data necessary for developing the model.

Table 3 shows the in-cluster mean values of the road characteristics for each of the three clusters, or road families. It was observed that Cluster 1 consisted of a family of roads that are in hilly areas and leading to tourism destinations, having in-cluster mean values of 0 and 1 for these features, respectively. Furthermore, in this family, traffic load conditions were generally medium, cross and longitudinal drainage conditions were good, and the roads were less important and not leading to the industrial or mines and minerals areas. Cluster 2 represents the family of highly important roads with high traffic load in the plain areas, as the mean values for high traffic load and pavement terrain was 1, and the mean value for road importance was 0.94. Other factors such as cross and drainage conditions were found to be good, and the roads were not leading to tourism areas nor were they industrial traffic roads. Similarly, Cluster 3 as found to be a family of road sections leading to mines and mineral areas, with an in-cluster mean value of 1, while drainage condition of the roads was fair, the roads were less important, had medium traffic, and were not leading to tourism or industrial areas.

Figure 2. Dendrogram of road sections by road characteristics and distribution by clusters.

3.2 Markov deterioration prediction model

Next, the Markov deterioration prediction model was developed for each of the three families selected from the cluster analysis. The 3x3 transition probability matrices obtained for three road families are shown in Table 4. Using the transition probabilities and assuming the road sections in each road family begin in good condition, the predicted condition distributions for the 10-year time period for each road family are shown in Figures 3, 4, and 5.

From the deterioration model, it was observed that the rate of deterioration of the family of roads in hilly areas with medium traffic load (Cluster 1) is more than the plain areas (Cluster 2) with high traffic load. In Khyber Pakhtunkhwa province of Pakistan, the extreme climatic impact may be the cause of the early deterioration of pavements in hilly areas. There is a snowy season for four (4) months in northern areas of Pakistan. The erosion may be the factor responsible for the early deterioration of pavement surface in mountainous regions. In winter, when water fills

Table 3. In-cluster mean values for each road characteristic.

Variables	Description of variables	Cluster 1 n=16	Cluster 2 n=18	Cluster 3 n=33
Pavement Terrain	Hilly=0, Plain=1	0.00	1.00	0.25
High Traffic load	Yes=1, No=0	0.13	1.00	0.12
Medium Traffic load	Yes=1, No=0	0.80	0.00	0.75
Low Traffic load	Yes=1, No=0	0.06	0.00	0.12
Strategic importance	Yes=1, No=0	0.19	0.20	0.21
Road importance	Yes=1, No=0	0.46	0.94	0.50
Good culvert condition	Yes=1, No=0	0.96	0.94	0.00
Fair culvert condition	Yes=1, No=0	0.04	0.03	1.00
Bad culvert condition	Yes=1, No=0	0.00	0.03	0.00
Good drainage condition	Yes=1, No=0	0.80	0.50	0.00
Fair drainage condition	Yes=1, No=0	0.00	0.15	1.00

Industrial roads	Yes=1, No=0	0.00	0.31	0.12
Mines and minerals roads	Yes=1, No=0	0.06	0.46	1.00
n=numbers of count in each cluster				

small cracks in the pavement’s surface and it gets frozen, the expansion in volume can cause internal pressure, damage the pavement, and lead to erosion of roads. Salt used for deicing is another cause of pavement deterioration in snowy areas (Amir et. al., 2022). When salt mixes with water, it increases freeze-thaw damage and road scaling problem (Althoey et. al., 2021). On the other hand, the lower rate of deterioration for the roads of the plain area with high traffic (Cluster 2) may be because the roads are appropriately designed for the high traffic volume.

The rate of deterioration for the family of road sections that lead to mines and minerals (Cluster 3) is very high as compared to the other two families. If there is no maintenance, it is predicted that the roads will deteriorate completely within four years. This may be due to uncontrolled overloaded vehicles frequently using these roads because overloading had been an issue for the provincial highway network in Khyber Pakhtunkhwa province due to its quarrying, logging, and mining industries and related traffic, especially in the marble-producing areas. These pavements are designed following AASHTO specification with a single axle load of 18000lb but, according to a report published by Asian Development Bank (ADB), trucks in Khyber Pakhtunkhwa are overloaded up to 95% above the permissible load limits (ADB, 2018). Due to overloading, the design life of pavement reduces and results in pavement deterioration (Amir et. al., 2022). The provincial road authority needs to give more attention to mines and minerals areas roads. The implementation of routine and periodic maintenance may aid to slow the rate of deterioration, if practiced properly, and may help in increasing the life of the pavement.

Table 4. Deterioration Transition Matrix for Cluster 1, Cluster 2, and Cluster 3

States	Good	Fair	Bad	States	Good	Fair	Bad	States	Good	Fair	Bad
Good	0.79	0.21	0	Good	0.88	0.11	0	Good	0.39	0.61	0
Fair	0	0.80	0.20	Fair	0	0	1.00	Fair	0	0.15	0.85
Bad	0	0	1.00	Bad	0	0	1.00	Bad	0	0	1.00
Cluster 1: Hilly areas, tourism roads, medium traffic, good drainage cond.				Cluster 2: Plain areas, high traffic, good drainage condition.				Cluster 3: Mines and minerals roads, medium traffic, fair drainage cond.			

4 CONCLUSIONS

The research aimed to develop the pavement deterioration prediction model based on the existing data of the provincial road network at the network level that can be utilized for budget

Figure 3. Pavement deterioration model w.r.t age for Cluster 1 (Hilly areas, tourism roads, medium traffic, good drainage condition).

Figure 5. Pavement deterioration model w.r.t age for Cluster 3 (Mines and minerals roads, medium traffic, fair drainage condition).

optimization. At the network level, the pavement condition data with time is sometimes difficult to collect for the entire pavement network. The study intended to develop the approach for predicting pavement deterioration based on the existing data available with the road department by classifying the road network into different families using Cluster Analysis before applying Markov Chain Analysis. The Agglomerative Hierarchical Cluster Analysis assisted to classify the road sections into families having similar characteristics with the identifications of dominant road variables for each family. The technique of using AHC was found effective for network-level analysis where the road characteristics are not uniform, and it is difficult to classify the road sections with similar characteristics into groups before applying the Markov Chain approach. The Markov chain model can then be easily developed for each family for determining pavement deterioration with time for network-level management. By knowing the per unit cost of maintenance for different types of pavement conditions, the highways authority can formulate the maintenance management plan for the network level for future years.

ACKNOWLEDGEMENT

The authors would like to express their gratitude to the Japan International Cooperation Agency (JICA) for their support through the Road Asset Management Platform, to Shibaura Institute of Technology (SIT), Tokyo for providing the environment for the research, and to Pakhtunkhwa Highway Authority, Communication and Works Department, Peshawar, for sharing the data and requisite information.

ABSTRACT: The excavation-induced tunnel displacement is an increasing problem with the intensive utilization of urban underground space. To rapidly and accurately predict the deformations in different scenarios, this study proposed a practical framework to build a digital twin of the tunnel–soil–foundation pit by a hybrid finite element (FE) and surrogate model approach. First, a parametric FE model is constructed, with 13 parameters as inputs and tunnel deformations at 5 positions as outputs. Then, a uniform design is adopted to generate the parameter sampling space of the FE examples, which reduces the number of samples for machine learning (ML) and computational cost. Finally, a surrogate model based on back propagation neural network (BPNN) is established, and the FE computation results and measured data from a real project are employed for verification. The results show that the accuracy of the validation set is more than 91.38%, the accuracy of the test set is more than 80%, and the error with the measured data is less than 1.5 mm. The BPNN-based surrogate model is high-efficient with a computational time of milliseconds. The established surrogate method could replace the expensive physics-based FE model for faster computation. The contribution is valuable in constructing digital twins of the tunnel during operation, especially suitable for safety assessment of existing tunnel in the scenario of adjacent engineering activities.

1 INTRODUCTION

Intensive utilization of underground space in urban areas has resulted in an increased number of excavations. A certain number of foundation pit projects must be located close to existing tunnels. However, it has been reported that the excavation of adjacent foundation pit threatens the structural safety and service life of the existing tunnel (Ai, et al., 2023). Therefore, rapid and accurate prediction of the deformation of existing tunnel in different scenarios is necessary to mitigate the risks involved during operation.

Analytical solution and FE simulation are the traditional methods for studying the response of existing tunnels during the excavation of adjacent foundation pits. Owing to the requirements of real-time response and computational accuracy, it is difficult to apply these two methods for rapid prediction and accurate evaluation of the excavation-induced deformation of an existing tunnel.

In recent years, artificial intelligence (AI)-based surrogate models have been introduced to solve forecasting problems during tunnel construction and operation. Their applications focus on the prediction of surface settlement or building damage caused by tunneling or excavation

(Zhang et al., 2020c; Ou, Teng, & Li, 2020). Furthermore, some studies have focused on AI-supported optimization of construction parameters, such as shield steering, grouting pressure, and face pressure (Zhao et al., 2019; Freitag et al., 2018; Cao et al., 2020; Ninić, Freitag, & Meschke, 2017). However, the application of an AI-based surrogate model to predict the response of existing tunnels during excavation of adjacent foundation pit is limited (Zhang et al., 2020a). It is challenging to predict the response of existing tunnels during excavation of adjacent foundation pit in different scenarios.

With advances in digital technology, digital twins have emerged as promising tools for risk management of urban infrastructure operations and maintenance (Liu et al., 2022). Owing to the complex modeling process and high computational cost of FE numerical simulation, a surrogate model can be introduced to simulate complicated and time-consuming numerical calculations. Therefore, with the ultimate purpose of constructing a digital twin of a tunnel–soil–foundation pit system, this study proposes a hybrid FE simulation and surrogate model approach for predicting excavation-induced deformation of an existing tunnel in various scenarios.

2 FRAMEWORK OF THE PROPOSED METHOD

Surrogate model refers to the method of establishing an approximate mathematical model to simulate complicated and time-consuming numerical calculations through limited samples and their responses, where the samples are often selected by experimental design (Meng et al., 2021; Kapusuzoglu et al., 2022). The proposed method performs FE simulations for physics-based interpretation of tunnel deformation, adopts an optimized experimental design to reduce the number of samples for ML, and employs a BPNN to build a surrogate model. The framework of the proposed method is shown in Figure 1.

Figure 1. Framework of the proposed method.

3 PARAMETRIC FE MODEL

3.1 Scenarios in parametric FE model

To realize flexible modeling under a large number of parametric combinations, Python scripting API embedded in PLAXIS 3D was used in this study. The relative positions of the tunnel and foundation pit include three scenarios: tunnel is located below the foundation pit; tunnel is located parallel to the lateral side of the foundation pit; and tunnel intersects the foundation pit diagonally as shown in Figure 2.

Figure 2. Scenarios of relative position of tunnel and foundation pit: (a) tunnel is located directly below the foundation pit, (b) tunnel is located on the paralleled lateral side of the foundation pit, and (c) tunnel intersects the foundation pit diagonally.

3.2 Model simplification and parameterization

The problem of excavation-induced tunnel deformation is influenced by several parameters. The parameters can be divided into soil, geometric, relative position, material, retaining structures of the foundation pit, and construction stages.

The geometric parameters of the tunnel and foundation pit include the outer diameter of tunnel D , buried depth of tunnel T_d , length of the foundation pit F_l , width of the foundation pit F_w , and depth of the foundation pit F_d .

The relative position parameters of the tunnel and foundation pit include the distance from the foundation pit to tunnel D_t and angle between the tunnel and foundation pit θ .

The retaining structures of the foundation pit are complicated; therefore, they are simplified into diaphragm walls and inner supports. We have assumed that the diaphragm wall is isotropic and continuous and all inner supports are of the same material and dimensions. The main parameters of the plate and beam elements are thickness, unit weight, and Young's modulus.

Among the abovementioned parameters, some with a small range of variation are set as constants. A total of 13 input variables are defined for the parametric model: soil unit weight γ , Young's modulus of soil E , effective cohesive force c' , effective internal friction angle ϕ' , buried depth of tunnel T_d , length of foundation pit F_l , width of foundation pit F_w , depth of foundation pit F_d , distance from the center of the foundation pit to tunnel axis D_t , angle between the tunnel axis and longer edge of foundation pit θ , thickness of diaphragm wall t_w , Young's modulus of diaphragm wall E_w , and horizontal spacing of support D_b . The outputs of parametric model are horizontal displacement u_{y_i} and vertical displacement u_{z_i} ($i = 1, 2, 3, 4, 5$) of five positions on the tunnel that act as evaluation indices of tunnel deformation.

4 EXPERIMENTAL DESIGN FOR GENERATING FE SIMULATIONS

4.1 Overview of uniform design

This study adopted a uniform design for generating samples for FE simulations. Uniform design is an experimental design method in which samples are distributed uniformly throughout the test space through a set of carefully designed tables (Fang et al., 2000). It is particularly suitable for multilevel tests because the number of tests is equal to the number of levels. The samples were selected using a uniform design table and corresponding use table. The uniform design table is represented by $U_n(q^m)$ or $U_n^*(q^m)$, indicating that the table is applicable to n tests, q levels, and m variables at most.

4.2 Experimental design of this study

In this study, we used 13 variables at 130 levels; that is, 130 FE simulations. The samples were designed using the $U_{130}^*(130^{130})$ table. The range of values of each variable determined by the literature research (Ye, Zhao, & Wang, 2021; Zhang, Xie, & Zhang, 2018; Zheng, & Wei, 2008), relevant specifications (JCSS, 2001), and measured data are listed in Table 1, and the value of each level is determined accordingly. After the FE numerical calculation, samples that are unfeasible on the relative position of the tunnel and foundation pit or whose calculation

results are not convergent owing to large deformation during construction are not considered. Ultimately, 77 groups of effective samples and their responses were obtained.

Table 1. Range of values of variables.

Variables/unit	Value range
Soil unit weight γ / ($\text{kN}\cdot\text{m}^{-3}$)	[16, 22]
Young's modulus of soil E / kPa	[4000, 16000]
Effective cohesive force c' / kPa	[1, 21]
Effective internal friction angle φ' / °	[14, 30]
Buried depth of tunnel T_d / m	[6, 24]
Length of foundation pit F_l / m	[10, 100]
Width of foundation pit F_w / m	[10, 80]
Depth of foundation pit F_d / m	[6, 24]
Ratio of distance from the center of the foundation pit to tunnel axis to length of foundation pit D_t / F_l	[0, 2]
Angle between tunnel axis and longer edge of foundation pit θ / °	[0, 90]
Thickness of diaphragm wall t_w / m	[0.6, 1.2]
Young's modulus of diaphragm wall E_w / kPa	$[2 \times 10^7, 3.3 \times 10^7]$
Horizontal spacing of support D_b / m	[3, 7]

5 SURROGATE MODEL BASED ON BPNN

5.1 Structure of the BPNN-based surrogate model

A BPNN-based surrogate model was adopted in this study. BPNN is popular and powerful for complex nonlinear function fitting or sample recognition and classification, and it has been adopted in many studies in the tunneling field (Zhang et al., 2020b).

As mentioned in Section 4, the inputs of 77 samples are used to generate uniform design and their outputs, and their outputs are calculated using the parametric FE model established in Section 3. The outputs of each sample are the horizontal displacement u_{yi} and vertical displacement u_{zi} ($i = 1, 2, 3, 4, 5$) at five positions on the tunnel. The relative location L of the five positions was taken as the input of BPNN, and the horizontal displacement u_{yi} or vertical displacement were the outputs. Thus, two BPNNs with 14 input dimensions, one output dimension, and 385 training data (77 samples \times 5 positions) were established. The two BPNNs had the same network structure, including two hidden layers containing 14 and 4 neurons, as shown in Figure 3.

Figure 3. Structure of BPNN.

5.2 Training of the surrogate model

In this study, the horizontal displacement is defined as positive when the tunnel moves toward the foundation pit, and the vertical displacement is positive when the tunnel rises. Considering that unavoidable errors exist in actual measurements, if the error between the predicted value and actual measurement is less than ± 1 mm, the prediction will be considered accurate.

Therefore, the accuracy rate (*ACC*) is defined as the proportion of accurate predictions as shown in Equation (1),

$$ACC = \frac{1}{N} \sum_{i=1}^N I(|f(x_i) - f^*(x_i)| \leq 1) \tag{1}$$

where $f(x)$ is the actual value, $f^*(x)$ is the predicted value, N is the number of data points and $I(\cdot)$ is the indicator function, which is equal to one if the condition in the bracket is satisfied and zero otherwise.

The predictions of BPNN-based surrogate model are shown in Figure 4. In addition, Table 2 shows the accuracy rates of the horizontal and vertical displacement predictions, which are calculated using Equation (1). To predict the horizontal displacement, the accuracy rates for the training and validation sets were 97.40% and 96.55 %, respectively. For predicting the vertical displacement, the accuracy rates were 94.05% and 91.38% for the training and validation sets, respectively.

Figure 4. Accuracy of the BPNN-based surrogate model on training and validation sets: (a) BPNN vs FE simulation by horizontal displacement and (b) BPNN vs FE simulation by vertical displacement.

Table 2. Accuracy rate of the BPNN-based surrogate model.

Data set	Accuracy rate	
	Horizontal displacement	Vertical displacement cm
Training set	97.40%	94.05%
Validation set	96.55%	91.38%

Figure 5. Accuracy of BPNN on test set: (a) BPNN vs FE simulation by horizontal displacement and (b) BPNN vs FE simulation by vertical displacement.

5.3 Validation by FE simulation

Additional 16 samples were randomly generated based on the parametric FE model as the test set. The displacements predicted by the BPNN-based surrogate model and original results calculated by parametric FE simulation are plotted in Figure 5. The accuracy rates for the test set of horizontal and vertical displacements are 85.00 and 80.00%, respectively. The computational time ranges from microseconds to milliseconds and decreases with the computed number of scenarios, so that the surrogate model is capable of real-time response and large amounts of calculation.

6 ILLUSTRATIVE EXAMPLES

6.1 Information of the investigated project

The measured data of a real project in Shanghai were used to verify the performance of the BPNN-based surrogate model. The project block is divided into nine sections for foundation pit excavation. The north side of the excavation (foundation pit 1a) is adjacent to a metro line, and the nearest distance between the existing metro tunnel and foundation pit is only 9.2 m.

The foundation pit 1a is rectangular in shape and its area is approximately 4133 m². The excavation depth of the foundation pit is 22.1 m with five layers of concrete support. The buried depth of the existing adjacent metro tunnel is approximately 10 m. The profiles of the foundation pit excavation and existing tunnels are shown in Figure 6.

Figure 6. Profiles of the foundation pit excavation and existing tunnels.

6.2 Parameters as the inputs of surrogate model

To adapt to the parametric FE model established previously, the foundation pit was simplified as a rectangular structure with a length of 71.5 m and width of 57.8 m. The angle between the tunnel and foundation pit was approximately 13°, and the distance between the center of foundation pit and axis of the tunnel was approximately 63 m. The parameters are listed in Table 3.

6.3 Results and discussions

The values predicted by the BPNN-based surrogate model and measured values are compared in Figure 7, where the midpoint of tunnel *M* corresponds to the measuring point position of zero. The predicted and measured values are of the same order and trend with an error of less

Table 3. Model parameters drawn from the investigated project.

Parameters / unit	Value
Soil unit weight γ / ($\text{kN}\cdot\text{m}^{-3}$)	16.81
Young's modulus of soil E /kPa	8149
Effective cohesive force c /kPa	4
Effective internal friction angle φ° / °	24.7
Buried depth of tunnel T_d / m	10
Length of foundation pit F_l / m	71.5
Width of foundation pit F_w / m	57.8
Depth of foundation pit F_d / m	22.1
Distance from the center of the foundation pit to tunnel axis D_t / m	63
Angle between tunnel axis and longer edge of foundation pit θ / °	13
Thickness of diaphragm wall t_w / m	0.8
Young's modulus of diaphragm wall E_w / kPa	2.87×10^7
Horizontal spacing of support D_b / m	9.1

than 1.5 mm indicating that the surrogate model is reliable. The predicted values, measured values, and error between them are listed in Table 4.
