Combined with simulation games (also known as *serious games*), empirical studies provide a valuable environment to test different design methods and procedures statistically. Inspired from military simulation games – *Kriegsspiel* being considered one of the oldest – they emulate an environment where behavior and decision-making can be studied more thoroughly (see Figure 1). A few studies have taken an empirical approach to study flexibility in complex systems design (Cardin et al., 2013, Cardin et al., 2015, Jiang et al., 2018, Gil et al., 2015), but many more are needed to thoroughly validate new computational methods, algorithms, and innovative digital processes emerging from research.

3.4 Decision support systems, digital twins, and metaverse technologies

There is a need to develop and evaluate new computational aided engineering tools to support the design and decision-making process in industry. Many of the methods developed through research take the form of algorithms or equations that are difficult to visualize for end users in practice. There is a need to embed the research output into relevant software tools that can be used in a practical setting to support decision and policymaking.

This work is currently taking place at different scales. As mentioned before, recent developments in data science and machine learning provide wide ranging opportunities to make better use of increasingly accessible datasets on engineering systems. For example in the UK, the Data Analytics Facility for National Infrastructures (DAFNI) provides datasets, models, and algorithms on infrastructures for research development (STFC et al., 2020). At a project and portfolio scale, work is ongoing to develop a control room for construction (Farghaly et al., 2021). Figure 2 shows another example through an integrated data-driven decision support system for designing large-scale complex engineered systems. The system integrates data visualization and analytics capability, optimization input and output visualization, as well as visualization of the optimization outputs in a 3D virtual environment. It overlays an optimization model developed for design and planning of waste-to-energy systems in Singapore (Kuznetsova et al., 2019). This kind of system provides designers and decision-makers with a tangible environment for training and decision-making, in a more intuitive setting than complex models and equations.

The ideas above are in line with recent developments in digital twin modelling, where complex high-fidelity models are developed and improved over time from large datasets, as well as metaverse technologies such as augmented and virtual reality (AR/VR) for digital project delivery (Nikoli et al., 2019, Whyte et al., 2019, Sacks et al., 2020). Such technologies are useful to support visualization, optimization, planning, and design decision-making under uncertainty in a highly immersive environment. They have been, however, largely unexplored in the context of flexibility in design. They have the potential to enhance significantly design activities, as well as training, and decision-making. By closely emulating a real-world environment and changing environmental and operational conditions, such system can be used to quickly prototype system design alternatives, stress-test their performance in a simulated environment, and find optimal configurations. It can be used to train operators to operate the systems and determine when it is appropriate for the system to adapt, reconfigure, or evolve, which is especially useful for systems operating in a harsh

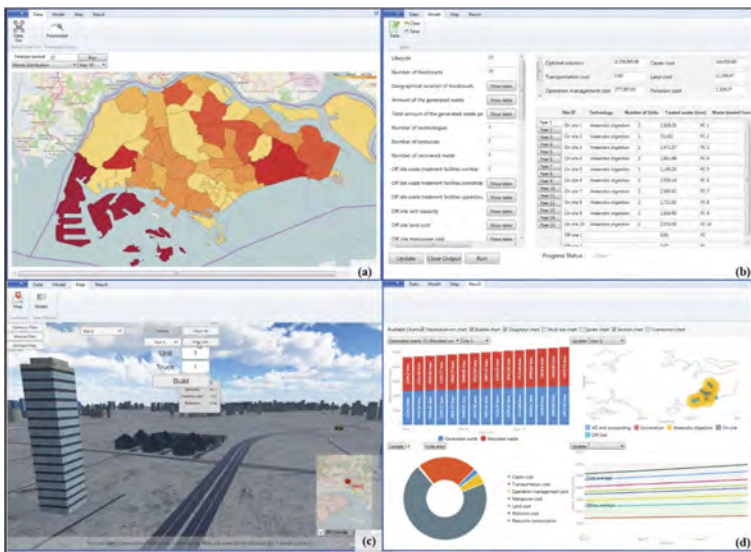

Figure 2. Example of integrated data-driven decision support system for example waste-to-energy systems. (a) Data analytics and visualization. (b) Optimization variable and parameter input definition. (c) 3D virtual environment. (d) Optimization output visualization.

environment, e.g., mining, drilling, and space (Malone et al., 2022). New knowledge on explainable AI (XAI) is particularly well suited to enhance the quality of design and operational decision-making. Overall, digital twin modelling, complemented by metaverse technology, XAI and decision-support systems yield very high potential for future research developments.

4 CONCLUSION

At a time where infrastructure systems face significant threats from climate change, pandemics, and terrorism, there is a need to change our approach to infrastructure systems design, management and operations (Lethanh and Adey, 2015). There is a need to consider uncertainty explicitly early in the design process, to extract better value for society, through improved economic performance, sustainability, and resilience. Designing infrastructure systems for flexibility is of utmost importance for future generations of systems designers and operators, policymakers, and business leaders. It prepares systems for change, adaptation, reconfiguration, and evolution in ways that ensure not only better survivability, but also better value in the long term. While the field of flexibility in design emerged in part from real options analysis, it is now evolving on its own, and at a steady accelerating pace. Researchers continually develop and evaluate novel design methods and computational procedures to enable flexibility, as a systematic value enhancement mechanism. The community is growing, as seen by the expanding volume of literature on the topic. This paper provides an overview of such evolution over recent decades, motivated by an important need in industry and policymaking. The overview exposes the multi-disciplinarity of the field, which involves finance, systems engineering and design, optimization, statistics, and uncertainty modeling, with applications in many relevant sectors such as aerospace, automotive, energy, real estate, transportation, space, and water systems. The research overview paves the way to exciting and applied new opportunities, much needed in industry practice and academia. Such opportunities involve a unifying paradigm for sustainability and resilience by design, data-driven flexibility analysis, empirical studies and simulation games, as well as AI and machine learning for decision support, digital twin modelling, and virtualization.

ABSTRACT: The optimization of interventions for urban regeneration projects is a complex task that involves substantial investments and impacts the service provided to stakeholders over a long period. Part of the complexity of optimizing interventions on large building portfolio is that they are typically financed by a subset of the affected stakeholders, i.e., the owners or building developers who are understandably inclined to maximize their own interests and not those of the wider community. Another part is the need to account for uncertainty in future market demand across a portfolio of buildings, e.g., the possible future large-scale use of remote working, makes it questionable whether the current fixed configurations of many buildings (e.g., offices that have been dimensioned for a fixed demand, and residential units without proper places to work) will enable an optimal use of space, affecting the service provided to multiple stakeholders. This problem is particularly acute in urban areas. In recent years, the possibility has been put forward to use the real options method for optimizing the design and management of assets considering future uncertainty. The method, however, has never been used to determine optimal design of multiple buildings for multiple stakeholders. In this paper a general methodology is presented to evaluate design modifications for a building portfolio considering future uncertainty and the interests of multiple stakeholders. The methodology makes explicit that there is a need to consider the effects of regulations and incentives in to encourage owners to select design modifications that are in the best interest of all stakeholders.

1 INTRODUCTION

The optimization of design modifications on large real estate portfolios, which is common in urban regeneration projects, is a task that involves substantial investments and impacts the service provided to stakeholders over a long period. The repurposing of several buildings in an urban area modifies the service provided in these areas, in economic, social and environmental terms. Part of the complexity of determining the design modifications is that they are typically financed by a subset of the affected stakeholders, i.e., the owners or building developers who are understandably inclined to maximize their own interests and not those of the wider community. Another part is the need to account for uncertainty in future market demand across a portfolio of buildings, e.g., the possible disposal of a large amount of office space in the future due to the expanding use of remote working, and the possible disposal of retail spaces due to the continued rise of e-commerce.

Despite the fact that the economic, social and environmental impacts of urban regeneration projects can be large, and they are subject to considerable uncertainty, there has been little effort to try to optimize the required design modifications. This is largely due to the fact that comparing the impacts of all possible design modifications over a sufficiently representing set of future scenarios is a computationally intense task, that also requires quantifying the impact of each loss of service with the consensus of all involved stakeholders. Tackling such a problem requires being able to: (i) estimate the consequences of alternative design modifications on the provided services, (ii) take into account the future uncertainty affecting the provision of services (e.g., changes in population, technological developments), and (iii) quantify the needed incentives and regulations to align the interests of the investors with these of the wider community.

In recent years, the possibility has been put forward to use the real options method for optimizing the design and management of assets considering future uncertainty (De Neufville & Scholtes, 2011). Despite the undoubted merit of having extended the time dimension in the evaluation of the design of construction and infrastructure, the real options method has so far been focused on the design of single assets mainly, and always with the objective to use flexibility to maximize the economic interests of the owner. No attempt has been made yet to evaluate the designs of building portfolios considering future uncertain demand and the interests of multiple stakeholders. The first step in being able to do so requires adapting a methodology designed to use the real options method to allow the mapping the building portfolio for the characteristics that influences the market demand as well as costs and possibilities of design modification, the estimation of the impact of alternative sets of design modifications on the services provided over the investigated time period, and quantifying the needed incentives and regulations to align the interests of the investors with those of the other stakeholders (Martani et al., 2021). In this paper, an adaptation to the methodology proposed by Esders et al., 2020 is presented to cover the current gaps and enable optimizing the designs of building portfolios considering future uncertainty and the interests of multiple stakeholders.

2 LITERATURE REVIEW

Several attempts have been made in the past to optimize decisions on building designs considering future uncertainty. Examples are shown in Table 1, along with the uncertain future trends and stakeholder interests considered. It can be observed from Table 1 that all the works except one (i.e., Geltner & Neufville, 2018) have focused on single assets. Moreover, all the works have focused on maximizing only the economic interests of the owner. Indeed, despite a wider set of interests (i.e., economic, social and environmental) and stakeholders (i.e. owner, users, directly and indirectly affected people) have been considered in the design optimization of other types of constructions, e.g., highways (Martani et al., 2022), this has never been the case for buildings. As a consequence of the predominant focus on the economic interests of the owners, none of the works have considered the incentives and regulations required to align the interests of the owners (i.e. the investors) with these of the wider community.

3 METHODOLOGY

The outline of a general methodology to evaluate the possible designs of a building portfolio (i.e. either the design of new buildings, or the design modification of existing ones) considering future uncertainty and the interests of multiple stakeholders is presented in Figure 1. The methodology is an extension of that presented in (Esders et al., 2020) to optimize the designs of single buildings. The steps added are highlighted in grey. The methodology consists of 13 steps over 5 main areas, color coded in Figure 1: (1) Boundaries and objective definition, (2) Portfolio characterization, (3) Uncertainty recognition and modelling, (4) Design definition, and (5) Results generation, analysis and verification. The five following sub-chapters describe the steps in each area.

Table 1. Examples of research investigating flexible designs using the real options method.

Infrastructure	Source	Future uncertainty considered
Hospitals and clinics	de Neufville et al., 2008	Changes in demographics, changes in patterns, causes and effects of health and disease, changes in medical technology
Heating and cooling systems in office buildings	Eswers et al., 2019, 2020	Change in patient demand
	Martani et al., 2015, 2016	The prices of gas and electricity, heating and cooling loadings and performances of the systems
Building façades	Eswers et al., 2016	Operating costs
Buildings	Menassa, 2011	Changes in performance of materials and components
Military barracks	Eswers et al, 2015	Space demand
Buildings	Fawcett & Chadwick, 2007; Fawcett & Rigby, 2009	Demand of working space
Building ground floors	Ellingham & Fawcett, 2007	Commercial rents
Office buildings	Guma A. & de Neufville, 2008	Future cash flows (rents), and demand for office space
Ground floor ceilings in buildings	Martani et al., 2018	Use change rate
Buildings	Ashuri et al., 2011	Energy price
Multi-level parking facilities	De Neufville et al., 2006; De Neufville & Scholtes, 2011; Elvarsson et al., 2021	Number and types of parking plots required
Buildings portfolio	Geltner & Neufville, 2018	Real estate demand for destination of use

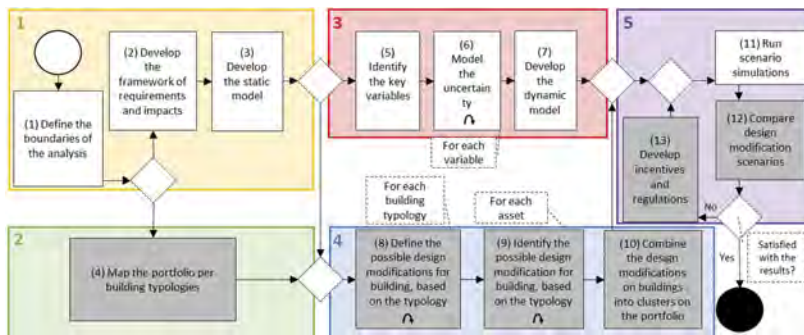

Figure 1. Methodology to evaluate the designs of multiple buildings in a building portfolio considering future uncertainty and the interests of multiple stakeholders.

3.1 Boundaries and objective definition

Step 1 - Define the boundaries. The first step is to conduct a context analysis to define the boundaries of the study. This includes defining the assets and stakeholders to be considered, as well as the time horizon of the analysis. This is crucial because the optimal combination of building designs in a portfolio is dependent on the boundaries. In other words the optimal designs for a portfolio over one time period may not be the same another portfolio or the same portfolio but another time period (as in Elvarsson et al., 2021).

Step 2 - Develop the framework of requirements and impacts. The second step is to specify the requirements of each of the stakeholders, e.g. for the tenant of a commercial unit one key requirement is the ability to operate their business for the working hours of each business day,

along with an estimate of the unit reduction of each of these services, e.g. the loss of profit if the commercial unit is unable to operate one day. Examples of extensive lists of the services provided by other types of assets are given in (Adey et al., 2020).

Step 3 - Develop the static model. The static model is the mathematical formulation of the objective of the stakeholders (also known as objective function) and it is developed to enable quantification of the expected impacts on the different stakeholders. The static model depends on different constant or fixed parameters (Esders et al., 2020).

3.2 *Portfolio characterization*

Step 4 - Map the portfolio per building typologies. The buildings defined in step 1 are here characterized by typology, i.e., for the main features that have an influence on the demand per use, as well as the type of design modifications that can be made and their costs. For example: (i) location (e.g., urban-central, urban-periphery, rural), (ii) size, and (iii) predominant use of the area (e.g., residential, office, commercial and mix use). This is done assuming that, the repurposing of each building is conditional on all three aspects, e.g., the possibilities for repurposing a small building in a peripheral residential area are different than these to repurpose a large building in a central mixed area.

3.3 *Uncertainty recognition and modelling*

Step 5 - Identify the key variables. Once the static model has been developed, the parameters within it whose values have a non-negligible probability of changing in a way that will affect the provision of level of service are identified. These parameters are typically contextual conditions that do not depend by the physical characteristics of the buildings but influence their service and their market, e.g., the demand for small studio units in central urban areas.

Step 6 - Model the uncertainty. After the variable parameters within the static model have been identified, the long-term uncertainties associated with each of these has to be modelled. These include, the demand for space, which is highly variable depending on demographic and economic developments, the demand for energy, parking space and level of utilities automation, which are subject to technological developments, the demand for delivery spaces, which is dependent on the development of e-commerce, etc. The uncertainty associated with these aspects makes it difficult for any portfolio of residential buildings to guarantee a satisfactory level of service, e.g. enough parking spaces. In this step, the probability distribution over all possible values that an uncertain variable can take are estimated over time based on the best current knowledge of the modeler on the future evolution of each variable (e.g. as in Martani et al., 2015, 2016). This is done by collecting information on future trends of the key parameters to gain insight into which possible future scenarios may occur and with what likelihood. Analyze their past evolution and changes in trends when data is available. Solicit expert opinion when necessary. Use the information collected to model the uncertainty of the key parameters.

Step 7 - Develop the dynamic model. In this step the static model is extended to consider the variations in the key parameters, the interactions between them and their influence on the system. Evaluate the effect of variations in the values of the key parameters on future benefit. An example of how this is done can be seen in (Elvarsson et al., 2021).

3.4 *Design modifications definition*

Step 8 - Define the possible design modifications per building typology. Following up with the mapping of the portfolio of assets (step 4), the set of all possible design modifications that can be executed for each typology, i.e., according to their characteristics (e.g., location, size and predominant use of the area), is defined. This is done to create a catalog of all the plausible modifications to be considered for each specific building based on its characteristics and location. Amongst the possible design modifications there should be a “do nothing” design

modification, since it cannot be taken for granted that implementing a design modification is always a good idea, i.e. any modification requires a consistent upfront investment. If these are not compensated by long-term benefits, it is preferable not to make any modification. This requires considering the interest of the owners, and analyzing the marked demand for destination of use per area and size. Moreover, for each of the design modifications defined, a unit cost (e.g. €/ sq. mt.) of execution is estimated to later (in step 9) allow estimating the cost of modifications for specific buildings based on their dimensions.

Step 9 - Identify the possible design modifications for buildings based on the typology. Once the building typologies (i.e., location, size and predominant use of the area) have been mapped (step 4), and the set of possible design modifications have been identified for each building typology (step 8), the extent of the design modifications are identified for each specific building. For each specific design modification on a building the cost is estimated by multiplying the unit cost of the design modifications as from step 8 for the dimension of the specific building.

Step 10 - Combine the design modifications on buildings into clusters on the portfolio. After the possible design modifications have been identified for all buildings these are grouped into all the possible combinations for all buildings in the portfolio. This is done considering external constraints in order to filter the clusters of modifications and avoid considering unrealistic ones, e.g., if in an area the number of residential units cannot exceed 70% of the buildings, all combinations of design modifications that do not respect this are excluded.

3.5 *Results generation, analysis and control*

Step 11 - Run scenario simulations. With all above conditions defined, multiple design modification scenarios, i.e. long-term scenarios generated by each of the interventions proposed to modify the existing building, are simulated using the Monte Carlo method, to estimate their impact on the objective function in light of future uncertainty. Through this technique, the stochastic scenarios are developed considering the evolution of all variables through time according to the uncertainty modeled as in Martani et al., 2018. At this stage the total risks on requirements are estimated for all design modification scenarios.

Step 12 - Compare design modification scenarios. In this step the design modification scenario that provides the minimal estimated negative impact on the objective function is selected as the optimal one among these considered and, if it is considered satisfactory (i.e., if the optimal cluster of design modifications is also the one that minimize the negative impact for the owners), the process is finished. Otherwise, the incentives and/or regulations need to be introduced to align the interests of the investors with these of the objective function.

Step 13 - (if needed) develop incentives and regulations. If the design modification scenario that minimizes the negative impact on the objective function is not the same as the one that minimizes the negative impact on the owners of the buildings, consideration has to be given as to the regulations and/or incentives that can be introduced to persuade the owners of the buildings to make the design modifications that have the best chance of reducing the risk on the interests of multiple stakeholders. This action is not solely at the planners' prerogative, but requires the cooperation of the planners with the legislative and executive government to implement any of the policies, regulations or incentives deemed useful. An example incentive is tax benefits that encourage the renewal of existing buildings instead of the demolition and construction of new buildings or using heating from renewable energy sources. Example regulatory constraints are forcing the use of a minimum share of recycled material during the modifications. The development of incentives and regulations needs to continue until the impact on the requirements of the objective function are considered satisfactory.

4 CONCLUSIONS

In this paper a general methodology is presented to evaluate design modifications for a building portfolio considering future uncertainty and the interests of multiple stakeholders. The methodology makes explicit that there is a need to consider the effects of regulations and incentives in to encourage owners to select design modifications that are in the best interest of all stakeholders. It also calls for the use for the first time of the real options methodology beyond the traditional scope of evaluating the design of single buildings. The use of the proposed methodology requires a high level of interdisciplinary integration as it combines skills that are typical in architecture, i.e., classifying buildings in techno-typological clusters, skills that come from the field of urban studies, i.e., GIS spatial mapping of buildings as a function of their characteristics, and engineering skills, such as uncertainty modelling and scenario simulation, as well as an understanding of the market dynamics, which are more traditionally economic skills.

The methodology presented is expected to provide guidance to individuals who are evaluating possible design modifications on building portfolios while accounting for future uncertainty and aiming to ensure that interests of a wide set of stakeholders are met as best possible both now and in the future. It will be tested in the near future on a case study repurposing of 12 bank branches in Zurich where the best assets repurposing intervention is to be determined, finding the optimal point of equilibrium between the owner's interest of maximizing the revenues, and all the social, environmental and economic implications for the directly and indirectly affected citizens

Exploratory modelling for transport infrastructure planning under future uncertainty

O. Roman, A.B. Elvarsson & B.T. Adey

Chair of Infrastructure Management, ETH Zürich, Switzerland

ABSTRACT: Planning transport infrastructure is particularly difficult due to infrastructure's long-lived nature, unpredictable technological progress and changing mobility trends in society. In complex systems facing major uncertainties, exploratory modelling can help define salient system characteristics and discover potential risks and opportunities by evaluating large ensembles of potential conditions during the planning process. This paper demonstrates how exploratory modelling can provide planning support for a federal highway from Dübendorf to Hinwil in Zürich, Switzerland. We model the future traffic flows at peak hours considering uncertainty in urban development, jobs distribution and future modal share. Current road infrastructure and further potential capacity expansions and reallocations are then tested on their robustness to provide adequate performance (in terms of travel delays) in multiple future scenarios. We use quantitative methods to identify the subset of scenarios representing risks and opportunities for the infrastructure system. The visualization of such subset of scenarios in uncertainty maps can help target interventions only when needed.

1 INTRODUCTION

Transport infrastructure planning is particularly difficult due to its long-lived nature, unpredictable new technologies, changing trends in society, and environmental change effects. Furthermore, transport infrastructure has widespread economic, environmental and social impacts and therefore numerous stakeholders, with different interests and value frameworks, are involved in the decision-making process. The difficulty of estimating the future, the complexity of how infrastructure systems work and the uncertain valuations that can be put into infrastructure outcomes by different stakeholders make decision-making particularly challenging. Therefore, transport infrastructure planning often involves making decisions under deep uncertainty.

When dealing with complex systems under deep uncertainty, the assumption that we can identify a “best-guess” future condition might no longer be appropriate. Instead, the projection of multiple plausible future scenarios is increasingly seen as an alternative even when those scenarios cannot be ranked in terms of their likelihood (Maier et al., 2016). A wide exploration of many potential alternatives is warranted to gain a better understanding of the system and identify decision-relevant scenarios (e.g. scenarios that could result in high risks or valuable opportunities). This approach is commonly known as Exploratory Modelling (Bankes, 1993) and includes the use of quantitative techniques such as Feature Selection (Kwakkel, 2017) and Scenario Discovery (Bryant & Lempert, 2010). To measure system performance under multiple scenarios, robustness is often the preferred metric as it rewards plans that perform satisfactorily under many future conditions instead of focusing on isolated predictions (Maier et al., 2016). Common robustness metrics include regret metrics (e.g., quantification of performance in each scenario in comparison with a baseline) and satisficing metrics (e.g. quantification of the number of scenarios that meet certain requirements) (Herman et al., 2015).

Despite the increasing recognition that transportation systems face deep uncertainty, traditional methods for transport planning are inadequate to deal with this level of uncertainty

(Lyons & Davidson, 2016; Wall et al., 2015). Most research efforts have focused on increasing the granularity and complexity of models to gain accuracy, which further impedes a wide exploration of scenarios (Milkovits et al., 2019).

This paper uses a macroscopic transportation model to simulate a wide range of future scenarios and quantify robustness. Exploratory modelling techniques are used to identify the most relevant uncertain factors and subsets of decision-relevant scenarios. Furthermore, we show how the identification of such scenarios, through the development of uncertainty maps, can inform transport infrastructure planning by targeting interventions, such as road expansions only when needed, and road space reallocations, only when feasible. As an example, we use the road infrastructure between Dübendorf and Hinwil and their potential expansions and modifications in the future. Travel times on the corridor are estimated as a measurement of the level of service provided by the infrastructure. Future changes in travel times and potential delays are modelled annually to evaluate system performance’s adequacy in multiple plausible futures.

2 STUDY AREA AND MODEL

The corridor Dübendorf-Hinwil extends from the Zürich city border between the Pfannenstiel and the Zurich Highlands. Table 1 shows the population (Statistisches Amt des Kantons Zürich, 2022a) and jobs (Statistisches Amt des Kantons Zürich, 2022b) in each of the towns within the corridor, being Zurich the major urban centre. Different population projections for the Canton of Zurich vary between 0.5% and 1.1% per year (Bundesamt für Statistik, 2020) which might also drive growth in job opportunities and further changes in the region.

Table 1. Population and jobs within the corridor in 2020.

Town	Population	Jobs
Zurich	420'891	495'223
Dübendorf	29'854	19'362
Schwerzenbach	24'034	14'169
Uster	35'295	17'370
Seegräben	1'423	593
Wetzikon	25'038	14'088
Hinwil	11'344	7'150

The A15 federal highway (4 lanes) is a main component in the corridor connecting Dübendorf to Uster. After Uster, a cantonal road (2 lanes) continues to connect Uster to Hinwil. The Federal government has given the green light to the extension of the A15 from Uster to Hinwil but it is still not clear when the expansion will be realized. These expansion plans are being discussed and considered at both the cantonal and federal levels.

In this paper, the corridor is modelled as a simple linear link-node network as illustrated in Figure 1. The road infrastructure capacity along the corridor is estimated to be approximately 100 lane-km, including the federal highway and the cantonal road. To calculate the number of trips originating and ending in each of the towns, a gravity model is used with the population and jobs generating travel demand from each of the node pairs (de Dios Ortúzar & Willumsen, 2011). The generalized costs of travelling between the nodes, which are used to distribute the trips in the corridor model, are assumed to be related to the distance between each node pair. The modal share of cars in the canton of Zürich is estimated at 25% according to the 2015 Microcensus (Bundesamt für Statistik, 2017) and was used in the generation of trips.

Zürich, as the largest city, is a regional hub that serves and influences multiple networks in its surroundings, including the corridor from Dübendorf to Hinwil. Jobs in Zürich attract people living in the corridor, and people living in Zürich are also attracted by jobs in the corridor, both generating more trips. Several model parameters were calibrated to fit the traffic levels at peak hours for the traffic measuring points in the corridor (Kanton Zurich, 2019) including the portion of Zurich generating trips along the corridor which was estimated as 10%.

Figure 1. Simplified illustration of the corridor zürich-dübendorf-hinwil.

In the corridor model, as the population and jobs grow, the traffic volume is expected to grow. Increasing population leads to increased travel demand and potentially, to increased travel delay, particularly when demand is closer to the road capacity.

The average traffic flow at peak hours in the corridor is modelled using a Macroscopic flow model (de Dios Ortúzar & Willumsen, 2011). The input variables are the travel demand (expected traffic flow) and the infrastructure supply (road capacity available). We use a fundamental diagram of traffic flow to estimate the relationship between speed, flow and density in the model as shown in Figure 2.

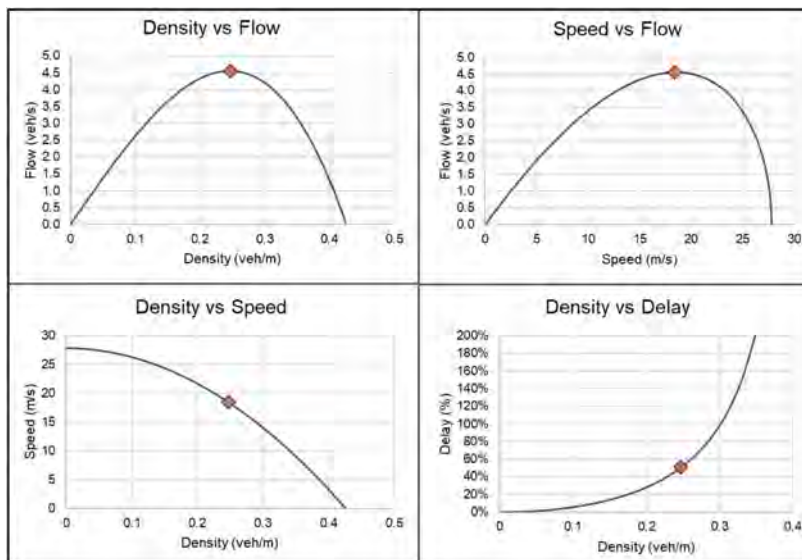

Figure 2. Fundamental diagram of traffic flow for the corridor. The critical density is shown in orange, i.e. the number of cars, as a ratio of the supply of lane-km available, that generates the maximum flow in the road. This will result in a certain speed being travelled on average across the system.

Besides classical flow-density, flow-speed and speed-density curves, Figure 2 also shows an estimation of the travel delay-density curve. Travel delay (in percentage) is estimated, as the additional travel time with respect to the free flow travel time (i.e. the travel time at the maximum allowed speed on the road). The calibrated model estimates that current delays are about 5% in the corridor. Figure 2 shows that reaching the critical density (orange diamond) generates a delay of about 50%.

For the evaluation of the ensemble of future scenarios, robustness was calculated by defining satisficing criteria (i.e. the level of performance considered adequate). For the satisficing criteria in this paper, we defined a delay of 20% as tolerable if it is not permanent. Therefore the first satisficing criterion is to not reach more than 20% of delay for more than 5 years until 2050 (one-sixth of the time). Additionally, reaching a delay of 50% (i.e. reaching road capacity and entering the congestion phase) is considered inadequate. The corridor performance will be simulated until 2050 under multiple scenarios and will be considered adequate if both

satisficing criteria are met. The satisficing criteria set for this paper reflects the need to avoid severe delays (e.g. the congestion state) and also assume the ability of infrastructure managers to act when delays reach 20% and consequently improve the performance in a reasonable time. Satisficing criteria can also be based on planning instruments, historic performance or elicited from stakeholders (Hadjimichael et al., 2020).

3 EXPLORATORY MODELLING

The model was used to evaluate the corridor performance under multiple future scenarios. Exploratory modelling was then carried out to identify the most relevant uncertain factors and the subset of decision-relevant scenarios (risks and opportunities). A scenario is defined as a particular combination of uncertain factors. Risk scenarios are the ones in which current capacity will not meet the satisficing criteria, indicating that expansions are needed. Opportunity scenarios are the ones in which reduction of road capacity (50% of the A15 federal highway) will still meet the satisficing criteria, indicating that road space can be reallocated to other uses (e.g. bike paths or bus priority lanes).

When scenarios are developed to represent a broad range of future conditions, their generation is usually done using numerical modelling and/or sampling (Kwakkel et al., 2015; McPhail et al., 2020). Key uncertain factors are first selected based on literature (Kwakkel et al., 2012; Milkovits et al., 2019; Wall et al., 2015) and during the process of model calibration (selecting the factors with bigger impact on performance). The selected uncertain factors were: 1) population growth, 2) job growth, 3) the change in the modal share of cars, and 4) the change on the influence of the city of Zurich in the corridor. Table 2 provides a short description of the factors along with their respective ranges of uncertain values. We develop an ensemble of future scenarios by sampling within the ranges using the Latin hypercube sampling method (McKay et al., 1979).

Table 2. Uncertain factors considered to generate future scenarios.

Uncertain Factor	Short Description	Range
Population Growth	Annual population growth rate in each town	(0%, +3%)
Job Growth	Annual job growth rate in each town	(0%, +3%)
Change in the influence of Zurich	Annual change in the portion of Zurich population and jobs that generates trips within the corridor	(-1%, +1%)
Change in Modal Share - Cars	Annual change in the proportion of trips done by car	(-1%, +1%)

As the gravity model works by generating trips based on population and jobs, they were selected as key uncertain factors for the future. Population growth forecasts for the canton of Zurich range between 0.5% and 1.1% per year (Bundesamt für Statistik, 2020). In this paper, we expand the potential range of population growth from 0% to 3% in order to explore a wider set of future scenarios. We use the same range for jobs growth as specific job projections are not available.

During the calibration of the model, the most sensitive parameters were the proportion of Zurich influence on the corridor and the car share, therefore, they were selected as key uncertain factors of the model. The proportion of Zurich influence on the corridor in the future will depend on regional dynamics which are uncertain. Future mode share is also uncertain as societal preferences (e.g., towards active mobility or automated vehicles) can drastically change mobility patterns. We selected a plausible but wide range of potential change of $\pm 1\%$ per year for each factor (i.e., ranging between -26% and $+35\%$ by 2050).

We generated 500 equally plausible scenarios (i.e. without assigning probability distributions) using the Exploratory Modeling Workbench (Kwakkel, 2017). For each of the 500 scenarios generated, a single value in the range was selected and applied to each modelled year until 2050. The factors were assumed to be consistent across all sub-regions. As part of the exploratory modelling, we identified the most relevant uncertain factors by applying feature

selection techniques which are typically used to rank and prioritize the input variables in a model. Table 3 shows the results of the feature selection over the 500 modelled scenarios by using two common algorithms: an extra trees and a random forest algorithm. As a higher score means a higher influence of the factor with respect to meeting the satisficing criteria (as defined in Chapter 2), Job growth and the Change in modal share are the most relevant uncertain factors for the corridor model.

Table 3. Feature selection scores to identify the most relevant uncertain factors.

Uncertain Factor	Algorithm	
	Extra Trees	Random Forest
Population Growth	0.098	0.076
Jobs Growth	0.49	0.54
Change in the influence of Zurich	0.12	0.093
Change in Modal Share - Cars	0.28	0.28

Figure 3 shows the uncertainty map of the performance of the road system over the 500 modelled scenarios for the road infrastructure along the corridor. As the robustness metric, we calculate the fraction of scenarios that meet the satisficing criteria (Herman et al., 2015; Schneller & Sphicas, 1983). In Figure 3, each point represents one scenario as a combination of the uncertain factors. Dark diamonds (48% of the total) indicate adequate performance of the current infrastructure by 2050. Red circles (14% of the total) indicate inadequate performance of the current infrastructure by 2050 (i.e. risk scenarios). Blue squares (38%) indicate adequate performance by 2050 with a reduced road capacity (i.e. opportunity scenarios). The two most relevant uncertain factors, identified in Table 3, are used as the axes of the graph so it is possible to visualize the combination of uncertain factors that generate risks and opportunities. A high increase in mode share for cars and high jobs growth represent high likelihood of inadequate performance with the current infrastructure. On the other hand, decreases in car share and low jobs growth represent high likelihood of adequate performance with reduced road capacity.

Figure 3. Uncertainty map and scenario discovery results for the future performance of the road infrastructure along the corridor.

Scenario discovery is used to estimate the boundaries of the adequate/inadequate performance regions of the uncertainty map. Some common algorithms for scenario discovery are

Patient Rule Induction Method (PRIM) and Classification and Regression Trees (CART), however, one limitation of them is that they divide the space with boundaries orthogonal to the axes (Reed et al., 2022). Given that the adequate/inadequate boundary in our case study shows a non-orthogonal and non-linear shape, we use logistic regression, as the classification algorithm, for the scenario discovery (Hadjimichael et al., 2020). Figure 3 shows the classification as colored regions according to the probability of obtaining risk and opportunity scenarios in the uncertainty map.

Exploratory modelling techniques help identify likely risk and opportunity regions of the uncertainty map and therefore, shed light on which combinations of uncertain factors require particular attention of infrastructure planners. For this paper, we use the expansion of the road infrastructure capacity as the only intervention to reduce delays and meet the satisficing criteria in the risk regions. We use the reallocation of road capacity (i.e., for others uses) as an intervention in the opportunity regions. The model was rerun by targeting expansions and reallocations to be deployed in the risk and opportunity regions in Figure 3. As road expansions have a considerable time from planning decisions to implementation (assumed to be 4 years in this case), planners need to decide well in advance of reaching inadequate performance (e.g., congestion). The triggering of expansions is modelled as a simple decision rule of expanding 10 lane-kms of capacity (approx. a double lane road between any two nodes in the corridor) every time the corridor reaches 75% of road capacity (i.e., the maximum flow in the fundamental diagram). The triggering of road reallocations is also modelled as a simple decision rule of reallocating 10 lane-kms of capacity when the road capacity use is lower than 60%. The decision rules are implemented as function of the traffic flow as the traffic flow is an easily measurable indicator given that several real-time traffic monitoring stations function along the corridor.

The implementation of decision rules to trigger road expansions and reallocations conditional to traffic flows will produce different number and timing of interventions for different future scenarios. Higher travel demands will produce more frequent expansions while lower demands will produce sporadic expansions only, in the risk regions. Higher travel demands will produce sporadic reallocations while lower demands will produce more frequent reallocations, in the opportunity regions Figure 4 shows the uncertainty map for the 500 modelled scenarios with the targeted interventions. Dark diamonds (97% of the total) and red circles (3% of the total) indicate an adequate or inadequate performance by 2050, respectively. Figure 4 shows that the targeted implementation of the expansions greatly increases robustness (i.e. the number of scenarios with adequate performance). The residual number of scenarios with inadequate performance can be tackled by additional targeted interventions or just left untreated if stakeholders consider such a combination of uncertain factors as unlikely to happen. The absence of blue squares indicate that the decision rule was able to reallocate road space in all opportunity scenarios.

4 DISCUSSION

In this paper, we present a simple macroscopic flow model for the road infrastructure in the Dübendorf-Hinwil corridor. The model estimates the number of trips originated and attracted by each town, depending on the population and job numbers, and calculate the average flows, densities and speeds on the road. The model is used to evaluate the robustness of the road in an uncertain future (i.e., the provision of adequate performance under multiple future scenarios). While current performance indicators for transportation planners are numerous including carbon emissions, sustainable development indicators, accessibility or economic impacts, we focus on travel times only as an example. Similar techniques can be applied to evaluate multiple performance indicators and the trade-offs between them in an exploratory manner. Furthermore, while we assume arbitrary satisficing criteria for robustness evaluation purposes, this can be established in planning guidelines or directly elicited from stakeholders.

The model developed in this paper is able to capture some non-linear dynamics between supply of and demand for infrastructure through the fundamental diagram of traffic flow. However, the model can be further expanded to better represent the complexity of the road system along the corridor. For example, the model could be expanded to capture network effects in the region, to consider the different travel modes explicitly, or to include a broader

Figure 4. Uncertainty map and scenario discovery results for the future performance of the road infrastructure by targeting expansions and road space reallocations.

range of interventions such as further modifications of the current infrastructure, demand management and other transport policies. Modelling efforts can also be directed to include endogenous feedbacks such as induced travel demand and spatial dynamics in the region.

The paper showcases the importance of considering a wide spectrum of future scenarios when planning transport infrastructure. The set of uncertain factors used in this paper can be further expanded and the development of future trends can be refined for more detailed results. It is the belief of the authors that further refinements and expansions of the modelling side will only bolster the value of the techniques presented in this paper, as exploratory modelling is particularly suitable to navigate complexity and uncertainty.

5 CONCLUSIONS

This paper demonstrates that the use of simulations and quantitative techniques, when displayed in an interpretable way, can provide valuable planning support in infrastructure planning. We produce uncertainty maps in which decision-makers can visually identify risk and opportunity regions. Furthermore, we implemented simple decision rules for expansion and reallocation interventions targeted to the risk and opportunity regions, respectively, on the uncertainty map to increase the robustness of the road.

The results show that the current road infrastructure capacity in the corridor might not be able to provide adequate service (risk) in 14% of the scenarios. Furthermore, 38% of the scenarios can provide an adequate level of service even if the road capacity is reduced by 50% in the A15 federal highway (opportunity). Feature selection and Scenario discovery methods helped identifying the combination of uncertain factors that result in risk and opportunity regions. Therefore, the techniques shown here can help decision-makers to target efforts only in a subset of scenarios. In this case, the implementation of targeted interventions result in the seizing of opportunities and a reduction of the risk scenarios to only 3% of the uncertainty map.

ABSTRACT: In the coming decades, the storm surge barriers in the Netherlands will reach their end of the designed life time of 100 years. Therefore, the Dutch storm surge barriers are preparing for major renovations. Next to this, as a result of the expected sea level rise, the hydraulic loads and the number of necessary closures will exceed the original design requirements. This gives urgency to look further than an one-to-one replacement or conservation and it a good moment to include changes in functional requirements. The functional end of life is, however, typically surrounded by large uncertainties. Since storm surge barriers bear multiple functions (e.g. hydraulic safety, the environment, shipping and road traffic infrastructure connection), changes in conditions can lead in several ways to the *functional* end of life. In this paper we explore what aspects should be added to current asset management strategy to include the functional performance of our hydraulic structures.

1 INTRODUCTION

The Netherlands has a long history of protecting the hinterland against high water by building dikes and dams. After the flood disaster of 1953, by far the largest Dutch natural disaster of the 20th century, the Delta works were built to defend the ‘provinces Zeeland’ and ‘Zuid Holland’ for the high tide from the sea. This was done, in addition to the reinforcement of the dikes, by constructing dams and storm surge barriers to close the estuaries and reduce the length of the high water defense system. The complete system consists of five storm surge barriers, two locks and six dams. The first storm surge barrier was built in 1958: the ‘Hollandsche IJsselkering’. The last, the Europort barrier, consists of the ‘Maeslantkering’ and the ‘Hartelkering’, was finished in 1997.

Most barriers were designed for 100 years with the sea-level rise expectations set during construction. These predictions were conservative at that time but are rapidly caught up and under-rated by the latest predictions. This implies that the storm surge barriers may reach their functional end of life well before the originally anticipated date. Therefore, it is important to also include the functional end of life the strategic asset management of the storm surge barriers.

This paper wants to answer the question if the current risk-based inspection method in combination with the Statutory Assessment of water safety is sufficient to determine the end-of-life of storm surge barriers.

2 DUTCH MAINTENANCE AND SAFETY ASSESMENTS

The infrastructure of the Netherlands that is maintained by Rijkswaterstaat (Rijkswaterstaat is part of the Dutch Ministry of Infrastructure and Water Management and responsible for

the design, construction, management and maintenance of the main infrastructure facilities in the Netherlands) has a great diversity. It ranges from floodplains and road(side)s to tunnels, pumping stations and storm surge barriers. To make the right choices risk-driven maintenance is introduced. This is done, depending on the complexity and the consequence of the objects, by qualitative or (semi)quantitative risk analyses. Separately from the risk-driven maintenance, the Dutch water act prescribes its own system for the periodic safety assessments of the main flood defenses. The two systems complement each other in the sense that the one focusses on technical and the other on functional aspects. Yet, both systems are not coordinated with each other. In this section of the paper we give a brief overview of the main aspects of both systems.

2.1 *Risk based asset management*

For the risk based asset management in the Nederland's line objects (roads and waterways) an initial risk analysis is made on which the maintenance is based. And in order to maintain the quality level and to determine the maintenance requirements of all the different objects every six years a technical inspection of all the infrastructural object is made. With the results of this technical inspection the financial reservation for the maintenance and a prediction for the end of life is made. With the prediction for the end of life, major replacement and renovation projects are started in a separate project with separate budgeting. The starting point of the end of life determination is this technical inspection. Afterward the economical choices are made with the option of renovation or replacement. In this process the new functions are combined in a new design or renovation plan. This is an organic and logical way to work with the majority of the infrastructural objects. For the more critical objects it's better to look at the different lifespans separately.

2.2 *The Dutch Water Act*

Since December 22, 2009, the Dutch Water Act merges eight previous water management laws, several water pollution laws and which we will discuss further here the law on flood defenses. The Dutch water act provides two types of standards for each dike trajectory. The lower limit is the actual standard and the (stricter) signaling level is established as an alert for when to take action. According to the Water Act, the flood defenses must be assessed if they meet the safety standards once every 12 years. This is elaborated in the Statutory Assessment Instruments (Van Waal 2018), which states that the uncertainties in load and strength are included in the assessment of the flood defenses.

When the dike or object meets the requirements for signaling value the barrier is approved. If the signaling requirements are not met, a plan must be drawn up to meet them. This signaling value is typically a factor 3 higher than the lower limit. In this way, the sea level rise is implicitly anticipated for.

If the barrier meets the requirement of the signaling value, it has to be proved it will stay that way through good management, translated from Dutch it is called 'duty of care'. This can be done by a good maintenance plan for dikes and simple structures. For more critical structures by the substantiation of the reliability based maintenance, with the aim that everything remains in good condition until the end of its life.

2.3 *The National Delta Program*

Besides the management and the Dutch Water Act, the Delta Program is a national program of the Dutch government that describes how to maintain a the climate-resilient and water-robust design of the Netherlands. How do we protect the Netherlands against flooding and how do we ensure sufficient freshwater? And how do we ensure a water-robust and climate-proof design. The Delta program provides qualitative and quantitative information about

Table 1. Overview of the rating categories of the WBI.

Cat.	Designation of test assessment category per subject per test track	Limit category $P_{f,dsn}$ = probability of failure per section (section or structure) [1/year] $P_{eis;sig}$ = signaling value [1/year] $P_{eis;ond}$ = lower boundary [1/year] $P_{eis;sig;dsn}$ = probability of failure [1/year]
I _v	Sufficiently wide of the signaling value	$P_{f,dsn} < 1/30 P_{eis;sig;dsn}$
II _v	Meets the signaling value	$1/30 P_{eis;sig;dsn} < P_{f,dsn} < P_{eis;sig;dsn}$
III _v	Meets the lower limit and possibly the signaling value	$P_{eis;sig;dsn} < P_{f,dsn} < P_{eis;ond;dsn}$
IV _v	May meet the lower limit and/or the signaling value	$P_{eis;ond;dsn} < P_{f,dsn} < P_{eis;ond}$
V _v	Does not meet the lower limit	$P_{eis;ond} < P_{f,dsn} < 30 P_{eis;ond}$
VI _v	Well below the lower limit	$P_{f,dsn} > 30 P_{eis;ond}$
VII	No judgment yet	

climate, water systems, water use and land use in different scenarios. With the purpose of a robust nation resilient to water related challenges in 2050 and 2100. The Delta Scenarios are based on the IPCC predictions which now predict stronger increases than were initially expected (Wolters). The Delta Scenarios will be updated in 2023 on this basis.

With the help of the scenarios and the forecast of the IPCC, the delta program has come to realize that the functional end of life of the storm surge barriers may be reached before 2050. The delta program has therefore initiated a study into the functional end-of-life of the Maeslant barrier, no results of this study have been produced yet.

2.4 Discussion current asset management and assessment strategies

The current asset management process does not pro-actively include changes in functional and performance requirements. The functional requirements are only assessed when the technical state requires renovation or replacement. This seems adequate for relatively simple, non-critical structures, as temporarily reduced performance has only manageable consequences for the greater network. For critical structures, however, replacements may take much more time and their reduced performance may have large consequences for the overall functioning of the network.

For flood defenses, potential future changes in the safety requirements or hydraulic loadings are implicitly accounted for by the introduction of the signaling safety level. The 12 year assessment cycle is likely to be sufficient for dams and dikes. For critical hydraulic structures this is however questionable, since they typically bear many other functions and their replacement can take several decades.

3 END OF LIFE INFRATRUCURAL OBJECTS

For the determination of the end of life of the objects, Rijkswaterstaat has identified three different ways for an object to reach its end of life, corresponding with the used asset management. These are:

Functional, this is determent by the answer to the question if the object still fulfills the functional demands

Economical, this is determent by the costs to retain the object

Technical, this is determent by the initial expected end of life and the condition of the object
 The definitions Rijkswaterstaat uses are given in Table 2.

Table 2. Definitions for three categories of lifespans.

Technical lifespan
The time period until an asset is no longer able to fulfill its functions according to the original functional requirements due to deterioration of non-replaceable components or the use of outdated technologies.
Economical lifespan
The time period over which the costs of owning and operating an asset are still less than the costs of equivalent alternatives. With equal functional requirements
Functional lifespan
The time period during which an asset complies with the functional requirements. The end of the functional life could be reached due to changing physical conditions, societal developments, or altering functional requirements.

For a timely anticipation of the end of life of critical hydraulic structures requires the combined assessment of all types of end of life.

3.1 Procedure technical end of life

The technical end of life of an object will be predicted by its designed lifespan and will eventually be determined by the inspection of the object. When the end of life is imminent the actions that can be taken are threefold:

- (1) The functionality of the object can be reduced, for instance a reduction of the load on a bridge or the reduction of the speed limit on a highway.
- (2) Or one could strengthen the bridge with an emergency solution or with an renovation program.
- (3) And the last option is a replacement of the object.

The choice for renovation and the replacement of the object is re-evaluated after each inspection. Inspections help plan the necessary work and there will be time to take the appropriate action.

Actually for the technical end of life can be prolonged with an technical solution and this can be done endlessly, there is always a technical solution. The boundary here is not defined by the technical possibilities but by the economic value or changed desires.

3.2 Procedure economical end of life

The economical end of life will submerge when the costs of maintaining will rise to a point that it is not justifiable anymore to maintain the structure with the required expenses. For the Dutch infrastructure after each technical inspection, the EELI 'Economical End of Life Indicator' is automatically determined by the results of the inspection. The Economic End of Life Indicator (EELI) is determined by the sum of the cost of future periodic replacement and current maintenance costs of the object divided by the sum of the costs of a new construction and maintenance costs of the new object 'formula 1' (Bakker 2016).

$$EELI = \frac{\text{future periodic replacement} + \text{current maintenance costs}}{\text{new construction} + \text{periodic replacement} + \text{maintenance costs new object}}$$

Formula 1 determination of the EELI

An EELI of 0,8 to 1,0 indicates that its becomes uncertain if the object is economically sustainable. With this indicator it's easy to make a first selection what objects will be reviewed with a more in-depth study to decide if maintaining the object is still economically justified. As already mentioned, the technical end of life can be prolonged endlessly, but with the technical information the economic end of life can be determined. With this information the schedule of the major structural project can be made.

3.3 Procedure functional end of life

The functional end of life is determined by changes in the functional and performance requirements of the network and other demanded functional changes, like changes of the law. All the Dutch objects have, in addition to all building standards, functional requirements which are usually set for an agreed capacity, availability and reliability. A change in the agreed capacity, availability and reliability, is a decision for change of network functionality, this is almost always a political choice. If the choice is made to change the requirements of a network link all the objects must comply with these requirements and all the objects reach their end of functional life. Although the objects still comply with the original technical requirements.

For instance, the road network is overcrowded, the functional requirements has changed overtime. Here there is a choice if we want to fulfill the new requirements or exempt more traffic jams, which is a political choice. If the politics want to reduce the traffic congestion, the traffic links have to be studied with the accompanying objects. In this case it is a political decision to improve the function.

This is the case with road networks and waterways. This will not be the case with high water safety objects. This is because of the Dutch water act that prescribes safety requirements, so that the technical requirements automatically grow along with the hydraulic loads. A flood defense can therefore be in perfect condition to withstand the original design loads, but still no longer meet the unchanged statutory safety requirements because the design loads have increased.

For instance a dike is in perfect condition but the waves pounding on the dike are increased. The dike can't fulfill its safety water safety task and has to be strengthened. This is in the Nederland's obliged by the water act and must be carried out.

The storm surge barriers are specials in this case and will be discussed in chapter 4.

4 END OF LIFE FOR STORM SURGE BARRIERS

Storm surge barriers are special objects for the reason that the decision to build a storm surge barrier is not only made to ensure water safety. If the storm surge barrier had no other function than high water safety the building of a dam would be sufficient. There are always other aspects that come into play. Some of these aspects for example are, an open passage for shipping, the preservation of an ecological system or the accessibility of an island. This has to be taken in account by determining the end of life of the object. Although the results of the determination of technical and the economical end of life give similar results as the other objects, for the functional end of life of the storm surge barriers this is different.

First thing is that the hydraulic conditions change and will become greater than the initial predicted conditions. The effect will be on all the functions the storm surge barriers end of life. The consequence of this is that the end of life of a storm surge barrier isn't one end of life point but for every function there will be an end of life. Choices what function requirements are mandatory and which one not have to be determent and choices eve to be made.

For example a storm surge barrier has a functional description to close with a chance of failure of 1/1000 years and has to close at a certain high water level. In the design stage the prediction is that this would only occur in the winter, the storm period. Maintenance is done in the summer when there is no risk of high water. While in maintenance the barrier will be secured and fixated by a beam, while not obstructing the waterway (one of the design requirements) and the maintenance work can be done. This way in the summer the chance of failure will be greater than 1/100 years, this is no problem because no summer storm is expected. Till the end of the technical life cycle there are no problems to be expected. Unfortunately sea level rise is accelerated and the chance of closing in the summer period is imminent. The normal procedure of blocking the barrier while maintaining is not possible any more. The structure is still strong enough in this example the functional requirement change is dominant.

The above example suggest there is no other option and the life cycle of the storm surge barrier can't be extended, this is true if not all functional requirements are reevaluated. By

reassessing all the functional requirements and reevaluating all the consequence of not only the object but of the whole system affected by the storm surge barrier. And mitigating measures can be made were is has the best result, see Figure 1(Klatter 2019).

Figure 1. Overview of scenarios consequences of storm surge barrier functionality due to sea level rise.

As can be seen in Figure 1 a sea level rise can have several direct consequences, with the several subsequent functional consequences with the mitigating measures, this also implies that there is not one solution but multiple and the options are not only found in improving the object.

If we continue with the previous example, in the summer there is not a storm free period anymore. This influence has functional consequences for instance in the functions of shipping, aging and maintenance. And one must define the consequences is the safety of the hinterland. The consequences of a summer storm can be less than the winter storms. For example only buildings outside the dike could be flooded. Are there hinterland mitigating preventive or corrective measurements possible. An evacuation plan can be made and dikes can be strengthened.

We now only look at the function water safety, the key can be in the other functions the storm surge barrier has. We return design of the storm surge barrier, what were the functions and are they still of importance. For instance the storm surge barrier is built with the base of an open waterway. With the progress of time, the settings change. The reasons of the open waterway can be diverse, in this case we take only shipping. It must be determined all requirements are still opportune. For instance shipping can be less important than originally expected or a detour is possible. We could also be that the open waterway also has an ecological need. And it has to be researched if the waterway has to be opened all the way or can be closed for a longer time. These options open opportunities to maintain the storm surge barrier for a longer time.

The example shows that the functional requirements can't be viewed separately and a functional end of life can't be given on one of the functional requirement. It's a combination of the different requirements. With the example you can also conclude that the different requirement are also not of the same importance and with all the functional requirements you have to take all the functional requirements and the influence for the hinterland into account.

Commissioned by Rijkswaterstaat an end of life study of the 'Hollandsche IJssel' storm surge barrier is made(Vader). This study states the following: 'The Hollandsche IJssel storm surge barrier is designed to last another 40 years, but replacement or renovation may be needed sooner than anticipated due to factors such as climate change and societal developments'. The study indicates that with various sea level rise projections and the combination of the performance levels expressed the remaining life of the Hollandsche IJssel barrier were obtained. The study found that the end of life of the storm surge barrier was significantly shorter than originally designed. The study concluded that even with a moderate sea level rise scenario, there is a significant probability that the end of life of the barrier could be reached within 20 years. The storm surge barrier is technic and economical not for long at its end of

life. With this study mitigating measures have to be re researched in the coming years to ensure the safety of the hinterland.

5 CONCLUSION

The end of life of most objects is determined by technical factors which often can be solved technically. The main factor is the technical solution is still financially viable. Therefore the economic factors become leading and the economic lifespan is decisive for predicting the end of life. The EELI is a good indicator to use in these cases.

For storm surge barriers the functional lifespan is a main factor for the determination of the end of life. The acceleration of the high water level rise is the main factor of the end of life of the storm surge barriers, and can significantly shorten the life span of all storm surge barriers.

The statutory assessment of flood defenses is a good instrument for a test whether it meets the requirements and a guarantee that the quality remains guaranteed with the maintenance.

As observed the water level rise can have surprisingly functional consequences. Due to the complexity of the functional consequence and the different mitigating measures, it will need time to get to an acceptable solution.

As indicated, the end of the life of barriers depends on the functional requirements of the barrier, it has to be clear whether all requirements, that were initially established, are still valid and whether the water system has not changed compared to the period of construction. It is therefore recommended to verify all functional requirements of the barriers at regular intervals, my proposal is to carry this out every 12 years in parallel with the safety assessments. And it need to be studied if the signaling value is sufficient for the storm surge barriers and other constructions that are hard to replace which have major consequences in case of failure.

ABSTRACT: Next decades, many hydraulic structures in the Netherlands will reach their end of life. Timely mitigation requires accurate estimates of the end of life. This appears however hard since many external drivers and multiple functions may lead in many plausible combinations to insufficient technical or functional performance. As a consequence, a complete integrated assessment is rather labour intensive and time consuming. This study shows a quick-scan of the end of life of five storm surge barriers and three other critical hydraulic structures in the Netherlands. The quick-scan reveals that sea-level rise is the major driver for the end of life of most coastal hydraulic structures since it impacts both the free discharge capacity and the flood protection function. Yet, the strategy to adapt the river delta to climate change may be even more important. Future developments are however such uncertain that the life time assessments may prove especially useful for the exploration of adaptive asset management strategies and to a lesser extent as an accurate planning tool.

1 INTRODUCTION

The Netherlands are currently preparing for a major replacement and renovation of large parts of their aging infrastructure as many objects are approaching their technical or economic end of life.

The planning and management of this massive replacement task ideally builds on accurate estimates of the end-of-life. For hydraulic structures, the decision to replace may also be triggered by changes in requirements or loadings as a result of socio-economic developments and/or climate change (Klatter et al. 2019, Bredeveld & Kramer 2019). In those cases, it is the (perceived) insufficient functional performance that determines the end of life.

Critical hydraulic structures typically bear multiple functions such as protecting against flooding, facilitating navigation and enabling the discharge of rivers and precipitation. The performance of these functions might be affected by divergent external drivers. End of life assessments therefore require a systematic approach that ensures that all pathways that might lead to the end of life are assessed (Vader et al. in press, Van Baaren et al. 2019).

Recently, Vader et al. (in press) proposed a four step ‘top-down’ approach for the systematic assessment of the end of life of storm surge barriers in order to identify the dominant pathways. First, clear and unambiguous definitions of the different life span concepts (technical, economical

and functional) should be set to avoid confusion in the subsequent steps. Second, a functional analysis and physical decomposition are performed. Third, the relevant external drivers and their impacts on the technical state and the different functions are listed. And fourth, the most important external drivers and pathways that may lead to the end of life are identified.

The usefulness of the framework is convincingly demonstrated by means of a case study with the oldest storm surge barrier in the Netherlands, the Hollandsche IJssel barrier (HIJK). Yet, the framework is rather labour intensive and a full assessment of all Dutch storm surge barriers and other critical hydraulic structures may require considerable time. Therefore, this paper presents a quick-scan in order to explore to what extent end of life assessments of different hydraulic structures reveal common pathways to the end of life that deserve more attention. The quick-scan assesses the end of life of five storm surge barriers, a discharge sluice, a flood gate and a pumping station by loosely applying the framework of Vader et al. (in press).

2 METHOD

In this study we adopt the same life time concepts as defined by Vader et al. (in press).

- The technical life is the time period over which an asset is able to fulfil its functions according to the original requirements before it must be replaced due to deterioration of non-replaceable components or the use of outdated technologies.
- The functional life is the time period during which an asset complies with the functional requirements, such as the exceedance frequency of the critical water level or the acceptable number of closures.
- The economic life is the time period over which the costs of owning and operating an asset are still lower than the costs of equivalent alternatives.

Since this quick-scan mainly focusses on the functional end of life, the system analysis is restricted to a functional analysis (see section 3). Furthermore, explicit performance requirements are not determined as the purpose of this assessment is only to identify the most threatened functions and the major drivers that may cause insufficient functional performance. Instead, it is assumed that the structures more or less comply with the current requirements and can be adjusted for small changes in requirements or loads.

The analyzed physical drivers are based on Vader et al. (in press) complemented by a recent, first interpretation of the Sixth Assessment Report of the IPCC (2021) for the Netherlands by the Royal Netherlands Meteorological Institute (KNMI, 2021). For the socio-economic developments this study uses the four principle adaptation strategies to sea-level rise as recently presented by the Dutch Delta Program (Van Alphen 2022, Haasnoot & Diermanse 2022).

3 SYSTEM ANALYSIS OF HYDRAULIC STRUCTURES

In this study we assess the end of life of five storm surge barriers, one major discharge sluice, a flood gate and a pumping station (Table 1 and Figure 1). Storm surge barriers are partly movable barriers that only close at extreme storm surges to keep the water levels behind within acceptable/safe limits and such to protect the hinterland against flooding (Mooyart & Jonkman, 2017). The Netherlands count five storm surge barriers that were constructed between 1954 and 2002. The Hollandsche IJssel barrier (HIJK), the Eastern Scheldt barrier (OSK), Maeslant barrier (MK) and the Hartel barrier (HK) protect the southwestern delta against extreme storm surges from the North sea and the Ramspol barrier (RK) protects an area in the eastern part of the Netherlands against surges from Lake IJssel.

The Haringvliet sluices (HV) also play an important role in the flood protection of the South-western delta. At low tide, they enable the free discharge of the Rhine and Meuse rivers into the North Sea, while they prevent the water of the North Sea to flow back during high tide.

Floodgate Ravenswaaij (FGR), is a 80m wide vertical lift gate in between the Lek (one of the Rhine branches in the Netherlands) and a reach of the Amsterdam-Rijn Canal. Like storm

Table 1. Main characteristics of the assessed hydraulic structures.

Structure name (abbreviation)	Type	Gate/pump type	Design life
Hollandsche IJssel barrier (HIJK)	Storm surge barrier	Double lift gate (80m)	1958-2058
Haringvliet sluices (HV)	Discharge sluices	17 Tainter gates (56.5m)	1971-2071
Eastern Scheldt barrier (OSK)	Storm surge barrier	62 lift gates (42m)	1986-2136
Maeslant barrier (MK)	Storm surge barrier	2 floating sector gates (360m)	1997-2097
Hartel barrier (HK)	Storm surge barrier	2 lift gates (98m, 48m)	1997-2097
Ramspol barrier (RK)	Storm surge barrier	3 inflatable rubber gates (80m)	2002-
Floodgate Ravenswaaij (FGR)	Flood gate	Lift gate (80m)	1978-2078
Pump-weir complex IJmuiden (PWIJ)	Pump	4 Stork pumps (40m ³ /s)	1975-2025
		2 Nijhuis pumps (50m ³ /s)	2004-2054
	Weir	7 movable weirs	2040-

Figure 1. Overview of the assessed hydraulic structures.

surge barriers, the floodgate is open under normal conditions and only closes in case of extreme river water levels to protect the hinterland from flooding.

The main function of Pump-weir complex IJmuiden (PWIJ) is to manage the water level and quality in the North Sea Canal and Amsterdam-Rijn Canal. The complex separates the canal system from the North Sea, discharges precipitation and excessive water from the surrounding polders and regulates the salt intrusion.

Besides the water management functions, the assessed structures all bear several other functions (Table 2). Navigation is facilitated at or near all structures. The Hollandsche IJssel barrier, Floodgate Ravenswaaij and the Hartel barrier allow free passage under normal conditions and by means of adjacent navigation locks when closed. The Maeslant barrier and the Ramspol barrier only allow free passage of ships under normal condition and at Pumping-weir complex IJmuiden, the Haringvliet sluices and the Eastern Scheldt barrier ships can only pass through nearby navigation locks. Furthermore, the structures have ecological, monumental/iconic and road functions.

Table 2. Main functions of assessed hydraulic structures.

Function*	HIJK	FGR	HV	GSIJ	OSK	MK	HK	RK
Retain extreme water levels	x	x	x		x	x	x	x
Facilitate navigation	x	x				x	x	x
Provide discharge capacity for polders	x	x	x	x				x
Allow (natural) river discharge			x					x
Provide fresh water	x							
Prevent salt intrusion	x		x	x				
Allow tidal flow	x		x		x			
Provide corridor for fish migration			x		x			x
Provide road connection	x	x	x		x			
Provide iconic/monumental value	x		x		x	x		

* Functions of adjacent and nearby navigation locks are not taken into account

4 FIRST ORDER EFFECTS PHYSICAL DRIVERS

Analysis of the identified functions leads to the same short-list of potentially relevant physical drivers (Table 3.) as found by Vader et al. (in press). This seems logical as the assessed structures are located in nearby and comparable areas and together only serve two additional functions with respect to the Hollandsche IJssel barrier (allow natural river discharge and provide corridor for fish migration).

Careful analysis reveals that sea level rise is *the* dominant driver for changes in the functional performance of the assessed hydraulic structures. Sea level rise will directly increase the exceedance probability of critical levels. It is estimated that a rise of 50-75 cm will increase the exceedance probabilities roughly with a factor 10 and a rise of 100-150 cm with a factor 100 (e.g. Haasnoot et al. 2020). Without adaptation, this has a direct impact on the required reliability (operational, structural and height) and on the number of closures (and consequently on the hindrance for navigation).

Moreover, sea level rise will substantially decrease the capacity and time window for free discharge because the levels at low tide will also rise. For pumping-weir complex IJmuiden it is for instance estimated that 30 cm sea level rise might reduce the free discharge capacity by 90%, which needs to be compensated by sufficient pumping capacity (Van Gijzen & Bakker 2023). For the Haringvliet sluices it will be way more challenging to replace the free discharge capacity by pumps as it needs to discharge the rivers Rhine and Meuse.

Next to sea level rise, precipitation and drought deserve some attention. Precipitation extremes are expected to increase substantially, but this especially concerns local, relatively

Table 3. Identified potentially physical drivers.

Driver	General consequence
Temperature	Extreme temperatures can temporarily reduce the operational reliability. The impact on the hydraulic performance is considered minor since extreme temperatures do typically not occur in stormy conditons.
Precipitation	Increased precipitation extremes may result in higher pump volumes from polders.
Land subsidence	Lowering of the crest height of dikes. Foreseen subsidence is however small compared to projected sea level rise.
Sea level rise	Increase in exceedance probability of critical water levels. Higher number of storm closures. Decrease in free discharge capacity.
High river discharges	Higher volumes to be discharged
Low river discharges	Reduction of (navigation) depth and fresh water availability
Drought	Salt intrusion Dike instability Increase in fresh water demand
CO ₂ concentration	no impact on requirements, use or loads
Wind	minor changes in wind regime expected (KNMI 2021)

short term precipitation (KNMI 2021). Increases in larger scale, multi-day events that are more determinant for the necessary discharge capacity will be more moderate. Also more frequent droughts may urge for substantial system adaptations and potentially increase the importance of the fresh water retention function of the Haringvliet sluices and the Pump-weir complex IJmuiden. However, the direct impacts of sea level rise on the functional performance may be several orders of magnitude and will dwarf the potential effects of the other physical drivers.

5 EFFECTS OF SYSTEM ADAPTATION TO CLIMATE CHANGE

Next to physical drivers, socio-economic developments can seriously affect the functional performance of a hydraulic structure. In the decades to come, the functional performance is likely to be dominated by the chosen strategy to adapt to sea level rise.

Recently, the Dutch Delta Program presented four principal adaptive strategies to (accelerated) sea level rise (Van Alphen 2022, Haasnoot & Diermanse 2022). The first strategy ‘Protect-open’ basically is a continuation of the current policy. First and second line flood defenses will be strengthened in line with the changing hydraulic loads while maintaining an open connection with the sea. The second strategy ‘Protect-closed’ focusses on the strengthening of the first line of defense and will close the connection with the sea to prevent higher levels and salinization of the inland water bodies. This strategy will however require enormous pump capacity to drain the rivers Rhine and Meuse (see also section 4). The third strategy ‘Advance’ advocates to extend the present coastline seawards to be able to build more robust flood defenses and create new land and water storage. The fourth strategy ‘Accommodate’ proposes to accept changes and prepare for the ‘living with water’ concept and/or retreat.

The studies argue that the current policy ‘Protect-open’ may be continued up to 1m sea level rise, maybe 2m if the closure levels of the storm surge barriers are heightened. This may, however, require substantial adaptation or even replacement of the current storm surge barriers. For instance, the Maeslant barrier was originally designed for only 25cm sea level rise during its entire design life time and the Maeslant barrier is currently already struggling to meet the strict requirements for the operational reliability and the gradually shrinking time window for maintenance.

In 2014, a group of six experienced Dutch engineers led by Frank Spaargaren proposed to replace the Maeslant barrier by a closed dam with navigation locks, watering sluices and a pumping station in order to anticipate the sea level rise induced challenges (e.g. Dokter et al. 2016). This potential first step towards ‘Protect-closed’ would imply the end of life of the Maeslant barrier, but also substantially impact the remaining life of other hydraulic structures. The Hollandsche IJssel barrier, for instance, is located behind the Maeslant barrier. The replacement of the Maeslant barrier by a closed dam would significantly reduce the impact of sea level rise which could imply the elongation of the functional life. Yet, severe reduction of the extreme water levels could also nullify the flood protection function which would imply the economic end of life. On the other hand, heightening of the target water levels in the southwestern Delta in order to longer benefit from free discharge would immediately increase the functional relevance of the Hollandsche IJssel barrier again.

In contrast to a closed dam, the sea level rise induced challenges of the Maeslant barrier could also be tackled by ‘Advancing’. A recent study of Mooyaart et al. (in review) suggests that a second sea ward storm surge barrier could be cost effective at sea level rise beyond 0.45m. This second, redundant barrier would actually elongate rather than end the remaining life of the Maeslant barrier.

It is clear, that every step in the system adaptation can have enormous impact on the remaining functional and economic life of hydraulic structures. It is however impossible to predict which adaptation step will be implemented first as this is a political decision. This means that accurate functional end of life estimates are actually impossible for more than several decades ahead.

6 CONCLUSIONS

The quick-scan presented in this paper suggests that sea-level rise is *the* determinant factor for the functional end of life of coastal hydraulic structures. It is not expected that a more thorough assessment will identify other physical drivers as the potential effect of sea level rise can be several orders of magnitude larger.

The large uncertainties in future sea-level rise projections also make the functional end of life estimates intrinsically uncertain. Maybe more important are the uncertainties in the exact adaptation pathway to sea level rise (and maybe drought). Many plausible adaptation options exist. Yet, which adaptation option is implemented when is a political choice and the impact on the functional and economic end of life really depends on the implementation details.

Accurate estimates of the functional end of life for more than several decades ahead are not possible under rapidly, but uncertain changing circumstances. Nevertheless, functional end of life assessments may prove very useful for the exploration of detailed adaptation pathways.

Deltares, Delft, The Netherlands

H. Berger & A. Barneveld

Ministry of Infrastructure and Water management, Utrecht, The Netherlands

ABSTRACT: In the life-cycle of infrastructure assets, distinction can be made between technical, economical and functional performance. When the performance does not meet the requirements anymore, end-of-lifetime is reached. By considering functional aspects of hydraulic structures -like meeting the requirements on flood protection, navigation, water availability or ecology- an integral analysis for the life-cycle can be performed. The framework functional performance assesses the impact of climate and socio-economic changes and (future) policy decisions on the functional performance of hydraulic structures in time. This framework can be applied to systematically 1. Identify the current functional performance; 2. Identify end-of-life tipping points and 3. Assess renewal and renovation options. It was applied to one of the steps in the preparation process for the renewal of the weirs in the Dutch part of the river Meuse. Since functional lifespan is rarely quantified, our next step is the development of (rapid assessment) tools to quantify the functional performance in time for other structures, drivers and functions in order to fill the framework and make it applicable for policy analysis.

1 INTRODUCTION

Physical infrastructure is vital for a society. As in many countries, much of this infrastructure in the Netherlands was built in the 20th century. Since then, the performance of the infrastructure required to keep our country safe, accessible, and habitable has been maintained by means of intensive management and maintenance.

In the coming decades, the loads and demands on infrastructure networks, particularly in delta areas such as the Netherlands, are expected to change dramatically. Nevertheless, existing components such as structures in the current infrastructure constitute an excellent basis for ongoing construction (even in uncertain future scenarios). However, long-term exposure to degradation has rendered components outdated. As a result, the parts with the longest lifespan will soon be reaching the end of their service life. Moreover, the networks are being used more intensively and are already being affected by developments in the fields of climate (adaptation), sustainability and social-economics. This means that simply maintaining the current performance level will require extra effort from managing authorities.

To make a well-considered and substantiated investment decision about immediately renewing (or first extending the lifespan) of infrastructure components, asset managers require essential information about its current condition and the risks involved in different decisions. Methods are needed to support the asset managers regarding complex decisions on renewal and renovation of infrastructure components, as part of a strategy towards a future-resilient network. The objective of this paper is to provide a framework how to consider functional performance of hydraulic structures in an integral and structured way.

In the life-cycle of infrastructure assets, distinction can be made between technical, economical and functional performance (how well a structure fulfills its requirements). When the performance does not meet the requirements anymore, end-of-lifetime is reached. Slightly different definitions are used for the technical, functional and economical end-of-lifetime, for example Hermans (1999), Hertogh et al. (2018) and Vader et al. (2023). Here, we consider technical end-of-lifetime as the moment that an asset is no longer able to fulfill its functions due to deterioration of non-replaceable components or the use of outdated technologies. Functional end-of-lifetime is considered as the moment that an asset does not meet the functional requirements, such as the exceedance frequency of the critical water level or the acceptable number of closures. End of technical lifetime thereby always leads to end of functional lifetime. Economic end-of-life is the moment that the costs of owning and operating an asset are higher than the costs of equivalent alternatives.

Technical end-of-life is often taken into consideration in the Netherlands, and almost always at least a theoretical value is available (Klatter et al. 2022). Technical performance of structures is monitored regularly. Functional lifespan is something which is rarely quantified, and functional performance is rarely monitored. By considering functional aspects of hydraulic structures -like meeting the requirements on flood protection, navigation, water availability or ecology- an integral analysis for the life-cycle can be performed for existing and to-be-build hydraulic structures.

Although this paper focuses on structures in the water infrastructure – in other words, hydraulic structures, retaining walls (e.g. quay walls) and the associated structural parts - the method functional performance must also be applicable to decision-making for other infra-structural components.

2 METHOD FUNCTIONAL PERFORMANCE

2.1 *Functional lifetime*

Various studies have already been carried out in the Netherlands into tipping points in the system and the infrastructure (eg Kwadijk et al., 2010). The study for the Thames Barrier is an international example of these tipping points (Hall et al., 2019). The method of using decision points or tipping points has been further developed in recent years for hydraulic structures, often within large, multi-year programs such as VONK (Iv-Infra/HKV, 2014; HKV, 2015), ROBAMCI (Risk and Opportunity Based Asset Management for Critical Infrastructures with various case studies; Robamci.nl) and the Knowledge Program on Hydraulic Structures (Dutch abbreviation KpNK, Bredeveld & Kramer, 2019). Functional lifespan had been included in a limited amount of policy documents, the IMA (including lock capacity bottlenecks in various scenarios, Rijkswaterstaat (2021)) is one of the examples.

An exploratory study into the functional lifespan of hydraulic structures has been carried out in KpNK. Discussions in that context about a (practical) method for determining end of functional life have led to an inventory of available knowledge, models and information (KpNK, 2018).

KpNK (2018) argues that the need to define a generic transparent Functional Lifetime Method to determine the end of functional lifespan. Subsequently, there was a need for a practical, preferably generic, working method in which the relationship between the (future) functional performance(s) of an object and the subsystem of which it is part is included. To this end, the Toolbox Functional Lifespan has been drawn up (Bredeveld & Kramer, 2019).

This Toolbox is intended to facilitate the estimation of the end of functional life for individual structures and groups of structures at various levels of detail. The least detailed level concerns an elaboration of the Functional Lifespan-light (MFL-light) Method, which is a simplified qualitative assessment based on expert judgment that can be used to determine the points of attention for a more detailed assessment of end-of-functional life. This further analysis can take place based on existing information (medium) or by performing additional calculations with prediction models (heavy).

2.2 Framework functional performance

In Bredeveld & Kramer (2019) the Toolbox Functional Lifetime was developed to select the main drivers (sea level rise, changes in precipitation etc.) for the set of functions of a hydraulic structure. This methodology was applied to several cases to identify the end-of-functional-lifetime based on expert judgement.

In (Van Baaren et al 2022a; Van Baaren et al 2022b) this research continued into the development of the Framework Functional Performance (Figure 1). Instead of indicating a fixed end of lifetime, functional performance, defined as how well a structure fulfills its functions, can change in time. The framework functional performance assesses the impact of climate and socio-economic changes and (future) policy decisions (drivers in Figure 1) on the functional performance of hydraulic structures in time (number 4 in Figure 1). Information at structure and system level about the functions, acreage and requirements are needed to derive this performance (number 3 in Figure 1). If the functional performance in time does not meet the requirements, bottlenecks can be identified. Which can lead to new alternatives for Renewal and Renovation (number 2 in Figure 1) or a change in guiding principles or requirements (number 3 in Figure 1). Translation of the functional performance into input for the economic assessment can be used for an economic assessment. In case of Renewal and Renovation of infrastructure we foresee several iterations from the first end-of-life signal towards a system analysis towards the planning phase for the new infrastructure. Depending on the answers needed in that phase, the Method Functional Performance light, medium or heavy can be used. Every step is a selection of relevant parameters (drivers, functions, options), so the number of functions and drivers decreases from light towards medium towards heavy.

Drivers can influence the functional performance, so this performance is not (always) constant over time. For each function, the future functional performance could be described, provided requirements or goals are described for the hydraulic structure for that function.

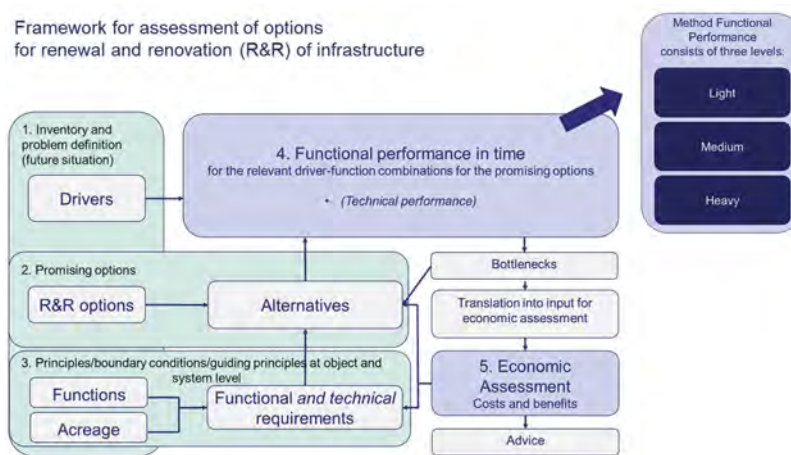

Figure 1. Framework for assessment of options for renewal and renovation (R&R) of infrastructure.

2.3 Applications

This framework can be applied to systematically:

1. Identify the current functional performance of hydraulic structures

For each function, the functional performance could be described, provided requirements or goals are described for the hydraulic structures for that function. The functional performance can be measured at object level, but there is also a wish (Klatter et al., 2022) to add (elements of) the functional lifespan of hydraulic structures to the analysis of the (residual) lifespan. In this application the number of promising options (see step 2 in Figure 1) is limited to one (only the current situation).

2. Determine decision moments for Renewal and Renovation

Decrease in the functional performance can lead to decision moments at which the functional performance of hydraulic structures decreases to such an extent that:

- The end of the functional lifespan of the structure reached; or
- Large investments in management or renovation must be made to maintain the functional performance of the structure at a sufficient level; or
- Large decrease in benefits in the system arise due to a decrease in the functional performance of the structure.

The method is applied to a storm surge barrier are in Van Baaren et al. 2022a and Vader et al. 2023. In this application the number of promising options (see step 2 in Figure 1) is limited to one (only the current situation).

3. Assess renewal and renovation options

After reaching end-of-life of hydraulic structures, assessment of renewal and renovation options is carried out. By quantifying the functional performance for different Renewal and Renovation options, options can be compared. The differences in functional performance between the options can then be translated into benefits in a cost benefits analysis. Requirements for the functional performance are desirable, but without wishes the options can still be compared by translating the differences in functional performance into benefits. See chapter 3.

3 APPLICATION TO THE ASSESSMENT OF OPTIONS FOR RENEWAL

The framework was applied to one of the steps in the preparation process for the renewal of the weirs in the Dutch part of the river Meuse (Van Baaren et al. 2022b). These weirs will soon reach their end-of-technical lifetime.

3.1 Case description

There are 7 weirs in the Meuse in the Netherlands (Borgharen, Linne, Roermond, Belfeld, Sambeek, Grave and Lith) that were built at the beginning of the 20th century. The design life of these weirs is around 100 years. Monitoring and inspections show that the weirs Linne, Roermond, Belfeld, Sambeek and Grave will soon reach their end of life. These five weirs, with outdated Poirée techniques, will have to be replaced. The regional analysis of the Meuse weirs concluded that the current guiding principles, namely water drainage and shipping, will continue to be leading in the future, and that new weirs are required for this. The forthcoming replacement and renovation assignment of the seven weirs on the Meuse is based on the preservation of seven weirs, which will be located at approximately the same location as now.

Most of the time, the weir is closed, and ships pass through the lock. In the case of high river discharge, the weir is opened, and shipping can choose to pass the weir complex via the weir or via the lock. If the river discharge increases even further, the water level will rise further, also on the upstream side of the complex. At a certain point, the water will flow over the lock gates and the lock operation must be stopped. At even higher discharges, the water will partly flow via the floodplains. Ships then only have the option of passing through the weir complex until the river is found to be unnavigable.

3.2 Application framework functional performance

An important question when designing the new weirs is whether they should be navigable at high water, as is currently the case with the weirs at Roermond, Belfeld, Sambeek, Grave and Lith. This is a choice to be made at the system level. However, this does not necessarily mean that the same choice must be made for all weirs. This choice provides a precondition for the design of the weirs in the Meuse. Navigability during high water is one of the important

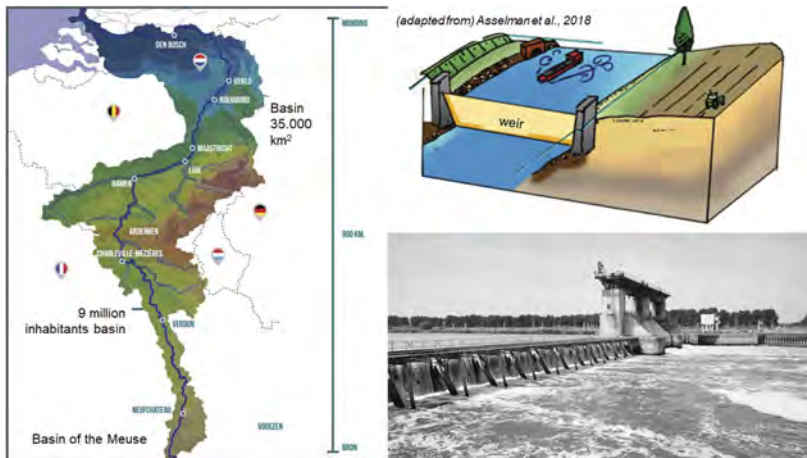

Figure 2. The basin of the Meuse with 7 weirs in the Netherlands (not shown in the map).

decisions that policy must take in the initial phase, a decision that must take into account existing policy documents. This is number 1 in Figure 1, the ‘inventory and problem definitions (future situation)’.

The Knowledge Program for Hydraulic Structures has addressed and answered a number of questions regarding the mapping of current shipping intensities at the various river discharges and future navigability. The developed framework for assessment of options for renewal and renovation (R&R) of infrastructure (Figure 1) was applied to this case study to systematically assess the differences between the alternatives for the new weirs for all functions.

The research conducted focused on 3 alternatives, (number 2 in Figure 1):

1. A navigable weir
2. An impassable weir
3. An impassable weir, combined with an elevation of the lock

Figure 3. Three alternatives for the weirs on the Meuse: a. a navigable weir; b. an impassable weir; c. an impassable weir combined with an elevation of the lock.

The study started with an inventory of the functions of the weir complexes (the weir including the lock, fish passage, bridge and so on) and the underlying requirements/ambitions/ desires for the functions (number 3 in Figure 1). Then the underlying drivers that influence the extent to which these functions will be fulfilled in the future were identified (number 1 in Figure 1). Together with several stakeholders the Method Functional Performance ‘Light’ was applied to this case study, identifying the effects of drivers on the functions of the various alternatives. This was done by means of several workshops and specific interviews with asset owners, hydraulic engineers responsible for the new design, and experts on specific functions. The systematic approach followed shows that whether weirs are navigable or not also influences other functions, which should therefore also be considered in the policy decision on navigability. However, a supported prioritized set of requirements is still lacking, and is very important for an integral analysis of all functions.

Since navigability was one of the priority functions, the functional performance for navigation under the driver climate change was quantified (Method Functional Performance

'Medium' in Figure 1). The focus was on high river discharges because the analysis in the Method Functional Performance 'Light' showed a large distinction in functional performance for this driver between the different alternatives for the weirs. The least and most extreme future climate change scenarios (WH and GL, Dutch scenarios for national climate change) for 2050 and 2085 of KNMI (2014) and a reference scenario for the current climate in the Netherlands were considered, and a translation of these climate change scenarios to a representative dataset of river discharges made by Deltares (2016) was used to quantify the number of navigable days per alternative.

An analysis based on IVS90 shipping data shows that, in the current situation, once the weir has been opened, a large proportion of shipping prefers to pass through the weir rather than passing through the lock that is still operational (more than 90%). The benefits of a weir that can be passed through for shipping partly depend on climate developments and socio-economic developments. Due to a changing climate, the number of days with higher discharge increases, and therefore the number of days per year that a weir is open will increase, which means that the benefits of a navigable weir will also increase. And with an increase in the total value of the ship's cargo, the benefits will also increase. Based on the available scenarios, estimates have been made about the number of days and the duration that shipping can benefit from the navigability. Future (policy) decisions have additional influence on the benefits, but these are so uncertain that they have not been quantified.

4 CONCLUSIONS

Currently, functional performance of hydraulic structures is mainly used to identify the system's tipping points. More detailed information and knowledge on the hydraulic structures and application of the Method Functional Performance can lead to more insights in the renewal and renovation process of hydraulic structures in three settings:

1. Identify the current functional performance of hydraulic structures;
2. Determine decision moments for Renewal and Renovation
3. Assess renewal and renovation options.

A major task of studies awaits Renewal and Renovation of infrastructure. Therefore, a systematic approach is needed that can facilitate the Renewal and Renovation. The approach from this study takes functions, requirements/ambitions/wishes, drivers into account and – through objective analyzes of a combination of datasets – leads to insight into the differences between the alternatives for Renewal and Renovation in a transparent manner. It is recommended to test this data-driven methodology for other (more diverse) alternatives to the weirs and other cases. It is also recommended to further elaborate the functional performance of hydraulic structures for other functions and drivers, and to translate this information into decision information. This creates a data-driven toolbox for functional performance analysis, in order to arrive at a systematic elaboration of alternatives for the major Renewal and Renovation challenge. Since functional lifespan is rarely quantified, our next step is the development of (rapid assessment) tools to quantify the functional performance in time for other structures, drivers and functions in order to fill the framework and make it applicable for policy analysis.

A supported set with prioritized requirements/ambitions/wishes/principles is the basis for deriving the differences between the alternatives. This set is often not available at the level of the structures. Translation from system expectations into structure requirements is challenging and not constant in time. It is important, in the context of traceability and stackability of analysis and decisions, to also keep items with a (at first apparently) low priority. After all, the priority can change during the process.

It is recommended that a good climate change data series will be drawn up and translated into local discharges, water levels and possibly salinity for large bodies of water in the Netherlands as a result of rising sea levels and changing discharges. So that datasets are available with clear user conditions for all situations – dry, average, high and extreme situations. Substantiating the Renewal & Renovation task with data provides insights, clarity and substantiation.

Determining the future functional requirements of a pumping-weir station with the help of data-analysis

L. van Gijzen & A.M.R. Bakker

Technische Universiteit Delft, Delft, The Netherlands
Rijkswaterstaat, Utrecht, The Netherlands

ABSTRACT: The pumping-weir complex at IJmuiden plays an important role in the drainage of excess water in the Western Netherlands. Multiple pumps need replacing as 4 out of 6 pumps near their end-of-life term. The optimal replacement strategy critically hinges on the future required pumping capacity. Yet, currently available models are not suited to assess the effect of sea level rise or extremer precipitation events as they ignore certain complexities of the water system. Preliminary data analysis in this paper showed the sensitivities of the system. The required pumping capacity is sensitive to the ability of free discharging during extreme water events. Yet, it is less susceptible to extremer precipitation events. Further research will aim at including more of the water system's complexity in the model. Due to the node-like structure and high availability of data, a neural network modelling approach will probably be suitable.

1 INTRODUCTION

The pumping-weir complex located at IJmuiden functions as a separator between the complex water system of the Amsterdam Rhine Channel - North Sea Channel and the North Sea. Most pumping stations are found in sewage systems or in prevention against urban floods due to heavy rainfall. Yet, not often are they found at the end of a channel system with over 200 access points such as weirs, sluices and local pumps.

The water system situated in the Western Netherlands has been the result of efforts over the last centuries to protect the land from the sea and facilitate navigation at the same time. The result is a channel from the Rhine, via Amsterdam to IJmuiden (North Sea), into which the surrounding low-lying polders excess water (Figure 1). The channel from Amsterdam to IJmuiden was officially opened in 1876, with locks separating the channel from the North Sea. In 1940 the weirs were constructed, through which excess water was discharged and they are still part of the complex today. By 1975 four pumps were added to the complex, to be able to closer regulate the channel's water level and to be able to discharge the water to the North Sea during high tide. Two extra pumps were added in 2004 to increase the discharge capacity. By now, the 4 oldest pumps in the complex are nearing their technical end-of-lifetime and need to be replaced.

The new pumps will need to meet their functional requirements for at least 30 years into the future. Therefore the predicted sea level rise along the Dutch coast plays an important role in determining those future functional requirements. For as the sea level rises, the window for regular discharging through the weirs will get shortened and more volumes will need to be disposed of by means of pumping

Additionally, the extreme rainfall events are expected to get more intense (KNMI, 2014). In terms of precipitation a distinction can be made between the area precipitation and peak rainfall. The area precipitation is expected to increase by 2.5-5.5 % depending on the scenario, which will lead to a similar increase of volumes that will need to be pumped out of the ARC-NSC system. Earlier research has concluded that the current pump capacity will suffice to process this increase

Figure 1. Left) System overview of the NSC-ARC (in dark blue). The catchment area is pictured in green (direct) and yellow (indirect), adapted from (Rijkswaterstaat, 2019). Top right) Pumping-weir complex at IJmuiden (NGS, 2022). Bottom right) Location of the 6 pumps (red) and 7 weirs (yellow).

as the volumes are averaged out over time (van Veen, 2022). Yet, an increase in extreme peak rainfall events might require extra pump capacity in the future. Therefore new functional requirements need to be determined for the pumps. Due to the complex nature of the system, the more traditional methods of designing a pumping station are likely not feasible in this case.

The most important questions for the pump set-up are: How much pump capacity will be required, how often will it be required and with what reliability during its proposed lifetime? These questions are difficult to answer at this moment, as the current available models are not suitable to estimate the required future capacity. A long sequence of historical operational data of the pumps is available at Rijkswaterstaat. Presumably, a lot can be learned from the historical data, which can help estimating the future requirements of the pumps.

This paper shows that historical data analysis can indeed provide various useful insights, which helps estimating the future required pump capacity. Additionally, the sensitivities of the system can be identified based on the conducted data analysis. Following this new information, new methods will be suggested to improve the estimation of the required pump capacity for the pump-weir complex in future studies.

Due to the difficult acquisition of data, the outcomes in this paper are preliminary results. Therefore, the goal of this paper is not to provide precise and direct answers on the required pump capacity and reliability. It is the goal to showcase the complexity of the system, show the sensitivities and propose subsequent steps that can be taken to determine the required capacity.

2 SYSTEM OVERVIEW

The water system North Sea Channel - Amsterdam Rhine Channel (NSC-ARC) fulfils an important role in navigation and draining the surrounding low-lying areas of excess water, thereby it prevents flooding events in the Western Netherlands. The water level in the system is highly regulated as all incoming water sources except for precipitation are regulated by pumping stations, sluices or weirs. The system provides drainage of an area of approximately

2300 km² (Rijkswaterstaat, 2020), which includes highly developed regions surrounding Amsterdam and Utrecht (Figure 1). The target water level is NAP¹ -0.40 m for the entire channel system, but the margins for variations are small. An increase of 10 cm can lead to importunity in the low-lying surrounding polders, a decrease of 10 cm can harm navigation by going below the required navigation depth. The ‘alarm’ water level of NAP -0.30 m was only exceeded for 10 days in the last 10 years and the water level of NAP -0.20 m was never reached . Numerous smaller pumping stations excess water into the water system, with a maximum combined discharge of 360 m³/s. Yet, the largest and most important pumping station is located at IJmuiden, which discharges all water to the North Sea.

The North Sea Channel - Amsterdam Rhine Channel guides the excess water of the surrounding regions (Figure 1) towards IJmuiden like a funnel, where the largest portion of water exits the system through the pumping-weir complex to the North Sea. The pumping station has 3 main functions: 1) Regulating the daily water level (max NAP -0.30/min NAP -0.55), 2) Prevention of extreme water levels, 3) Salt/freshwater regulation.

The pumping station at IJmuiden consists of 6 pumps and 7 weirs with each different discharge capacities (Table 1). At this moment about 50% of the water is discharged through the weirs and 50% is pumped out of the system (Vermeulen et al., 2021). Discharging through weirs is always preferred as this requires no energy, except for lowering the weir doors. The pumps 1-4 were constructed in 1975 and need replacement in the near future.

Table 1. Characteristics of the pumps and weirs.

	capacity	unit	operational head	unit	quantity	since
Pumps 1-4	40	m ³ /s	0 – 2.3	m	4	1975
Pumps 5-6	50	m ³ /s	-0.2 – 2.7	m	2	2004
Weirs	72	m ³ /s	-0.12 and lower	m	7	1940
Total pumps	260	m ³ /s				
Total weirs*	500	m ³ /s				

* The preferred flow rate under normal circumstances is 300 m³/s. Under extreme circumstances 700 m³/s is possible but undesirable.

** Head difference between sea and channel when the pumps can operate.

3 DATA COLLECTION & METHOD

3.1 Data collection

Operational pump data of the time period 1984-2018 was obtained from Rijkswaterstaat where the data quality is internally assessed. The following variables are entered manually: date, start time of operation [HH:MM], end time of operation [HH:MM], discharged volume [m³] and the number of activated pumps. The discharge of the pumps is determined based on measurements with pressure sensors, but their accuracy is uncertain as additional information could not be obtained at this point in time.

To analyse the relation between pumped volumes and the historical data of surrounding stations was obtained from the KNMI (Royal Dutch Meteorological Institute) (KNMI, 2022a). The data is collected at the so called precipitation stations where the daily sum of precipitation is measured. It concerns the precipitation from 08:00 UTC on the previous day to 08:00 UTC at the mentioned date. The quality of that data is guaranteed by the internal control service of the KNMI. There is no data available on the freely-discharged volumes via the weirs for the 1984-2018 period. Data will likely be obtained in a later stage, when it will be incorporated in the analysis.

¹ NAP = Dutch Ordnance Datum, which approximately corresponds to mean sea level

3.2 Analysing the outgoing discharge volumes during extreme events

First, a trend-analysis was conducted by analysing the annual daily maxima and averages. After that, the general characteristics of the usage of the pump will be determined. To assess the required outgoing discharge capacity, a simple water balance is assumed (Figure 2).

In section 4 the return period of daily pumped volumes during extreme events will be determined based on historical data. The current free-discharged volume (Q_{weirs}) is assumed to be equal to the pumped volume (Q_{pumps}) (Vermeulen et al., 2021).

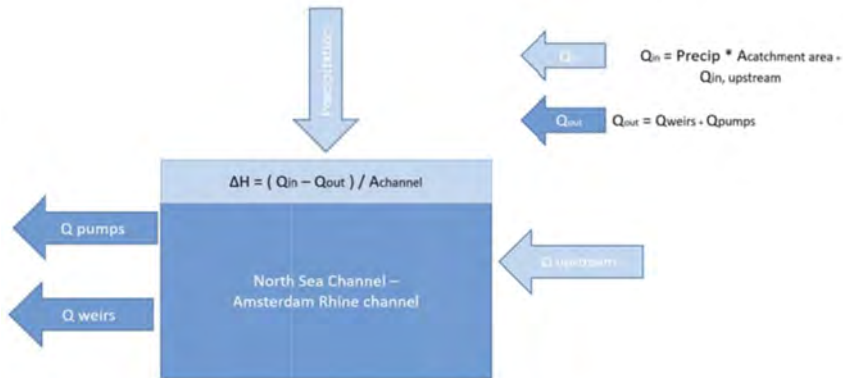

Figure 2. Conceptual scheme of the simplified water balance of the water system.

3.3 Assessment of the future requirements

The future Q_{in} is assumed to increase as the precipitation increases. Additionally, the distribution between Q_{weirs} and Q_{pumps} will likely change as the window for free-discharging is reduced due to sea level rise. Therefore, the required Q_{pumps} would increase with sea level rise. An estimation of the required pump capacity during future extreme events is made by adding the lost capacity of Q_{weirs} to the required Q_{pumps} . Possible future rainfall sequences were generated with the KNMI Transformator (Bakker, 2015) to assess the effect of more extreme rainfall events on the required Q_{pumps} . The newly calculated return periods will provide an indication if the more extreme rainfall events requires more pump capacity.

4 ANALYSIS OF HISTORICAL DATA

Historical pump data is available from 1984, which allows for analysing long-term trends. Both the annual average daily volume per year and the annual maximum daily volume were calculated and have been depicted in Figure 3. The daily maximum shows a clear jump since 2004, which coincides with the installation of 2 extra pumps. Therefore the historical sequence will be divided in two different periods for further analysis: 1984-2003 when 4 pumps were available and 2004-2018 when 6 pumps were available.

The pumps have been activated about +/- 30 % of the time since 1991. Figure 3 shows that most of the time only 1 or 2 pumps are activated, so the pumps are mainly used to regulate the daily variations to maintain the target water level of NAP -0.40 m. The older pumps are operated at full capacity (40 m³/s), but a varying discharge amount can be used at the 2 newer pumps (max. 50 m³/s). If 5-6 pumps are activated, it can indicate that the pumps are used to prevent extreme water levels in the channel, with a maximum capacity of 260 m³/s. This is the case for 3.8 % of the time. However, the 'alarm' water level of NAP -0.30 m was only exceeded for 10 days in the last 10 years and the critical water level of NAP -0.20 m was never reached. Insufficient data is available to identify so called pump-stops due to high tide, while it was required due to high water levels in the channel.

The return periods of daily pumped volumes during extreme events are shown in Figure 4 do not include Q_{weirs} . Different analyses were conducted for a 1-day sum, multi-day sum, weekly sum and a monthly sum. In all sub-plots the pumped volumes seems to approach its maximum asymptotically as the return period increases, which can be explained by the finite

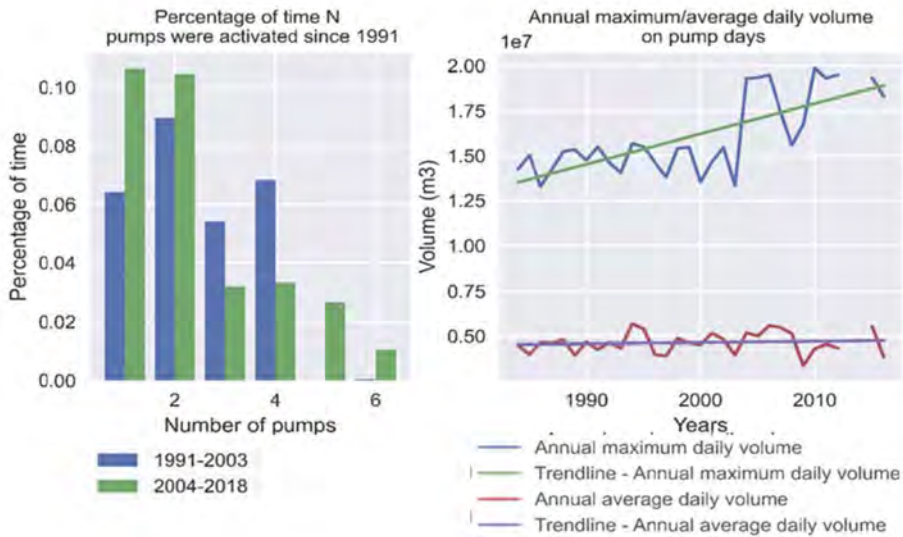

Figure 3. Left) An overview of the usage of the pumps. A distinction is made between the time periods 1991-2003 and 2004-2018. Right) The daily maximum pumped volume each year in blue and the yearly averaged daily pumped volume. The data from 2013, 2014, 2017 and 2018 was excluded from the analysis due to large gaps in the data sequence.

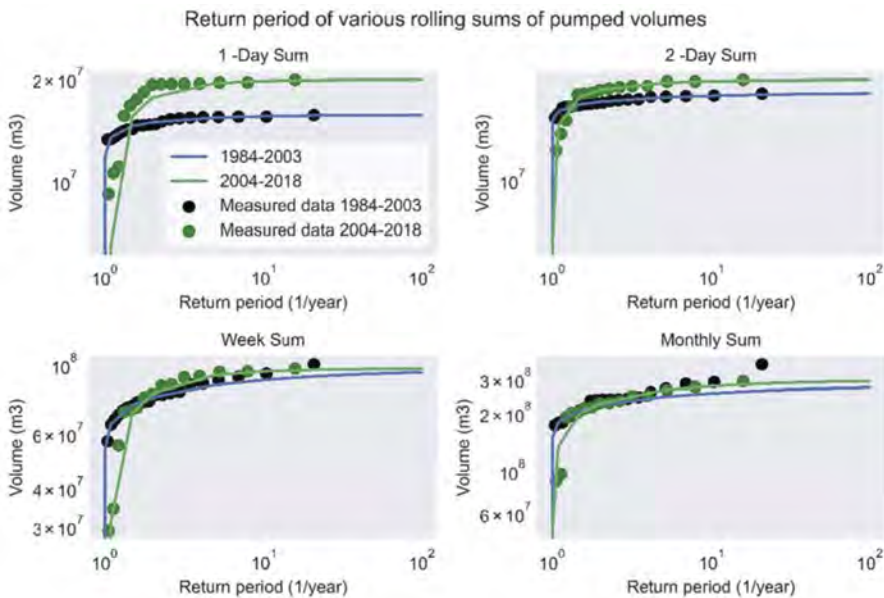

Figure 4. Depiction of the return period of the daily pumped volumes (Q_{pumps}). The total sequence was divided into the period of 1984-2003 when there were two pumps in the complex and 2004-2018 when two extra pumps were added. These volumes do not include Q_{weirs} .

capacity of the pumps. Higher extremes are found in the 1-day sum. Yet, the 2-day sum subplot shows a reduced difference between the extremes. This indicates that not all 6 pumps were required during 2 consecutive days. This difference decreases even further when the weekly sum and the monthly sum are concerned.

5 FUTURE EXPECTATIONS

5.1 Reduction of free-discharge as a result of sea level rise

For the ARC-NSC system we are interested in the absolute sea level rise, as a fixed target water level is maintained and the surrounding dikes can be heightened (Vermeulen et al., 2021). In this paper the following quantities of absolute sea level rise will be considered, it is yet uncertain when these will occur: 10 cm, 30 cm and 80 cm SLR.

Currently, the distribution of discharging through pumps and weirs is approximately 50 \%/50%. The reduction of free-discharging capacity (Q_{weirs}) due to sea level rise was determined by (Vermeulen et al., 2021) and can be found in Table 2. To approximate the required pumping capacity in the future (Q_{pumps}), the reduction of Q_{weirs} will be added to Q_{pumps} , keeping Q_{out} constant. Simultaneously the effect of 2 possible mitigation measures will be assessed: 1) increasing the target water level from NAP -0.40 m to NAP -0.20 m, 2) introducing an extra pump (50 m³/s). Figure 4 (right) shows the new return periods of pumped volumes for several amounts of SLR. The current maximum daily pumping capacity is indicated in yellow, which is exceeded for every scenario. If an extra pump is added the maximum daily capacity will increase, which is depicted in the dashed blue line. In that cases, the maximum daily capacity is exceeded with 80cm SLR. In Figure 4 (right) the target level is increased to NAP -0.20 m, which will result a lower reduction of free-discharging capacity. This results in different return periods than the left, especially for 0.30 cm SLR.

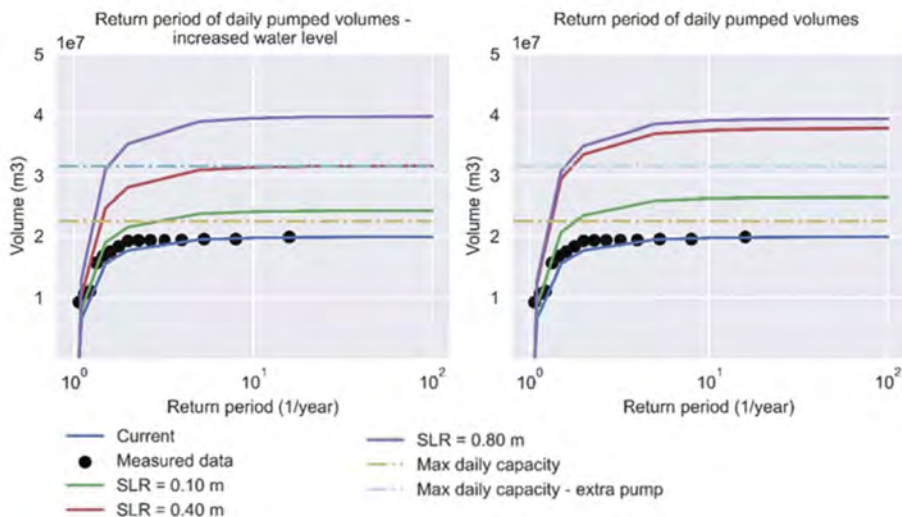

Figure 5. Return period of the daily pumped volumes of the historical data (black) which was fitted in blue with the generalized extreme value distribution. The return periods for 0.10 cm, 0.30 cm and 0.80 cm SLR are depicted in green red and purple. The new return periods were determined by adding the reduction of Q_{weirs} to Q_{pumps} . Left) The new return periods can be compared to the current maximum pump capacity (dashed yellow) and if an extra pump is added (dashed light-blue). Right) In this subplot target water level is increased with 0.20 cm, so less free discharge capacity is lost. This results in different return periods than the left, especially for 0.30 cm SLR.

Table 2. Reduction of volumes to be freely discharged as the sea level rises for 10 cm, 30 cm, 80 cm. Calculated for a target level of NAP-0.40 m and NAP-0.20 m, from (Vermeulen et al., 2021).

SLR	Reduced free-discharge volume	
	Target level	Target level
	NAP 0.40 m	NAP 0.20 m
10 cm	33 %	22 %
30 cm	90 %	59 %
80 cm	99 %	98 %

5.2 Precipitation patterns

In this section the effect of an increased Q_{in} during extreme rainfall events on the required pump capacity is analysed, while Q_{out} and Q_{weirs} remain constant. Possible future precipitation sequences were generated with the KNMI Transformer (Bakker, 2015) for 2030, 2050 and 2080 (Figure 6, left) conform the WI scenario.

The return period of extreme rainfall events are shown in Figure 6. Even for an 1/100 year extreme rainfall event in 2080, it will only result for a 10 cm increase of the water level. This will not result in many issues, as the 10 cm lie between the regulatory margins and the extra volume can be disposed of by the current pump capacity (van Veen, 2022). However, it's difficult to determine how the effects of both sea level rise and extreme rainfall events will coincide with current modelling. The higher volumes of precipitation may not lead to an extension of the complex, but they are likely to lead to a higher required Q_{out} over multiple days. If such a period would coincide with a period when little to no free-discharging is possible, extra pump capacity might be required.

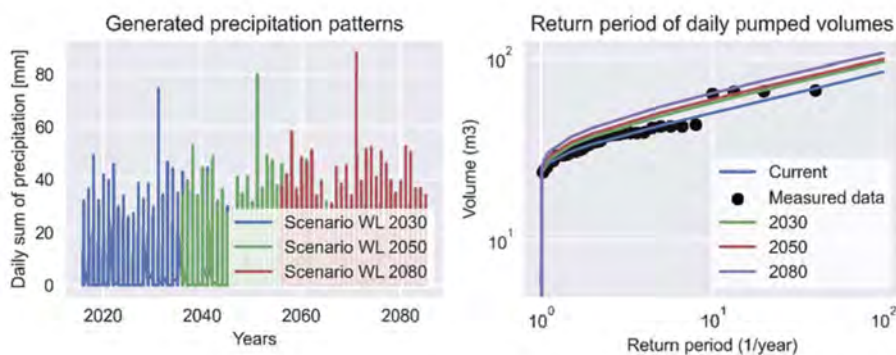

Figure 6. Left) Generated sequences of daily precipitation with the KNMI transformation tool (KNMI, 2022b), with “real” historical data in blue. Precipitation station: Wijk aan Zee. Right) Extreme value analysis of the daily sum of precipitation of the historical data from the weather station Wijk aan Zee and the generated sequences from the right figure.

6 CONCLUSIONS

The analyses in the previous sections provide an indication of the effect of climate change on the return periods of pumping volumes during extreme events. Additionally, they show the sensitivities in the system. The system seems to be dependent on the capacity of free-discharging during extreme water events, which will likely reduce as sea level rises. The system seems to be less sensitive to more extreme precipitation events.

In reality, the system is more complex and several crude assumptions were necessary in this analysis. Most importantly, the change of the capacity of free discharging was calculated by uniformly adding the sea level rise to the water levels of an one-year historical time sequence, not taking into account the impact on tides. Secondly, the assumption of a current 50%/50% distribution between pump and weir discharging is quite straightforward, as it varies under seasonal trends and differs for daily and extreme conditions. Though the free-discharging data is currently not available, it will most likely be in the future.

Additionally, the maximum pump capacity could be lower than displayed in Figure 6, as the pumps cannot operate during low tide or very high water levels. Therefore the exact maximum pumping capacity varies per extreme event, which was not included in this general analysis. However, if the real maximum capacity was overestimated due to a long period of low water levels, it is likely that free-discharging is possible. Discharging via the weirs has a higher discharge capacity than the pumps themselves, which can compensate the overestimation of the pump capacity.

Finally, the influence of the failure probability of the pumping station has not been included in this analysis. The interaction between failure probability of the pumps and the water system is not included in this paper, but it is very important to include this in the future. Malfunctions of the pumps can influence the return period of exceedance of the critical water level. If a malfunction coincides with an extreme water event, more pumping capacity will be necessary to maintain a constant return period of exceedance of the critical water level.

The complexities of the system cannot be included in a straightforward analysis. Therefore a different approach will be explored in the future. Modelling the system with neural networks will probably be a feasible for this problem due to the node-like structure of the channel and the high availability of data. This method has already been applied successfully in the field of water management (Palmitessa et al., 2022). Additionally, more research is required on the effect of sea level rise on tidal harmonics and storm surges. Recent studies predict that tidal amplitudes in the North Sea may increase (Deltares, 2020, Idier et al., 2017), so the window for free-discharging might not decrease as much as was assumed in Vermeulen et al. (2021). Due to the sensitivity of the system to free-discharging, it is important to provide a more detailed estimation in the future.

Resilience through superelasticity

D. Shook & M.P. Sarkisian

Skidmore, Owings & Merrill, San Francisco, USA

C. Horiuchi

Skidmore, Owings & Merrill, San Francisco, USA (formerly)

ABSTRACT: To reduce the impact of climate change we must incorporate carbon-reducing materials while increasing the resiliency of buildings and infrastructure. Shape memory alloys (SMAs) offer a unique opportunity to achieve these goals. SMAs are unique materials which experience phase changes due to stress allowing large, fully recoverable deformations, energy dissipation, and significant restoring forces. This is particularly helpful in regions of high seismicity. The SMA properties allow for a fully elastic seismic force resisting system. This stands in contrast to traditional steel moment frames which have significantly higher embodied carbon and buckling restrained braces (BRBs) which have a known tendency to have residual drift – rendering the building unusable. Moment frames and BRBs systems cannot achieve the combined goals of carbon reductions and resiliency. Component, prototype, and large-scale shake table testing has been conducted to validate this approach.

1 A NEW ERA OF RESILIENCE

1.1 Growing environmental risks

Rapid decarbonization is critical considering the time-value of carbon (CLF, 2017). The world is seeing promising near-term advancements of common high-volume building materials such as concrete, timber, and steel. New concrete alternatives such as algae-based cements (Prometheus, 2023) and ground glass pozzolans (Sioneer, 2023) are creating local, circular economies. Timber is being more widely used with increased code acceptance, and embodied carbon of steel is being mitigated with wider use of electric arc furnaces on cleaner electrical grids. As whole building life-cycle assessments of buildings and urban environments have shown, these common high-volume materials must decarbonize to meet the carbon reduction needs.

Many new building materials are being used as carbon storage vaults to lock up harmful carbon from emitting back into the atmosphere. For example, CO₂ is being injected into concrete for enhanced properties and long-term storage (CarbonCure, 2023), expanded use of mass timber, and other new carbon sequestering technologies are emerging rapidly. The importance of protecting these structures has expanded from one of life-safety to one of vital environmental consequence. This is of particular importance in areas of moderate to high seismic risk where a single event can emit mass quantities of carbon into the atmosphere due to the initial damage and during the subsequent carbon-intensive repair and rebuild.

Figure 1. Resiliency.

Thus, the need for resilience in buildings is growing as buildings become carbon sinks addressing climate change. This is especially true for buildings located in regions of seismically activity. Thus, a new era of resilience is here which expands beyond its traditional definition to include the carbon stored in the built environment.

1.2 *Urgency for fully recoverable seismic systems*

Nearly all seismic force resisting systems in today's building code are fundamentally based on controlled damage resulting in hysteretic damping and energy dissipation. The damping and energy dissipation are vital to reduce the seismic demands to manageable levels. Concrete shear walls, eccentric braced frames, and steel/concrete moment frames are used in nearly every building construction throughout the world and all of them work on this principle. While this approach, when detailed and constructed correctly, has been shown to be reliable for life-safety in a single large earthquake (Maffei, 2014), they have also been shown to require significant repairs or entire replacement after a large seismic event.

The development of cost-effective seismic force resisting systems which can be easily repaired or require no repair at all are vital to the protection of life during an earthquake, minimization of repair/replacement after an earthquake, and long-term protection of carbon storage in buildings. The use of non-traditional materials which meet these needs is required. These materials must be rigorously developed, tested, and smartly deployed to be effective.

1.3 *Shape memory alloys*

Shape Memory Alloy (SMA) materials such as Nitinol (nickel-titanium) have been used in niche applications since the 1970s, but in recent years it has become widely used in medical devices such as heart stents, aerospace components, and deep space applications due to their reliable performance, high corrosion resistance, while reducing material costs.

SMA are metallic alloys typically composed of multiple metallic elements including nickel-titanium ("Nitinol"), copper-zinc-aluminum, and iron-manganese-silicon-chromium-nickel (Ozbulut, 2011). While not the lowest cost, nitinol is the most widely used SMA type due to its favorable performance at a wide range of temperatures and high-corrosion resistance. Copper-based SMA are typically the lowest cost and have similar performance in many regards to nitinol, but Copper-based SMA have lower-stiffness than nitinol and do not share nitinol's corrosion resistance. Iron-based SMA are stiffer, but do not share the wide performance range of nitinol. While copper-based and iron-based SMA have potential for further development in seismic-force resisting systems, nitinol is ready for immediate application and considered for this investigation.

SMA are complex materials whose physical response to deformation depends on the magnitude of strain and material temperature. Also, as described above there are a wide variety of SMA material types. To describe their behavior for this investigation the following focus on superelastic nitinol at a material temperature range of 0C to 40C (32F to 104F).

1.4 *Traditional steel and SMA behavior under deformation*

Steel used in building applications is ductile. This ductility stems from the crystalline structure of common structural steels which have numerous slip planes. The high number of slip planes allow for numerous successive slips to occur under increasing deformation. Each new slip plane allows for further and further elongation which structural engineers call ductility. As described above, ductility allows for energy dissipation which is fundamental to traditional seismic force resisting systems.

SMA have few slip planes. Typically, this is not favorable for building applications because materials with few slip planes tend to crack or rupture because the crystalline structure cannot slip along multiple planes. Instead of moving along slip planes the SMA material undergoes a stress-induced or temperature-induced phase change between a stiffer austenite phase and a softer martensite phase which can experience significant deformations without forming slip

planes. A phase change due to temperature change is typically termed the ‘shape memory effect’ and a phase change due to stress is typically termed ‘superelasticity’. Since slip planes are not created, only phase changes are occurring, the deformation is fully recoverable.

To control and fine tune the behavior of SMAs at common temperature ranges an SMA is produced to be either a shape memory SMA or a superelastic SMA. Both types can be nitinol-based but their exact metallurgy and resulting behaviors are fine tuned for specification applications.

The ‘movement’ of SMAs is due to the current phase ‘wanting’ to shift to a lower energy state. For shape memory SMAs this is commonly seen when applied heat changes the lowest energy state causing the material to change phase and therefore ‘move’ to a prior ‘trained’ geometry. For superelastic SMAs this is commonly seen when applied stress changes the phase, but the new phase is not the lowest energy state causing the material to ‘pull’ back to its prior geometry as the applied stress is reduced.

2 RECOVERABLE MATERIALS

2.1 Behavior of single SMA wire

Superelastic SMA is used for this application. The material can be composed into a wide range of geometries including wire, bar, spring, washer, etc. SMA wires can be commercially procured ranging from 0.02mm to nearly 2mm. For this application 1mm wires are used.

The stress-strain relationship of superelastic nitinol material is well represented by a single wire. Below is the stress strain relationship for a superelastic nitinol wire. Several common terms are defined below and described in Figure 2:

- UPS: Upper Plateau Stress
- LPS: Lower Plateau Stress

Figure 2. Stress vs strain of single nitinol wire.

For the nitinol used in this investigation the UPS is 483 MPa (70 ksi) and the LPS is 138 MPa (20 ksi). The UPS and LPS plateaus are generally flat in their martensite phase within their recoverable range. Beyond 6% strain permanent deformation occurs. At the strain a peak stress of 1,241 MPa (180 ksi) is observed. It is noted that these properties appear change when composed into a wire rope, but that is a result of geometry, as discussed later.

As can be observed, the hysteresis is fully recoverable up to 6% strain which is quite remarkable considering traditional structural steel is only fully recoverable (elastic) up to about 0.2% strain.

As a comparison of single superelastic SMA Nitinol wire and traditional structural steel (A592 Grade 50 ksi (350 MPa)), a stress versus strain relationship is shown below. As evident in the Figure 3, steel has a much higher initial elastic stiffness. Also, the yield stress of steel is between the upper and lower plateau of nitinol. Beyond 6% strain the nitinol stress ramps up quickly while steel remains relatively constant. This relationship will change for different steel and SMA materials, but the general trends are important for building designers to understand.

Figure 3. Stress vs strain for SMA nitinol wire and structural steel.

2.2 Behavior of SMA wires composed as a rope

The behavior of wires composed into a rope is different than a single wire. This is due to several factors, but perhaps most predominate is the differential elongation of each individual wire in the rope. If the rope has a uniform strain, each wire will have different strain magnitudes due to the different lengths of each individual wire.

For this application a 7x7 wire arrangement is used with 1 mm diameter wires. The total 49 wires act as a single unit, but the stress strain behavior differs from that of a single wire as shown below. The upper and lower plateaus are sloped compared to a single wire and the energy dissipation is slightly less. In Figure 4 below the solid blue line shows testing within the fully recoverable range of 6%, beyond 6% some of the individual wires will strain beyond their fully recoverable limit while the remainder are fully recoverable. Even up to 7% strain enough of the 49 wires remain fully recoverable such that the residual strain is negligible.

Several key studies considering strain rate effect (Ozbulut & Hurlebaus, 2010), corrosion (McCarty, 2006), and other key factors (Ozbulut et al., 2011) have been reported on by prior researchers.

2.3 Analytical representation of SMA wire or rope

This numerical representation of SMA wire or rope is a unique challenge for structural engineers since most seismic components with established numerical models are based on traditional structural steel with plastic/permanent deformations. The fully recoverable ‘flag’ shaped hysteresis of SMA is unique. Domenico & Gandelli (2021) proposed a novel modeling method which can be used in traditional structural analysis software such as ETABS and SAP2000. This method has been successfully adopted for the current investigation as demonstrated below comparing laboratory testing results and numerical modeling in ETABS.

Figure 4. Stress vs strain of nitinol wire rope used in this investigation.

Figure 5. Numerical modeling of SMA wire rope.

3 CONNECTING TO BUILDING FRAMES

3.1 Swaged connection

Studies conducted by Ozbulut et al. (2011) reviewed prior works and explored the potential of a wire rope swaged connection with favorable results. Prior efforts with rods and threaded connections were unable to develop the full material strength and elongation due to localized concentrations of strain. The swaged connection was able to develop the material's full potential of 13.5% strain at wire rope failure. This is very similar to a single wire showing the connection develops the potential of the wire rope without stress concentrations. Also, the failure was within the gage length and not in the connection.

Figure 6. SMA wire rope swaged connection.

Investigators tested SMA wire rope swage connections produced from several traditional swaging companies in blind testing, and all showed similar results to that found by Shi et al (2021).

3.2 Swage to tension rod

The swaged connection must be composed into a building frame to resist seismic forces of the building. Investigators elected to use a novel connection that concentrically develops the force of multiple wire ropes. When composed into a tension-only bracing system a simple, yet effective bracing system is conceived which is termed SMA Tension Rod System. This system could be used in a variety of configurations including “X”, “V”, and inverted “V”. A key advantage of this system is the revival of tension-only braces as a seismic force resisting system which is generally not permitted for large structures in moderate to high seismic zones. The use of tension only bracing can allow new opportunities for structural and architectural designers to incorporate slender and minimal exposed systems into building architecture instead of relegating it to non-visible locations.

Figure 7. SMA connection to tension rod render (top) and photo (bottom).

4 SHAKE TABLE TESTING

4.1 Shake table testing description

To better understand the dynamic behavior of the SMA Tension Rod System and its sub-assemblies in a building frame, shake table testing was conducted by the investigators in a large-scale testing frame with three floors at the Pacific Earthquake Engineer Research (PEER) Center. Detailed instrumentation included floor displacement, floor acceleration, overall tension rod axial displacement, device axial displacement, tension rod force, and other key recordings. The beam-column connections were fixed, thus the lateral force resisting system was the SMA tension rod system and an elastic moment frame. Numerous ground motions were scaled from 20% to 100% of the original recording. Strains in the devices went up to 8% for select ground motions. Even though some ground motions exceed the anticipated recoverable limit of the devices, they continued to perform well in subsequent testing. This demonstrates the robust nature of the SMA tension rod system.

Figure 8. Shake table frame on table (left) and enlarged elevation of level 1 (right).

4.2 Shake table testing results

After the shake table testing the obtained data was reviewed and post-processed to better understand the numerical model prediction of the SMA Tension Rod System force response. In general, the experimental results align well with the numerical prediction in comparison to shake table testing of traditional seismic force resisting systems. It is noted that the acceptable accuracy of numerical prediction in a shake table test compared to pseudo-static testing is different. For shake table testing results, it is determined that the results of numerical prediction are acceptable when compared to other similar testing of steel and concrete energy dissipation components.

Figure 9. Numerical prediction vs shake table results.

5 CONCLUSION

With the increasing acceptance of carbon storage in as a means to mitigate climate change, a new era of resilience is here. The implementation of fully recoverable seismic force resisting systems is vital to the increased protection of our environment. As shown through this investigation, the use of shape memory alloys composed in a SMA tension rod system can be an important part of the resiliency of our urban fabric. The numerical and experimental testing results of this system demonstrate that SMA wire ropes composed into a SMA tension rod system are ready for full-scale deployment in buildings in regions of moderate and high seismic risk.

Design of the urban sequoia tower

M.P. Sarkisian, E. Long, A. Beghini, K. Micallef & S. Jaberansari
Skidmore Owings & Merrill, San Francisco, CA, USA

ABSTRACT: What if builds were more like trees and cities were more like forests? The concept of Urban Sequoia combines optimized structural design with low embodied carbon materials, efficient construction, and carbon-capturing technologies to transform carbon producers into carbon consumers. These carbon-capturing approaches allow buildings to start their service life with an ultra-low embodied carbon and sequester additional carbon over time, becoming net carbon negative. The structural approach to Urban Sequoia incorporates nature-based, living materials that embody far less carbon than conventional structural solutions while absorbing additional carbon over time. When combined with non-structural systems such as exterior wall systems that incorporate biomass and algae and technologies including Direct Air Capture (DAC), tall buildings could absorb three to five times the amount of carbon emitted at the time of construction. Urban Sequoia includes ideas that can be applied to buildings at all scales and uses. The floor framing system, for example, could be used in a building with only a few floors or one that has a hundred floors. The strength of the concept is enhanced when buildings that make up a city combine to become a source of biofuel that can be used to power heating systems, automobiles, and aircrafts and create bioprotein. An even broader impact could include using carbon byproducts for infrastructure.

1 INTRODUCTION

The concept of Urban Sequoia (Figure 1) combines optimized structural design with low embodied carbon materials, efficient construction, and carbon-capturing technologies. These carbon-capturing approaches allow buildings to start their service life with an ultra-low embodied carbon and sequester additional carbon over time, becoming net carbon negative. The structural approach to Urban Sequoia incorporates nature-based, living materials that embody far less carbon than conventional structural solutions while absorbing additional carbon over time. When combined with non-structural systems such as exterior wall systems that incorporate biomass and algae and technologies including Direct Air Capture (DAC), tall buildings could absorb three to five times the amount of carbon emitted at the time of construction. Urban Sequoia includes ideas that can be applied to buildings at all scales and uses. The floor framing system, for example, could be used in a building with only a few floors or one that has a hundred floors. The strength of the concept is enhanced when buildings that make up a city combine to become a source of biofuel that can be used to power heating systems, automobiles, and aircraft and create bioprotein. An even broader impact could include using carbon byproducts for infrastructure.

2 LOW EMBODIED CARBON

The initial embodied carbon in a structure must be driven to absolute minimums to go beyond carbon neutrality. Materials and construction are vital components in a building's initial embodied carbon assessment. Materials must have low embodied carbon, high strength-to-weight ratios,

components with injected carbon, and components that have already sequestered carbon. The construction process must require minimal time to build and include alternative processes such as robotics. Before conceptualizing the structural design of Urban Sequoia, available low-carbon materials and emerging technologies needed to be understood and a construction process curated for them.

Figure 1. Urban Sequoia concept applied at a city scale.

Figure 2. Urban Sequoia concept plan and diagram.

3 ADVANCED MATERIAL INCLUDING THOSE THAT ABSORB CARBON

High strength materials combined with optimization analyses that carefully assess the placement of materials for given loadings are an essential initial basis for design to reduce embodied carbon. However, this approach alone is not nearly enough. Advancing existing materials to lower their embodied carbon and developing new building materials which absorb carbon is also essential to success.

Portland cement is currently responsible for more than 5% of global CO₂ emissions. Therefore, low embodied carbon products used to replace part or all of the portland cement content in concrete like fly ash or slag can directly impact and significantly reduce global carbon emissions. An alternative Supplementary Cementitious Material (SCM) is recycled ground glass.

Low-carbon concrete made with carbon-neutral portland cement and other cementitious materials could become an environmentally friendly material that yields similar or superior performance characteristics to traditional portland cement and has a low carbon impact. An emerging technology, for example, allows for the extraction of lime (CaO), which is used to produce ordinary portland cement, from calcium silicate (Ca₂SiO₄) rather than limestone (CaCO₃); thus eliminating the CO₂ emission due to traditional lime extraction. Furthermore, as a waste byproduct of this process, magnesium hydroxide (Mg(OH)₂) can absorb CO₂ from the air resulting in magnesium carbonate (CMgO₃) that permanently sequesters CO₂. The overall process reduces the CO₂ emissions associated with portland cement production by up to 60%, which, combined with the sequestration from magnesium hydroxide, renders the final produced cement net-zero or even net negative carbon.

High-strength recycled steel typically contains up to 70% recycled content. Strengths of available structural steel and reinforcing steel for concrete continue to increase along with increasing fire and corrosion resistance. Ultra-high-strength reinforcing materials such as carbon fiber offer an excellent alternative to conventional reinforcing in concrete and can also replace high-strength reinforcing steel commonly used for prestressing.

Structural materials which sequester and store carbon over their life include algae-based concrete, hempcrete, timber, Mycelium, and carbon sequestering fillers and aggregate. algae-based concrete, developed at the University of Colorado, Boulder, is a Living Building Material (LBM) created by combining a sand-hydrogel scaffold with *Synechococcus* sp. PCC 7002, a photosynthetic cyanobacterium. The algae-based concrete are essentially made of food-based products and use biology to provide a structural binder to any aggregate type. When using fine sand without coarse aggregate, the structural material strength of the algae-based concrete is comparable to common concrete masonry units, with the advantage that the tensile strength of the material is considerably higher, offering a potentially wide range of applications where some tension demands exist.

Hempcrete is a biocomposite material that is a mixture of hemp shives (the woody inner portion of the hemp stalk broken into pieces), water, lime, and sand or cement binder. The strength of the material is limited, so the use is typically appropriate for non-structural components.

Carbon sequestration of timber-based products occurs when atmospheric CO₂ is sequestered in the production of biomass through photosynthesis. The trees emit oxygen in return and permanently store the carbon until the material is combusted for fuel or decays in a landfill. Bamboo and other fast-growing grasses, including straw, are considered one of the best carbon-sequestering materials because of the rate at which it grows. For example, *Guadua Angustifolia* bamboo sequesters as much carbon in 6 years as douglas fir does in 34 years.

Mycelium consists of a mass of thread-like branching fungus and is typically combined with natural fibers to increase its strength characteristics. Although overall material strengths are low, Mycelium has an excellent strength-to-weight characteristic and are used in non-structural components (e.g., insulation).

Finally, emerging technologies have resulted in carbon sequestering aggregates that can sequester carbon from the atmosphere. For example, through the process of mineralization, carbon is captured from natural gas-fired or similar fossil fuel-generated energy facilities and permanently stored in synthetic limestone.

4 DESIGN FOCUSED ON CONSTRUCTION

A significant amount of carbon is emitted during the construction process, in some cases accounting for up to 25% of a building's embodied carbon. The carbon associated with site construction includes emissions from machinery required to build, materials shipped from disparate locations, transportation of personnel required, and the like. Given the known properties of low carbon materials, how do we design for construction differently? What properties does low Portland Cement or even low-carbon concrete have, and how do we address them via the construction process, such as setting time? What type and size of steel are available from electric arc furnaces fueled with renewable energy? The answers to these questions should inform structural design.

As a widely used material for building structures, concrete has known embodied carbon associated with the construction process primarily centered around formwork and the number of days per floor in the construction cycle. Optimizing cores and columns for ease of vertical forming systems and floor plate geometry (for ease of horizontal forming systems) can help reduce floor-to-floor cycles from 7 days to 5 days to even 3 days. A common characteristic of low portland cement and low-carbon concrete is low early strength and extended time to gain higher design strengths. While this seems at odds with the desire to achieve fast floor-to-floor cycles, the construction process could involve precast to allow the material to reach necessary strength off-site and be quickly erected on-site, still achieving fast floor-to-floor cycles. Another approach is to provide formwork systems that are part of the permanent structural design such as algae-based concrete masonry unit or similar carbon-neutral materials from emerging technologies. These formwork systems are not removed, allowing the low-carbon concrete to have extended time to reach design strength. These approaches to the construction process lead to the pre-assembly of major building components to minimize construction time, waste, and associated carbon.

5 STRUCTURAL SYSTEM

The Urban Sequoia Tower is conceptually organized around a tubular geometry integrating systems of vertical circulation, movement of air to the Direct Air Capture system, and movement of biomass and algae around the perimeter of the program space. The programmatic space is organized into eight petals around the tubular core (Figure 2). The structural system is directly integrated into this tubular geometry. It is articulated in a central structural core, perimeter gravity columns, and a floor framing system spanning between the core and the perimeter columns.

The low-carbon concrete core is considered a circular tube divided into four quadrants. Each quadrant contains two circular shafts forming the basis of the precast concrete module. Elevators can occupy a circular shaft, or two shafts could be combined to create a stair shaft. The shafts are lined with a recycled steel liner that extends above the top of the precast, serving as a shear key between precast units. The precast units are vertically tied together with vertical post-tensioned recycled steel strands and linked horizontally with a link beam element (Figure 3).

Figure 3. Urban Sequoia structural system overview.

Perimeter precast columns with low-carbon concrete are located in the inner concave portions of the petals geometry. The horizontal framing system is similarly organized around the eight programmatic floor spaces directly connecting the perimeter columns to the center core. The low-carbon precast beam framing is curved in plan around each petal, leaving an open circular floor space in the center of each petal (Figure 3). The precast beams incorporate prefabricated ducts for post-tensioned strands and large diameter air ducts to directly capture outside air from the perimeter and channel it to the central tubes inside the core using the naturally occurring positive and negative air pressures from wind. The precast columns are also laced together with post-tensioned strands made with recycled steel.

The circular floor space between post-tensioned precast beams is infilled with leave-in-place algae-based concrete masonry unit formwork panels cast into eight pie-shaped elements and an octagonal (or circular) centerpiece. The pie-shaped segments are vaulted to keep the material in pure compression and minimize the thickness required. The flooring system is completed with a low-carbon concrete topping slab that works compositely with the formwork (Figure 3).

6 COMPARISON OF URBAN SEQUOIA TO A BENCHMARK BUILDING

The continuously growing industry of residential high-rise construction provides a meaningful basis to evaluate the carbon emission reduction potential of the Urban Sequoia Tower. The Benchmark Tower project is a high-performing 42-story, 420-foot-tall, 450,000-square-foot

reinforced concrete residential tower recently designed and constructed in San Francisco (Figure 4a). The structural system for the tower includes a core-only lateral load-resisting system and perimeter gravity columns with post-tensioned flat slabs for the gravity system. The typical tower floor plan and size of structural elements are illustrated in Figure 5a. This project is located in a high seismic hazard zone and was designed with particular attention to seismic resilience and environmental sustainability.

The tower considered was designed using a performance-based design process and was highly optimized in terms of structural material utilization compared to other structures of similar height, geometry, and site characteristics. This approach led to a reduction in structural embodied carbon by more than 20% compared to a similar building.

The total embodied carbon equivalent intensities associated with A1-A3 (Cradle-to-Gate) Life-cycle stages, according to the EN 15804 standard for the primary structural components for the Benchmark Tower, are reported in Table 1 for reference.

Table 1. Benchmark Tower A1-A3 embodied carbon intensities.

Structural Element ¹	Concrete ² (lb.CO ₂ e/sf)	Post-Tensioning Tendon ³ (lb.CO ₂ e/sf)	Steel Reinforcement ⁴ (lb.CO ₂ e/sf)
Shear wall core	10.0~11.0	0	5.5~6.5
R/C columns	1.5~2.0	0	1.0~1.5
PT slabs	20.0~21.0	2.2~2.7	2.5~3.0

Notes:

1- Embodied carbon metrics of the miscellaneous structural elements are not listed in the table.

2- Embodied carbon metrics are taken as 708~928 lb.CO₂e/cy depending on type of concrete based on the NRMCA, Member Industry-Average EPD For Ready Mixed Concrete.

3- Embodied carbon metrics are taken as 2.27 lb.CO₂e/lb based on the ICE, Industry average: Steel, Wire rod.

4- Embodied carbon metrics are taken as 0.98 lb.CO₂e/lb based on the CLF, 2021 Material Baselines.

Figure 4. Axonometric view of the Benchmark Tower (a) and Urban Sequoia Tower (b).

The Urban Sequoia Tower represents the next generation of residential buildings with excellent opportunities to reduce embodied carbon and become net negative carbon over its operational life. For example, considering an Urban Sequoia Tower of equivalent floor and the total area to the Benchmark Tower results in an overall tower diameter of 126 feet (Figure 5b) with the same typical 10-foot floor-to-floor height, number of stories, and total tower height.

The precast cellular core has wall thicknesses varying from 24 inches at the base to 14 inches at the top and utilizes low-carbon concrete with a strength of 8,000 psi at the bottom two-thirds of the tower and 6,000 psi in the top one-third of the tower. The crescent-shaped precast columns vary from 170 by 30 inches at the base to 170 by 20 inches at the top. The columns utilize low-carbon concrete with a strength of 8,000 psi in the bottom two-thirds of the tower and 6,000 psi in the top one-third of the tower.

Figure 5. Structural plan of Benchmark Tower (a) and Urban Sequoia Tower (b).

The total embodied carbon equivalent intensities associated with the primary structural components for the Urban Sequoia Tower are summarized in Table 2.

Table 2. Urban Sequoia Tower A1-A3 embodied carbon intensities.

Structural Element	Concrete ² (lb.CO ₂ e/sf)	Post-Tensioning Tendon ³ (lb.CO ₂ e/sf)	Steel Reinforcement ⁴ (lb.CO ₂ e/sf)	Steel Plate ⁵ (lb.CO ₂ e/sf)
Precast shear wall core	1.2~1.4	1.7~1.9	1.4~1.7	0
Precast columns	0.3~0.4	0.7~0.9	0.7~1.0	0
Precast beams & girders	1.2~1.4	0.9~1.1	0.2~0.4	0
Algae-based concrete masonry unit ⁶ formwork	~0.0	0	0	0
Topping slab	1.4~1.6	0.9~1.1	0.4~0.6	0
Steel liner	0	0	0	0.5~0.7

Notes:

1- Embodied carbon metrics of the miscellaneous structural elements are not listed in the table.

2- Embodied carbon metrics are taken as 106~139 lb.CO₂e/cy based on the NRMCA, Member Industry-Average EPD For Ready Mixed Concrete and modified for Low-Carbon Concrete emerging technologies.

3- Embodied carbon metrics are taken as 2.27 lb.CO₂e/lb based on the ICE, Industry average: Steel, Wire rod.

4- Embodied carbon metrics are taken as 0.49 lb.CO₂e/lb based on the Nucor Recycled Steel Rebar EPD.

5- Embodied carbon metrics are taken as 1.26 lb.CO₂e/lb based on the CLF, 2021 Material Baselines.

6- Material alone yields net carbon absorption (net-zero with the current assembly process).

The total A1-A3 structural embodied carbon of the Benchmark Tower adds 9,500~11,700 tons of CO₂e, while the Urban Sequoia Tower contains only 2,800~3,400 tons of CO₂e, representing more than 70% reduction in CO₂e. This extremely low starting point for structural embodied carbon is achieved by employing technologies available today or otherwise close to commercialization. Further embodied carbon reduction will be achieved by replacing low carbon concrete with biogenic materials opening up avenues to structural embodied carbon neutrality. For example, with the current developments of the algae-based concrete material, it is anticipated that the material and related assembly process will yield net carbon absorption. Nevertheless, the low embodied carbon based on today's technologies combined with the additional carbon absorption enabled by the algae façade and Direct Air Capture technologies renders Urban Sequoia Tower in Figure 4b can absorb 39,000 tons of CO₂e over a 60-year life span, where 25% of operational carbon sequestration comes from the algae façade and Direct Air Capture technologies sequester the remaining 75%.

7 CONCLUSIONS

The urban sequoia concept combines a broad range of sustainable design thinking, including emerging technologies, and applies them at scale in a tower. By combining optimized structural design resulting in minimal materials and integrating biomaterials, biomass concepts, and carbon-capturing technologies into an integrated system, the urban sequoia can achieve substantially more carbon reductions than using these techniques separately. Combining these systems in a typical residential tower based on today's technologies can result in the sequestration of as much as 650 tons of carbon per year, equivalent to 31,500 full-grown trees each year.

M. Stringer

Holmes US, San Francisco, USA

N. Wang

Skidmore, Owings & Merrill, San Francisco, USA

ABSTRACT: The SE2050 program is sponsored by the Structural Engineering Institute (SEI) of the American Society of Civil Engineers (ASCE) with the aim to reach net-zero embodied carbon of structural materials by the year 2050. This goal is based on global carbon targets for building materials required to limit to a 1.5-degree temperature increase per the Paris Climate Agreement. Approximately 100 independent design firms across the U.S. have joined this program. Firms committing to join the program follow four steps: sustainable practice education, embodied carbon tracking on projects, embodied carbon reduction in designs over time and advocacy for change with architects, contractors and owners. SE2050 is building a structural embodied carbon database for U.S. projects to establish carbon benchmarks and track industry-wide carbon emissions towards a net-zero future.

Engineers looking at the bigger picture should think holistically about limiting environmental impacts. This paper explores this program in comparison to other global industry efforts for embodied carbon reduction. The structural design process impacts are explored, presenting resources provided to designers and how firms incorporate carbon calculations into practice.

1 INTRODUCTION

The SE 2050 Commitment Program is a collection of US-based structural engineering firms who have committed to reducing the embodied carbon of the structural materials in their designed buildings by 2050. This paper will present an overview of the program, including its development and current status at the national scale. To understand how this commitment program affects the work of individual firms, a summary of specific items from Skidmore, Owings & Merrill (SOM), an early member of the program, will be provided.

2 TIMELINE OF SE 2050

The SE 2050 Commitment Program originated in grassroots style from structural engineers who recognized the necessity of the structural engineering profession to engage more actively in conversations surrounding sustainability. Upon the announcement of the American Institute of Architects (AIA) 2030 commitment program in 2009, several structural engineers began to formulate a program that would specifically address the embodied carbon of structures. These early conversations occurred predominantly within the Carbon Leadership

Forum (CLF) community, a US-based organization of engineers, architects and other designers interested in addressing embodied carbon in buildings. In collaborating with key national organizations, including the American Society of Civil Engineers Structural Engineering Institute (ASCE-SEI), the AIA and the United States Green Building Council (USGBC), the CLF created a commitment program focused on embodied carbon reduction, This SE 2050 Challenge was presented and endorsed by the SEI Board of Governors.

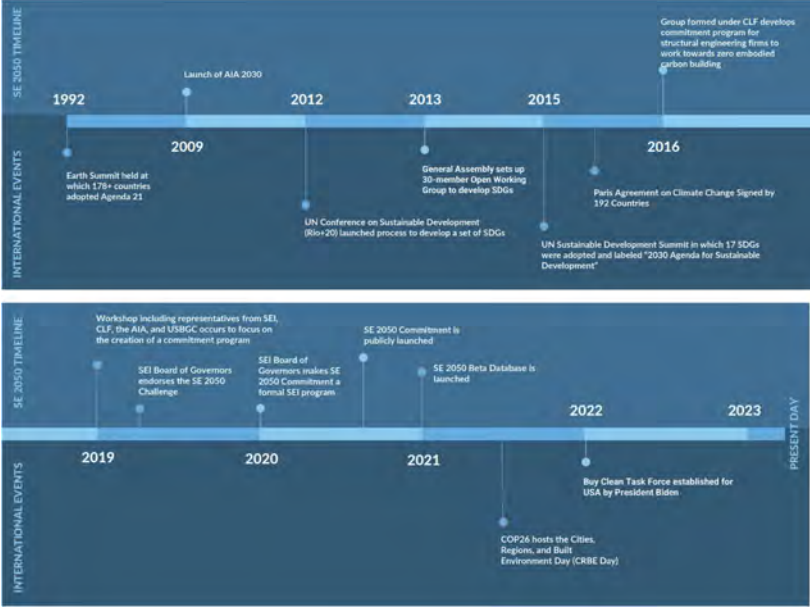

Figure 1. SE 2050 Timeline.

After endorsing the SE 2050 Challenge, SEI officially launched the SE 2050 Commitment as a subcommittee of the SEI Sustainability Committee in 2020. The SE 2050 subcommittee has gained over 30 dedicated members and the support of nearly 100 engineering firms across North America. In mid-2021, SE 2050 launched its beta database in which firms submit life cycle assessment (LCA) data on their projects. Still in the early stages of its existence, SE 2050 continues its focus on advocacy for sustainable structural design, growth of firm commitments, and refinement of the database. Figure 1 (TOP) highlights key moments of SE 2050 to this point.

It is important to recognize how SE 2050 fits into the broader landscape of sustainability-focused movements. To demonstrate, Figure 1 (BOTTOM) additionally displays notable conferences and governmental commitments related to international cooperation on addressing the climate crisis.

Such a timeline shows how international declarations spur on conversations within industry. Between the Launch of AIA 2030 in 2009 and the SE 2050 Challenge of 2019, ten years of international work on developing the United Nations Sustainable Development Goals (SDGs) took place. These SDGs are widely considered the most comprehensive assessment on the meaning of sustainability, and they act as goal posts for both governments and the private sector. Indeed, the UN SDGs are referenced within several of the ECAPs submitted to SE 2050 (read more in Section: ECAPS). The Figure 1 timeline shows that within half a decade of governments signing the Paris Agreement on Climate Change, the recognized importance of establishing sustainability within the built environment grew significantly. This is exemplified by COP21 at which an entire day was labeled Buildings Day. This day studied the operation and embodied carbon of buildings and put specific items on the international agenda as they

relate to the embodied carbon of buildings. COP21 was the first time an inter-governmental event on climate action has dedicated such a significant amount of time to buildings.

As sustainability movements related to structural systems continue to grow, SE 2050 aims to use the momentum of international movements as well as its own recent history of influence and transform them into education and action across the structural engineering industry.

3 SE 2050 ENGAGEMENT: ADVOCACY & EDUCATION

Since officially launching at the Greenbuild International Conference & Expo in November 2020, SE 2050 has sought to increase industry engagement in the embodied carbon conversation through education and advocacy.

Over the past two years, subcommittee members of SE 2050 have presented at building conferences and conventions across North America. Members have presented at notable building conferences such as Greenbuild International Conference & Expo (2020), Structures Congress (2020), the International Association for Bridge and Structural Engineering (IABSE, 2021), the Structural Engineering Association of California (SEAOC, 2021), and the Net Zero Conference (NZT, 2022).

In addition to speaking at large-scale conventions, SE 2050 has targeted smaller audiences through presentations at local CLF meetings, seminars for students at high schools and colleges, and by providing presentations to firms who are interested in joining the SE 2050 program and/or are new to the embodied carbon conversation and have questions.

More recently, SE 2050 has been called upon to develop seminar series to provide guidance in performing life cycle assessments (LCAs) on structural systems. SE 2050 members have developed several documents on best practice methodologies for specific structural systems, which can be found at the SE 2050 website. Developing educational tools is particularly noteworthy for, while the definitions and methodologies for such practices continue to take new form, establishing common principles amongst practitioners is crucial to validation. Therefore, SE 2050 acting as a common thread amongst firm sustainability education is an important new phase of the program.

Taken together, these advocacy and education actions highlight the reach that SE 2050 has attained since its launch. Dedicated SE 2050 members have spoken and advocated data-driven sustainability goals to hundreds, if not thousands, of structural engineers. It is now common for subcommittee members to be attendees at seminars in which SE 2050 is referenced as a key industry movement. Presenting to industry professionals has been crucial to SE 2050's growth and such presentations continue as a key aspect of the program's net zero strategy.

4 SE 2050 COMMITTED FIRMS

The SE 2050 program is premised on volunteered firm engagement. As such, both the level of engagement the number of committed firms are primary attributes of the program's achievements.

Figure 2. SE 2050 Committed Firms.

SE 2050 is proud of the steady growth in firm commitments over the past 2 years. Through advocacy of the program and education on the cause, SE 2050 has successfully garnered the commitment of about 100 firms within two years.

Additional to the remarkable speed at which structural engineering firms have committed to the SE 2050 program, is the demographic range of these firms. As shown in Figure 2, firms are committed across all Northern America. It is worth noting, that pegged locations represent the original “signed on” firm such that firms with multiple offices are represented with only one peg. Therefore, Figure 2 conservatively visualizes the office locations that are working to achieve the SE 2050 stated program goals. As a note, multiple offices are captured in the SE 2050 program requirements—for example, a multi-office firm is currently required to submit two LCAs per office (though not required to submit more than five LCAs across offices).

In addition to office location, the number of employees of committed firms ranges considerably. Firm size is an important aspect of how the SE 2050 Subcommittee continues to discuss and formulate future program requirements. As a program, inclusivity and representation across the full range of structural engineering firms is considered critically important to achieving carbon reduction goals (read more in Section on Future Goals).

Figure 3. SE 2050 Firm Types.

5 EMBODIED CARBON ACTION PLANS

Embodied Carbon Action Plans (ECAPs) are central to firms’ engagement with SE 2050 and the path to net zero embodied carbon structures. The ECAP articulates how a firm will Educate, Report, Reduce, and Advocate for the sustainability of building structures. When firms engage with SE 2050, they are referred to the SE 2050 Program Requirements Guidance Document. In addition to other program requirements, this document provides details on ECAP deliverables which can be summarized in the following actions:

- Provide an outline of your firm’s strategy to educate employees about embodied carbon and advocate for net zero embodied carbon structures
- Provide an outline of your firm’s embodied carbon reduction work to report externally
- Specify measurable goals to assess your firm’s process in reducing embodied carbon in project work

ECAPs are to be submitted yearly and published on the SE 2050 website. Currently, 65 firms have published their ECAP. Several firms have already submitted an updated ECAP for their second committed year.

The collection of ECAPs that SE 2050 has aggregated is a unique and encompassing data set in and of itself. For this paper, all submitted ECAPs were assessed. The outcome of the study revealed common goals, actions, and statements of firms as they relate to sustainability. Additionally, this study shows the general status of data collection capabilities as well as embodied carbon reduction strategies.

5.1 Educate and advocate

Embodied Carbon Action Plans (ECAPs) are central to each firm’s engagement with SE 2050 and the path to net zero embodied carbon structures. The ECAP articulates how a firm will Educate, Report, Reduce, and Advocate in its commitment to SE2050.

From the 65 unique firm ECAPs, it is apparent that the structural engineering industry acknowledges their role in the management of embodied carbon and supports the SE 2050 mission to achieve net zero embodied carbon for structures by 2050. In the ECAPs, all firms state a repeating educational event for sustainability. More specifically, 60% of ECAPs showed the creation of internal working groups for embodied carbon reduction as separate from a general sustainability team.

Most ECAPs refer to the AIA 2030 Commitment and several go on to explain the relationship between operational carbon versus embodied carbon. Noted here is the chart demonstrating the in-step relationships carbon reductions on both fronts should attain (SEI Sustainability Committee, 2018).

Figure 4. SE 2050 Firm Types.

In addition to AIA 2030, ECAPs demonstrate that most firms engage with several sustainability-related organizations and movements. In fact, 65% of ECAPs list their partnerships with other “green” organizations (e.g., CLF, USGBC, LEED, NCSEA, Green Globes, IStructE, etc.). Less common, but of interest, is that 23% of firm ECAPs state the firm’s interest in driving policy and/or code requirements as related to sustainability structural systems. SE 2050 is itself explicitly partnered with CLF, IStructE, and NCSEA and believes that the combined influence of like-minded organizations is important to achieving net zero.

A common set of statements amongst firm ECAPs surrounds advocacy of processes that would better facilitate sustainable design. As a percentage of ECAPs: 65% stated the need to onboard the client as an initial or highly important step, 60% referenced the benefit of greater access to product specific EPDs and their desire to use them in specifications, and 46% stated a high benefit in engaging across disciplines and stakeholders early in the design process for sustainability goals.

5.2 Report

As stated, firm reporting is integral to the success of SE 2050. Therefore, ECAPs are required to explain how a firm will collect and report its LCA data. As such, 72% of firms explicitly listed the LCA tool they are using. Most firms are using external tools like Tally, OneClick, or Athena, but 22% of firms reported that they are developing internal tools to conduct LCAs. Currently, these tools are shown to have significant differences in GWP evaluation. As explain in the SE 2050 Database Section, one input parameter for the SE 2050 database is the LCA tool used. Understanding how outcomes differ across tools will be important in refining the LCA process.

With the need for tool refinement in mind, it is unsurprising that 72% voiced the need for more data prior to establishing reduction targets. This signals a clear need for the database that SE 2050 is developing. While SE 2050 is working to establish program requirements related to year-by-year reductions, 11% of firms studied have already established their own internal reduction targets ranging 5% - 30% over the next few years. Oppositely, 14% of firms state limited resources availability to establish baselines making reduction targets difficult to establish.

5.3 Reduce

While reporting and setting clear reduction goals is important to achieving net zero, there are many actions firms can take now to reduce the embodied carbon of their designs. Many firms recognize this and list actions for reduction in their ECAP. The most common action being taken is editing General Notes/Specifications. Sixty percent of firms state they will be implementing requirements related to material GWP values and product-specific EPDs. These contractual requirements will (1) serve to both reduce a project's total GWP via materials selection and (2) spur on manufacturers to produce products more sustainably and document the outcome via creating product-specific EPDs.

Other means of reducing embodied carbon relate to firms' goals to design with materials known as being more sustainable and/or to incorporate sustainable methodologies into design outcomes. For example, 38% of firms stated they aim to increase designs featuring biogenic construction materials. Additionally, another 12% of firms stated their goal to design for adaptive reuse and/or regenerative design.

6 SE 2050 DATABASE - OVERVIEW

An acknowledged limitation to setting embodied carbon reduction targets for structural systems is the current lack of knowledge/confidence in baseline data that structural systems will embody. As such, the SE 2050 database will be a powerful tool for embodied carbon reduction. While still in the beta stage, SE 2050 is focused on ensuring smooth processes of data collection as well as increasing the quantity of data collected.

The SE 2050 Database anonymizes and aggregates firm submitted LCA data for structural systems. To date, firms have collectively submitted 100+ LCAs. There exists no other cross-firm database on embodied carbon that has such widespread support in North America. The requested data inputs include, but are not limited to, the following (*note: published data differs from this list and is currently limited to Total GWP, Project Sq Ft, and Height):

- project zip code
- primary building use type (public assembly, education, retail, etc.)
- construction type (new construction, major renovation, etc.)
- gross square footage
- build height, number of stories above and below grade
- typical column grid by spacing
- risk category and other seismic/wind classifications
- material of primary gravity system

- material of primary lateral system
- geotechnical attributes such as allowable soil bearing pressure and foundation system type (piles, shallow footings, etc.)
- LCA tool used (Tally, OneClick, Athena, hand calculated, etc.)
- Total GWP in kg-CO₂eq

As outlined in the SE 2050 Program Requirements Guide, firms are currently required to submit two LCAs per year, which inform the database. For firms with multiple office locations, the requirement states that two LCAs are to be submitted per office, but that a firm is not required to submit more than five LCAs in total. This data is not public and only signatory firms can access the database viewer.

New project LCAs are being added to the SE 2050 database each week. This data will provide new insights into GWP baselines for a variety of structural design. As such, one of SE 2050's primary upcoming goals is the analysis and reporting of the anonymized data.

7 SOM'S COMMITMENT TO SE 2050

SOM's commitment to SE 2050 is part of the firm's climate action plan to reduce resource usage and taking the lead toward a zero-carbon economy. As an interdisciplinary design practice, SOM is also a signatory of the AIA 2030 Commitment, the Architecture 2030 China Accord and World Green Building Council Bringing Embodied Carbon Upfront. Structural designers are active in groups such as the SOM Climate Action Group, working to reduce carbon across urban planning principles, material usage and research, and building construction.

The SOM SE 2050 champions organize activities to implement the Embodied Carbon Action Plan. The Structural Life Cycle team develops the workflow used for LCA and internal reporting efforts for all structural projects at all design phases. All structural designers are encouraged to participate in the firmwide discussion about the principles of embodied carbon and its reduction, and project case studies are presented to share innovations for and setbacks to successful embodied carbon reduction that can be applied to on-going and future projects. Structural designers also collaborate with industry partners to bring research to market for implementation into built projects and advocate for best practices in sustainable design both internally and in professional practice groups outside the firm. Furthermore, advocacy with both clients and builders aligns design and development interests to implement appropriate sustainable goals for all projects.

ABSTRACT: As designers, efficient material use to achieve a certain design is a well-established principle that is evolving to be centered around the whole building decarbonization. From early design to construction to operation and end of life, calculating the embodied carbon of building structures based on a bill of materials helps to quantify the impact of design decisions and build a database of design-specific carbon values that can be used to improve a design and to benchmark across different building types and structural systems. Ultimately, decarbonization will require the specification of low-carbon material technologies and the establishment of material- or product-specific global warming potential (GWP) limits, used to better qualify the embodied carbon of a specific design.

Quantifying embodied carbon takes different forms at the various stages of design, with all tools sharing a central repository of industry-wide carbon factors. As the industry works toward carbon reduction, designs can specify project-specific low-carbon materials, which will refine the calculation to include product-specific carbon factors. Alternatively, for some building materials, accounting for and reducing the use of carbon-intensive ingredients, in addition to collaboration with industry partners early in design to create and select materials based on performance and project goals, will drive decarbonization over the next few decades.

Attendees will learn about the calculation of embodied carbon of building designs, the use of material specifications to realize project-specific design goals and the feedback loop from carbon quantification and specification efforts to future building design.

1 RESILIENCE AND CARBON

1.1 *Whole building decarbonization*

To address the climate emergency, the spotlight on carbon emissions has shifted from a focus not only on operational carbon emissions but also on embodied carbon emissions, among other environmental impact factors relating to whole-building life cycle assessment (LCA). Agencies like LETI and IStructE have established guidelines on recommended embodied carbon targets relative to building area based on building program or height. In addition, other pathways to limiting global warming potential (GWP) per unit weight or volume in specific building materials come from policymakers by way of new provisions such as Buy Clean California and the Marin County Low Carbon Concrete code. Other groups like SE2050 aim to collect an industry-wide database of structural embodied carbon for its membership's designed projects that will report on the current state of the industry and provide the basis for specific embodied carbon targets.

Decarbonization is not possible without continued advancements in the building material industry. In recent years, cement production with lower emissions and energy usage coupled with low-carbon alternatives to cements have been directed at the heavy-hitting Portland cement, known to be an intensive-carbon building material. The use of carbon-sequestering materials such as timber allow for the storage of carbon in building materials until the building is demolished and technologies such as bioenergy with carbon capture and storage (BECCS) can permanently remove the EC.

1.2 *Embodied carbon*

Embodied carbon (EC) refers the carbon dioxide (CO₂) emissions emitted during the raw material extraction, transportation and manufacturing of building materials; during the construction and use of buildings; and at the building end of life. Through detailed design EC calculations, it is common to consider mainly the product and construction stages, as most environmental product declarations (EPDs), for a building material product, report environmental impact factors for LCA modules A1, A2 and A3 (EN 15978). When designing for long-term resilience, it is important to also consider the building use and end of life stages, for example, where buildings are not designed for immediate occupancy and limited repair after design-level seismic events. The consideration of carbon-sequestering building materials also allows for carbon storage over the building service life that factors into strategies for reducing upfront embodied carbon.

1.3 *Carbon accounting to achieve decarbonization*

To align the discussion on embodied carbon, industry-wide carbon accounting through calculation and specification is needed. By understanding and limiting the carbon emitted in construction today, this accounting can provide important justification for low-carbon materials and pave the way for net zero embodied carbon buildings.

EC calculations provide the cornerstone for benchmarking the industry and setting up future policies to achieve net-zero embodied carbon goals in the next three decades. Through standardization and automation of these calculations, the database has increased consistency and facilitates comparison across many building types regarding material efficiency. Establishing these benchmarks will allow for a clear pathway to EC reduction in building structures.

The building design forms the basis of the embodied carbon calculation. During the building design phases, the designer determines the best reduction strategies given the design space. The specifications then implement those reduction strategies, working with industry partners such as the contractor and material suppliers to achieve those EC reductions. Post-construction LCA is also a reliable tool for ensuring the design meets the intended EC goals.

2 CALCULATIONS AND CARBON DATABASE

2.1 *Building carbon calculations*

Each building structure is a function of design constraints based on parameters including project site and architectural program. The database of carbon values for each building design includes these parameters which give the database dimensionality for the establishment and selection of appropriate benchmarks to be used for future designs. Recording data at each design phase tracks the change associated with design decisions and development and its relative impact on EC. As a designer, many of the construction, use and end of life stage LCA modules may be estimated, but the contributions of these stages may vary in the final project delivery. Thus, current calculations consider LCA modules A1-A3, also known as measuring “cradle-to-gate”, to align data across different projects.

An example structural carbon calculation is developed in the following sections for a six-story cultural center project in Northern California, from the bill of materials to the carbon factors associated with local material procurement to the final summary of structural embodied carbon.

2.2 Establishing the bill of materials

Effective material use for decarbonization depends on how the material is used in the building structure. To quantify the impact of the building structure, it is important to categorize the building materials based on location in the building superstructure/substructure/foundation, structural element type, general material category, specific material type, etc.

All structural materials are categorized as defined in the material specifications. The structural steel, reinforcement and connection tonnages and the concrete and timber material volumes can be calculated and sorted into a clear bill of materials based on the categorization.

Alignment on the definition of structural material quantities is important to the development of the EC database. Automation and standardization of the quantity takedown from all design and documentation tools and software ensure consistent calculations, ensuring that all project EC is calculated. During early design phases, estimated quantities are based on prior experience and architectural design models. During later design phases, structural analysis models and BIM documentation models form the basis for the bill of materials. A post-construction bill of materials validates the design phase assumptions.

Depending on the design phase, different structural models may be used to establish the bill of materials by assigning products or material properties to specific modeled elements. These properties include, but are not limited to, structural element type, material strength, material density, material composition and region of production. In earlier phases, analysis models are used to validate and approximate the material quantities associated with in-progress designs. In later phases, building information modeling (BIM) allows for a detailed accounting of model elements and their assigned materials aligned with the level of development during design – accounting that can be verified in collaboration with the general contractor during construction.

Figure 1. The bill of materials can be established from both early-phase and later-phase models, including structural analysis models (left) and BIM models (right).

2.3 Selecting carbon factors

EC factors are dependent on the construction market, as different factors including, but not limited to, the energy used during the project stage, the raw and recycled materials available and the transportation from the production facility to the construction site are region-specific. Regions such as North America and Europe/UK have more robust environmental product declaration (EPD) databases (*Standard for building carbon emission calculation*, GB/T 51366-2019, provides Chinese code-based EC factors), but other regional markets may rely on databases such as the Inventory of Carbon and Energy (ICE) for building materials with a shortage of EC information. Where the information is available or limits are defined separately, each LCA module (e.g. A1, A2 and A3) has its own EC factor.

For materials such as timber, biogenic carbon may be considered a negative value (carbon removal) in LCA module A1 and added as a positive value in modules C3/C4 at the end of life

stage when the timber waste after demolition releases the carbon emissions where the LCA study measures beyond cradle-to-gate (A1-A3). Based on product-specific EPDs collected, NRMCA has published a member national and regional LCA benchmark report, used to develop a range of concrete EC factors for the project workbook study and the specification GWP limits. Concrete mixes are made of carbon-intensive materials such as cement with EPDs. Since the use of supplementary cementitious materials (SCMs) lowers the GWP impact of concrete, some LCA tools and industry-wide EPDs allow for more granularity in the concrete carbon factors based on the aggregate type, concrete strength or material grade and the percentage of cement replacement.

The A1-A3 EC factors for the example project are selected based on an average factor for steel and reinforcement produced and fabricated in the United States; and on average factors for concrete of a specific strength and supplementary cementitious material (SCM) replacement typical for concrete mixes supplied in the Pacific Southwest region.

2.4 Calculating embodied carbon

To benchmark and show improvements to the building's embodied carbon, the designer calculates the impact of building materials from earlier concept phases through later design phases. Early estimation tools such as the assumptions included in the Environmental Analysis Tool™ developed by SOM allow for EC calculations when the building has not yet developed a bill of materials, with minimal inputs including building area, program and site conditions. In the proposed embodied carbon workflow, an engineer inputs project information and structural material quantities based on the bill of materials in the project workbook. This workbook is linked to (1) an EC factor database with information generally from industry-wide EPDs and (2) a project database backend that compiles all the information stored for each project based on the final summary at the end of a design phase (e.g. Schematic Design, Design Development, Construction Documents, etc.). As the structural material quantities are associated with specific material types and market regions, the embodied carbon is calculated and summarized automatically. Where coordination with other designers is required, LCA tools such as One Click LCA® are used for a more comprehensive study.

The A1-A3 embodied carbon in units of carbon dioxide equivalent (CO₂e) is calculated based on applying the EC factor in kg CO₂e per weight of metal material or per volume of concrete or wood material. With proper segmentation, the calculated embodied carbon can be associated with a specific structural system, structural object or element or structural material, allowing for further analysis and comparison between different building structures in the database.

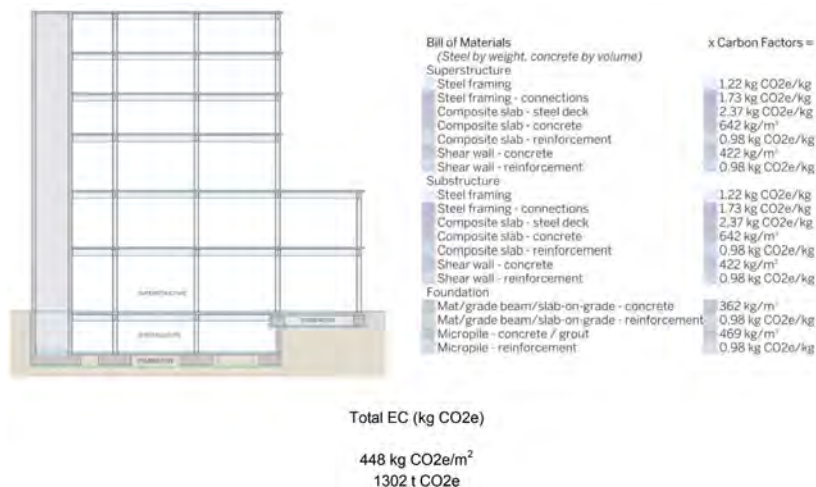

Figure 2. Summary of the baseline embodied carbon calculation for the project-specific and design-specific bill of materials.

Figure 3. Summary of the baseline embodied carbon calculation by element type.

The following figure summarizes the structural embodied carbon study for 90 current and recent projects. Active studies include categorization of building structure parameters such as architectural height and EC targets based on current data trendlines that evolve between the years 2025 and 2040.

Figure 4. Graphical investigation of embodied carbon data for 90 current and recent projects from the Project Workbook database.

3 SPECIFYING MATERIALS

3.1 Understanding the market

To meet carbon emissions reduction targets by way of the Paris Agreement, low-carbon codes are being adopted, imposing GWP limits on some building materials. Buy Clean California set GWP limits for eligible materials such as unfabricated structural steel sections and concrete reinforcing steel. Marin County’s Low Carbon Concrete policy limits cement usage and embodied carbon by concrete mix or by project. These code-based limits will increase industry awareness, shifting the focus from client- and designer-driven GWP limits through specifications to industry-wide reduction of building material carbon emissions. These policy changes are needed as the industry move toward net-zero carbon building construction.

Carbon emission reductions are best achieved by understanding the regional construction practices and material availability. Some market regions may be able to reduce the carbon emissions associated with cement and have high availability of concrete mix components, whereas some market regions produce steel with high recycled content. These market factors should impact the structural system selection and the material specifications.

3.2 *Tuning material specifications to achieve project-specific targets*

Structural materials are a large component of the whole-building embodied carbon emissions, particularly the upfront carbon released by the end of construction. The material specifications implement the EC factors assumed during an LCA study, or design-phase carbon accounting, forming an important basis for the construction and material procurement.

Electric arc furnaces (EAF) melt recycled or scrap steel whereas blast furnaces can also melt raw iron ore for steel production. The energy intensity and the carbon emissions produced with EAF steel production allow for significantly lower GHG emissions. For concrete reinforcing and structural steel, an average recycled content should be specified to reduce the GWP impact. If the project is in a region where EAF is prevalent, limiting the structural steel sections specified based on availability so structural steel can be locally milled also lowers the EC.

For concrete materials, the material specification allows for two conformance paths that demonstrate the GWP limits for the project can be met. Compliance Method A - Total Carbon Budget relies on the contractor to account for the concrete supplied on the project with a final report showing the EC across all concrete supplied for the project. Compliance Method B - Individual Mix Carbon Limits relies on the concrete supplier to deliver mixes that meet individual limits and the designer to set limits that meet the overall project EC target. In addition, cement usage can be reduced where concrete mixes can achieve the compressive strength requirements beyond 28 days as defined by ACI 318 where slower strength gain is an acceptable structural performance criterion. Concrete cementitious replacement can be specified or limited, and limits can be developed from EN 15978-compliant LCA tools.

Table 1. Example Individual Mix Carbon Limits for projects using Compliance Method B.

Typical Application of Concrete Class/Mix Design	Design Strength (psi)	Maximum GWP per EPD (kg/m ³)
Footings, Pile Caps and Grade Beams	5,000	295
Slabs-on-grade	5,000	295
Basement Walls (Shotcrete)	5,000	337
Shear Wall (CIP)	See Elev.	312
LWC Fill on Metal Deck	4,000	466
NWC Fill on Meta Deck	4,000	288
Curbs, Pads, Column Encasements and Miscellaneous	4,000	288

3.3 *Allowing for material technology adoption*

Net-zero carbon construction relies not only on the carbon optimization of current building materials, but also on the development of new materials that can be specified as structural materials. An example is carbon dioxide mineralization, where mineralized CO₂ is introduced as an admixture, sequestering carbon in the concrete mix. Performance-based specifications also allow for these available and upcoming materials such as recycled concrete aggregates, carbon-sequestered aggregates and pozzolan cements.

4 CONCLUSIONS

Environmental impacts of building structures must be minimized. First, policy makers, developers, contractors and designers continue to work carbon accounting and reduction strategies

as a common part of the design and construction process. Second, establishing an EC benchmark or target pushes the industry to reduce material usage and explore new material technologies. Third, designers specifying more efficient material usage and new material technologies will expedite their adoption into the coming generation of building structures. Fourth, this cyclical process continues with each generation of buildings until structures are net-zero embodied carbon from cradle-to-grave.

Carbon optimization of hybrid material structures

M.P. Sarkisian, D. Shook & A. Zha
Skidmore, Owings & Merrill, San Francisco, USA

C. Horiuchi
Skidmore, Owings & Merrill, San Francisco, USA (formerly)

ABSTRACT: It is commonly known that the structural materials included in building construction contribute significantly to global emissions due to the associated carbon required with their extraction, production, and transportation. The most common structural materials, concrete and steel, can also have the greatest impact in part due to their high volume of usage. However, with requirements of fire protection, vibration, seismic detailing and constraints of constructability, it is not feasible to simply eliminate all concrete and steel from our buildings. Instead, structural engineers can look to make intelligent replacements of carbon-intensive materials with low carbon, fiber-based materials such as timber. In this way, engineers can make noticeable reductions in buildings immediately and not wait until codes catch up with new structural systems. This topic has been explored by the authors with a variety of materials and geometries. Recently the authors designed a built hybrid mass timber and steel structure in a height seismic zone. In each case the use of timber is expanded and therefore overall embodied carbon incrementally reduced.

1 HYBRID SOLUTIONS

1.1 *Rethinking design and construction with hybrid solutions*

Traditional construction methods are on the cusp of rapid change. The architectural, engineering, and construction (AEC) communities are seeing a significant realignment fueled by the urgency of climate change. In a market controlled by costs, governments are raising the standards to reduce embodied carbon. The industry will likely continue to be a cost-driven sector, but reconsideration of past assumptions is needed to efficiently meet the needs of the pending climate crisis.

To reduce carbon quickly and efficiently the use of mass timber must be expanded. A key short coming of mass timber are the larger structural dimensions required. Also, spans are typically reduced resulting in less flexible spaces. To ensure that building remain flexible in the future, selective use of steel and concrete can create a balance between significant carbon reductions while maintaining flexible spaces.

1.2 *Evolving requirements from designers, owners, and governments*

The past 5 to 10 years have seen numerous US design organization such as the American Institute of Architect (AIA), Structural Engineers Association, nearly every major consumer market company (e.g. Google, Ford, Lendlease), and several regional governments (e.g. States of California, Oregon & Washington) all adopt a wide range of commitments and requirements pertaining to reducing embodied carbon. As a signatory of SE 2050, Skidmore, Owings & Merrill (SOM) has committed to bringing meaningful carbon reductions to a wide spectrum of buildings.

1.3 *How these changes will affect structural system construction and design*

As the two above changes unfold (increased use of low-carbon materials and AEC commitments) it is likely that general contractors will rethink how they can have more sub-contractors internally self-perform key tasks such as mass timber fabrication/installation. There is already precedent in the industry of this with concrete, drywall, cabinetry, etc. Alternatively, traditional concrete and steel sub-contractors may seek to have more trades under their control such as mass timber. The second is a potentially beneficial realignment with sub-contractors finding best ways to adopt low-carbon materials complimented by their traditional work. This hybrid option could greatly expand the use of low-carbon materials to a wider range of buildings.

2 EXPLORATIONS OF MASS TIMBER HYBRID STRUCTURES

While the number of commonly used structural materials is limited: concrete, steel & timber, their combinations can be composed in a wide variety of ways. The following outlines several explorations, incrementally increasing the use of mass timber, seeking material and cost efficiency balanced with performance and aesthetics.

2.1 *Floor system explorations*

Floor systems compose 35% to 45% of the total embodied carbon of most mid-rise and high-rise structural systems, based on data collected internally by SOM, making them the largest single culprit of embodied carbon. Thus, their decarbonization is vital. The structural frame of floor systems typically also provides acoustic and fire separation between floors. While traditional steel and concrete have found effective methods for these separations, mass timber will require its own solutions. Acoustic separation is typically provided by an acoustic mat and a minimum of 50mm (2") of concrete (Johnson, 2021). The concrete may or may not be part of the structural system but must be included. An early exploration by SOM utilized a concrete slab supported by glulam beams, see Figure 1, at the United Nations Office at Geneva. This was complimented by the façade system aesthetic to create a unique and efficient building composition.

Figure 1. Example of built hybrid floor systems.

In parallel, SOM also considered the potential of composite behavior of cross-laminated timber (CLT) panels with the concrete topping already required for acoustics. This was found through full scale testing to be highly effective in controlling deflection over a 7.3m (24'-0") span (Johnson, 2017a).

Figure 2. Hybrid composite floor system full scale testing (Johnson, 2017a).

Further explorations of hybrid floor systems considered steel beams with composite CLT panels spanning between composite steel beams, see Figure 3. This efficient system also had the benefit of a flat soffit which has numerous benefits from MEP coordination to aesthetics.

Figure 3. Hybrid floor system concept (Johnson, 2017b).

2.2 Building system explorations

As part of a total building exploration of mass timber it was found that select regions enhanced with reinforced concrete would be important in achieving the long gravity framing spans and lateral strength common in high-rise construction (Johnson, 2014).

Figure 4. Timber tower systems (Johnson, 2014).

3 PROTOTYPE OFFICE BUILDING

3.1 Mass timber in a cost-focused building

In what follows, a recently constructed office building shows how designers can work effectively with all trades, contractors, and owners to achieve a cost-effective, low-carbon solution meeting the dynamic needs of our urban fabric.

Figure 5. COB3 building rendering.

The COB3 building will redefine the San Mateo County Government Center with an iconic, forward-looking design that reflects the values of the community. With a mass timber/CLT structural system, ultra-low carbon footprint, and net zero energy goal - the design sets a new standard for sustainable, generational, civic buildings beyond the Bay Area. The 5-story mass timber building totaling 19,325sqm (208,000sqft) is in downtown Redwood City and surrounded by existing county buildings, including the San Mateo Superior Court. The building configuration features a north and south public plaza linked by a transparent building lobby creating a connection between the downtown Redwood City Theater District and the San Mateo County buildings. The building houses the main public functions at the ground level, including the Board of Supervisors Chamber.

The project is being developed by the Project Development Unit, with SOM as the architect and structural engineer and Truebeck Construction as the general contractor. Scheduled for completion in late 2023, with the goal of both net-zero energy and a significantly reduced embodied carbon footprint, SOM's structural engineering design team responded to the challenges of the nation's first net-zero energy mass timber civic building.

3.2 Building structural systems

Designed in conformance with the 2018 International Building Code (IBC, 2018) with State of California Amendments (CBC 2019), the civic building is assigned to Category II per occupancy load limits of 2019 CBC Table 1604.5. The structure is classified as a Type IV HT (Heavy Timber) construction per fire-resistance rating requirements of 2019 CBC Table 601. The building is located not only in a high seismic region, with a seismic design category D, but also in a region highly susceptible to liquefaction with a seismic site class F.

COB3 is characterized by its H-shaped layout with the gravity system consisting of glue-laminated (glulam) timber beams and columns with a cross-laminated timber (CLT) floor system. The plan dimensions of the building are typically 85m by 60m (280ft by 195ft).

Distinctly, glulam beams are utilized only in a single direction: a pair of glulam beams, each measuring 22cm by 65cm (8¾-inch by 25½-inch), span 10.7m and 9.1m (35ft and 30ft) bays. The long spans were achievable with relatively shallow beam depths by having beams continuous over the center supporting column.

Figure 6. COB3 hybrid structural frame with steel (Grey) and timber (Brown).

Figure 7. COB3 hybrid structural frame with concrete (Grey) and timber (Brown).

All glulam columns are of consistent width perpendicular to the beam spans to allow for a continuous beam configuration with the beams running past the side faces of the rectangular columns. A unique connection system is utilized to secure the glulam beams at column supports while also acting as the splice connection for the columns. Having a repeatable dual-purpose connection system, combined with off-site fabricated, allowed for an efficient erection schedule by reducing the number of picks that needed to be made on-site as well as reducing the overall steel material quantities. Only simple screw-type connections are needed on-site, in pre-drilled holes, to secure the structural elements. As part of the HT classification, all timber connections are hidden from view with a nominal layer of timber for fire protection.

Because timber beams only occur in one direction, the 17cm (6 7/8in)-thick 5-ply CLT slab system acts predominantly as a one-way spanning system spanning the 6.1m (20ft) bays. Therefore, no additional spandrel beam is required around the perimeter of the building. CLT panels are nominally 2.6m (8'-6") wide, and 12.2m (40ft) long. The length of the panels provides a double span condition over the center supports, reducing the deflection of the panels, which is critical to achieving the large span-to-depth ratio of the panel.

The composition of the CLT was optimized for cost and performance. The CLT outer plies comprise a strong Structural Select grade of Douglas fir, while the inner three layers are of a weaker but stiff Coast Sitka spruce. This composition allowed the exposed CLT layers to match the similarly exposed glulam beams and columns while providing the strength required of the panel. The weaker but stiff inner CLT plies significantly reduced the panels' costs while providing the required stiffness to limit deflection and floor vibrations, often an issue in long-span timber buildings.

The structure consists of four separate cores located at the reentrant corners of the building. The cores are supported between W14 (36cm) columns with floors comprised of composite steel beams. The composite steel slab system generally consists of 11cm (4½in) normal-weight concrete fill over 8cm (3in) metal deck. The cores also provide the lateral force-resisting system for the building. Buckling-restrained-braced frames (BRBF) are provided on all four sides of each core. Forces are developed into the BRBF system through the CLT diaphragm. CLT panels are spliced together using plywood splines and screw connectors, allowing in-plane shear transfer. Panels are also connected to each other and to the steel cores through steel straps and screws forming chords and collectors, creating a load path into the braced frames.

The deep foundation system consists of 46 cm (18in)-diameter auger cast-in-place displacement piles supported on pile caps that resist superstructure gravity and lateral load reactions at the base of the building. A total of 300 piles extends 22.8m (75ft) into the soil below. Grade beams interconnect pile caps with a 30cm (12in) pile-supported suspended slab on grade at the first-floor level.

Figure 8. COB3 Construction showing steel frames in mass timber construction.

Figure 9. COB3 Steel column and steel diaphragm connections.

3.3 *Net zero energy and embodied carbon*

The COB3 design team focused on passive design strategies. With narrow floor plates, a balance between daylighting and solar heat gain to lower the lighting power density could be achieved. This also enabled the configuration of the floorplates to allow natural ventilation for night cooling to reduce loads. The design optimized the active systems, tailoring the mechanical equipment to its use, leveraging efficient hydronic fan coil units at the perimeter and VAV air distribution at the interior core spaces. The interior design strategically places the engineering systems within centrally located cores to minimize distribution distances for the most effective

services. The exterior windows have automated window shades that reduce solar heat gain and reduce glare. Once the design loads were reduced, the energy required to operate the building was offset by on-site renewable energy generated by photovoltaics on the project’s roof and the roof of the nearby parking garage, making it a net-zero operational energy building.

In addition to being net-zero operational energy, the project has reduced its embodied carbon by 70% primarily by using advanced structural technologies, including Cross Laminated Timber slabs, with Glued Laminated Timber beams and columns. The below embodied carbon life-cycle assessment was conducted using OneClick LCA regional average values.

To reduce the embodied carbon footprint of a building, the starting point should be the structure, as it is the largest contributor. While using mass timber instead of a steel or concrete structure yields significant savings in the embodied carbon of any project, additional savings through engineering design and close collaboration with architecture and other trades can be had.

Optimal bays and column spacings considering modules based on office spaces, the layout of mechanical systems, fire sprinklers, and lighting, among other items, all in conjunction with the quantity, size, and thicknesses of glulam beams and CLT required for each configuration, were considered. In addition, the pieces and connections could be priced in real-time with the contractor’s help. The solution was ultimately to reduce the number of beams and have them run in only one direction, leading to a reduced number of pieces and connections, creating an efficient bay size that works well with the office layouts.

By running beams continuously over supports, long spans could be achieved with relatively shallow beams, saving overall timber quantities compared to traditional post-and-beam timber framing systems. In addition, by running the beams in only one direction, a more efficient ceiling/floor structure is achieved by integrating the MEP distribution parallel with the beam direction, which reduces the typical floor-to-floor height and the overall building height. Subsequently, with a reduced floor-to-floor height, the overall enclosure volume could be significantly reduced, saving further on the embodied carbon.

Figure 10. COB3 embodied carbon summary of options.

Setting an example of sustainability for the district, the new County Office Building will be an iconic and symbolic addition to Redwood City’s built environment. The material selection, structural optimization, and collaborative approach achieve enhanced performance, reduced embodied carbon impacts, net-zero energy, and a LEED Platinum rating.

4 CONCLUSION

The COB3 structural material selection facilitated significant cost and carbon reduction in non-structural systems such as ceilings, walls, and façade. While this project's general contractor utilized separate steel and timber fabricators and installers, the commonly perceived cost and coordination issues of having multiple large structural sub-contractors was successful. In the future, it is likely that the mass timber work could be under a single steel or concrete sub-contractor that could unlock improved design and construction efficiencies.

A study on the mutual effect on fatigue damage of orthotropic steel decks and pavements

B. Wang, D.L. Wang, R. Ma & A.R. Chen
Tongji University, Shanghai, China

ABSTRACT: The fatigue issue on orthotropic steel decks (OSDs) is closely related to the mechanical property of pavements. On the other hand, the fatigue cracks on OSDs can lead to local deteriorations of the supporting conditions of pavements, and therefore accelerates the fatigue damage evolution. This paper attempts to investigate the mutual effects on the OSD-Pavement system with existing cracks. Firstly, the finite element model of the OSD with penetrating cracks on the rib-to-deck welded joint is established. By obtaining the stress intensity factors along the crack front, the fatigue crack growth behavior is analyzed. The fatigue damage evolution on pavement is then studied using a continuum damage model in terms of the first principal strain range. According to the results, it can be addressed that the mechanical performance of pavements may help to resist growth of penetrating cracks on rib-to-deck welded joints on OSDs. On the other hand, the cracks will accelerate the fatigue damage on pavements as well. For a crack that reaches $0.75t$ (t as the deck plate thickness), the damage initiation on the pavement can be accelerated by about 16%. The results can be helpful in the decision making for the pavement maintenance of bridge, as well as the retrofitting works on OSDs, which may further benefit the life-cycle performance of the bridge.

1 INTRODUCTION

Fatigue cracks are commonly observed on orthotropic steel decks (OSDs). Different types of cracks are addressed at welded joints and their vicinities. Among them, the crack that grows to penetrate the deck plate is quite unfavorable. Since this type of crack may initiate at the weld root of the rib-to-deck joint, it is quite difficult to detect and consequently, to prevent the growth in early-stages. On the other hand, penetrating cracks on an OSD can reduce its local stiffness, and alter the boundary conditions of pavements, ultimately resulting in premature damage of pavements. Studies have shown that the weld defects, specifically the lack-of-penetration (LOP) and the coarse-grained heat-affected zone, are the key to penetrating cracks on OSDs (Wang et al., 2019; Wang et al., 2021).

Figure 1 demonstrates an example of a bridge that suffers from this issue, in which the cracks can be observed by removing the pavements. Although there are only a few cracks observed on the deck top, the corrosion seems more severe by covering rusts in a large range longitudinally. These sites follow the location of the rib-to-deck joints, indicating the early damage site on the waterproof layer of the pavement. Other similar examples are provided by the reports in the Netherlands (Maljaars et al., 2012) and Japan (Yamada & Samol, 2008).

By any measure, it is irrational to deem the OSD as a failure upon the occurrence of fatigue cracks. Hence, it introduces the serviceability concern on an OSD with fatigue issues, which is even more important to the structural safety concern due to the high redundancy of such large-scale engineering works. For the problems presented above, it is crucial to prioritize the

Figure 1. Fatigue cracks on actual OSDs and the corruptions due to pavement damage.

coupling effect between the OSD and the pavement during the fatigue process. The possible premature damage of pavements, which is induced by the cracked OSD, should be noted.

On the other hand, it is also necessary to address the benefit from the pavement to keep the OSD from cracking. Though the mechanical performances are often ignored in the designing phase, the pavement can be a significant factor in realistic projects, according to the practices on actual bridges (Rao & Ji, 2019).

This paper aims to investigate the fatigue damage on OSDs and pavements, namely the OSD-pavement system, which may enable the proposal of more specific fatigue failure criteria and maintenance approaches. For the first step, the effect from the pavement on the fatigue crack growth on OSDs is given. Afterwards, the pavement damage induced by a cracked OSD is investigated by considering typical crack positions and sizes. According to the results, the conclusions are drawn.

2 FATIGUE CRACK GROWTH ON A PAVED OSD

2.1 *FE model of the cracked OSD*

The FE model of a typical section of OSD is built using ANSYS 19.0, as shown in Figure 2. It consists of five trapezoidal ribs and three diaphragms. With consideration of the computational intensity, the 4-node shell element, i.e. SHELL181, is used for the majority of the model, and the 8-node solid element, i.e. SOLID185, is used in the region of interest. The two parts are connected by applying the multi-point constraint (MPC) in the model. The fatigue crack at the rib-to-deck welded joint is modeled by FRANC3D, a fracture mechanics based software that enables to embed the crack in the ANSYS model. The boundary condition of the model is applied by fixing the vertical displacements of the bottom flange of the diaphragms, and the displacements on the lateral and the longitudinal directions on the respective edges.

Also, a 70-mm-thick pavement layer is modeled by solid elements, and the bonding contact is applied, meaning an ideal connection between the OSD and the pavement. The material of the OSD part is steel, whose elastic modulus is 206 GPa and the Poisson's ratio is 0.3. The material of the pavements is the asphalt concrete, whose elastic modulus and Poisson's ratio are 1.5 GPa and 0.25, respectively. Considering the symmetry of the structure, it is applied a symmetric load of a 5-ton-weighted wheel with the size of 300mm×200mm, resulting in a pressure on the OSD-pavement system of 0.82 MPa.

Figure 2. FE model of the cracked OSD.

2.2 Fatigue crack growth behavior based on SIF ranges

By the FE model of the cracked OSD, the crack growth can be predicted based on the SIF ranges along the crack front. For a contrastive analysis, the FEA is firstly conducted using the OSD model by removing the pavements, and both the root crack (RC) and the toe crack (TC) are considered. With respect to the commonly-accepted fatigue failure criteria of OSD, the crack depth of half thickness ($a = 0.5t$) and 3/4 thickness ($a = 0.75t$) of the deck plate is assumed.

For OSDs, the Mode-I cracking behavior is often dominant. The results from the OSD model with a root crack are provided in Figure 3, which shows that the value of K_I is larger than K_{II} and K_{III} by an order of magnitude. Consequently, the SIF range, i.e. ΔK , is generally the same as the range of K_I .

Figure 3. Comparison of the three-mode SIFs ($a = 0.75t$).

By comparing SIF ranges of RC cases and TC cases, it can be addressed that the two groups of results are quite close, except for the slight difference when the crack depth is $0.75t$, as shown in Figure 4. It means that the crack at the rib-to-deck joint, regardless of the specific site of weld root or weld toe, will grow in a similar rate. Therefore, the effect of pavement on SIF ranges is investigated based on RC cases only.

The results, as shown in Figure 4, depict the important effect of the pavement when ideally connected to the OSD. Even for a conventional asphalt concrete overlay, it may reduce the SIF range by about 70~80%. In terms of fatigue crack growth rate (CGR), it can be quite low as the SIF ranges along the crack front are mainly in the near-threshold region.

On the other hand, the distribution of SIF ranges along the crack front indicate that the maximum SIF range can be at the crack tip when the crack depth is $0.5t$ or smaller. While as the crack propagates, the location of the maximum value will shift laterally, indicating a larger tendency for the crack to grow in length. Combining with the low CGR, it implies the difficulty for the crack to penetrate through the deck plate, and also explains the few cracks observed on the deck top as shown above.

Therefore, it can be inferred that when the pavement and OSD behave in a composite structural way, the growth of the typical cracks (i.e. $a = 0.5t$ & $0.75t$) is slow, and can hardly reach the unstable fracture stage. It further implies the possibility of using an overlay with a higher mechanical performance to retrofit the cracked OSD, though further discussions are required on various aspects, including the contact effect to the cracked OSD, the viscoelasticity, and the temperature stability.

Figure 4. SIF ranges along the crack front by the OSD-pavement model.

3 PAVEMENT DAMAGE EVOLUTION ON A CRACKED OSD

3.1 Model description

Considering the high cycle fatigue damage induced by axle loads, the damage on pavements is evaluated using continuum damage mechanics. For a linear-elastic study, the damage evolution model can be given as follows (Jin, 2015),

$$\frac{dD}{dN} = \alpha \left[E(\varepsilon - \varepsilon_{th}) \sqrt{1 - D} \right]^m \tag{1}$$

where D is the damage index of the pavement, α and m are the material properties, N is the cycle count, E is the Young's modulus, ε is the range of first principal strain, ε_{th} is the threshold strain range for the fatigue limit.

The damage evolution is then simulated for part of the pavements, namely a region of $1m \times 2m$. Without loss of generality, the value of α is set as 1605.63, m equals 2.69, and ε_{th} equals zero, adapted from the ε - N curve provided in (Sun, 2013). For the sake of the computational efficiency, the damage evolution process is calculated for 10 steps, with the step size that the maximum damage index increases by 0.1.

3.2 Damage evolution

By assuming different crack conditions, the effect of promoting the fatigue damages on pavements can be obtained by comparison. The results of pavement damage evolution on the uncracked OSD are given as the benchmark. Figure 5 presents the damage for the first two steps. The corresponding results obtained by the case with a crack, whose depth is $0.75t$, is shown in Figure 6.

Figure 5. Early stage damage for the pavement on the uncracked OSD.

Figure 6. Early stage damage on the pavement on cracked OSD ($a = 0.75t$).

Accordingly, it is clear that the damage evolution is symmetric if no crack is embedded. While it is no longer symmetric for the cracked case, and the damage initiation site is right above the cracked RD joint. Meanwhile, the cycle count to reach $D_{max} = 0.1$ for the uncracked case is 57826, and that for the OSD with cracks are prominently smaller. The count for crack with a depth of $0.5t$ and of $0.75t$ are 51726 and 48706, respectively. The former indicates the 11% faster in pavement damage evolution, and the percentage for the latter is 16%.

On the other hand, the difference in damage distribution when D_{max} reaches 1 is not as significant, as shown in Figure 7. Generally, the damage on the lower side is always severe, as can be expected by using first principle strain in the damage evolution model. Hence, the damage index is always kept in a low level for the area that directly compressed by the wheel load. In terms of the cycle count, the case of the crack with the depth of $0.75t$ is smaller by about 14%.

The damage evolution in the early stage seems to be more affected by the penetrating cracks. Yet, it should be noted that the connection between the pavement and the OSD is assumed stable during the fatigue progress. In reality, the increment on shear strain may lead to the failure of the connection layer. When the damage initiates at the bottom layer of pavements, it accompanies the deterioration on the connection to the OSD, and is highly possible to result in a worse result thereafter. A reasonable consideration should be given to understand the behavior of the partially or completely detached pavement to the OSD in the future.

Figure 7. Fatigue damage on the pavement when $D_{max} = 1$.

4 CONCLUSIONS

With respect to the fatigue problem on OSDs and the subsequent effects on pavements, the fatigue crack growth behavior of penetrating cracks at the rib-to-deck joint on OSDs and the damage evolution on pavements are studied. The following conclusions are drawn.

1. The benefit from the pavement on resisting crack growth on OSDs is significant when the connection between them is kept in good shape. Even for a conventional asphalt concrete overlay, it may reduce the SIF range by about 70~80%.
2. The growth of the penetrating cracks is not likely to reach the unstable fracture stage under ordinary traffic loads on OSDs. And according to the distribution of SIF ranges along the crack front, it will rarely go through the deck plate.
3. By conducting damage evolution analysis on pavements on OSDs with cracks in different depths, the crack does promote the premature pavement damage. The damage initiation is 11% faster when the penetrating crack depth is $0.5t$, and the percentage for the crack with a depth of $0.75t$ is 16%. For a comprehensive understanding of this effect, further consideration of the possible deterioration of the connection between the OSD and the pavement is still required.

Modeling of coarse aggregate based on 3D point cloud and spherical harmonics

J.J. Zhang & Z.C. Pan

College of Civil Engineering, Tongji University, Shanghai, China

ABSTRACT: Aggregate morphology is an important part of concrete at meso-scale. In this study, a numerical method is proposed to model the coarse aggregate based on 3D point cloud and spherical harmonics. A total of 200 aggregates, including 100 pebbles and 100 crushed-stones, are collected by using the 3D point cloud technology. The aggregate is constructed by the spherical harmonics using 3D point cloud data. A typical example of a crushed-stone is presented to verify the feasibility of the proposed method. The distortion coefficient is defined to measure the similarity between the modeled and real aggregates. The effects of the sampling point number and calculation order on the accuracy of modeling the aggregate are investigated. The results show that proposed method has a promising application to establish a huge database of real aggregate shapes.

1 INTRODUCTION

The corrosion of reinforcement has a significant influence on the durability of reinforced concrete. Therefore, the initiation corrosion time of steel bars is an important index to predicting the life of RC Structures. Some studies have shown that the index can be affected signally by mass transport processes, such as chloride ion erosion in the chloride salt environment, CO₂ diffusion in the atmospheric environment, etc. Thereby, the resilience of RC structures under long-term environmental effects can be characterized by the transport properties of these masses. Some studies have shown that the meso-scale model of concrete has a noticeable effect on the properties of concrete (Thai et al., 2021, Mehdipour and Khayat, 2018). At the meso-scale, the transport path of the mass will be affected by the impermeability of aggregates (Pan et al., 2016), which is known as the tortuosity effect. The tortuosity effect is largely determined by the shape and distribution of aggregates. Thus, it is necessary to build meso-scale models of realistic concrete.

At meso-scale, concrete can be considered as a composite material consisting of aggregate, cement mortar, and interfacial transition zone (ITZ) (Chen et al., 2016). In this case, the cement mortar is a homogeneous material. ITZ is a special microstructure attached to the aggregate surface, whose thickness is related to factors such as cement particle size and curing conditions (Chen et al., 2004). Hence, the essence of modeling the concrete at meso-scale is to simulate the shape and distribution of aggregates in the cement mortar.

At present, there are two typical methods to model aggregate shapes. The first one is the pixel-based or voxel-based method (Kroener and Dornenech Carbo, 2013, Cheng et al., 2020). This method discretizes the aggregate into voxels and models the aggregate by storing the coordinates of each voxel. In this method, the accuracy of the aggregate model depends on the number of voxels. Thus, a huge amount of the storage space is required to ensure the accuracy (Tong et al., 2011). Duris et al. (2016) analyzed the two-dimensional shape features of particles based on pixels and evaluate the effect of the number of pixel points on shape parameters.

The other method is based on mathematical model (Melinska et al., 2017, Wei et al., 2018, Zhao et al., 2017, Xu et al., 2010). This method is to store the shape of the aggregate surface through a mathematical function. The coordinates of aggregate surface points will be calculated when modeling the aggregate. Compared with the voxel-based method, this method requires less

storage space but the modeling process is more complex. (Garboczi, 2002, Kiryati and Maydan, 1989). Shi et al. (2016) analyzed the two-dimensional shape parameters of real aggregates based on complex Fourier analysis and reconstructed the aggregate. Recently, to improve the refinement of aggregate models, modeling methods based on real aggregate have gradually become a research hotspot. Sun et al. (2020) and Li et al. (2021) used 3D point cloud techniques to extract several characteristic parameters and shape indicators such as isometric ratio, flake ratio, and sphericity of aggregates. Fu Ru et al. (2018) carried out a quantitative analysis of the shape parameters such as sphericity, roundness, and elongation of sand by spherical harmonics. At present, the modeling method based on real aggregate usually uses the CT scan to obtain aggregate data. This method needs to combine the scanned images, and the process is complicated. Moreover, the extant research scantily discusses how to select the number of data points for modeling and the calculation order of spherical harmonics for preservation. In this study, three-dimensional point cloud technology, which is a convenient method to collect aggregate information, is used to construct the aggregate model. The selection method of data points number for modeling and the calculation order of spherical harmonics is discussed.

This paper proposes a modeling method for constructing coarse aggregates which combines 3D point cloud with spherical harmonics. Firstly, the basic principles of 3D point cloud technology and spherical harmonics is expounded, and the accuracy of the aggregate model is evaluated by distortion coefficient.; Secondly, the modeling method proposed in this paper is validated with an example of a crushed-stone. Finally, the influence of the sampling point number and calculation order on the accuracy of aggregate is investigated.

2 MODEL AND METHOD

2.1 Point cloud obtained by 3D laser scanner

Firstly, a 3D laser scanner was used to obtain point cloud data of the aggregate shape. The basic principle is that a laser is emitted from the scanner to the aggregate, and the distance between the surface of the aggregate and the scanner is measured according to the phase difference between the emitted laser and the returned laser. The horizontal angle and vertical angle of each point are recorded Combined with the angle measurement system in the scanner. then the 3D coordinates of each point on the surface of the aggregate are obtained. Secondly, the resulting point cloud data is subjected to the necessary post-processing. Due to factors such as surface roughness and lighting conditions, some data points will deviate significantly from the surface of the aggregate. Thus, methods such as Gaussian filtering are used to denoise the initial point cloud. Finally, the coordinates of the sampling points are obtained by differencing the coordinates of the data points in the point cloud.

2.2 Aggregate model constructed by spherical harmonics

There are two requirements when modeling aggregates using the spherical harmonics. Firstly, anyone ray from the center of mass of the aggregate can only have a unique intersection with the surface of the aggregate. Secondly, the aggregate cannot have internal voids. The essence of the spherical harmonics is to solve the Laplace equation in the spherical domain. To do this, the Cartesian coordinates of the point cloud are converted to spherical coordinates. The origin of the spherical coordinates coincides with the quality center of the aggregate, using the top angle (θ), azimuth angle (φ), and distance (r) to characterize the position of the point, as shown in Figure 1. The coordinate transformation equations are shown in Eqs. (1)-(3).

$$x = r\sin(\varphi) \sin(\theta) \quad (1)$$

$$y = r\cos(\varphi) \sin(\theta) \quad (2)$$

$$z = r\cos(\theta) \quad (3)$$

The general form of the spherical harmonics is given by:

Figure 1. Schematic of spherical coordinate and position of sampling point.

$$r(\theta, \varphi) = \sum_{n=0}^{\infty} \sum_{m=-n}^n a_{n,m} Y_{n,m}(\theta, \varphi) \quad (4)$$

where the $a_{n,m}$ is the spherical harmonic coefficient. $Y_{n,m}(\theta, \varphi)$ is the real spherical harmonics ($0 \leq \theta \leq \pi, 0 \leq \varphi \leq 2\pi$), which is given by:

$$Y_{n,m}(\theta, \varphi) = \begin{cases} (-1)^m \sqrt{2} \sqrt{\frac{2n+1}{4\pi} \frac{(n-|m|)!}{(n+|m|)!}} P_n^{|m|}(\cos \theta) \sin(|m|\varphi) & m < 0 \\ \sqrt{\frac{2n+1}{4\pi}} P_n^m(\cos \theta) & m = 0 \\ (-1)^m \sqrt{2} \sqrt{\frac{2n+1}{4\pi} \frac{(n-m)!}{(n+m)!}} P_n^m(\cos \theta) \sin(m\varphi) & m > 0 \end{cases} \quad (5)$$

where n and m represent the order of the spherical harmonics. P_n^m is the Associated Legendre polynomial, which is the solution of the Associated Legendre Equation.

The $a_{n,m}$ in Eq. (4) is the coefficient to be solved according to the following definition:

$$a_{n,m} = \int_0^{2\pi} \int_0^{\pi} r(\theta, \varphi) Y_{n,m}(\theta, \varphi) \sin(\theta) d\varphi d\theta \quad (6)$$

The corresponding discrete format is given by:

$$a_{n,m} = \frac{4\pi \sum_{i=0}^N r_i Y_{n,m,i}}{N} \quad (7)$$

where N is the number of sampling points, r_i is the distance from sample point i to the origin of the coordinates, $Y_{n,m,i}$ is the value of the spherical harmonics for the sampling point i corresponding to the order n and degree m .

Note that the theoretical value range of n in Eq. (4) is $[0, \infty)$. Eq. (4) can be expanded to a sum of infinite numbers. Therefore, it is necessary to truncate at order n_0 (hereafter referred to as the calculation order), to use the spherical harmonic coefficients of the first n_0 orders for aggregate modeling. The value of n_0 has a significant influence on the accuracy of the aggregate model.

The data points need to be sampled uniformly over the surface of the aggregate to calculate $a_{n,m}$ by Eq. (7). Otherwise, it may lead to distortions in local areas. As shown in Figure 1, φ and $\cos(\theta)$ are each divided into k equal parts. The number of sampling points N is k^2 . The r_i corresponding to any combination of φ_i and $\cos(\theta_i)$ will be obtained by interpolating the coordinates of the data points.

There are three steps to construct an aggregate model by spherical harmonics:

- (1) The value of the spherical harmonics $Y_{n,m}(\theta, \varphi)$ is calculated for each sampling point on the aggregate surface and each combination of n and m by Eq. (5).
- (2) $a_{n,m}$ is calculated by Eq. (7).
- (3) The shape of the aggregates is described based on $a_{n,m}$ and Eq. (4).

2.3 Distortion coefficient

When determining the number of sampling points and the calculation order, it is necessary to design an index to quantitatively characterize the similarity between the aggregate model and the actual aggregate shape. In some research, average error of the distance from the coordinate origin to the surface of the figure was used to measure the similarity between the two-dimensional figures (Tang et al., 2009), as shown in Figure 2, this paper uses the difference between the distance from the actual aggregate surface point to the coordinate origin (\bar{r}_i) and the distance from the aggregate model surface point to the coordinate origin (r_i) to define the distortion coefficient of the aggregate model:

$$\sigma = \sum_{i=1}^N \frac{|\bar{r}_i - r_i|}{N \cdot \max(\bar{r}_i, r_i)} \quad (8)$$

Figure 2. Schematic of distortion coefficient.

3 VERIFICATION

To verify the correctness of the method, a crushed-stone was modeled in this paper using different numbers of sampling points and calculation orders. The actual shape of the aggregate and the

Figure 3. Shape of aggregate used in typical case study.

simulation result are shown in Figure 3 and Figure 4, respectively. It can be seen from Figure 4 that when n_0 is constant, the aggregate model gradually approaches the true shape and then no longer appears to change significantly as N increases. When N is constant, the aggregate model first gradually changes to the real shape as n_0 increases. But when n_0 exceeds a critical value, the aggregate model shows significant local distortions that affect the overall realism of the model. Therefore, it is necessary to determine the reasonable values for N and n_0 during aggregate modeling.

Figure 4. Effects of N and n_0 on aggregate model.

The σ under various simulation results are shown in Figures 5 (b)-(f). According to Eq. (8), it can be seen that with the σ value close to 0, the aggregate model is gradually accurate.

4 EFFECT OF SAMPLING POINT NUMBER AND CALCULATION ORDER

4.1 Sampling point number

To determine a reasonable value for the number of sampling points, a statistical analysis of the distortion coefficients of 100 pebbles and 100 crushed-stones was carried out using

Figure 5. Schematic to distortion coefficient of aggregate model.

different sampling points and calculation orders. The results are shown in Figure 6, it can be found that for pebbles and crushed-stone aggregates, the distortion coefficient decreases monotonously with the increase of sampling points. It can be seen from Eq. (7) that the increase in sampling points will lead to a decrease in modeling efficiency. In this paper, sampling points of $N = 400^2$ and $N = 500^2$ are used for pebble and crushed-stone, respectively. Compared with pebble, crushed-stone need more sampling points to express surface texture.

Figure 6. Plot of distortion coefficient of aggregate model as a function of N and n_0 .

4.2 Calculation order

As shown in Figure 4, when the calculation order is too large, the local area of the aggregate model will appear obvious distortion. Due to the characteristics of the spherical harmonics, this distortion generally occurs at the intersection of the aggregate model and the Z axis. Therefore, The most appropriate calculation order is determined by monitoring the distance between the two intersections of the aggregate model and the Z-axis in this paper to establish the aggregate model. This method can avoid the distortion of the aggregate model caused by excessive calculation order. The specific process is shown in Figure 7.

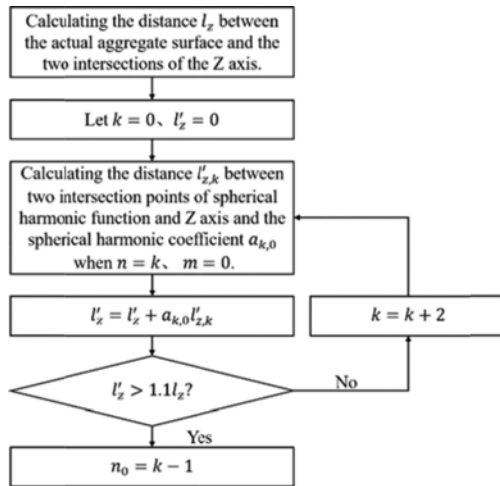

Figure 7. Procedure to determine optimized calculation order.

The optimal calculation order of each aggregate is calculated for 100 pebbles and 100 crushed-stone studied in this paper, as shown in Figure 8. It can be seen that for most pebbles and crushed-stone, the optimal calculation order is between 11 ~ 13 and 11 ~ 15, respectively.

Figure 8. Optimized calculation order of pebble and crushed-stone.

5 CONCLUSION

In this paper, a coarse aggregate modeling method combining 3D point cloud technology with spherical harmonics is proposed. By this method, 200 aggregates are modeled. The accuracy of the aggregate model was evaluated by distortion coefficient. Effect of sampling coefficient and calculation order on distortion coefficient is evaluated. The determination process of aggregate sampling point number and optimal calculation order of spherical harmonics is proposed. According to the research of this paper, the following conclusions can be drawn:

- (1) Using the spherical harmonics, the three-dimensional point cloud data of aggregate which is easy to collect can be transformed into the function which is easy to store. In this process, the shape characteristics of aggregate can be retained.

- (2) An optimal calculation order determination method based on Z-axis local distortion monitoring of the aggregate model is proposed. Under the condition of the same number of sampling points, the aggregate model can be more accurate.

Bridge tower aesthetic assessment using convolutional neural network

D.L. Wang, Y. Ning, C. Xiang & A.R. Chen

College of Civil Engineering, Tongji University, Shanghai, China

ABSTRACT: With the rapid social and economic development and social progress, bridges are no longer purely to meet traffic demand. The huge span, strong body-shape expression, and extraordinary scale of the bridge may even reshape the urban or terrestrial landscape. Therefore, it is urgent to pay more attention to bridge aesthetics in the process of bridge design. In this paper, a neural network for assessing bridge tower aesthetics is proposed, which can classify a bridge tower into low or high aesthetic quality automatically, and better serve the bridge aesthetic design. Firstly, 150 cable-stayed bridges and 118 suspension bridges with the highest spans in the world were selected. For each bridge, several high-quality images were screened from the Internet, and the standard bridge tower diagram of each bridge was obtained through semantic segmentation and projection mapping. Then, a WeChat Mini Program for bridge tower aesthetic assessment was constructed and released, and the aesthetic assessments of the above bridge towers from different groups of people were obtained. Finally, the bridge tower aesthetic assessment network (BTAANet) was trained with the above standard bridge tower diagram and the corresponding assessment label, and the aesthetic quality can be obtained automatically with the well-trained BTAANet. The proposed method can provide an important reference for bridge design and promote the implementation of bridge aesthetics.

1 INTRODUCTION

Aesthetics is a manifestation of human evolution toward advanced civilization and the pursuit of a higher spiritual world, permeating the entire vein of human civilization. Bridge aesthetics is also a hot issue in contemporary bridge construction, especially in the stage of conceptual design and scheme selection of bridge, so the fusion of bridge aesthetics thought and innovative technology is a new direction of bridge development (Liang *et al.* 2020).

In recent years, deep learning methods have been widely applied in computer vision tasks, such as image recognition, object detection, automatic driving, and image classification (Arman *et al.* 2021). Convolutional neural networks (CNN) have also been applied to image aesthetic assessment and significantly contributed to the development of image aesthetic assessment due to their powerful feature extraction and image-based decision-making capabilities. (Lu *et al.* 2015) implemented image global and local feature capture by constructing and training a two-column CNN network to support heterogeneous inputs. (Xin *et al.* 2016) introduced a CNN to solve the problem of image aesthetic classification, that is, automatically classifying the aesthetic quality of images into low-quality and high-quality. (Tan *et al.* 2016) used a CNN photo aesthetic classifier with both depth and breadth to achieve fine-grained aesthetic quality prediction. (Li 2018) proposed a two-channel CNN image aesthetic quality assessment method based on semantic information, which can extract aesthetic features from both the whole and part of the image, thereby improving the accuracy of image aesthetic quality assessment. (Dou *et al.* 2018) developed an automatic quantitative assessment method of webpage aesthetics using CNN, and the performance of the model is improved by transferring the knowledge from the image style recognition task into the proposed network.

Although the deep learning method has been widely used in the field of image aesthetic assessment, the above studies are mostly based on traditional neural network (TNN) with large amounts of parameters and high computational cost, which does not conform to the trend of lightweight development of neural network and the development demand of mobile applications. Therefore, a lightweight neural network (LNN) for bridge tower aesthetic quality assessment is proposed in this paper, which realizes the automatic assessment of bridge tower form aesthetic quality and improves the efficiency of aesthetic assessment.

The remainder of this article is organized as follows. Section 2 introduces the process of generating standard bridge tower diagrams and assessment labels, and the training of BTAANet based on TNNs and LNN. Section 3 compares and evaluates the performance of the two types of networks from the perspective of precision and complexity. Section 4 concludes this article.

2 BRIDGE TOWER ASSESSMENT

2.1 *Standard bridge tower dataset*

The supervised learning model is used to achieve intelligent assessment of bridge towers due to the lack of mathematical definition in bridge aesthetics. The performance of the model depends on the quality of the dataset, so it is crucial to construct a high-quality training dataset. To help better reflect the current situation of bridge design and makes the tower data more representative, the tower data in this paper is selected from the built large-span bridges worldwide. A total of 150 cable-stayed bridges with a span larger than 400m and 118 suspension bridges with a span larger than 500m were selected as the source bridge tower data.

The images adapted in computer vision research often have various distortions that affect the quality of the images. Perspective distortion is one of the most common kinds of image distortion, which occurs when the image plane of the shooting equipment is not balanced with the plane of the shooting object. This kind of distortion is common in the pictures we collected from the Internet. To make use of such images in the neural network, it is first corrected to eliminate the perspective distortion, as shown in Figure 1(a) and (b). The contour of the bridge tower is then extracted to eliminate the environmental background of the corrected bridge tower image, as manifested in Figure 1(c).

During the training of the neural network, the images that are fed into the network need to be the same size. Therefore, the obtained bridge tower contour is further standardized with a size of 128*256. The height of the bridge tower is scaled to 256, the width is scaled in equal proportion, and the excess is filled with 0.

Figure 1. Perspective distortion correction of the bridge tower images.

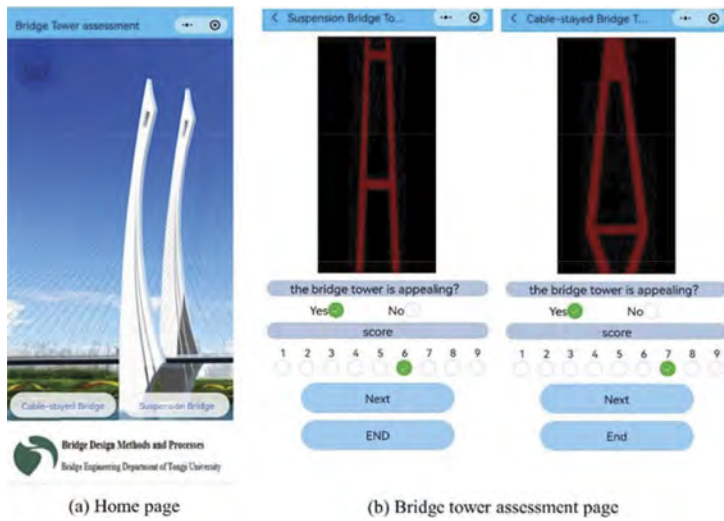

Figure 2. WeChat Mini Program for bridge tower assessment.

Supervised learning should work with labeled data, and the label of whether the bridge tower form is appealing or not is obtained by questionnaire survey. This paper develops an HBuilder X-based bridge tower assessment WeChat Mini Program to efficiently implement questionnaires and obtain the labeled data applicable to the BTAA Net. The applet in this paper contains three main pages: home page, cable-stayed bridge tower assessment, and suspension bridge tower assessment, as shown in Figure 2.

To make sure the credibility of the assessment results, a sufficient number of samples is required when performing the questionnaire survey. Here, a total of 44 complete evaluation results were collected through the applet, including 32 people majoring in civil engineering and the rest were not, and 20 people with master's degrees or above. Relevant studies (Liao *et al.* 2021, Loos *et al.* 2022, Lima and Grasse 2022) show that 44 assessment results can meet the requirements of aesthetic assessment. Some assessment results of the bridge towers can be found in Figure 3.

In determining whether the bridge tower form is appealing or not, increasing the difference in assessment criteria can improve the accuracy of aesthetic classification in some ways (Xin *et al.* 2016, Tan *et al.* 2016). Therefore, in this research, when more than 55% of people (24) give a positive evaluation for the bridge tower form, it is assigned the label 1, otherwise, the tower is assigned the label 0. Moreover, the size of the training dataset is expanded by using a data enhancement method that flips the image horizontally and uses the same evaluation labels as the original image. In this way, a total of 550 samples are generated in the bridge tower aesthetic assessment dataset (BTAA Dataset), and they are randomly divided into the training set, validation set, and test set with a ratio of 8:1:1.

Figure 3. Assessment results of some bridge towers (a/44, a is the number of appealing results).

2.2 The proposed BTAA Net

Taking into account the richness of image information, the size of the BTAA Dataset, and the complexity of the bridge tower form aesthetic classification problem, TNN, like VGGNet, GoogleNet as well as ResNet, and recently proposed LNN, including the MobileNet, SqueezeNet, and ShuffleNet were tested to find the most appropriate base model for BTAA Net. For TNN, they usually possess a large number of parameters, which leads to expensive computational costs. In comparison, in LNN, the number of parameters is significantly reduced due to the operations like depthwise separable convolution, deep compression, and channel shuffle, so that the size of the model is also reduced dramatically, which significantly improves the efficiency of the model and facilitates model saving and transferring. For instance, ShuffleNet significantly reduces the number of parameters and the computational cost by changing the data flow direction using channel shuffle, as shown in Figure 4.

Besides, deep learning usually requires a large amount of high-quality data. To improve the performance of the model, the strategy of transfer learning is adopted (Lu et al. 2015, Xin et al. 2016, Talebi and Milanfar 2018), that is, the model is pre-trained on the ImageNet, and then the model weight is transferred to the bridge tower assessment task, as shown in Figure 5. Models that use transfer learning strategy are followed by -TL.

Figure 4. The unit architecture of ShuffleNet.

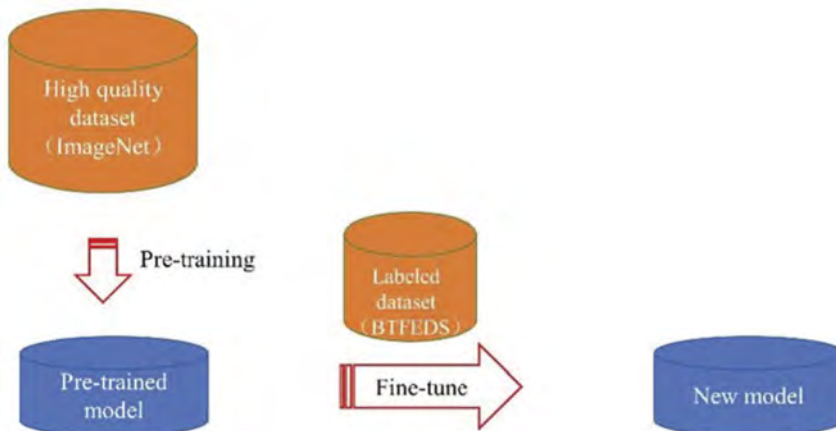

Figure 5. Transfer learning for bridge tower assessment based on ImageNet.

2.3 Training the neural network

All models mentioned in Section 2.2 were trained and tested on a computer with an Intel[®] Core[™] i7-8700k CPU and an NVIDIA GeForce GTX1080 Ti GPU using the Keras framework.

The Adam was used to determine the optimal weights of the networks, and the loss function adopted CrossEntropy Loss. During training, the initial learning rate was 0.0001. When the validation accuracy does not increase for 10 epochs, the learning rate will decay by 0.1 times and the training will stop when the validation accuracy does not increase for 30 epochs.

2.3.1 Traditional neural networks

Table 1 illustrates all TNN models and the corresponding validation accuracy. The number of fully connected units (4096, 512, 256) and dropout ratios (0.2, 0.5) was modified for the top layer of the network in the VGG16 model. Inception V1 and Inception V3 models were selected under the inception architectures, and ResNet34, ResNet50, and ResNet101 models were selected under the ResNet architectures. In addition, transfer learning is performed for the above models.

Under these three architectures, the one that performs the best on the validation set were all trained by the transfer learning method, and the validation accuracy of VGG16-TL, Inception V1-TL, and ResNet101-TL model was 90.74%, 90.70%, and 92.59%, respectively.

Table 1. TNN model and validation accuracy.

Architecture	VGG	Inception	ResNet
Model (validation accuracy)	VGG16-1 (77.80%)	Inception V1 (85.20%)	ResNet34 (83.33%)
	VGG16-2 (87.04%)	Inception V1-TL (90.70%)	ResNet34-TL (87.04%)
	VGG16-3 (83.30%)	Inception V3 (87.04%)	ResNet50 (83.33%)
	VGG16-4 (79.60%)	Inception V3-TL (88.89%)	ResNet50-TL (83.33%)
	VGG16-5 (77.80%)		ResNet101 (74.07%)
	VGG16-TL (90.74%)		ResNet101-TL (92.59%)

2.3.2 Lightweight neural networks

Table 2 shows all the LNN models and the corresponding validation accuracy, where MobileNet V1~V3 were selected under the MobileNet architectures, SqueezeNet1_0 and SqueezeNet1_1 were selected under the SqueezeNet architectures, and under the ShuffleNet architectures ShuffleNet_v2_x0_5 and ShuffleNet_v2_x1_0 were chosen. In addition, the transfer learning method is also used here.

Figure 6 shows the loss and accuracy variation during the training of the shuffle-net_v2_x0_5-TL model. The validation loss decreased and converged to about 0.35, and the validation accuracy of the model reached a maximum of 92.59% at the 69th epoch.

Similar to the TNN models, the LNN models with the best performance on the validation set were all trained by the transfer learning method, and the validation accuracy of MobileNet V3-TL, SqueezeNet1_0-TL, and ShuffleNet_v2_x1_0-TL was 92.59%, 94.44%, and 96.30%, respectively.

Figure 6. Loss and accuracy variation during training of shuffle-net_v2_x0_5-TL model.

Table 2. LNN model and validation accuracy.

Architecture	MobileNet	SqueezeNet	ShuffleNet
Model (validation accuracy)	MobileNet V1 (90.74%)	SqueezeNet1_0 (90.74%)	ShuffleNet_v2_x0_5 (87.04%)
	MobileNet V1-TL (88.89%)	SqueezeNet1_0-TL (94.44%)	ShuffleNet_v2_x0_5-TL (92.59%)
	MobileNet V2 (80.36%)	SqueezeNet1_1 (87.04%)	ShuffleNet_v2_x1_0 (83.33%)
	MobileNet V2-TL (90.74%)	SqueezeNet1_1-TL (94.44%)	ShuffleNet_v2_x1_0-TL (96.30%)
	MobileNet V3 (85.19%) MobileNet V2-TL (92.59%)		

3 EVALUATING THE NEURAL NETWORK

3.1 Prediction of the neural network

The trained neural network in Section 2.3 was used to predict the aesthetic quality of the bridge tower images in the test set, and some prediction results of the ShuffleNet_v2_x1_0-TL model are shown in Figure 7. The one-hot form was used to encode the label in the dataset, the first value is the probability of not appealing and the second value is the probability of appealing, and whichever value is greater is the final classification result.

Table 3 shows the test accuracy of the model with the highest validation accuracy under different architectures. It found that both kinds of networks can handle the bridge tower aesthetic assessment task well, but LNN better in terms of validation accuracy and test accuracy. The three kinds of LNN achieved the same test accuracy, but ShuffleNet had the highest validation accuracy, followed by SqueezeNet and MobileNet. Therefore, from the perspective of model accuracy, the ShuffleNet_v2_x1_0-TL model performs best in the bridge tower aesthetics assessment task, followed by Squeezenet1_0-TL, and MobileNet V3-TL.

Table 3. Test accuracy of the model with the highest validation accuracy.

Type of neural network	Model	Validation accuracy	Test accuracy
TNN	VGG16-TL	90.74%	87.50%
	Inception V1-TL	92.59%	82.14%
	ResNet101-TL	92.59%	85.71%
LNN	MobileNet V3-TL	92.59%	89.29%
	SqueezeNet1_0-TL	94.44%	89.29%
	ShuffleNet_v2_x1_0-TL	96.30%	89.29%

Figure 7. Part of the predicted results.

3.2 Complexity evaluation of the neural network

To comprehensively evaluate the performance of TNN and LNN, the complexity of the six models in Table 3 was further evaluated by the following indexes: model size, number of parameters, floating point of operations (Flops), multiply-add operations (MADD), memory required for node reasoning (Memory) and memory usage of graphics card (MemR+W). The results for each model complexity are shown in Table 4.

Table 4. Complexity results for each model.

Model	Model size/ MB	Number of parameters	Flops	MADD	Memory/ MB	MemR+W/ MB
VGG16-TL	512.0	1.34×10^8	10.2 G	20.3 G	71.5	655.4
Inception V1-TL	21.5	5.60×10^6	984.0 M	2.0 G	19.6	67.8
ResNet101-TL	162.0	4.25×10^7	5.12 G	10.2 G	105.6	373.8
MobileNet V3-TL	16.2	4.20×10^6	148.8 M	293.3M	31.5	71.7
SqueezeNet1_0-TL	2.82	7.36×10^5	474.2 M	940.2 M	21.9	47.4
ShuffleNet_v2_x1_0-TL	4.95	1.26×10^6	97.7 M	193.1 M	13.6	32.8

The complexity of the LNN is significantly smaller than that of the TNN. In terms of model size and parameter, the SqueezeNet1_0-TL model has the smallest size of 2.82 MB and the least number of parameters of 7.36×10^5 , while that of VGG16-TL and ResNet101-TL are 1-2 orders of magnitude larger than those of the LNN. For the indexes of MADD, Flops, Memory, and MemR+W, the shufflenet_v2_x1_0-TL model has the smallest values for each of these metrics, and the values for the TNN are all much greater than those of the LNN. Therefore, comparing the complexity indexes of all models, the Shufflenet_v2_x1_0-TL model has the lowest complexity, and the Squeezenet1_0-TL and MobileNet V3 large-TL show similar complexity.

In summary, taking into account both model accuracy and complexity, the LNN perform better than the TNN and Shufflenet_v2_x1_0-TL performs is the most ideal network architecture for the bridge tower aesthetic assessment task with the highest accuracy and lowest complexity.

3.3 Comparison with similar studies

To verify the applicability of the proposed method, some comparisons are made between that of similar studies. The results can be found in Table 5, which shows the accuracy achieved by the proposed method is only second to the model obtained by (Dong *et al.* 2015). Admittedly, the model of the neural network obtained by training with the different datasets is not rigorous enough, but it also reflects the feasibility of the proposed method.

Table 5. Accuracy of relevant study models.

Model	Dataset	Accuracy
(Lu <i>et al.</i> 2015)	AVA dataset	75.42%
(Kong <i>et al.</i> 2016)		77.33%
(Talebi and Milanfar 2018)		81.51%
(Dong and Tian 2015)		83.52%
(Hou <i>et al.</i> 2022)		83.10%
(Tan <i>et al.</i> 2016)	Dpchallenge dataset	87.10%
(Schwarz <i>et al.</i> 2018)	AROD dataset	75.83%
(Dong <i>et al.</i> 2015)	CUHKPQ dataset	90.76%
The proposed model	BTFE dataset	89.29%

4 CONCLUSION

In this study, a BTAANet based on the LNN is proposed to realize efficient and accurate automatic evaluation of the aesthetic quality of the bridge tower forms. A BTAA Dataset was constructed combined with the standard bridge tower contour image and the evaluation results obtained through the applet. With the BTAA Dataset, TNN models and LNN models were trained. The trained models were then used for aesthetic quality prediction of bridge tower images in the test set, and the prediction accuracy and complexity of these models were evaluated.

The results show that the bridge tower aesthetic assessment is efficiently and accurately implemented using the trained neural networks, and the BTAANet that takes ShuffleNet_v2_x1_0-TL as the base model, not only has the highest accuracy but also the lowest model complexity, which performs best in the bridge tower aesthetics assessment task. In addition, a comparison with similar studies revealed the high accuracy and feasibility of the method in this paper. The proposed method provides an important basis for designers in the design process of bridge towers and promotes the development of bridge aesthetics.

Influence of different curing condition on seismic performance of reinforced concrete bridge piers

Qiang Peng Wen, Liang Lu Wen, Lin Li Feng & Dong Tang Ya

School of Civil Engineering and Architecture, Beijing Jiaotong University, Beijing, China

Feng Xu Lin

Beijing Municipal Design Institute Co., Ltd., Beijing, China

ABSTRACT: In order to explore the influence of different curing conditions on the seismic capacity of reinforced concrete (RC) piers in construction, the mechanical properties of concrete under different curing conditions were tested. Based on the experimental data of concrete mechanical properties and numerical simulation method, the finite element models of RC piers under different curing conditions are established. The quasi-static analysis method is used to compare and analyze the influence of different curing conditions on the seismic performance of RC piers. The results show that the elastic modulus of C50 fine stone concrete is lower than that of cube compressive strength and axial compressive strength, but increases rapidly after 14 days of curing. The basic shape and development trend of the hysteresis curve of RC piers under different curing conditions are similar. The fullness of the hysteresis curve of the same curing temperature and humidity increases with the increase of age. When the curing temperature and humidity are the same, the yield load, ultimate load and ultimate displacement of RC piers increase with the increase of age, and the yield displacement decreases slightly with the increase of age. The curves of cumulative displacement ductility coefficient of RC bridge piers under different curing conditions are similar, and the maximum cumulative displacement ductility coefficient increases with the age when the curing temperature and humidity are the same. Before the horizontal displacement of RC pier top reaches yield displacement under different curing conditions, the change of viscous damping coefficient is small, and the viscous damping coefficient increases sharply after reaching yield displacement. When the curing time is the same, the difference in seismic performance of RC piers between standard curing and natural curing is small; when the curing temperature and humidity are the same, the seismic performance of RC piers at different ages varies greatly.

1 INTRODUCTION

The gradual hardening and strength growth of concrete is the result of cement hydration, which requires certain humidity, temperature and time, and when the construction site temperature and humidity do not meet the curing requirements, the concrete needs to be maintained manually. Differences in curing conditions can lead to significant effects on the mechanical properties of the concrete structure. The precast and cast-in-place concrete structures may not reach the expected strength within the specified time, and the mechanical properties of bridge piers as load-bearing members are more obviously affected by the curing conditions.

Many scholars have conducted a lot of research on the seismic damage of bridges in the construction phase and the seismic performance of bridge piers in the operation phase. Zheng Yuguo (Zheng & Yuan 2013a, b) analyzed the seismic response spectrum of three different pier-shaped large-span continuous girder bridges during the whole construction process, and obtained the change law of seismic response of piers during the whole cantilever construction

process. Tong, Dawei (Tong et al. 2022) considered analytically the effect of construction process and different backfill compaction qualities on the seismic response of prestressed steel barrel concrete pipes. Shi Yan (Shi & Xiong 2013a, Shi & Zhang 2020b) proposed an equivalent load calculation formula for the internal forces of main girders and main piers based on the equivalent load method applicable to the construction phase of continuous rigid frame bridges, and obtained the seismic susceptibility curves of the bottom and top of main piers and the root of main girders by means of finite element software. Yang Cheng (Yang & Chen, et al. 2016) proposed a vulnerability index for bridge construction process with a vulnerability model considering the construction process. Many other scholars (Bai 2019; Jia 2022; Guo 2022; Cao 2021; Lu 2021; Shao 2022; Cheng 2017; Li 2011) have also studied the seismic performance of different bridge piers in the operation phase.

In this paper, the mechanical properties of C50 concrete under different curing conditions were analyzed through tests, and the seismic performance of RC piers under different curing conditions was analyzed based on the test data and using OpenSees finite element software.

2 CONCRETE MECHANICAL PROPERTIES TEST

2.1 Specimen material

The mass ratio of raw material composition of C50 fine stone concrete is: $w(\text{cement}):w(\text{water}):w(\text{sand}):w(\text{stone}):w(\text{Silicafume}):w(\text{admixture}) = 1:0.36:1.81:2.72:0.2:0.014$. Among them, the cement is P-O42.5 cement; the stone is 5-25 continuous grained gravel; the sand is river sand with maximum particle size of 3.2mm; the water is natural water; the fly ash with fineness of 9.4% is chosen as the compound material; the water reducing agent is polycarboxylic acid water reducing agent with water reduction rate of 29%, and the specific ratio is shown in Table 1.

Table 1. Material dosage of C50 fine stone concrete.

Material dosage (kg/m ³)					
cement	water	sand	stone	Silica fume	admixture
400	147	726	1088	83	5.9

2.2 Specimen preparation and curing

Prepare 16 groups of 100mm × 100mm × 300mm prismatic specimens, 3 groups of 100mm × 100mm × 100mm cubic specimens, 8 groups of prismatic specimens and 4 groups of cubic specimens into the curing room for standard curing condition (temperature (20±2)°C, humidity ≥95%), the rest of the specimens are placed in the precast concrete workshop (average daily temperature (18±2)°C, humidity ≥65%) for natural curing condition.

2.3 Test results

The average values of cubic compressive strength f_{cu} , axial compressive strength f_c and modulus of elasticity E_c were determined under different curing conditions up to 7, 14, 28 and 45 days, as shown in Table 2.

3 RC BRIDGE PIER FINITE ELEMENT

3.1 RC bridge pier finite element model

Based on the OpenSees, the Concrete02 material model is selected to simulate the concrete constitutive relationship, and the compressive stress-strain curve is shown in Figure 1(a), where f_{pc} is the compressive strength of concrete; The strain generated when *eposco* concrete reaches its compressive strength; f_{pcu} is the residual compressive strength, for unconfined zone

Table 2. Mechanical properties of C50 fine stone concrete at different curing conditions.

Curing conditions	age/day	f_c /MPa	f_{cu} /MPa	E_c /GPa
Standard Curing	7	43	56	30.4
	14	46.5	61.3	34.7
	28	53.2	68.3	44.1
	45	59.3	71.2	46.6
Natural Curing	7	39.2	50.9	26.4
	14	43.3	56.6	30.2
	28	51.1	62	39.4
	45	53.6	65.3	43.4

concrete take $f_{pcu} = 0.2f_{pc}$; For the core concrete principal structure constrained by hoop reinforcement using the Mander model for calculation, the compressive strength of concrete in the core area of the rectangular section constrained by hoop reinforcement is calculated as:

$$f'_{cc} = f'_c(1 + k_1\bar{x}) \quad (1)$$

In the formula: $k_1 = [0.1 + \frac{0.9}{1+B\bar{x}}]$; f'_c is the cylindrical compressive strength of concrete; A and B are parameters for the increase in concrete strength due to hoop restraint, and the specific values are taken with reference to the literature (Chang & Mander 1994); $\bar{x} = \frac{f'_{11} + f'_{12}}{2f'_c}$, $r = \frac{f'_{11}}{f'_{12}}$, $f'_{11} > f'_{12}$, f'_{11} and f'_{12} are two directional restraint stresses in concrete.

The longitudinal reinforcement tensile stress-strain curve is shown in Figure 1(b). Where f_y is the tensile yield stress; f_u is the tensile ultimate stress; E_s is the tangential modulus in the elastic phase; E_{sh} is the initial tangential modulus in the strengthening phase; ϵ_{sh} is the initial strain in the strengthening phase; ϵ_{su} is the strain when the stress reaches its peak.

Bond slip model of pier bottom reinforcement using Bond_SP01 material model. The skeleton curve is shown in Figure 1(c). Where K is modulus of elasticity of reinforcement; F_y is yield stress of reinforcing steel; F_u is ultimate stress of reinforcing steel; S_y is yield slip of reinforcement; S_u is ultimate slip of reinforcement. In addition, when setting the model parameters, the values of the stiffness reduction factor b and the pinch factor R should be considered, In this paper, the numerical simulation b takes the value of 0.4, R takes the value of 0.8, and each parameter takes the value of reference (Zhao & Srtharan 2007).

Figure 1. Constitutive relation curve of material model.

3.2 RC bridge pier finite element model reliability verification

In order to test the reliability of the numerical simulation method of RC piers, the simulation of reduced-scale RC concrete solid piers carried out by Fang Lin (Fang. 2016) of Southwest Jiaotong University was examined, in the test, the vertical force at the top of the RC bridge pier was constant, and the horizontal direction was subjected to reciprocal cyclic loading. The concrete grade of RC bridge pier is C40, the longitudinal reinforcement is HRP400 and the stirrup is HRB335, and the parameters of the specimen are shown in Table 3.

From Figure 2, it can be seen that both the experimental and simulated hysteresis curves show pinching phenomenon, the morphology and size of both hysteresis loops are similar. The yield loads and yield displacements obtained using Park (Park,R. 1989) method are

Table 3. Specimen parameters.

Number	Size/m	Height/m	Axial pressure ratio	Reinforcement rate	Stirrup spacing	Stirrup ratio
B1	0.5×0.5	2.95	0.5	1.79%	70	2.44%
B2	0.5×0.5	2.95	0.5	1.79%	140	1.22

shown in Table 4. As can be seen from Table 4, the relative errors of yield load and yield displacement obtained from the test and simulation are less than 5%, indicating that the finite element model established in this paper is highly reliable.

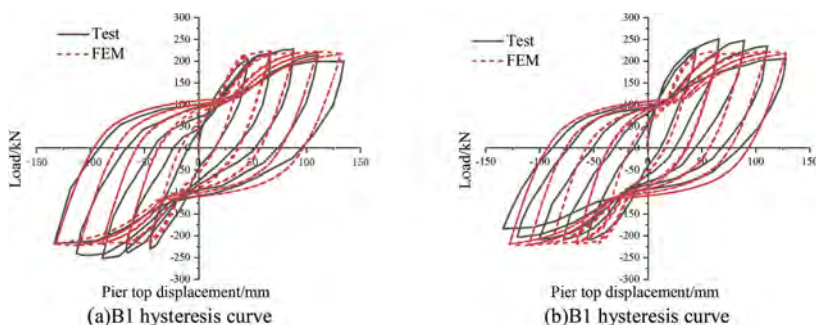

Figure 2. Comparison of test and FEM results.

Table 4. Specimen parameters.

Number	Yield load(kN)			Yield displacement(mm)		
	Test	Simulation	Relative Error	Test	Simulation	Relative Error
B1	210	201	4.29%	40.63	39.5	2.78%
B2	206	198	3.88%	37.72	36.3	3.76%

4 SEISMIC PERFORMANCE OF RC BRIDGE PIERS

4.1 Hysteresis curve

In this paper, the numerical simulation adopts the variable displacement loading system, and the loading level is divided into 9mm, 18mm, 27mm, 36mm, 45mm, 54mm, 63mm, 72mm, 81mm, 90mm, 100mm, 110mm, 120mm及140mm. The hysteresis curves of RC piers under different curing conditions were obtained by numerical simulation once per loading cycle, as shown in Figure 3. From Figure 3, the basic shape and development trend of the hysteresis curve of RC piers under different curing conditions are similar, and the fullness of the hysteresis curve grows with the age when the curing temperature and humidity are the same.

4.2 Skeleton curve

To further compare the seismic performance of RC piers under different curing conditions, the skeleton curves were extracted, as shown in Figure 4. From Figure 4, the horizontal ultimate bearing capacity of the top of the pier grows with the growth of curing time, Standard curing 7 days, 14 days, 28 days and 45 days of the top of the pier horizontal limit bearing capacity of 246.6kN, 250.8kN, 257.6kN and 262kN respectively. The horizontal ultimate bearing capacity of the top of pier for 7 days, 14 days, 28 days and 45 days of natural curing are 241.4kN, 247.1kN, 255.6kN and 257kN respectively.

Figure 3. Hysteresis curves of RC piers under different curing conditions.

Park method is used to calculate the yield displacement of RC piers under different curing conditions, and take the pier top horizontal bearing capacity down to 85% of the ultimate bearing capacity. Yield load f_y , yield displacement Δ_y , ultimate load f_u and ultimate displacement of RC piers under different curing conditions Δ_u are shown in Table 4.

Figure 4. Skeleton curves of RC piers under different curing condition.

Table 5. Numerical simulation results of RC bridge piers under different curing conditions.

Curing conditions	Age/day	f_y /kN	Δ_y /mm	f_u /kN	Δ_u /mm
Standard Curing	7	211.1	20.2	209.6	126
	14	223.9	19.8	213.2	130
	28	229.2	19.2	218.9	135
	45	233.4	18.7	223.1	140
Natural Curing	7	216.1	20.6	204.9	122
	14	221.8	20.2	210.1	126
	28	221.2	19.3	217.3	128
	45	229.1	19	219.2	136

Note: f_y is the yield displacement; Δ_y is the yield displacement; f_u is the ultimate load; Δ_u is the ultimate displacement.

4.3 Cumulative displacement ductility factor

In order to analyze the deformation capacity of RC piers under different curing conditions, the cumulative displacement ductility factor N_Δ is used to analyze its deformation capacity.

N_Δ is calculated as:

$$N_\Delta = \sum_{i=1}^n \frac{\Delta_i}{\Delta_y} \quad (2)$$

in the formula: Δ_i —The average value of positive and negative peak displacement of the i -th cycle loading; Δ_y — Yield displacement; n —The number of cycles loaded in the current state.

The N_Δ variation curves of RC concrete piers under different curing conditions are shown in Figure 5. From Figure 5, the curves of cumulative displacement ductility coefficients of RC piers under standard curing conditions and natural curing conditions have similar trends, and the cumulative displacement ductility coefficients increase with the increase of curing age. The ratio of the maximum cumulative displacement ductility coefficient of 7, 14 and 45 days of standard curing to 28 days of curing is 0.945, 0.964 and 1.02; the ratio of the maximum cumulative displacement ductility coefficient of 7, 14 and 45 days of natural curing to 28 days of curing is 0.936, 0.955 and 1.01. RC bridge pier ductility performance increases with curing time. When the curing time is the same, the difference between standard curing and natural curing RC pier cumulative displacement ductility coefficient maximum value are less than 3%.

Figure 5. Cumulative displacement ductility coefficient of RC under different curing conditions.

4.4 Viscous damping coefficient

In order to analyze the energy dissipation of RC piers under different curing conditions, the viscous damping coefficient ζ_{hys} is used to analyze their energy dissipation capacity. ζ_{hys} is calculated as:

$$\zeta_{hys} = \frac{1}{2\pi} \frac{E_{hys}}{E_{els}} \quad (3)$$

In the formula: E_{hys} —Total energy dissipated during the complete hysteresis cycle; E_{els} —Elastic strain energy corresponding to the maximum displacement in the hysteresis cycle.

The variation curves of ζ_{hys} of RC concrete piers under different curing conditions are shown in Figure 6. From Figure 6, it can be seen that the variation of ζ_{hys} curve under standard and natural conservation conditions is similar. The horizontal displacement of the top of the pier reaches 27mm when the RC piers of different ages have yielded, so that the ζ_{hys} of the RC piers of different ages increase sharply when the next level of loading is carried out. When the horizontal displacement of the top of the pier is less than 64 mm, the ζ_{hys} curves of RC piers at different ages basically overlap, and the ζ_{hys} decreases slightly with the growth of age when the horizontal displacement of the top of the pier is greater than 64 mm, which is due to the growth of both E_{hys} and E_{els} with the growth of age, but the growth rate of E_{els} is slightly greater than E_{hys} resulting in a slight decrease of ζ_{hys} with the growth of age. The maximum values of ζ_{hys} for 7, 14, 28 and 45 days of standard curing were 0.334, 0.325, 0.32 and 0.318, respectively; the maximum values of ζ_{hys} for 7, 14, 28 and 45 days of natural curing were 0.339, 0.328, 0.321 and 0.32, respectively. When the curing time is the same, the difference between the maximum value of viscous damping coefficient of standard curing and natural curing RC piers is less than 2%.

Figure 6. Viscous damping coefficient of RC under different curing conditions.

5 CONCLUSIONS

This paper investigates the seismic performance of RC piers at different ages using the proposed static analysis method based on the results of C50 fine stone concrete mechanical performance tests and the verification of the reliability of the numerical model. The study concluded as follows:

- (1) The basic shape and development trend of RC pier hysteresis curves under different curing conditions are similar, and the degree of fullness grows with the age; The yield load, ultimate load and ultimate displacement of RC piers all increase with age, and the yield displacement decreases with age.
- (2) The curves of cumulative displacement ductility coefficients of RC piers under different curing conditions have similar trends, and the maximum cumulative displacement ductility coefficients of RC piers under the same curing conditions increase with the growth of age.
- (3) Before the horizontal displacement of pier top reaches the yield displacement of RC pier, the change of ζ_{hys} is small; After the horizontal displacement of pier top reaches the yield displacement of RC pier, ζ_{hys} surge; When the horizontal displacement of pier top is less than 81mm, the ζ_{hys} curves of RC piers of different ages basically overlap; ζ_{hys} decreases with age when the horizontal displacement of pier top is greater than 81mm.
- (4) When the curing time is the same, the difference in seismic performance of RC piers with standard curing and natural curing is small; When the curing conditions are the same, the seismic performance of RC piers varies greatly at different ages.

ABSTRACT: The paper presents an application of the novel methodology for the assessment of structures using a semi-probabilistic approach exploiting advanced probabilistic modeling and experimental results. The selected existing bridge is represented by a costly finite element model, which reflects the non-linearity of concrete and the construction process. Due to a significant computational burden of each simulation, it is not feasible to perform a Monte Carlo simulation and a semi-probabilistic approach was thus adopted. In this study, we investigate the possibility of a Gram-Charlier expansion described by the first four central moments efficiently obtained directly from Polynomial Chaos Expansion metamodel together with the uncertainty quantification of input random variables described by a joint probability distribution obtained from experimental data combined with prior assumptions from codes. Obtained results are compared to the standard approach assuming a Lognormal probability distribution of structural resistance.

1 INTRODUCTION

Mathematical models of real structures, e.g. bridges, are typically analyzed by computationally expensive non-linear finite element method (NLFEM) reflecting material and geometrical non-linearity. Non-linear models are not compatible with standard partial safety factors (PSF) implemented in Eurocode (CEN 2002) and advanced probabilistic methods should be employed. Nonetheless, standard probabilistic design or assessment of structures represented by computational models solved by NLFEM is extremely time-consuming and it is usually necessary to use semi-probabilistic methods developed for NLFEM. The paper focuses on the semi-probabilistic assessment of concrete structures using simplified methods.

In the semi-probabilistic approach (Val et al. 1997, Novák & Novák 2021), the resistance of structure R is separated (similarly is in PSF by sensitivity factor α), and the design value R_d that satisfies safety requirements is evaluated, instead of the direct calculation of failure probability. The whole process represents the estimation of a quantile satisfying the given safety requirements under the prescribed simplifying assumptions. The given task is thus simplified to statistical analysis of target probability distribution of resistance (output of the model) – its mean value μ , coefficient of variation (CoV) etc. Safety requirements are given by codes in form of the target reliability index β dependent on consequence classes, e.g. β for the ultimate limit state, moderate consequences of failure and a reference period of 50 years is set at $\beta = 3.8$ according to the Eurocode 1990 (CEN 2002). In this paper, we investigate the role of simplifying assumptions regarding the probability distribution of input variables and resistance (output variable).

The procedure is a combination of the following steps:

- development of NLFEM finite element model of structure (high-fidelity model, computationally very expensive);
- stochastic model based on prior knowledge for input random variables;
- Bayesian approach - based on experimental data updating statistics of input random variables;
- development of surrogate model using Polynomial Chaos Expansion (PCE – low fidelity model, computationally cheap);
- determination of design value of resistance based on statistical moments of resistance directly obtained from PCE or estimated by Monte Carlo using surrogate model using Gram-Charlier expansion.

2 ASSUMPTIONS IN SEMI-PROBABILISTIC APPROACH

Existing simplified semi-probabilistic methods were developed for an estimation of CoV using very low number of samples (ECoV methods), e.g. ECoV by Červenka (Červenka 2013), Taylor Series Expansion (Novák & Novák 2020) or recently developed Eigen ECoV (Novák & Novák 2021). These methods are based on very strict assumptions, which allow to use simple formulas together with a few numerical simulations (e.g. 2 for ECoV by Červenka or 3 for Eigen ECoV) for an estimation of the first two statistical moments. The mean value μ and variance σ^2 are further used to describe an assumed 2-parametric probability distribution of resistance, typically Lognormal distribution or Gaussian distribution. Lognormal distribution is moreover recommended as a typical distribution for modeling of resistance in codes (fib 2013, CEN 2002, JCSS 2001). This has well-justified rationale: Lognormal distribution is non-negative (reflecting reality) and it is fully-described by the first two statistical moments (computational efficiency). However, this paper presents methodology for semi-probabilistic approach for medium-size experimental design (ED) 10-100 samples. In that case, it is possible to construct a surrogate model sufficiently accurate for an estimation of higher statistical moments. Additionally it will be shown that it is beneficial to use Bayesian updating of input variables to estimate a realistic R_d incorporating real data obtained from material experiments for input random variables.

2.1 Standard approach

The standard formula for the estimation of R_d , assuming a Lognormal distribution of R , is

$$R_d = \mu_R \cdot \exp(-\alpha_R \beta v_R), \quad (1)$$

where μ_R is the mean value, v_R is the coefficient of variation (CoV) and α_R represents sensitivity factor derived from First Order Reliability Method (FORM); the recommended value is $\alpha_R = 0.8$ according to Eurocode 1990 (CEN 2002). In this case, it is necessary to estimate only the first two statistical moments μ and σ^2 . Estimation of statistical moments using ECoV methods is based on numerical simulations with specific quantile of input random variables, e.g. mean values and characteristic values of material parameters. Although such an approach is extremely efficient, it is also very limited to assumed Lognormal distribution of resistance. There are many studies investigating this approach and comparing various ECoV methods (Schlune et al. 2011, Bagge 2020, Novák et al. 2022). Although ECoV methods are well-suited for extremely computational expensive numerical models, their limitations could lead to inaccurate results as probability distribution of resistance can differ from Lognormal distribution significantly in some cases (eg. high non-linearity). Thus the further paragraphs describe a methodology based on Polynomial Chaos and Gram-Charlier Expansions used for estimation of higher statistical moments and construction of an artificial probability distribution for structural resistance.

2.2 Polynomial chaos and gram-charlier expansions

An approximation of cumulative distribution function (CDF) F_R of structural resistance R by Gram-Charlier expansion (G-C) is a completely determined by the first four statistical

moments obtained here efficiently from Polynomial Chaos Expansion (PCE). Assuming that it is possible to write probability distribution of R as a perturbation of Gaussian Gaussian probability distribution function (PDF) ϕ . Once the R is normalized to be zero-mean and unit-variance, it is possible to write the Gram-Charlier approximation of CDF in the terms of its higher central moments (skewness γ_Y and kurtosis κ_Y) as:

$$F_R = \Phi(r) - \left[\frac{\gamma_Y}{3\sqrt{2!}} H_2(r) + \frac{\kappa_Y - 3}{4\sqrt{3!}} H_3(r) \right] \phi(r). \quad (2)$$

where $H_n(r)$ are probabilists' Hermite polynomials of n -th order and $\Phi(r)$ represents standard Gaussian CDF.

It is typically not feasible to get higher statistical moments by crude Monte Carlo simulation due to its computational demands, moreover the moments estimated from samples are highly sensitive to outliers. Fortunately, it is possible to get statistical moments analytically in case of PCE, which represents the output variable R as a function g^{PCE} of an another random variable ξ called the germ with given distribution and representing the original computational model $R = g(X)$ via polynomial expansion. A set of polynomials, orthonormal with respect to the probability distribution of the germ, are used as a basis of the Hilbert space of all real-valued random variables of finite variance. In the case of X and ξ being vectors containing M random variables, the polynomial $\Psi(\xi)$ is multivariate and it is built up as a tensor product of univariate orthogonal polynomials:

$$R = g(X) = \sum_{\alpha \in \mathbb{N}^M} \beta_\alpha \Psi_\alpha(\xi), \quad (3)$$

where $\alpha \in \mathbb{N}^M$ is a set of integers called the multi-index corresponding to polynomial orders in each term of PCE, β_α are deterministic coefficients and Ψ_α are multivariate orthogonal polynomials. Coefficients β_α can be usually obtained by ordinary least squares.

Once a PCE approximation is created, it is possible to obtain statistical moments of R analytically, which represents an enormous advantage with respect to this study, as will be shown in computationally expensive numerical example. Specifically, the first statistical moment (mean value) is equal to the first deterministic coefficient of the expansion

$$\mu_R = \langle Y^1 \rangle = \beta_0. \quad (4)$$

Further the variance $\sigma_Y^2 = \langle Y^2 \rangle - \mu_Y^2$ is obtained as a sum of all squared deterministic coefficients except the intercept, which represents the mean value:

$$\sigma_R^2 = \sum_{\substack{\alpha \in A \\ \alpha \neq 0}} \beta_\alpha^2. \quad (5)$$

Higher statistical central moments, skewness γ_R (3^{rd} moment) and kurtosis κ_R (4^{th} moment), can be similarly obtained analytically for Legendre and Hermite polynomials (Novák 2022).

2.3 Bayesian approach

Given some experimental data \mathcal{D} for input model parameters, a parameterized model for the data (likelihood function) $p(\mathcal{D}|\theta)$, and a prior probability density $p(\theta)$ for the model parameters, the posterior probability density function (PDF) $p(\theta|\mathcal{D})$ of the model can be identified by Bayesian theorem:

$$p(\theta|\mathcal{D}) = \frac{p(\mathcal{D}|\theta)p(\theta)}{p(\mathcal{D})}. \quad (6)$$

Although Bayes' rule looks simple, its efficient evaluation is still challenging and it must be calculated numerically, and thus Markov Chain Monte Carlo sampling (MCMC) is employed in this paper. For numerical calculation, we use existing algorithm implemented in UQPy package for Python (Olivier et al. 2020). Such an approach allows updating prior knowledge about the material characteristics (Rózsás et al., 2022). In this study, Bayesian approach is employed for updating of materials' statistics (mean and variance) obtained from codes combining prior knowledge and results obtained from laboratory experiments. Obtained updated statistics of input random variables together with prescribed probability distribution function were further used in Monte Carlo simulation using surrogate model in form of PCE. Note that evaluation of PCE is very fast even for very large number of simulations used for estimation of higher statistical moments. Estimated statistical moments were ultimately used for G-C expansion and an estimation of R_d as described in section 2.2.

3 NUMERICAL APPLICATION: POST-TENSIONED CONCRETE BRIDGE

The proposed methodology is applied for the existing post-tensioned concrete bridge with three spans. The super-structure of the mid-span analyzed by NLFEM is 19.98 m long with total width 16.60 m. In transverse direction, each span is constructed from 16 prefabricated bridge girders KA-61 commonly used in Czech Republic. Load is applied according to national annex of Eurocode for load-bearing capacity of road bridges by exclusive loading (by six-axial truck).

3.1 Finite element model

The numerical model is created in software ATENA Science based on theory of non-linear fracture mechanics (Červenka & Papanikolaou 2008). In order to reflect complex behavior of the bridge, the numerical model contains three construction phases as illustrated in Figure 1. The NLFEM consists of 13,000 elements of hexahedra type in the major part of the volume and triangular 'PRISM' elements in the part with complicated geometry. Reinforcement and prestressing tendons are represented by discrete 1D elements with geometry according to original documentation. The numerical model is further analysed in order to investigate the ultimate limit state (ULS) (peak of a load-deflection diagram) in order to determine the load-bearing capacity of the bridge. Load-deflection diagram from simulation using mean values of input random variables can be seen in Figure 2 together with typical crack pattern and highlighted 3 limit states: decompression, the first occurrence of cracks and ULS represented by collapse of the bridge.

Figure 1. Three construction phases of the bridge mid-span analysed by NLFEM.

3.2 Stochastic model

The stochastic model contains 4 random material parameters of concrete C50/60: Young's modulus E ; compressive strength of concrete f_c ; tensile strength of concrete f_{ct} and fracture

energy G_f . Characteristic values of E , f_{ct} , G_f were determined from f_c according to formulas implemented in the fib Model Code 2010 (fib 2013) – G_f , E , and prEN 1992-1-1: 2021 (CEN 2021) – f_{ct} . The last random variable P represents prestressing losses according to JCSS: Probabilistic Model Code (JCSS 2001). The stochastic model is summarized in Table 1. Mean values and coefficients the of variation were obtained according to prEN 1992-1-1: 2021 (Annex A) for adjustment of partial factors for materials. Statistical correlation among random variables was not considered in this study.

Table 1. Stochastic model of the numerical example.

Var.	Mean	CoV [%]	Distrib.	Units
f_c	56	16	Lognormal	[MPa]
f_{ct}	3.64	22	Lognormal	[MPa]
E	36	16	Lognormal	[GPa]
G_f	195	22	Lognormal	[Jm2]
P	20	30	Normal	[%]

3.3 Results

Once the stochastic model was defined and computational model was developed in ATENA Science, it was possible to create 30 realizations of input random vector generated by Latin Hypercube Sampling (Iman & Conover 1980, Novák et al. 2014, 2022), which covers the whole design domain, and thus it is suitable technique for construction of ED for surrogate modeling. Note that each simulation takes approximately 24 hours using standard hardware. The PCE is created with maximum polynomial order $p = 5$. The whole algorithm of adaptive construction of PCE connecting state of art techniques into stand-alone software tool can be found in (Novák & Novák 2018). The design values of resistance R_d are determined as a quantile of distribution of R with identified statistical moments and target reliability indices $\beta_{ULS} = 3.8$ according to EN 1990. Additionally, design values are reduced by global safety factor reflecting model uncertainties $\gamma_{R_d} = 1.06$ introduced originally in fib Model Code 2010. Note that we compare three design values obtained by described semi-probabilistic approach: i) standard approach assuming Lognormal distribution of R parameterized by the first two statistical moments obtained by PCE; ii) R_d as a quantile of artificial probability distribution constructed by G-C parametrized by the first four statistical moment obtained by PCE and iii) combination of G-C expansion of R and Bayesian updating of input parameters.

Figure 2. Design values of resistance obtained by semi-probabilistic approach determined by the described methods together with corresponding PDFs.

Bayesian updating is performed using artificially generated data: 20 experiments of concrete specimens. Note that artificially generated data have realistic CoVs of material parameters, which were identified in the previous experimental campaigns (Slowik et al. 2021). Prior distribution of material characteristic was assumed to be Uniform and likelihood distribution is selected according to Table 1, i.e. distributions provided in codes. Obtained results can be found in Figure 3: each row corresponds to a specific material characteristic, the first column shows estimation of mean value and the second column shows estimation of standard deviation. Both columns, the first and second, show also prior and posterior distribution identified by Bayesian approach. Vertical solid lines corresponds to values assumed by codes, obtained directly from experiments by statistical processing and the Bayesian estimation identified as a mean value of posterior distribution. The very last column shows 5000 samples used in MCMC for estimation of posterior distributions. Note that the identified values are significantly different in comparison to recommended values by codes, but this is dependent on real-life experimental results.

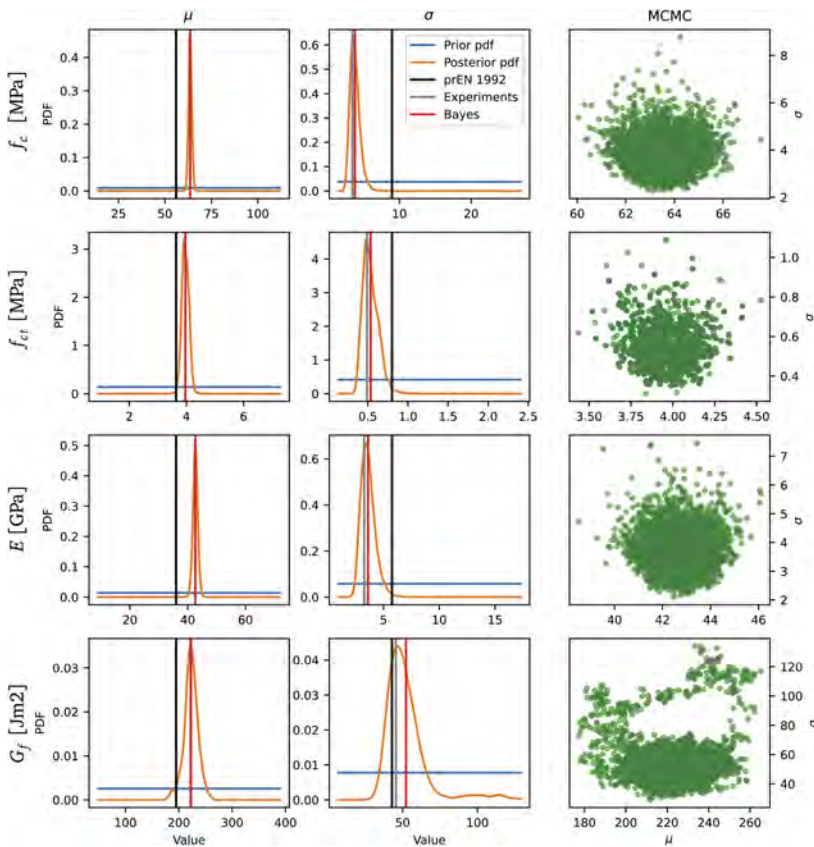

Figure 3. Bayesian estimation of mean μ and standard deviation σ of concrete material characteristics. Solid vertical lines show values determined by codes, experiments and Bayesian approach.

Once the PCE was created, it was possible to analytically derive statistical moments used for Lognormal (first two statistical moments) and G-C expansion (first four statistical moments). The difference between these two design values (corresponding to the identical percentile) is caused by higher statistical moments. Further, the created PCE was employed as computationally cheap surrogate model for crude Monte Carlo simulation with 106 realizations of input random variables identified by Bayesian approach. So Bayes G-C expansion was based on estimation of first four statistical moments needed for Gram-Charlier expansion by Monte Carlo simulation. Comparison of identified PDFs together with determined design values of resistance R_d can be found in 4.

4 CONCLUSIONS

The paper described the advanced semi-probabilistic methodology based on G-C and PCE for estimation of higher statistical moments and an approximation of probability distribution of structural resistance. Additionally, estimation was further improved by Bayesian estimation of input random variables combining likelihood distributions from codes with material experiments. The whole methodology was applied for an estimation of design value of resistance of existing post-tensioned concrete bridge. It can be seen from comparison of determined design values, that is beneficial to include additional information on structural parameters (Bayesian approach) as well as higher statistical moments (G-C expansion). Methodology was shown using concrete bridge example, exploiting additional experimental data and Bayesian approach resulted in less conservative design value here.

Figure 4. Design values of resistance obtained by semi-probabilistic approach determined by the described methods together with corresponding PDFs.

Probabilistic structural assessment of RC bridges under corrosion based on efficient simulation methods

F. Padovani

Amplia Infrastructures, Milan, Italy

L. Capacci & F. Biondini

Politecnico di Milano, Milan, Italy

ABSTRACT: The life-cycle assessment of structural reliability and seismic vulnerability of aging bridges is a key issue for optimal management of critical components of transportation systems. Predictive models of the structural performance should be able to integrate uncertainties associated with material properties and environmental stressors. In a life-cycle context, simulation-based methods relying on time-consuming non-linear structural analyses may require unfeasible computational efforts, especially when mechanical non-linearities are involved in structural response of deteriorating members. This paper presents a computational approach for lifetime structural reliability assessment of deteriorating Reinforced Concrete (RC) structures. The life-cycle numerical estimate of failure probability is evaluated over time based on suitable adaptation of Importance Sampling considering a Stationary Proposal distribution to efficiently select the sample structural models. The proposed methodology is investigated for seismic fragility assessment of a RC bridge pier under corrosion based on non-linear static pushover analysis.

1 INTRODUCTION

The performance of infrastructure networks depends on the structural integrity of stand-alone components, such as bridges in transportation networks (Capacci and Biondini 2020). In life-cycle analysis of civil structures and infrastructure systems, the random variability of basic input parameters can be exacerbated by aging and structural deterioration processes, such as fatigue and corrosion (Biondini and Frangopol 2016). In this context, life-cycle probabilistic frameworks adopted for the structural assessment of seismic capacity evolving over time need not only accurate analytical models properly calibrated by experimental data, but also effective numerical tools to accurately estimate statistical descriptors and failure probabilities. Numerical methods based on Monte Carlo Simulation (MCS) often lack efficiency, since the probabilistic assessment of structural systems typically involving small failure probabilities would require huge samples, leading to unfeasible computational efforts (Melchers and Beck 2018).

Variance reduction techniques have been formulated in the past decades to improve the efficiency of simulation methods by minimizing the structural samples needed to obtain sufficiently accurate estimates of failure probabilities. Importance Sampling (IS) exploits a proposal density to simulate basic random variables in proximity of the most relevant portions of the failure region. The main issue of IS approaches lies in the appropriate selection of the important density (Au and Beck 1999, Neal 2001, Rubinstein and Kroese 2004) and in their inefficiency when a large number of basic random variables are involved, i.e., the curse of dimensionality (Au and Beck 2003). Subset simulation exploits Markov-chain Monte Carlo procedures to provide a probability estimate as the product of conditional probabilities (Au and Beck 2001). Directional simulation (Ditlevsen et al. 1986, Bjerager 1988) and line sampling methods (Schuëller et al. 2004) deal with a reformulated version of the reliability

problem transforming basic RVs and evaluating the limit state function in polar coordinates. Failure regions in the sample space can be a-priori excluded in the simulation process by censor sampling techniques (Grooteman 2008, Thedy and Liao 2021). The sample space can be efficiently mapped also by means of data reduction techniques such as clustering algorithms (Capacci and Biondini 2022a) and by functional quantization (Miranda and Bocchini 2015). Simulation procedures can be enhanced at the sample generation stage adopting Latin hypercube sampling techniques (Helton and Davis 2003). Finally, surrogate models are adopted to enhance the efficiency of the reliability estimate by suitably calibrating approximate limit state functions (Kaymaz and McMahon 2005, Dubourg et al. 2011).

This paper presents an IS methodology tailored for life-cycle reliability problems by adopting a Stationary Proposal (SP) distribution. The basic concepts and implementation strategies of the proposed SP-IS approach are briefly illustrated. Potentialities and limitations of the proposed simulation procedure are hence investigated and discussed with reference to time-variant pushover analyses conducted on a four-span highway bridge under severe chloride-induced corrosion of the hollow core Reinforced Concrete (RC) piers.

2 STRUCTURAL RELIABILITY AND SIMULATION

2.1 Failure probability of deteriorating structures

The failure probability is associated with the failure region F in the sample space of the Random Variables (RVs) collected in a vector \mathbf{X} and characterized by the joint Probability Density Function (PDF) $f_{\mathbf{X}}(\mathbf{x})$. The boundaries of failure and safety regions are expressed by a limit state surface $g(\mathbf{X})=0$. The failure probability is conveniently expressed as the expectation of the indicator function I , which is unitary in the failure region (i.e., $\mathbf{X} \in F$) and null in the safety region (i.e., $\mathbf{X} \notin F$):

$$P_F = \int_{\mathcal{Z}} I[g(\mathbf{X}) = 0] \cdot f_{\mathbf{X}}(\mathbf{x}) d\mathbf{x} \quad (1)$$

Uncertainties in environmental hazard parameters, such as concentration of aggressive chemical agents and permeability of structural materials, may exacerbate the fragility of the structural system over time. Indeed, deterioration processes involves the evolution of the basic random variables described by the time-variant joint PDF $f_{\mathbf{X}}(t)$ and, in turn, will lead to a progressive decay of structural reliability.

2.2 Monte Carlo Simulation (MCS)

Simulation methods are robust and intuitive approaches to solve structural reliability problems with adequate accuracy. Traditional MCS provides an unbiased probability estimator through the artificial generation of a set of samples \mathbf{x}_i based on the actual distribution $f_{\mathbf{X}}(\mathbf{x})$ of the RVs:

$$p_{MCS} = \frac{1}{N} \sum_{i=1}^N I[g(\mathbf{x}_i) \leq 0] \quad (2)$$

The accuracy of the MCS estimate can be quantified by the Coefficient of Variation (CoV) of the failure estimator (Melchers and Beck 2018):

$$\text{CoV}[p_{MCS}] = \frac{\sqrt{p_{MCS} \cdot (1 - p_{MCS})}}{p_{MCS} \sqrt{N}} \approx \frac{1}{\sqrt{p_{MCS} \cdot N}} \quad (3)$$

For small values of the target failure probability P_f , the estimate CoV is inversely proportional to both sample size N and estimated probability p_{MCS} . Therefore, small failure probabilities require a significant computational effort, which would be unfeasible for complex non-linear

structural systems and time-consuming analysis methods. Nonetheless, such computational cost is further increased in life-cycle reliability problems, in which the reliability of the investigated structure is deemed to be estimated over a timeframe spanning its entire service life.

2.3 Stationary Proposal Importance Sampling (SP-IS)

The proposed SP-IS methodology relies on the selection of a convenient time-invariant density ψ to simulate samples of the basic RVs. An unbiased probability estimate is provided weighting the indicator function by the time-variant coefficient $W(\mathbf{x}|t)$ given by the ratio between the actual time-variant density $f_{\mathbf{x}}(t)$ and the proposal distribution ψ :

$$p_{IS}(t) = \frac{1}{N} \sum_{i=1}^N I[g(\mathbf{x}_i) \leq 0] \cdot W(\mathbf{x}|t) \quad (4)$$

Therefore, the reliability estimates are computed by weighting each failed sample based on the actual distribution of the stochastic processes describing the probabilistic evolution of structural damage throughout the system lifetime. A quantitative measure of the probability estimator accuracy can be expressed based on its variance estimate, as presented in Capacci and Biondini (2023):

$$\sigma_{IS}^2(t) = \frac{1}{N-1} \left\{ \frac{1}{N} \sum_{i=1}^N [I[g(\mathbf{x}_i) \leq 0] \cdot w_i^2(t)] - p_{IS}^2(t) \right\} \quad (5)$$

3 CASE STUDY

3.1 Four-span viaduct with RC piers exposed to chloride-induced corrosion

The life-cycle seismic reliability of the four-span RC viaduct shown in Figure 1 is investigated (Franchin et al. 2023). An isometric view representative of the structural model is shown in Figure 1a. RC bridge piers are composed by two bents with hollow-core rectangular cross-sections connected on top by a pier cap, as shown in Figure 1b. Along the longitudinal direction x , the static scheme of the bridge piers is similar to a vertical cantilever, whereas, in the transversal direction y , exhibits a frame type resisting mechanism. The steel-concrete composite deck is moderately free to slide in the longitudinal direction over both the outer joints at the abutments and the pier P1 whereas fixed-type bearings prevent the relative transversal displacements of the deck over the abutments and all piers. Figure 1c shows the geometry and the reinforcement layout of a single-bent base cross-section (pier P3). The wall thickness at the base of the tallest piers (P2 and P3) is 0.65 m over a length of 10 m and then reduced to 0.40 m. The wall thickness of the pier P1 is 0.40 m. The net concrete cover is 75 mm. The piers are considered exposed to a chloride concentration C_0 over external and internal surfaces of the hollow-core cross-sectional profile.

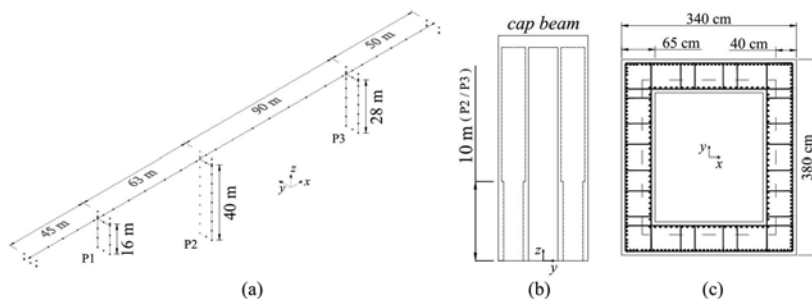

Figure 1. Highway bridge: (a) Structural model; (b) Transverse sectional view of a bridge pier; (c) single-bent cross-section at the base of pier P3.

3.2 Corrosion damage modeling

Chloride attack reduces the resisting area of steel reinforcement (Biondini et al. 2004):

$$A_s = [1 - \delta_s(t)]A_{s0} \quad (6)$$

where A_{s0} is the area of the undamaged reinforcement and $\delta_s(t) \in [0,1]$ is a dimensionless damage index representative of the percentage of steel mass loss. In addition, a progressive reduction in time of steel ductility ε_{su} is considered as proposed in Biondini and Vergani (2015).

$$\varepsilon_{su}(t) = \begin{cases} \varepsilon_{su0} & 0 \leq \delta_s \leq 0.016 \\ 0.1521 \cdot \varepsilon_{su0} \cdot [\delta_s(t)]^{-0.4583} & 0.016 \leq \delta_s \leq 1 \end{cases} \quad (7)$$

where $\varepsilon_{su0}=0.075$ is the initial steel strain elongation capacity. Corrosion is also responsible for the onset of expansion products inducing splitting cracks up to spalling over the concrete surrounding the reinforcement. This phenomenon is modelled applying a reduction of the concrete strength f_c over the concrete cover according to Coronelli and Gambarova (2004) based on the modelling strategy presented in Biondini and Vergani (2015).

Corrosion initiates at time t_{cr} when chlorides reach a critical mass concentration C_{cr} , i.e., $C(t_{cr})=C_{cr}$. In the damage propagation phase, the damage index δ_s is related to the concentration $C=C(t)$ of the aggressive agent by assuming a linear relationship (Biondini et al. 2004):

$$\frac{\partial \delta_s(t)}{\partial t} = q_s C(t) \quad (8)$$

where q_s is a damage rate coefficient.

The one-dimensional Fick's diffusion equation is often used to define the profile in time of the chloride concentration $C(x_c, t)$ at a given depth x_c with diffusivity D :

$$C(x_c, t) = C_0 \left[1 - \operatorname{erf} \left(\frac{x_c}{2\sqrt{Dt}} \right) \right] \quad (9)$$

This simplified approach is considered in this paper. However, it is worth noting that for structural members with complex geometry and non-uniform chloride concentration exposure the diffusion process should be more accurately described by two- or three-dimensional patterns of concentration gradients (Biondini et al. 2004, Titi & Biondini 2016).

3.3 Modelling of uncertainties

Uncertainties can be associated to mechanical properties of the pristine structure, such as concrete and steel strengths, as well as the governing parameters of the degradation phenomenon. Such variability is addressed by modeling the following parameters as statistically independent random variables: unconfined concrete strength f_{c0} , steel yielding strength f_y , concrete diffusivity D , surface chloride concentration C_0 , critical chloride concentration C_{cr} , damage rate q_s . Distribution type and statistical descriptors are reported in Table 1 for each random variable.

3.4 Structural modeling and non-linear static analysis

The three-dimensional structural model of the bridge is implemented in OpenSees (Mazzoni et al 2009). The deck is modeled with elastic beam elements. Elastic connections and rigid offsets are adopted to model the deck-to-abutment and deck-to-pier connections between the end nodes of the elements. A bilinear model with effective stiffness applies for the expansion joints at the abutments and a uniaxial viscous damper is also considered at one end. The pier bents are modeled with force-based fiber beam-column elements considering both material and geometrical non-linearities and taking into account the actual distribution of steel reinforcement over the height of the piers. More in detail, a trilinear model for the generalized shear stress-strain relationship is integrated within the force-based formulation to account for the post-elastic

Table 1. Probability distributions.

Random Variable	Distribution Type	Mean μ	CoV
Concrete strength f_{c0} [MPa]	Lognormal	40.02	12.50%
Yielding strength f_y [MPa]	Lognormal	487.58	6.15%
Diffusivity D [m ² /sec]	Normal*	15.8×10^{-12}	20.00%
Surface concentration C_0 [wt. %/c]	Normal*	3.0	30.00%

Damage rate q_s [1/(wt. %/c yrs)]	Normal*	1/(C_0 50 yrs)	30.00%

* Truncated positive.

** Bounded distribution $\in [0.2, 2.0]$ wt. %/c.

shear behaviour of the piers. A stress-strain model in compression with strength f_{c0} (Table 1), peak strain $\epsilon_{cc} = -0.002$, ultimate strain $\epsilon_{cu} = -0.0035$, and zero tensile strength is considered for unconfined concrete fibers. For confined concrete fibers, the concrete strength f_{cc} and the other constitutive parameters of the stress-strain model in compression are related to the transversal reinforcement ratio ρ_s according to Mander et al. (1989), with tensile strength $f_t = -0.1f_{cc}$ and spalling strain $\epsilon_{sp} = 0.007$. A bilinear elastic-plastic model is assumed for steel reinforcement with yielding strength f_y (Table 1), elastic modulus $E_s = 206$ GPa and post-yielding modulus $0.15E_s$. Further information about structural modeling of the bridge can be found in Padovani (2022).

Non-linear static pushover analysis represents an effective way to explore the seismic capacity of RC bridges as an alternative to computationally demanding non-linear time-history analysis (Petronijević et al. 2018, Isaković and Fischinger 2011, Biondini et al. 2014). Figure 2 shows the results of deterministic non-linear static analyses of the bridge performed in both longitudinal direction x (Figure 2a) and transversal direction y (Figure 2b) at different time instants ($t=0, 30$, and 50 years) by assuming mean values in Table 1 as nominal values and a load pattern consistent with the first modal shape. The capacity curves in terms of total base shear of the piers vs drift of pier P2 highlight the detrimental impact of corrosion in terms of stiffness, strength, and ductility. The reduction in terms of stiffness and strength is similar in both directions, while reduction of ductility is particularly critical in the longitudinal direction. Moreover, in the transversal direction the failure mode of the critical regions at the base of the piers is changing over time since structural capacity is attained with concrete failure at $t=0$ and 30 years and steel failure at $t=50$ years.

Figure 2. Nominal capacity curves in terms of total base shear of the piers vs drift of pier P2 at different time instants ($t=0, 30$, and 50 years): (a) Longitudinal direction; (b) Transversal direction.

3.4 Life-cycle probabilistic seismic analysis

The effects of uncertainties on the corrosion damage and seismic response are taken into account. Figure 3 shows the empirical CDF of the corrosion damage index δ_s every 10 years up to 50 years of lifetime based on MCS with sample size $N=10000$. The severity of the damage scenario is indicated by the large likelihood of corrosion initiation after 10 years, i.e., $P[\delta_s(10 \text{ yrs}) > 0] \approx 95\%$, and the probability of occurrence of extensive damage conditions progressively increases in time.

Figure 3. Empirical cumulative distribution function of the damage index.

Figure 4 shows the results of non-linear static analyses in the longitudinal direction based on a sample of 1000 realizations. The capacity curves in terms of total base shear of the piers vs drift of pier P2 in pristine conditions (Figure 4a), as well as after 30 years (Figure 4b) and 50 years (Figure 4c), highlight the impact of randomness of material properties in the structural response over time, that is particularly evident on stiffness, strength, and ductility. Random variability of concrete strength mainly influences the cracking capacity, whilst steel strength significantly influences both yielding and ultimate capacities. In the early loading stage, the stiffness is mildly affected in the elastic range by damage and spalling of concrete cover. Also, strength and ductility drastically reduce over time respectively due to steel mass loss and reduction of steel ultimate strain capacity. The significant correlation between displacement capacity and damage index can be informative for the selection of effective simulation densities in the SP-IS methodology.

Figure 4. Capacity curves in terms of total base shear of the piers vs drift of pier P2 based on a sample of 1000 realizations: (a) $t=0$; (b) $t=30$ years; and (c) $t=50$ years.

3.5 Life-cycle structural reliability and comparison of simulation methods

Time-variant failure probabilities are investigated with respect to damage limitation associated to the attainment of prescribed drift threshold values described by the following limit state function:

$$\{g_s(\mathbf{X}) \leq 0\} \equiv \{\theta_x^{ult}(f_c, f_y, D, q_s, C_0, C_{cr}) \leq \theta_x^{lim}\} \quad (10)$$

Two damage limitation conditions are considered, with limit state g_1 associated to drift limit $\theta_x^{lim}=1\%$ and limit state g_2 with $\theta_x^{lim}=2\%$. The estimate of the time-variant occurrence probabilities is obtained by MCS. The reliability index $\beta_{MCS}(t)=\Phi^{-1}[1-p_{MCS}(t)]$ is shown in Figure 5a. The related CoV versus the sample size is shown in Figure 5b. The reliability estimates are only available for a limited range of time instants from 20/30 years on, when failure tends to occur with a minor ultimate displacement due to structural deterioration. From Figure 5b is clear that more than 10000 samples would have been necessary to estimate with sufficient accuracy the reliability associated to limit state g_1 at 30 years, which is higher than 3.0. This emphasizes the need of effective variance reduction techniques, such as SP-IS, for life-cycle reliability problems.

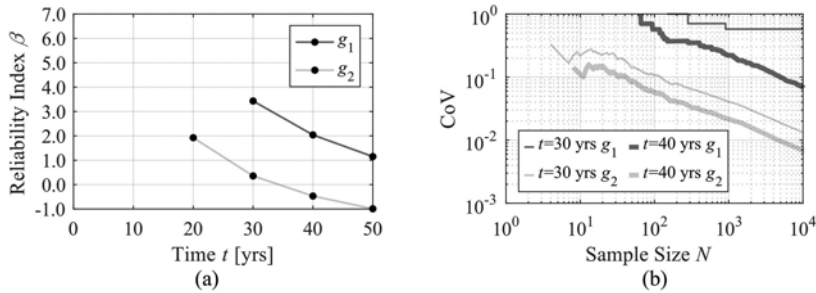

Figure 5. Time-variant reliability assessment based on MCS: (a) Reliability index and (b) CoV.

An intuitive choice for the SP-IS density function for the damage index is the distribution obtained at 50 years Figure 3. The actual time-variant PDFs of the damage index are analytically unknown. Therefore, the time-variant weighting coefficients w_i in the SP-IS framework can only be evaluated in an approximate way. They can be quantified either based on the calibration of suitable analytical distributions or by numerically estimating the empirical PMFs indicator over suitable statistical bins within the damage index sample space (Capacci 2020).

Figure 6a shows the SP-IS time-variant estimates of the reliability index β_{SP-IS} in comparison with the results obtained with MCS. The results of both methods are comparable, yet SP-IS allows to evaluate the reliability estimates for a denser set of time instants (i.e., every 5 years rather than 10) due to the minimal computational effort required by the evaluation of the weighting coefficients w_i in place of carrying out time-consuming structural analyses. Nonetheless, SP-IS can also provide reliability estimates at early time instants in which small failure probabilities are deemed to be estimated. Better accuracy for early time instants could be further achieved by establishing an SP-IS density also for the material strengths. Finally, the comparison between the CoVs of reliability estimates versus the sample size N shown in Figure 6b further consolidates that SP-IS outperforms MCS in terms of accuracy for limit state g_1 at 30 and 40 years.

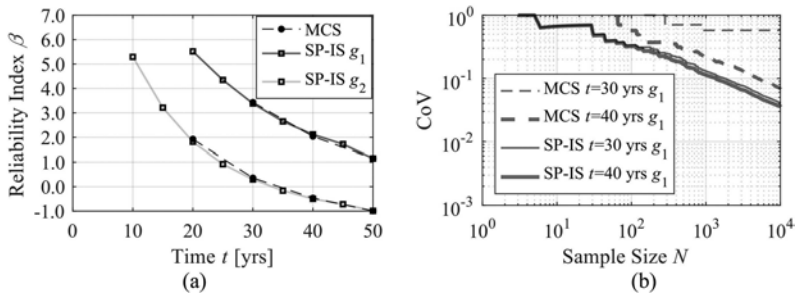

Figure 6. Stationary-proposal importance sampling reliability index of displacement capacity limit states (a) and related convergence of the estimate (b). Monte Carlo results are reported with dashed-lines.

4 CONCLUSIONS

Efficient numerical strategies for probabilistic structural assessment represent valuable tools to aid design and assessment, maintenance and repair, emergency management and resources prioritization under uncertainties of resilient infrastructure facilities such as bridges and viaducts. This paper discusses simulation-based approaches typically adopted in structural reliability analysis and raises the issue of efficiently estimating the time-variant failure probability of deteriorating structures. To this purpose, a novel methodology is formulated to extend basic variance reduction techniques, such as IS, to structural reliability problems with a life-cycle perspective. The method relies on the selection of a SP simulation density to efficiently sample structural systems accounting for time-variant modeling uncertainties typical of life-cycle reliability problems.

The proposed methodology can thrive when time-consuming analyses are required to assess the structural response of systems characterized by a limited number of time-variant constitutive parameters. The proposed SP-IS framework has been applied to probabilistic assessment of a RC bridge with two-bent piers exposed to chloride-induced corrosion. The results show that SP-IS can outperform traditional MCS approaches when a suitable proposal density is adopted.

Further research is currently ongoing to establish optimal criteria for the selection of the sampling distribution based on cross-entropy minimization methods for reliability problems extended to a life-cycle perspective as well as seismic risk assessment of vulnerable infrastructure lifelines (Capacci and Biondini 2023). Advances are necessary to address the feasibility limitations in high-dimensional reliability problems with complex deterioration patterns. The investigation of other potential fields of application of the proposed methodology should include calibration of time-variant seismic fragility curves of aging bridges (Capacci and Biondini 2022b), reliability analysis of structural systems under climate change considering non-stationary climate conditions (Nava et al. 2023), and reliability-based life-cycle design optimization, among others.

Life-cycle assessment of Tunnel Boring Machine (TBM) segments of a new tunnel: Carbonation attack and sulfate attack

F.T. Torabian, I. Vangelisti & C. Beltrami
Lombardi Ingegneria s.r.l., Milan, Italy

ABSTRACT: The life cycle of TBM segments of a new tunnel were assessed considering two main degradations for the side exposed to ambient air and for the side exposed to the ground. The two degradations were carbonation attack and sulfate attack, respectively. In order to numerically model these two degradations, Full-Probabilistic Approach (FPA) was employed, using fib34 and FEM model, respectively. To calibrate the model for the carbonation simulation, inverse carbonation resistance $R_{acc,0}^{-1}$ of the concrete mix (40% slag, w/c=0.35, cement = 467 kg/m³) used for TBM segments, was examined in the laboratory. The relative humidity values were also acquired from the nearest weather station in the area. To calibrate the FEM model for the sulfate attack, the chemical composition of the ground and groundwater was acquired from the nearest geological boreholes. The results showed that the carbonation penetration after 100 years of service life in term of 95th percentiles of normal distribution is 14 mm. The carbonation penetration depth in comparison to 50mm concrete cover of the TBM segment does not seem to be problematic and results in <0.1% failure probability. Moreover, thickness loss due to decalcification of CSH by sulfate attack in terms of 95th percentiles of normal distribution is 7.22mm. The thickness loss does not seem to be problematic for the extrados of the TBM segments, comparing to the 50mm concrete cover and to 14.5mm depth of embedded anchor of sealing gaskets. The findings imply that the sulfate attack does not result in loosening of the sealing gasket.

1 INTRODUCTION

Tunnel Boring Machine (TBM) concrete segments are prefabricated reinforced concrete segments which are in contact to ground on extrados and to ambient air on intrados for new tunnels. Therefore, depending on the chemistry of the ground and condition of the ambient air, several degradations might occur. For sake of this study, two degradations are identified for the concrete segments in the new tunnel under study.

Carbonation attack reduces the alkalinity of the concrete cover and if the carbonation front reaches the rebar, it results in onset of reinforcement corrosion in presence of the humidity. This degradation occurs on the intrados of the concrete segments.

Sulfate attack may occur if the ground and/or groundwater contain sulfate bearing elements and may cause disintegration of the concrete cover. If the disintegration front reaches the depth of rebar, the reinforcement becomes exposed.

In addition, in concrete segments, the EPDM gaskets are installed to seal the interior of the tunnel. The gaskets are maintained in their positions with an anchor embedded in the concrete (see Figure 1). If the disintegration front reaches the mid-depth of the anchor sealing (based on the recommendation of the manufacturer), the performance of the gasket will be compromised.

The mechanism of the carbonation attack and its consequences on the reinforced concrete have been extensively investigated in literature [Bertolini et al. 2012, “Corrosion of Steel in Concrete”].

The sulfate attack mechanism is developed in the following.

Figure 1. EPDM Gasket details.

1.1 Mechanism of sulfate attack

The main hydration products are calcium silicate hydrate (CSH), calcium hydroxide or Portlandite (CH), ettringite ($C_6AS_3H_{32}$), calcium monosulfoaluminate ($C_4AS_3H_{12}$), hydrogarnet (C_3AH_6), etc.

When sulfate ions penetrate a cement-based structure, a series of reactions take place [Sarkar et al. 2010]. Sulfate ions react with Portlandite to form gypsum and some calcium aluminate phases to form ettringite (as shown by the light arrows in Figure 2). Then gypsum reacts with calcium aluminate phases (as shown in the box in Figure 2), if present, to form ettringite (as shown in bold arrows in Figure 2).

Initially the calcium ions are supplied by Portlandite. When Portlandite is not available, CSH dissociates into silica gel, releasing calcium ions (as shown by the dashed arrow in Figure 2) for ettringite formation. Therefore, one of the consequences of the sulfate attack is dissociation of the CSH, that is the main hydration product in concrete.

Another consequence of sulfate attack is expansion of concrete, thus cracking (exfoliation) of the concrete cover. The main expansive products formed as a result of the reactions are ettringite and gypsum [Sarkar et al. 2010].

Figure 2. Schematic diagram of the chemical reactions due to sulfate ingress [Sarkar et al. 2010].

The change in volume due to the chemical reactions is obtained by subtracting the total volume of the products from the total volume of the reactants. The change in volume leads to volumetric strain if the volume of the products is greater than the volume of the reactants. The strain developed exerts pressure on the surrounding cement matrix. The structure starts cracking when the stress exceeds the tensile strength of the material.

As it was said above, the calcium silicate hydrate dissociation into calcium hydroxide and silica gel results in loss of strength because silica gel is not cohesive. Thus, the net effects of sulfate attack are expansion, cracking and strength loss.

1.2 Research significance

In TBM tunnels design nowadays, the durability of the concrete segments is receiving high attention between the contractors in construction industry. The contractors nowadays are very interested in mathematical calculations of the service life of the TBM tunnels subjected to degradations. So, providing the tools of service life calculation of executive projects is becoming important in construction industry. In this study, it was tried to employ the existing mathematical models of the service life calculations and to link the mathematical calculations to

executive projects, through some laboratory tests for calibrating the mathematical models. The measured environmental conditions are imposed as the degradation source.

In this article as a case study, degradation mechanisms of the TBM concrete segments of a new tunnel are studied. The advancement of each degradation in time is numerically modelled and the service life of the concrete segments is evaluated. The design of the concrete segments is adopted to the durability assessment, so that the concrete segment can fulfill its design life. The reference design life of the new tunnel under study is 100 years.

2 EXPERIMENTAL METHODS

2.1 Materials

The mix design of the TBM segment is shown in Table 1. The thickness of the segment is 380mm and nominal design concrete cover is 50mm.

For measuring the inverse carbonation coefficient, two samples are fabricated following the recommendations of fib34. The results of inverse carbonation coefficient measurement are shown in the following table with normal distribution with mean value and standard deviation.

Table 1. Mix designs examined for the TBM concrete segments.

Portland cement (Kg/m ³)		280
Slag (Kg/m ³)		187
Slag %		40
Total binder content (Kg/m ³)		467
Compressive strength (MPa) of 6 hr		10.0
Water(mls/m ³)		163.6
Water/Cement	ratio	0.35
Slump (AS1012.3.1)	mm	110
$R_{ACC,0}^{-1}((m^2/s)/(kg/m^3)) \times 10^{-11}$	mean value	0.40
	Std. dev.	0.34

2.2 Test procedure

Two approaches are used to simulate the carbonation attack on the concrete segment: deterministic approach and full-probabilistic approach. For sulfate attack, the full probabilistic approach is used to simulate the advancement of the degradation in time.

2.2.1 Carbonation attack

For carbonation modelling, the deterministic approach was performed by CARBUFF model. The full-probabilistic approach followed fib34 model code.

The limit state for the carbonation attack is when the carbonation front reaches the rebar depth. To estimate the service life of the TBM tunnel, the laboratory experiments were performed to calibrate the model and correctly estimate the service life. The inverse carbonation coefficient, $R_{acc,0}^{-1}$, is measured for various concrete mix designs based on the recommendations of fib34 (see Table 1). The target probability of failure, regarding the importance of the project is set at 1% equivalent to reliability index (β) if 2.3. The reliability index relates to the probability of depassivation of the steel and ultimate limit state.

2.2.2 Sulfate attack

For sulfate attack modelling, the full-probabilistic approach is performed by FEM model by STADIUM software. When sulfate attack is developing, the Calcium Silicate Hydrate (CSH) content reduces because of the dissociation. CSH dissociates to form ettringite in the last stages of the sulfate attack, after portlandite is consumed. Therefore, the thickness loss due to sulfate attack is consider the depth of the concrete, where the CSH content reaches 5%.

To calibrate the sulfate attack simulation, sulfate content of ground and groundwater were measured and collected from boreholes located close to the chainage of the tunnel.

The limit state for the sulfate attack is when the thickness loss due to sulfate attack reaches 7.25mm. When the thickness loss reaches the mid depth of the hook of the sealing gasket, $14.5/2 = 7.25\text{mm}$ (based on the recommendation of the manufacturer, see Figure 1), the sealing ability of the gasket is compromised. The full-probabilistic approach has been employed for the FEM model for sulfate attack. Thus, the thickness loss values due to sulfate attack, which were calculated through FEM model, was fit to a lognormal distribution and as a convention, 95th percentiles of the distribution is reported. To calibrate the FEM model for calculating the thickness loss due to sulfate attack, total void volume of concrete is measured by ASTM C642 for two samples. The results are shown in Table 5.

2.3 Environmental input data

2.3.1 Carbonation

The environmental data for carbonation simulation, was collected from closest weather station to the tunnel portal. The environmental data is as follows. The relative humidity is fitted by Beta distribution with a mean value of 73.6% relative humidity as follows.

Figure 3. (Left) Relative humidity of the tunnel portal from worldwetheronline.com from 2009 to 2020. (Right) Probability Density Function curve of the relative humidity data from 2009 to 2020, fitted by Beta distribution with $\alpha=8.85$, $\beta=3.16$ and mean value of 0.736.

2.3.2 Sulfate attack

The environmental data for the sulfate attack were collected from the perforated boreholes close to the tunnel chainage. The ground chemistry and groundwater chemistry are presented in Tables 2 and 3, respectively.

2.3.2.1 Ground data

The ground chemistry data are shown in the following table. Sulfate content of the rock, chloride content of the rock, and pH values for different boreholes are collected and are statistically analysed. Mean value and standard deviation of the abovementioned values are reported in the table below.

Table 2. A summary of the ground chemistry: sulfate content, chloride content and pH values extracted from series of boreholes located close to the tunnel chainage.

Parameter	pH	Sulfate content (by AS1289 4.2.1) (mg/kg)	Chloride content (mg/kg)
Mean	9.25	18.7	89,7
Median	9.3	17.9	57,6
Std. Dev.	0.27	10.6	112,4
Kurtosis	0.24	3.2	9,9
Skewness	-0.04	1.4	3,1
Minimum	8.3	6.2	8,9
Maximum	10	52	115.2
Count (n)	427	23	23

2.3.2.2 Groundwater data

The groundwater data are reported in the following table.

Table 3. Groundwater chemistry data measured from the boreholes.

Borehole designation	pH	electrical conductivity (µS/cm)	Eh (mV)	pe	T (°C)	Ca (mg/L)	Alk (as HCO ₃ /L)	SO ₄ (mg/L)	Cl (mg/L)	NH ₄ (mg/L)	NO ₃ (mg/L)	Langelier Saturation Index (L _i)
1	7.44	1902	-132.5	-2.3	15.3	56	158.5	608	52	0.006	0.04	0.8
2	7.36	1860	-164.2	-2.9	11	58	180.5	720	49	0.077	0.02	0.8
3	7.76	2082	-138.4	-2.5	11.3	54	202.4	798	49	0.006	0.02	1.2
4	7.59	1963	-202.9	-3.6	10.2	62	214.6	721	51	0.006	0.02	1.1
5	7.83	1906	-189.4	-3.4	10.2	60	250	826	54	0.026	0.02	1.4
6	7.68	2157	-139.5	-2.5	8.6	65	264.6	656	52	0.003	0	1.3
7	7.92	2117	-150	-2.7	9	64	293.8	817	63	0.003	0	1.6
8	8.04	1923	-224.2	-4	9.4	61	317	753	52	0.003	0.02	1.7
9	7.86	2131	-140.4	-2.5	8.8	60	352.4	648	57	0.003	0.03	1.6
10	7.64	1603	-157.6	-2.8	9.6	57	356	648	46	0.003	0.01	1.3
11	7.8	2045	-139.1	-2.5	11.2	65	435.3	848	54	0.024	0.03	1.6

Statistical analysis was performed on the groundwater data and are shown in the following table. Thus, for groundwater data for pH, chloride content and sulfate content, 95th percentiles of the data series are considered as the representative of the data set.

Table 4. Sulphates content, chloride content and pH for groundwater.

parameter	N	%	Mean	Median	Std. Dev.	90° p	95° p	99° p
pH	70	12.2	5.17	5.29	5.24	4.88	4.76	4.54
Chloride (mg/L)	6	2.9	191	191	14.5	210	216	227
Sulfate (mg/L)	12	10.9	729	725	80.7	835	869	937

Comparing the results of Table 4 with Table 2, the sulfate content of groundwater is more critical than the ground sulfate content. Therefore, for the sulfate attack simulation, the sulfate content of the groundwater is considered as the sulfate content of the aggressive media.

3 RESULTS

3.1 Carbonation attack

3.1.1 Deterministic approach

The input parameters for CARBUFF simulation are the following.

Figure 4. Input parameters and the results of the CARBUFF simulation.

The results of the carbonation modelling based on the concrete cover is shown in Figure 4. The results are obtained by CARBUFF model using a deterministic approach. The results shows that the time to corrosion (as for limit state for carbonation) for a concrete cover of 50mm is 112 years.

3.1.2 Probabilistic approach

The input table for the full-probabilistic carbonation simulation is reported below. The nominal concrete cover as per design is 50mm. The carbon dioxide content in each year is elevated based on the current global trend of carbon dioxide increase.

The carbonation depth calculated by full-probabilistic approach is fit by a normal distribution with mean values 12mm and standard deviation of 4.3mm.

The figure above shows that the carbonation depth does not overlap with the concrete cover. This means that the probability of failure is <0.1%.

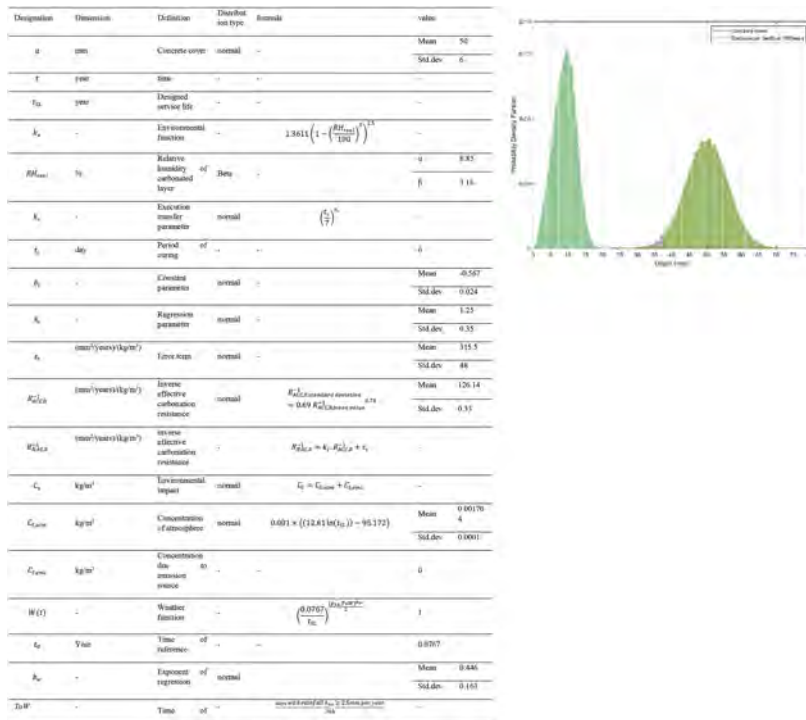

Figure 5. Description of all parameters with their values considered in the full-probabilistic approach. Probability density function for carbonation depth at 100 years and concrete cover of 50mm. The depth is considered from the segment intrados.

3.2 Sulfate attack

The input parameters for the FEM modelling of sulfate attack are reported in the following table.

The thickness loss due to sulfate attack is reported in the figure below a lognormal distribution for 25, 50, 75, 100, 125 and 150 years of service life.

Figure 6 shows the 95th percentiles of the thickness loss distributions as a function of time shown in Figure 6. Each data point in this figure is 95th percentiles of the relevant distribution as per the convention in this study.

The thickness loss after 100 years is equal to 7.22mm. Please note that as per convention in this study, the thickness loss value is equal to 95th percentiles of a lognormal distribution.

Table 5. Input parameters for sulfate attack simulation through full-probabilistic FEM model.

4 DISCUSSIONS

4.1 Carbonation

The results of carbonation modelling by either deterministic approach or full probabilistic approach show that the designed concrete cover of 50mm for TBM concrete segments fulfills the service life of the project that is 100 years.

By comparison between deterministic modelling and full-probabilistic modelling of carbonation phenomena, it can be inferred that the deterministic modelling is more conservative than the full-probabilistic approach.

One of the drawbacks of the deterministic modelling is that it is not calibrated by the laboratory results of the actual concrete mix by which the segments are going to be fabricated. In addition, the ternary mixes cannot be simulated by deterministic approach because this approach uses the predefined carbonation resistance data from literature for binary mixes.

The results above conclude that by calibrating the carbonation modelling with the laboratory results, more realistic life cycle assessment could be performed. Therefore, the full-probabilistic approach possibly can provide more accurate evaluation of the service life for the concrete structure subjected to carbonation attack than the deterministic approach. It should however be noted that the current fib34 does not consider the propagation time rather it considers only the initiation time of corrosion.

4.2 Sulfate attack

The results of sulfate attack simulation show that the performance of the sealing gasket in TBM segment is not compromised by the sulfate attack. The thickness loss due to sulfate attack after 100 years (7.22mm) does not reach the mid-depth of the gasket hook that is 7.25mm. Therefore, stability of gasket after 100 years of sulfate attack is confirmed and the sealing effect could be maintained.

5 CONCLUSIONS

The results above conclude that:

A thorough environmental investigation shall be performed during the design phase of concrete infrastructures to identify the main degradation mechanisms.

Full-probabilistic approach could be utilized for the numerical modelling of any degradation mechanism, which could be mathematically formulated by Fick's 1st & 2nd laws.

By performing simple and cheap laboratory experiments to calibrate the numerical models of degradation mechanism prior to the execution of the project, the durability of the concrete structures during the design service life of the project could be ensured.

To compare the carbonation depth calculated by fib34 with the nominal concrete cover, 95th percentiles of a normal distribution carbonation depth distribution, calculated by fib34, could be a suitable representative of the normal distribution of the carbonation depth.

Table 6 shows a guideline for the durability assessment of the segments of TBM tunnel. For each exposure condition, the relevant degradation is shown. Each degradation shall be numerically modelled and the approach for the modelling is categorized. The model shall be calibrated by means of several parameters. The relevant parameters are reported in the table, with associated reference and adequate number of samples.

Holistic assessment-framework for railway noise barrier constructions

M.F. Granzner & A. Strauss

University of Natural Resources and Life Sciences, Vienna, Austria

M. Reiterer

REVOTEC gmbh, Vienna, Austria

ABSTRACT: The high safety requirements for railway infrastructures are a basic demand that the railway user places on the railway operator. Noise barriers that are erected along high-speed railway lines are loaded by aerodynamic pressure and suction waves due to the passing trains. Noise barriers are an integral part of railway infrastructures, and their level of safety must be maintained throughout their entire lifetime. This concept paper discusses deterministic and probabilistic-based approaches for condition assessment and prognosis of remaining service life of railway noise barriers, embedded in a safety concept that takes damage consequence classes into account. These approaches are combined into a holistic assessment concept, in other words a progressive four-stage model in which the information content increases with each model stage and thus successively increases the accuracy of the determined structural conditions at the time of observation and the forecast for the remaining service life of the structure. The analytical methods used in the first stage of the developed holistic framework are based on common static calculations used in the engineering practice and, together with expert knowledge and large-scale fatigue test results of noise barrier constructions, form the basis for the subsequent stages. Linking routines that combine the condition assessments from the common executed visual inspections and additional information from permanent monitoring systems applied to failure-critical elements with the analytical methods of the first stage are implemented in the second stage of the holistic framework. With application of numerical finite element methods in the third stage and finally the probabilistic approaches in stage four, the highest degree of determination accuracy of the noise barrier condition at the time of observation and prediction accuracy of the remaining lifetime shall be achieved. Depending on how far the degradation of the considered noise barrier has already progressed, the corresponding stage of the holistic assessment concept is activated, which enable infrastructure managers to plan their future investments regarding maintenance, retrofit or rebuilt of noise barriers more economically. The aim is to integrate the project results into a supranational framework, which is established through orientation towards Europe-wide preliminary projects.

1 INTRODUCTION

Noise barriers (NB) are erected alongside railway lines, and they are exposed to high aerodynamic loading by passing trains. Due to the current increasing train frequencies and train speeds material fatigue becomes important for all construction parts of NB like the steel posts, fastening elements and the foundations. Hence, NB must be maintained at a level of safety and reliability specified by politics and society throughout their entire lifetime. This is basically the task of infrastructure managers, who, in addition to the safe and reliable

functionality of the infrastructure, must also manage its availability, maintainability, environmental compatibility and the necessary financial capital and workforce. Assessment of existing NB structures is nowadays often based on the subjective visual evaluation of the examiner or the responsible consulting engineer. However, designing and evaluating the design of new and existing NB structures as it is done with common engineering methods, doesn't yet include all the relevant information needed to predict the structural behaviour over time. The inclusion of information from visual inspections as well as information which, due to the technical progress of monitoring systems, is feasible but is not yet done regularly, has great potential to improve the accuracy of condition assessments and forecasts of the remaining service-life for NB constructions.

2 BACKGROUND RESEARCH

To plan the necessary maintenance measures for NB constructions in a resource-efficient way, concepts based on building/component conditions and minimum threshold values for maintenance are used in many European countries. Although there is no uniform supranational definition for these maintenance concepts. These throughout Europe varying maintenance concepts, condition-state definitions and lower limits of maintenance strategies are presented, discussed and compared in Strauss et al. (2022a). The management process of life cycles of individual objects or even entire infrastructure networks includes not only the inspection, i.e. the survey of the condition, and the assessment of the structural performance, but also the evaluation of the maintenance strategies. These management systems are usually based on deterministic performance prediction models to describe degradation processes of the considered structures. Increasing experience in the use of up-to-date measurement technology and rapid developments in computer processing power and storage capacity have caused a trend towards data-based approaches to condition monitoring. Identifying and implementing key performance indicators plays a major role here. The characterisation and systematisation of performance indicators for bridges and tunnel systems and how to link them to data-based performance assessment methods and inspection and monitoring concepts is another important point which is discussed in Strauss et al. (2022b). Incorporating practical condition monitoring systems into the safety concepts of existing standards at a national and European level is a step that is currently being taken and is urgently needed in order to make appropriate decisions about conservation and safety. Strategies to fill this gap are proposed in Strauss et al. (2022c). In developing the holistic model presented here, care was taken to ensure the best possible incorporation into the proposed supranational concepts. The linking of information from currently applied purely visual condition inspections, as well as new monitoring methods with existing expert knowledge from tests and calculations, based on artificial intelligence methods and the subsequent integration into a safety concept, which is based on a hybrid and model-based reliability index, has already been shown in preliminary projects on this topic (Reiterer et al., 2021). The condition prediction models developed from this, consisting of four model levels, provide the expected service life of the engineering structure under consideration, taking into account the corresponding damage consequence classes. These approaches are exemplarily applied to the highly aerodynamically stressed NB.

NB installed alongside the tracks of railway lines are exposed to air pressure waves caused by passing trains. These air pressure waves create a sinusoidal dynamic loading consisting of a pressure and a suction load. The size of the dynamic loading depends on the aerodynamic shape of the trains, the speed of the train, the shape of the structure as well as on the distance between the axis of track and the surface of the noise barrier (Figure 1). The dynamic amplification may become a factor of 6.6 in the most unfavourable case (Reiterer et al., 2020). Until 2005, train-induced aerodynamic loading has not been adequately considered in the design of NB as well as in the applied calculation methods (pure static analysis) and in the relevant normative specifications given in Eurocode. Causes for the resulting fatigue damage have been investigated by Hoffmeister (2007) and Hertle & Näfl (2005), among other things by investigating unfavourable structural responses of the NB, and the design of new NB constructions.

Figure 1. A) Aerodynamic loading situation in the longitudinal direction of the noise barrier during train passage. b) Aerodynamic loading situation over the height of the noise barrier during train passage.

The determination of the train-induced aerodynamic loading as regulated in the standards and guidelines currently in use was carried out and compared by Reiterer et al. (2017). The results of the current applied calculations were finally compared with the results from a permanent measuring point of the considered NB. In addition to the aerodynamic pressure-suction loads that occur when trains pass by, the corresponding dynamic reaction of the NB construction was also measured. As can be seen from the experimental investigations and evaluations of Reiterer (2019), NBs exhibit increased material fatigue especially at the welded seam connections between the steel post and the steel base plate and even more decisive at the threaded connection bolts between the concrete edge beam and the NB steel post (Figure 2), whereby the fatigue at the welded seams does not lead to a complete failure of the NB construction and is therefore not considered here. The more critical case is the fatigue failure of the fastening elements, i.e. threaded bolts installed to the concrete edge beam, which lead to an instant collapse of the NB construction. The experiments in Reiterer (2019) were carried out in form of fatigue tests with up to 5 million load cycles, which were simultaneously recorded by a measurement system. Different installation conditions of the steel post with different degrees of execution deficiencies, i.e. variation of preload, were investigated within the fatigue tests. The aim of the tests was to study the influence of execution deficiencies on the durability of NB constructions.

Figure 2. Exemplary photographs of the fastening situation of NB on the concrete edge beam.

One of the most important execution deficiencies is the fastening of the NB posts to the concrete edge beam with an insufficient preload. In further experiments, published by Reiterer (2019), the preload behaviour was investigated and evaluated, from which a procedure instruction for the nut-side prestressing could finally be derived (Reiterer et al., 2020). The behaviour of prestressed bolt-nut-connections is also shown in Alt et al. (2007), where settlement is observed after applying the preload and the beginning of rupture when fatigue tests are

conducted. In addition, the influence of superimposed tensile and bending stress on the fatigue behaviour was investigated.

3 HOLISTIC FOUR-STAGE MODEL

In the concept of the holistic four-stage model presented here, state-of-the-art safety concepts, as well as monitoring concepts and systems, are to be combined with time-honoured condition assessment methods in such a way that infrastructure operators can manage structural safety and track availability in the most economically and ecologically efficient way.

The core elements of the four-stage model are the currently applied standard methods of visual inspection with its resulting condition classes (ZK_v) and fatigue calculations according to RVE 04.01.01 currently carried out only in the design processes of NB. Figure 3 shows the individual model stages of the proposed holistic four-stage model, which are successively activated with ongoing degradation of NB. The activation of the respectively following model stage happens when a certain condition-state threshold is reached. With each model stage, the precision of the condition-state determination and prognosis of remaining lifetime is increased, whereby an increased monetary expenditure must also be expected. In a later paragraph of this chapter, the individual model stages are explained.

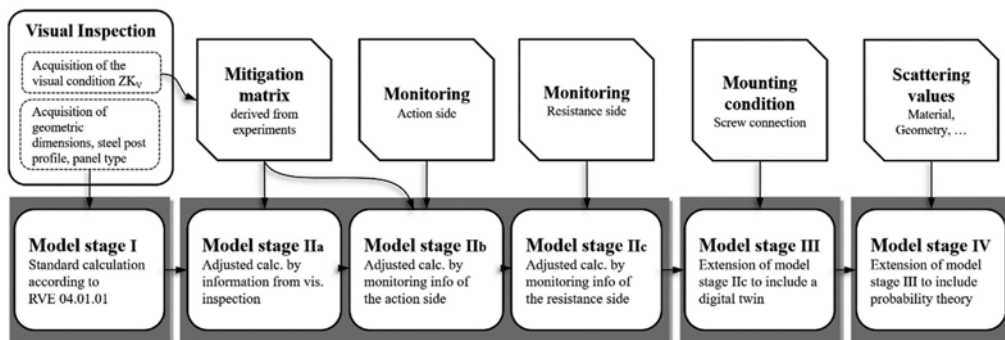

Figure 3. Scheme of the proposed holistic four-stage model.

By transferring/embedding the conducted calculations for the current conditions and forecasts of the technical service-life of NB into the reliability index β according to ÖNORM EN 1990, damage consequence classes can be considered. Based on the consequence class corresponding to the structure under consideration, in the case of noise barriers along railways its CC2, mechanical condition classes can be defined. In analogy to the visual condition classes (ZK_v), mechanical classes (ZK_m) are additionally defined in a kind of school grading system with class 1 for a good mechanical condition and class 5 for a bad mechanical condition. The mechanical condition describes the state of fatigue in a deeper level of detail, which is not or barely detectable in a purely visual inspection. To make another comparison visual condition classes contain visually detectable information, which is strongly dependent on the inspector's experience and knowledge, on the other hand the mechanical condition classes combine visual and monitoring information, information from experiments, applied standard calculations, and digital twins, from which a more stable and accurate solution is expected.

Figure 4 shows an example of the calculated end-of-lifetime of NB for four different cases and the linear progression of the mechanical condition classes in the reliability index space. The four cases have the same input parameters except for the visual condition class. The loading situation, which is 50 RailJets per day, with the train speed of 230 km/h, is as well the same for all cases.

Figure 4. End-of-life prediction of NB for four different cases in a reliability index framework.

The following section describes the proposed individual model stages of the previously introduced holistic four-stage model which is depicted in Figure 3.

Visual Inspection – The inspection of the NB construction, which takes the first position, is carried out by the expert/personnel of the operator. In this step, the structural conditions are recorded, which include the geometric dimensions, type of steel post, NB panel type/material, as well as the visually recognisable and assessable condition of the construction, components, and execution details. The data recorded during the visual inspection serve as input values for the standard calculation of the service life according to RVE 04.01.01, on which the first two model stages are based.

Model Stage I – Calculation according to current standards – The first and simplest model stage is based purely on a common applied standard durability calculation. For this project in particular, the calculations are carried out according to RVE 04.01.01, which refers to NBs on bridges and concrete supporting walls with the executed edge beam types 2.1 and 4.0 (Figure 1b) according to ÖBB regulations. The input parameters are the geometric dimensions of the NB structure, type of steel post, type of NB panel, load effect, etc., which were recorded during the visual inspection. The output of the calculations is a forecast of the technical service life, which in a further step is converted into a reliability index β (Figure 4).

Mitigation matrix – In the mitigation matrix, the visual condition classes from visual inspection are assigned to the corresponding reduction factors, which are included in the calculation of model stage IIa and IIb. The reduction factors, which are derived from experimental fatigue tests, are intended to consider the reduction of the stress vibration range in the mechanical fasteners caused by the applied preload, which is not considered in the common applied standard calculation.

Model Stage IIa – Enhanced calculation according to standards through visual inspection – By incorporating information from visual inspections, the next level of the four-stage model is reached. The normative fatigue calculation on which model stage I is based also forms the basis for model stage IIa, but here the condition classes assigned in the course of the visual inspection are also taken into account. The reduction factor is used in order to come closer to the actual effective stress vibration width in the fastening element of the NB.

Monitoring action-side – Monitoring of the action side takes place at check points on the tracks along the rail network, where the axle loads of passing trains are measured. By

subsequently analysing the data, the train type, train speed and number of trains per day can be precisely determined.

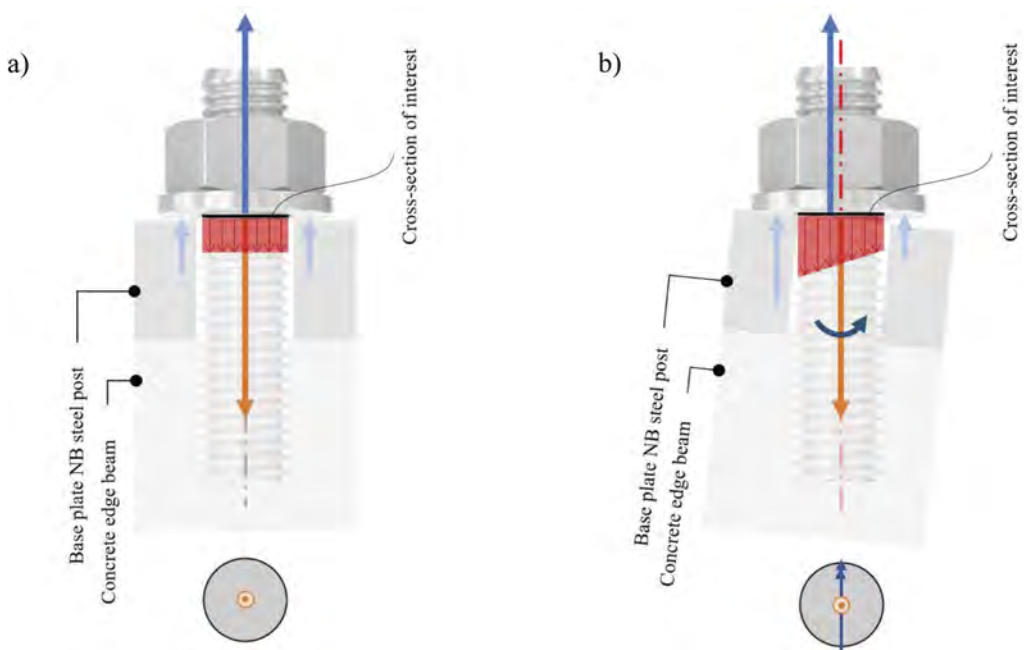

Figure 5. A) Ideal installation condition of threaded bolt. b) Faulty installation condition of threaded bolt.

Model Stage IIb – Enhanced calculation according to standards through monitoring load side – In addition to the correction of the stress variation range, which is carried out in model stage IIa by taking into account the visual condition classes, monitoring on the action-side is incorporated in model stage IIb, thus the degree of accuracy of the condition determination and prognosis is further increased.

Monitoring resistance-side – The preload and stress variation range in the threaded bolts is measured directly by means of a measuring nut.

Model Stage IIc – Enhanced calculation according to standards through monitoring resistance-side – Contrary to model stage I - IIb, in model stage IIc the entire calculation from the load action via the NB construction into the fastening elements is bypassed by resistance-side monitoring and thus also the associated uncertainties. Using the rainflow-method, the number and amplitude of the measured stress variations can be analysed precisely, which significantly increases the accuracy of the calculation of the partial damage.

Mounting conditions – The most prominent faulty mounting conditions are defined together with experts. Faulty installation conditions of the bolted joint can introduce bending moments in addition to the preload.

Model Stage III – Digital twin – In the previous model stages, the influence of the installation condition was broken down to one factor derived from visual information, and the monitoring system proposed offers only a limited possibility of recording the influence of the installation condition. This still clearly existing discrepancy between these highly simplified models and reality is to be further reduced in model stage III. For this purpose, various “faulty” installation conditions (Figure 5) are defined and modelled by means of a digital twin. An ideal installation condition has a constant normal stress in the cross-section under consideration (Figure 5a), whereas faulty installation conditions cause a moment, which results in an additional bending component in the normal stress (Figure 5b). By investigating

the influence of faulty installation conditions on the stress amplitude, the calculations can be calibrated and thus the influence on the fatigue behaviour can be determined.

Model Stage IV – Probabilistic Approach – In this stage probabilistic approaches are employed to model the degrading process over time. In these considerations, the observations, information, and methods of the previous stages can be included in relation to the boundary securities according to their significance.

4 CONCLUSIONS

The proposed holistic four-stage model has great potential to improve the accuracy of condition-state assessments and forecasts of remaining lifetime of NB constructions along railway lines by combining time-honoured condition assessment methods with state-of-the-art safety concepts and monitoring concepts and systems. This allows infrastructure operators to manage structural safety and availability of the railway tracks in a more economic and ecologic way. By investigating different installation conditions more or less favourable situations can be identified and avoided in future.

The state-of-the-art in health monitoring of long-span cable supported bridges in Turkey

O. Çetindemir & A.C. Zülfikar

Gebze Technical University, Kocaeli, Turkey

N. Memişoğlu Apaydın

Istanbul University-Cerrahpasa, Istanbul, Turkey

ABSTRACT: Long-span cable-supported bridges are one of the most important links in the transportation network of a city. This is why their structural health during construction and in operation is very vital and should be monitored. Especially over the last two decades due to safety concerns and to reduce costs, Structural Health Monitoring (SHM) systems have become extremely useful tools for making well-informed decisions regarding the operation and management of bridge structures. Numerous experts in SHM have identified and summarized the challenges and future trends of health monitoring for civil infrastructure. However, the field is extremely dynamic and rapidly evolving, so visions should be updated in a timely manner. Therefore, this work aims to provide the current status of long-span cable-supported bridges' health monitoring in Turkey by introducing SHM systems and their design considerations for eight long-span bridges. In addition, since these bridges are exposed to both strong seismic excitations and wind incidents due to the geographical locations where they are built, such extreme events may create critical load conditions on the bridges. For this reason, these events recorded by SHM systems are also provided in this work. It is believed that this study will be beneficial to bridge management authorities in order to extent their knowledge on the SHM and its potential use.

1 INTRODUCTION

Long-span bridges are one of the most vital lifelines in nations where they are built, as they shorten transportation by allowing passage of major waters such as rivers, canals, dams, and seas. Turkey is a critical transcontinental country between Asia and Europe because of its geographical location. In Turkey, where long-span bridges are subject to significant traffic and seismic risks, it is essential to monitor their structural health and execute maintenance in a timely and cost-efficient manner. Due to their size, these bridges are challenging to maintain. Periodic bridge inspections are usually planned every two to six years to examine the structure's condition (Kromanis, 2020). Nevertheless, inspections may be subjective and are still uncommon. Therefore, the most reliable technique for monitoring the structural state of such bridges in service is to install structural health monitoring (SHM) systems because of their high towers and difficult-to-access cables (Memisoglu Apaydin et al., 2022). This paper focuses on a concise overview of SHM systems for long-span cable-supported bridges in Turkey. In addition, experienced extreme events and the benefits of the SHM system are presented to help improve current systems and inform interested owners and users of such health monitoring systems.

The remaining sections of this paper are organized as follows: Section 2 represents a general description of long-span cable-supported bridges in Turkey. Section 3 provides essential information on the structural health monitoring of the bridges. In Section 4, extreme cases recorded through SHM systems on the bridges are provided. Section 5 concludes the paper by presenting the beneficial effects of the SHM system and sharing insightful recommendations.

2 LONG-SPAN CABLE-SUPPORTED BRIDGES IN TURKEY

The First Bosphorus Bridge was the 4th longest bridge in the world when it was completed in 1973. This bridge is currently the 40th longest suspension bridge in the world. The aerodynamic box section is utilized for a deck in order to require less maintenance than conventional truss systems, to decrease wind effect by one-third, and to use less materials to produce a lighter and more cost-effective solution. The main span length of the bridge is 1074 meters, and there are two approach viaducts (see Figure 1). The main span is suspended by hangers, whereas the viaducts' bases are supported by columns of varying heights. Additionally, they are simply supported on the ground near the anchors. After constructing a new beltway (O-2) in Istanbul known as the Trans-European Motorway (TEM), it became imperative to construct a second bridge over the Bosphorus Strait. The Fatih Sultan Mehmet (FSM) Bridge was the fifth longest suspension bridge in the world when it was completed in 1988; it is currently rated 36th. The FSM bridge is a long-span suspension bridge made of steel. The towers of the bridge are supported at ground level. Since the ends of the bridge's deck are on the same level as the tower's base, there is no approach span on the bridge. The main span length of the bridge is 1090 meters, while the width and height of the deck's aerodynamic box section are 39.40 and 3.00 meters, respectively. The bridge tower is a rectangular box with a total height of 110 meters. The mid-span deck is 64 meters above mean sea level. The length of the bridge is 1510 meters, with two 210-meter side spans (see Figure 2).

The Yavuz Sultan Selim (YSS) Bridge is a hybrid cable-stayed suspension bridge enabling rail and motor vehicle passage across the Bosphorus Strait. The YSS Bridge's construction started in 2013 and opened to traffic in 2016. It is located 5 kilometers north of the First Bosphorus Bridge at the entrance to the Bosphorus Strait and relatively close to the Black Sea. The YSS Bridge is among the widest suspension bridges, with a 59-meter-wide deck. It was the second-tallest bridge in the world after the Millau Viaduct in France, with a structural height of 322 meters; it is currently rated fifth. With a main span length of 1,408 meters, this bridge is the world's longest suspension bridge with a railway system. At a particular location, the stay cables and hanger cables of the YSS Bridge overlap a transitional section. Figure 3 illustrates the bridge's general layout. The Osman Gazi Bridge (OGB) was built at the narrowest point of Izmit Bay on the eastern side of the Marmara Sea. The OGB is the only bridge at Izmit Bay. Thus, it is a crucial transportation network between the Istanbul Motorway and the Izmir Motorway, reducing travel time by six times. Construction of the bridge began in 2013 and opened to traffic in 2016. With a primary span of 1550 meters, it is the 7th-longest suspension bridge in the world. It has two 566-meter-long side spans and a 1550-meter-long main span (see Figure 4). In addition, the bridge features two 120-meter transition spans at the anchorage blocks at the end of each side span. The bridge's entire span length is 2922 meters. Underwater concrete foundations support the towers, and their height is 252 meters. The approach spans are suspended using hangers rather than ground-based supports. The construction of the 1915 Çanakkale bridge began on March 18, 2017, and was recently opened to traffic on March 18, 2022. It is the longest mid-span suspension bridge in the world, with a length of 2023 m, exceeding the Japanese Akashi Kaiky Bridge. A 318-meter-tall H-shaped bridge tower is constructed as a rectangular hollow section, and the tower's foundation is 40 meters below sea level. As shown in Figure 5, the base and top tower sections have dimensions of 11.00 m by 10.50 m and 8.00 m by 7.50 m, respectively. 318 m is the elevation of the intersection point of the main cable, which is essential for design, actual tower height considering the tower top enclosure, is 334 m. This makes the bridge 2nd tallest bridge in the world. The deck is an orthotropic steel with three lanes in each direction, a height of 3.50 meters, and a width of 45.06 meters. The bridge's side spans (each 770 m) connect approach viaducts supported at the base of each side, measuring 385 m on the European side and 680 m on the Asian side.

The Agin (Karamağara) cable-stayed bridge is part of a provincial route that spans the Keban Dam reservoir lake. The bridge's construction began in 2001. Due to modifications to the project, construction was delayed, but work resumed on January 10, 2012, and the opening took place on October 26, 2015. The route connects Elazığ and Arapgir. The 520-meter-long cable-stayed bridge has spans of 120 + 280 + 120 meters and is supported by two 55-meter-tall

steel towers on concrete piers. The main deck comprises a 13-meter-wide orthotropic steel box section supported by stay cables in a central plane. The layout of the bridge is shown in Figure 6a (Megaba, 2016). The Nissibi cable-stayed bridge was erected on the Atatürk Dam Reservoir across the Euphrates River in Southeast Anatolia and opened to traffic in May 2015. The main and total lengths of the bridge are 400 m and 610 m, respectively. It is now the longest cable-stayed bridge in Turkey. The side spans of the prestressed concrete box section deck have a length of 2x105 m and a width of 24.50 m. The main span was designed as a steel box section deck with a width of 22.90 m and a height of 2.70 m. The bridge's plan is depicted in Figure 6b. The pylon foundations are 50 m x 20 m x 5 m rectangular spread footings, whereas the usual pier foundation is 13.3 m x 6 m x 1.5 m, and the abutment foundation is 28.7 m x 12.2 m x 1.5 m. The New K m rhan Bridge is a cable-stayed bridge that connects the Elazığ-Malatya Highway D.300 over the Karakaya Dam Lake on the Euphrates River in eastern Turkey. The bridge is located on the shortest route between Malatya and Elazığ and has no alternate route. Construction began in 2014, and the new bridge was officially opened on January 2, 2021. The New K m rhan Bridge replaced an older box-girder bridge built between February 23, 1983, and April 8, 1986, by the STFA Group. The total length of this 168.5 m tall cable-stayed bridge is 660 m, and its widest span is 380 m. With its 380-meter center span, it is ranked as the world's 4th longest single-pylon cable-stayed bridge. The cables connect to the bridge deck in the middle of the bridge on a single plane. The 21 cables that support the 380 m long main span are stabilized with the same number of cables anchored onto the 180 m long foundation block on the land side. The bridge's layout are shown in Figure 6c.

3 HEALTH MONITORING OF LONG-SPAN CABLE-SUPPORTED BRIDGE IN TURKEY

Petrovski et al. (1974), Tezcan et al. (1975), Erdik and Uckan (1988), and Brownjohn et al. (1989) completed prior research for the establishment of a health monitoring system on the First Bosphorus Bridge. The significance of a permanent SHM system was highlighted by these primary investigations that utilized a temporary SHM system with portable sensors. In 1993, the bridge was equipped with an essential permanent SHM system consisting of three subsystems: a sensor, data acquisition, and recording station. After a severe wind event in 2004, the national authority decided to extend the SHM system. The total sensor quantity is 168 and consists of various sensor types, including 12 force transducers, 19 accelerometers, 15 tiltmeters, 70 strain gauges, 6 weather stations, 8 laser displacements, 33 thermocouples, and 5 GPS. Figure 2a depicts the SHM system of the First Bosphorus Bridge. In 2001, based on the research by Apaydin (2002), Apaydin and Erdik (2001), a permanent SHM system was first built on the FSM Bridge, as well as the primary monitoring studies (Brownjohn et al., 1991, Brownjohn et al., 1992a, Brownjohn et al., 1992b). 12 accelerometers, 4 displacement meters, 2 seismometers, 2 GPS, a weather station, and a thermometer were installed on the FSM Bridge as an initiative SHM system. Before the YSS Bridge was built, the FSM Bridge was subject to significant truck traffic. Therefore, the traffic load was heavier than the First Bosphorus Bridge. Since the design specifications require high expansion joint movement capacity, all displacement sensors on the bridge are installed at the expansion joints. At ground level, four seismometers are installed on support points of backstay anchorages and tower legs. Later, KGM decided to conduct a preliminary study for enhancing the FSM Bridge's permanently installed SHM system. Among the most notable new planned sensors are on cable components, expansion joints, and anchorage locations. Figure 2 shows current and planned SHM system of the FSM Bridge.

The KGM prepared a comprehensive report on the primary objectives, requirements, and monitoring parameters of the SHM system to be installed on the YSS, based on the experience gained from the First and the Second Bosphorus (the FSM) Bridges regarding the optimal design and installation of an SHM system (KGM, 2014b). 18 triaxial, 56 biaxial, and 2 uniaxial accelerometers, 5 GPS sensors, 5 biaxial tiltmeters, 22 displacement meters, 5 wind sensors (speed and direction), 1 weather station, and 12 temperature sensors were utilized in consideration of the bridge's dynamic characteristics and critical points. Due to the importance of the

stress-strain history and cable vibration for long-span bridges, strain gauges, and force transducers are instrumented to monitor the reaction. At the tower top-saddle of the bridge, strain gauges are installed to monitor the high load and stress concentration. In addition, the width of the deck makes it more susceptible to torsional rotation and tilting. Therefore, accelerometers and tiltmeters have been mounted in the two corners of the deck. After analyzing the behavior of the bridge during extreme events, it is planned to improve its SHM system. Figure 3 shows current sensor configuration of the YSS Bridge. The SHM system of the OGB has six essential purposes: (1) wind monitoring, (2) road monitoring, (3) dynamics monitoring, (4) temperature monitoring, (5) stress/strain monitoring, and (6) fatigue stress monitoring (KGM, 2014a). In total, 386 sensors are utilized to understand the bridge's response to extreme events and environmental conditions. Those are 160 fiber optic strain measurements, 84 steel temperature sensors, 49 accelerometers (2D and 3D), 16 humidity sensors (external), 12 force transducers (LVDT), 8 GPS sensors, 8 mono-strand loadcells, 8 sonic distance sensors, 6 main cable surface temperature sensors, 6 pavement temperature sensors, 6 hanger temperature sensors, 4 pyranometers, 4 weather stations, 3 air temperature sensors, 3 static inclinometers, 2 dynamic inclinometers, 2 rain gauges, 2 weight in motion (WIM) stations, 2 load measuring pins, and road wear. Figure 4 depicts the general layout and current sensor configuration of the OGB. The SHM system employed in the 1915 Çanakkale Bridge is the most advanced in Turkey in terms of sensor variety and quantity. In total, 1049 sensors are installed, including 508 dynamic strain gauges, 103 accelerometers (1D, 2D, and 3D), 88 static strain gauges, 74 biaxial inclinometers, 64 displacement sensors, 52 steel temperatures, 36 corrosion sensors, 34 data acquisition units, 26 GPS receivers, 16 load cells, 8 asphalt temperatures, 6 weather stations, 4 air temperatures, 4 barometric pressures, 4 cable thermometers, 4 sensors in the damper, 4 humidity, 4 road weather measurement stations, 2 sensors in the buffer, 2 clearance-sonic distance sensors, 2 weight in motion system, 2 pyrometers, and 2 seismic stations. The general layout and sensor configuration on the bridge can be seen in Figure 5.

Figure 1. The general layout and sensor configuration of the First Bosphorus Bridge.

The SHM system of Ağın Cable-stayed Bridge is comprised of 40 sensors and 68 channels situated on the abutments, deck, pylons, and cables, including 16 accelerometers (2D and 3D), 10 structural temperature, 4 displacement meters of bearings (longitudinal and uplift), 3 video cameras, 2 wind sensors (3D ultrasonic), a solar radiation, 2 air temperature, and 2 air humidity sensors. Figure 6a illustrates the bridge's general and sensor layouts (VCE, 2012). Nissibi Euphrates Cable-stayed Bridge's SHM system has 29 sensors and 59 channels in total including 8 cable load cells, 16 accelerometers (1D, 2D, 3D), 2 wind sensors (3D ultrasonic), a solar

radiation, an air temperature, and an air humidity sensor. The SHM configuration are shown in Figure 6b. K m rhan Cable-stayed Bridge was equipped with a permanent monitoring system by VCE. This monitoring system comprises 56 sensors with 86 measuring channels. All measurement data are automatically evaluated and visualized in the password-protected BRIMOS web-user-interface and provided to clients. The bridge was equipped with a variety of sensors, including 2D and 3D accelerometers, strain gauges (for steel and concrete), load cells, GPS, weather stations (wind speed, temperature, and humidity), and pyranometers. Figure 6c illustrates the sensor configurations installed on the bridge (VCE., 2020).

4 EXTREME CASES RECORDED THROUGH SHM SYSTEMS ON BRIDGES

Using a SHM system, the structural and functional performance of a bridge can be examined in response to extreme events such as earthquakes, heavy traffic, strong winds, and human-induced loads. As a result, essential actions can be performed immediately. Extreme events recorded through SHM systems are presented as listed in Table 1.

5 CONCLUSIONS

This paper can be concluded as follows: (1) Lessons learned from the first applications of structural health monitoring (SHM) systems and extreme events experienced on the long-span bridges in Turkey provide valuable knowledge for implementing more comprehensive SHM systems on recently constructed bridges, (2) it was observed that SHM systems allow for rapid and

continuous health monitoring of the bridges. However, sometimes, the damage of some structural and/or non-structural elements may not be clearly understood as a result of SHM data analysis since they do not cause major changes in the dynamic properties of the structure. Therefore, although it may be difficult due to their large structural elements, field inspections might also be needed to verify analyses results, (3) the vast amount of different sensors assists in understanding the traffic condition in depth for the efficient management of bridge structures. Therefore, for especially recent SHM applications in Turkey, these new types of sensors provide the overall system with additional information on an autonomous basis, (4) The essential components of the SHM system to be built are the general structural elements such as the main cable, hangers, deck, and towers. A simple system is always the best option for the initial application when installing an SHM. Later, it would be the appropriate approach to establish a more complex SHM system in light of the data obtained from the first employed system. In conclusion, this state-of-the-art paper will contribute to the innovative efforts of SHM systems for users in general and provide invaluable insight and recommendations for scholars.

Informed assessment of structural health conditions of bridges based on free-vibration tests

M. Mazzeo, D. De Domenico & R. Santoro

Department of Engineering, University of Messina, Messina, Italy

G. Quaranta

Department of Structural and Geotechnical Engineering, Sapienza University of Rome, Rome, Italy

ABSTRACT: A consolidated procedure for the evaluation of current structural health conditions in bridges consists in the comparison between estimated modal features from in-situ tests and numerical values. This strategy allows making informed decisions for existing bridge structures to ensure structural safety or serviceability. Free vibration tests are common in bridges monitoring since they allow a quick and cost-effective determination of dynamic information about the structure, using a sparse network of few sensors and avoid long-lasting monitoring campaigns. Exploiting an identification method based on a tuned version of Variational Mode Decomposition and an area-ratio based approach, modal parameters are determined from free vibration tests. This technique is applied to the dynamic identification of cables in a stay-cabled bridge assumed as case study: the obtained results prove reliability of the adopted method as a useful tool for objective dynamic identification purposes, with focus on the structural health conditions of bridges.

1 INTRODUCTION

Modal parameters are key structural properties in characterization of dynamic behaviour of constructions: the comparison between experimental values obtained from the identification process and theoretical ones represents a significant tool to investigate the state of health in an existing structure as well as to identify possible defects. Particularly in large-scale civil structures such as bridges, the dynamic characterization via free vibration tests is becoming quite popular: the advantages are the use of a temporary network made up of a limited number of sensors, the possibility of carrying out a complete monitoring campaign in a relatively short time frame and the cost effectiveness.

Li et al. (2014) estimated the modal damping ratios of the cables of a cable-stayed bridge from their free vibration response. Both Clemente et al. (1998) and Tomaszewicz et al. (2022) dealt with the dynamic identification of cable-stayed bridges using free vibrations produced by a truck moving over a step fixed on the paving.

The identification of modal parameters in a multi-degree-of-freedom structure may be carried out prior to selection of significant components from dynamic response: this can be achieved using adaptive decomposition methods.

This study presents the results of a monitoring campaign in which free vibration tests were performed on the cables of a stay-cable bridge to investigate their actual condition via dynamic identification. The single-degree-of-freedom modal components are isolated using a variational decomposition framework. Modal frequencies are compared with estimation obtained from practical formulas whereas estimated modal damping ratios are compared with the ones obtained from ambient vibration.

2 IDENTIFICATION PROCEDURE

In this section a procedure for modal identification of structures such as existing bridges based on free vibration tests is recalled. This methodology combines a tuned version of the Variational Mode Decomposition (VMD) to isolate each modal mono-component signal and its correspondent natural frequency with an area ratio-based approach. An important feature of the method is its automatic implementation which averts user's subjective choices in the selection of VMD parameters. The adopted method has already been tested on benchmark signals and existing deck bridges (Mazzeo et al. 2023) proving its reliability in the dynamic identification of modal parameters.

2.1 Tuned Variational Mode Decomposition

Variational Mode Decomposition algorithm (Dragomiretskiy et al. 2014) achieves an adaptive decomposition of a multi-component target signal considering a variational framework in which the bandwidth associated to each modal component, called Intrinsic Mode Function (IMF), is assessed looking for the optimal solution of a constrained variational problem.

The optimization process is carried out in the frequency domain: each mode is iteratively obtained as the signal produced by a narrow-band Wiener filter applied to the signal estimation residual of all other modes. The assessment of the bandwidth for each mode is carried out calculating the associated analytical signal via Hilbert-Huang Transform, shifting its spectrum to baseband due to multiplication for a proper exponential function and subsequently calculating the H_1 Gaussian smoothness of demodulated signal:

$$\mathbf{BW}_k = \left\| \partial_t \left\{ \left[\left(\delta(t) + \frac{j}{\pi t} \right) * v_k(t) \right] e^{-j\omega_k t} \right\} \right\|_2^2 \quad (1)$$

Based on these steps, the following constrained variational problem is obtained:

$$\min_{\substack{v_1(t), \dots, v_K(t) \\ \omega_1, \dots, \omega_K}} \left\{ \sum_{k=1}^K \left\| \partial_t \left[\left(\delta(t) + \frac{j}{\pi t} \right) * v_k(t) \right] e^{-j\omega_k t} \right\|_2^2 \right\} \text{ s.t. } \sum_{k=1}^K v_k(t) = v(t) \quad (2)$$

where ∂_t is the gradient operator and $\|\cdot\|_2$ the L^2 -norm operator. By using a quadratic penalty term and the Lagrange multipliers technique to enforce the constraints, the search for the solution of this variational problem leads to the following augmented Lagrangian function:

$$\begin{aligned} L(v_1(t), \dots, v_K(t), \omega_1, \dots, \omega_K, \lambda) = & \alpha \sum_{k=1}^K \left\| \partial_t \left[\left(\delta(t) + \frac{j}{\pi t} \right) * v_k(t) \right] e^{-j\omega_k t} \right\|_2^2 \\ & + \left\| v(t) - \sum_{k=1}^K v_k(t) \right\|_2^2 + \left\langle \lambda, v(t) - \sum_{k=1}^K v_k(t) \right\rangle \end{aligned}$$

where α is the quadratic penalty factor, λ is the Lagrangian multiplier and $\langle \cdot, \cdot \rangle$ is the L^2 -inner product. The solution of the governing constrained problem is thus equivalent to the evaluation of the saddle point of the augmented Lagrangian function. This can be achieved using alternating direction method of multipliers, which solves two parallel sub-optimization problems which provide an estimation of the k -th IMF $v_k(t)$ and the center frequency ω_k , the latter is correspondent to the modal frequency in the adopted identification framework.

The performance of the VMD technique is highly dependent on the proper tuning of two main parameters, namely the number of IMFs to be extracted K and the penalty factor α . Therefore, a suitable procedure for the choice of this parameter is implemented to significantly limit the subjectiveness of the results. This tuning method evaluates the optimal K and α

separately: the selection for number of modes K starts considering a range of possible values $\tilde{K} \in [K_{\min}, K_{\max}]$ and for each one of them exploits the mean correlation measure $\rho_{k,k+1}$ between each two consecutive sampled IMFs:

$$K = \underset{K_{\min} \leq \tilde{K} \leq K_{\max}}{\operatorname{arg\,min}} \left\{ \frac{1}{\tilde{K} - 1} \sum_{k=1}^{\tilde{K}-1} \rho_{k,k+1} \right\} \quad (4)$$

Repeating this procedure for each value of α in a fixed range $[\alpha_{\text{start}}, \alpha_{\text{end}}]$, a stabilization diagram is built from each couple (α, K) and the number of IMFs is sought in the range $[\alpha_{\min}, \alpha_{\max}] \subseteq [\alpha_{\text{start}}, \alpha_{\text{end}}]$ in which K remains stable.

The estimation of the optimal penalty factor starts calculating for each value of $\tilde{\alpha} \in [\alpha_{\min}, \alpha_{\max}]$ two parameters called Power spectrum information entropy $\text{PSIE}_k(\tilde{\alpha})$ and uncorrelation factor $\text{UC}_k(\tilde{\alpha})$ defined as in literature (Yang et al. 2020). The optimal value of the penalty factor is obtained as:

$$\alpha = \underset{\alpha_{\min} \leq \tilde{\alpha} \leq \alpha_{\max}}{\operatorname{arg\,min}} \{ \overline{\text{PSIE}}(\tilde{\alpha}) + \overline{\text{UC}}(\tilde{\alpha}) \} \quad (5)$$

where $\overline{\text{PSIE}}(\tilde{\alpha})$ and $\overline{\text{UC}}(\tilde{\alpha})$ represent the dimensionless averaged values of the two parameters with respect to the selected number of modes K .

2.2 Modal damping ratios estimation

For each modal component the correspondent modal damping ratio can be obtained using an area-based approach (Huang et al. 2007). Under the assumptions that the k -th modal component can be seen as the free vibration response of the correspondent k -th SDOF modal oscillator and that it has $2N_k+1$ zero-crossing points, it is possible to relate the modal damping ratio with the $2N_k$ areas $S_{i,k}$ enclosed between the response function and the time axis as follows:

$$\zeta_k = \frac{1}{\sqrt{1 + (2N_k\pi/A_k)^2}} \quad (6)$$

being A_k the area ratio evaluable with any quadrature method and defined as:

$$A_k = \ln \left[\frac{\sum_{i=1}^{N_k} S_{i,k}}{\sum_{i=N_k+1}^{2N_k} S_{i,k}} \right] \quad (7)$$

The advantage of using this method for damping estimation is due its robustness against the noise: the area evaluation is less affected from local distortions due to noise in the signal which on the contrary may significantly influence the estimation of local maxima used in traditional logarithmic decrement method.

3 CASE STUDY: BRIDGE OVER GARIGLIANO RIVER

The case study herein analysed is the cable-stayed bridge over the Garigliano river (see Figure 1), part of the highway infrastructures connecting the cities of Naples and Rome (Italy). The structure consists of two spans of equal length for a total of 180 m and the deck consists of precast multicell block girders in prestressed reinforced concrete assembled in situ with height 2.45 m and width 26.1 m (see Figure 2). Both spans are simply supported at one end and constrained to a central pylon at the other one.

Figure 1. Overview of cable-stayed bridge over Garigliano river.

Each span is sustained by 9 couples of cables, each couple is spaced 1.7 m. The cables and have a variable number of 0.6" galvanized sheathed high-strength prestressing steel strands, from 45 to 55, and a variable length from 23 m to 87.5 m. The pylon is made up of three parts: the first 5 m are in reinforced concrete with a linearly variable transversal section from 4.6 m x 2.5 m to 4 m x 2.5 m, the second part, from height 5 m to 10 m, is a steel box linearly variable up to a section of 2.9 m x 2.5 m, and the last part, from height 10 m to 25 m, has constant hollow section made of steel. The central pier on which the deck and the pylon are connected is 8.4 m high and it has a 10 m x 2.5 m reinforced concrete rectangular section with rounded corners with radius of 1.25 m.

A monitoring campaign was conducted to monitor the state of health of the structure cables and, because of their large number, a suitable solution consisted in free vibration tests which are less expensive and require a minimal equipment. For each stay-cable, the test setup consisted of two piezoelectric uniaxial accelerometer (sensitivity 10 V/g) positioned at a medium height of 3.8 m from the bridge deck extrados.

Each couple of accelerometers was mounted on both faces of a steel angle as in to record both horizontal and vertical accelerations. The steel angle was connected to the stay-cable using nylon tightening straps. The stay-cables were excited with an impulsive load applied to the bridge in its service conditions, i.e., concurrent with environmental vibrations due to wind and traffic in both directions. By the application of a vertical impulsive load, both the accelerations in vertical and horizontal direction were recorded and are herein labelled V/V and V/H respectively; similarly applying a horizontal impulsive load, the acceleration in the horizontal direction is labelled H/H whereas the one in vertical direction H/V.

Figure 2. Bridge geometry and sensor layout of stay cables.

The selected ranges for VMD parameters are $K \in [2, 8]$ and $\alpha \in [1, 10000]$ respectively. In Figure 3, the IMFs retrieved for the stay cable B in Rome direction for the acceleration recording V/V are shown: the ideal number of IMFs is $K=3$ and the evaluation of the

quadratic penalty factor α must be executed in the narrower range $\alpha \in [1, 8500] \subset [1, 10000]$ and it leads to $\alpha = 76$.

An estimation of the natural frequencies is obtained by means of practical formulas which relates them to the correspondent cable force obtained under the assumptions that prestressing steel has a Young Modulus equal to 198,000 MPa, the linear weight for strands and PHED sheath are 1.305 kg/m and 5.68 kg/m respectively and the density of the grout filling equal is 1,440 kg/m³. The identified frequencies are compared with the obtained from practical formulas (Zui et al. 1996) for the first mode: data points focus on the quadrant bisector line showing a nice agreement between experimental and predicted values (see Figure 4). Predicted values of frequencies are slightly higher with respect to the experimental ones with differences under 7%. Missing outputs are dependent on the corruption of the related recordings.

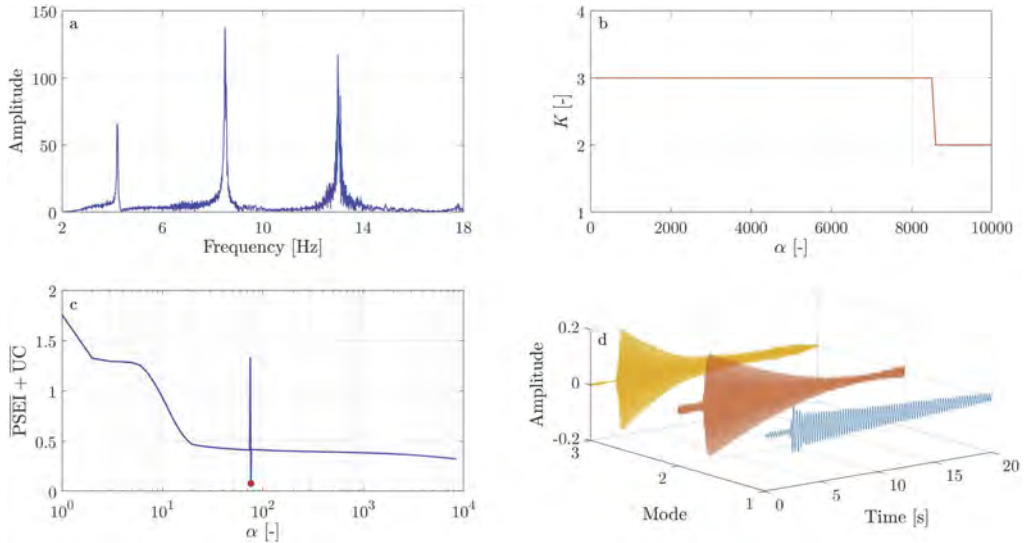

Figure 3. Elaborations on the signal V/V - Cable B in Rome direction: a) Fourier Transform, b) Stabilization diagram for K , c) Evaluation of optimal α and d) VMD of the signal with $K=3$ and $\alpha=76$.

Figure 4. Comparison between experimental and predicted frequencies for the first mode of cables in both the road directions.

For each stay cable, the considered identification method also allows the estimation of modal damping ratios from the free vibration response (see Figure 5). All modal damping ratios fall within the range 0-0.8% with an average value of 0.25%; these results are consistent with literature studies on cable modal damping ratios in cable-stayed bridges (Chen et al. 2019). The estimations for the first mode are compared with results obtained interpreting

ambient vibration tests executed on the same cables by means of the Natural Excitation Technique (James III et al. 1993) in Figure 6: consistent values can be observed between the two set of results obtained from two kind of vibration test with limited scattering.

Figure 5. Identified Modal Damping Ratio for the first mode in both the road directions.

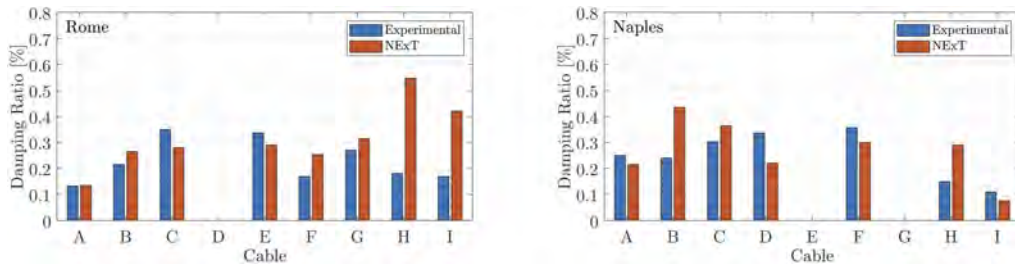

Figure 6. Comparison of modal damping ratios identified from free vibration tests (experimental) and ambient vibration tests (NExT).

4 CONCLUSIONS

In this contribution, the modal identification of cables in a stay-cabled bridge has been addressed. Using a tuned version of the VMD the modal acceleration components have been isolated and modal frequencies have been identified: comparing the latter to the ones obtained from theoretical formulations, good agreement has been achieved. Exploiting an area-ratio based approach, the modal damping ratio for the first mode of each cable has been evaluated. The estimations have been corroborated by the comparison with results from elaboration of ambient vibration data, showing good correspondence and reduced data scattering. The adopted decomposition method appears reliable also in case of cable-stayed bridges and the comparison between the parameters numerically identified and the theoretical ones may allow to make informed decisions for existing bridge structures in terms of eventual repair actions needed to ensure structural safety or serviceability.

The effect of road roughness on vehicle-bridge interaction modeling

A. Aloisio & R. Alaggio

University of L'Aquila, L'Aquila, Italy

A. Contento & B. Briseghella

Fuzhou University, Fuzhou, China

ABSTRACT: The study of the bridge response under moving loads is commonly investigated with two alternative approaches. One approach represents the vehicle as a moving load, the other with sprung mass models. This study is aimed to compare the two approaches and evaluate the difference in their accuracy to assess if there are cases where vehicle bridge-interaction modelling (i.e. the use of sprung mass models) is needed to accurately estimate the bridge response. For this purpose, both a moving load model and a one degree of freedom sprung mass model have been implemented and used to compare the bridge response under different road roughness. The probabilistic distributions of two indicators, used to compare the bridge displacement responses in three roughness scenarios with variable velocity and different vehicle mass and dynamics, are derived through Montecarlo simulations. It is found that an increasing level of road roughness modelled according to ISO-8608 increases the differences between the predictions of the models.

1 INTRODUCTION

Vehicle-bridge interaction (VBI) problems were extensively studied for several reasons that include the growing interest in the safety assessment of infrastructures. Additionally, the interest in vibration-based approaches for structural health monitoring (SHM) of infrastructures further fed the research in VBI modelling.

Additionally VBI models can be either coupled or uncoupled. In the coupled models, the moving vehicle contributes to the bridge vibration, whereas in the uncoupled models vehicle dynamics does not affect the bridge response. Uncoupled models are often preferred due to their relatively simple implementation, reduced computational cost, and robustness against numerical instability. However, the assumptions of the uncoupled approach cannot always be acceptable. In many cases the accurate modelling of VBI is essential for precisely predicting fatigue phenomena occurring when a structure is subjected to repeated load cycles, like bridges under vehicular traffic. The accurate prediction of the fatigue life is fundamental for the structure's life-cycle assessment (LCA). Thus, VBI modelling is necessary component of the mathematical framework needed for the LCA of infrastructure.

To the authors' knowledge, a few papers are attempting to understand the trade-off between model complexity and accuracy in VBI problems (González et al., 2022). Additionally, several investigations lack experimental validation and focus on the modal parameters, i.e. estimating the time-variance of the bridge response in terms of instantaneous frequency, damping and mode shape. Experimental investigations are generally based on time-frequency analyses using vibration data in terms of velocity or acceleration (Li et al., 2022; Quqa et al., 2022). Recently, Gonzalez (González et al., 2022) attempted to quantify the modelling error in predicting the bridge response under moving vehicles using uncoupled methods. However, his attempt lacks experimental validation and focuses on a few scenarios.

Within this framework, this paper's ultimate goal is to clarify when the assumptions of the uncoupled model are reasonable or not and to highlight the role of road roughness in the differences between the two approaches. For this purpose, the authors used a moving load

model and a one degree of freedom sprung mass model to simulate the bridge response under the effect of a running vehicle and performed Montecarlo simulations varying three parameters describing the vehicle dynamics (velocity, mass and natural frequency) and the roughness level according to the ISO:8608. The outcomes of the analyses lead to a probabilistic model to describe the difference between the two modelling approaches. Since the accuracy of the two models depends on the quantity being predicted (e.g. use the midspan deflection to estimate the maximum load effect and the time-history of a dynamic system), the authors select two discrepancy indicators (i.e. error estimates): the relative variation in the maximum deflection and (ii) the modal assurance criterion. The former is relevant for safety problems, where the primary intent is to assess the maximum load effect on the structure. The latter is essential for those researches where the bridge time-history is involved in the analyses. The elements of novelty can be summarised in

1. estimating the error gap between coupled and uncoupled approaches using mathematical models validated against experimental results;
2. developing a computationally efficient Finite-Difference (FD) formulation of the VBI problem;
3. fitting the discrepancy indicators with suitable probability density functions that can be used to estimate the modelling error when using concentrated load models.

2 VEHICLE-BRIDGE INTERACTION MODEL

The randomness of the road surface roughness can be represented with a periodic modulated random process. In ISO-8608 (ISO/TC et al., 1995) specifications, road surface roughness and vehicle speed are related through the relation between velocity power spectral density (PSD) and displacement PSD. The general expression for the displacement PSD of the road surface roughness is $S_d(n) = S_d(n_0) \cdot (n/n_0)^{-a}$, where $n_0 = 0.1$ cycles/m is the reference spatial frequency, a is an exponent of the PSD, and n is the spatial frequency (cycles/m). The classification of the road roughness is based on a constant vehicle velocity PSD by taking $a = 2$. The road roughness profile can be generated through the following equation:

$$r(x) = \sum_{i=1}^Q d_i \cos(n_i x + \Theta_i). \quad (1)$$

In the equation, n_i is the i -th spatial frequency, Θ_i is the random phase angle, and d_i is the i -th amplitude computed as $d_i = \sqrt{2S_d(n)\Delta n}$ with Δn denoting the sampling interval of the spatial frequency.

The dynamic equilibrium equation of the vehicle mass m_v can be written as follows:

$$m_v(\ddot{w}_v + \ddot{r} + \ddot{w}_b) + c_v \dot{w}_v + k_v w_v = 0, \quad (2)$$

where m_v , c_v , and k_v are respectively the sprung mass, the damping coefficient, and the stiffness of the vehicle. The absolute displacement of the vehicle mass is written as the summation of three terms: w_v , r , and w_b . Namely, w_v indicates the relative displacement between the road surface and the center of gravity of the vehicle mass, r indicates the road roughness, and w_b is the beam deflection measured from the line axis of the bridge. The contact force due to the vehicle oscillation f_c does not include the weight of the sprung-mass system and can be written as

$$m_w(\ddot{r} + \ddot{w}_b) + f_c - c_v \dot{w}_v - k_v w_v = 0, \quad (3)$$

where m_w is the mass of the wheel.

The bridge can be described as an Euler-Bernoulli beam. The EB beam has a constant mass per unit length $\rho_c A_c$ (where ρ_c is the specific mass of concrete and A_c is the cross-section area of the beam) and A_c constant flexural rigidity $E_c I_c$ (where E_c is the Young's modulus of concrete and I_c the cross-section inertia of the beam). The vertical displacement $w_b(x, t)$ of the bridge is governed by the following partial differential equation (Fryba, 2013):

$$\rho_c A_c \ddot{w}_b(x, t) + E_c I_c w_{r,xxxx}(x, t) = \delta(x - ct)(f_c + m_w g + m_v g) \quad (4)$$

where δ is the Dirac delta. The left and right boundary conditions for a pinned-pinned beam are

$$\text{Left : } w_b(0, t) = 0 \quad w_{b,xx}(0, t) = 0; \quad \text{Right : } w_b(L, t) = 0 \quad w_{b,xx}(L, t) = 0. \quad (5)$$

The VBI equations (Equations 2 and 4) can be written in matrix form by discretizing the beam into n elements with a Δx length. The spatial discretization is obtained using the finite difference method that leads to the following coupled system of equations:

$$\begin{aligned} & \begin{bmatrix} \rho_c A_c \Delta x \mathbf{I} + m_w \delta \otimes \delta^T & \mathbf{0} \\ m_v \delta^T & m_v \end{bmatrix} \begin{Bmatrix} \dot{\mathbf{w}}_b(t) \\ \dot{\mathbf{w}}_v(t) \end{Bmatrix} + \begin{bmatrix} E_c I_c \mathbf{D}_4 & -\delta k_v \\ \mathbf{0} & k_v \end{bmatrix} \begin{Bmatrix} \mathbf{w}_b(t) \\ w_v(t) \end{Bmatrix} + \\ & + \begin{bmatrix} \mathbf{C} & -\delta c_v \\ \mathbf{0} & c_v \end{bmatrix} \begin{Bmatrix} \dot{\mathbf{w}}_b(t) \\ \dot{\mathbf{w}}_v(t) \end{Bmatrix} + \begin{Bmatrix} \delta[-m_v g + m_w(\ddot{r} - g)] \\ m_v \ddot{r}(t) \end{Bmatrix} = 0. \end{aligned} \quad (6)$$

In Equation 6, \mathbf{I} and $\mathbf{0}$ are the identity and null matrices, respectively, and $\mathbf{D}_4^{\{n \times n\}}$ is the approximate fourth matrix derivative. Additionally, δ is the discretization of the Dirac function, $\mathbf{w}_b(t)$ collects the vertical deflection of the bridge discretized in N segments, and \mathbf{C}_r is the damping matrix. The damping matrix is estimated using the Rayleigh approximation and is assumed proportional to the mass and stiffness matrices following the Rayleigh approach (Chopra, 1975). The i -th term of the discretized Dirac function (δ_i) is

$$\delta_i = \begin{cases} 1, & \text{if } i = \left[\frac{ct}{\Delta x} + 0.5 \right] \wedge i = 1 \\ \frac{|ct - i\Delta x|}{\Delta x}, & \text{if } i = \left[\frac{ct}{\Delta x} + 0.5 \right] \wedge i > 1 \\ 1 - \frac{|ct - i\Delta x|}{\Delta x}, & \text{if } i = \left[\frac{ct}{\Delta x} + 0.5 \right] - 1 \wedge i > 1 \\ 0, & \text{else} \end{cases}, \quad (7)$$

where $[\cdot]$ denotes the rounding function. Equation 6 can be solved using the Dormand-Prince method based on an explicit Runge-Kutta temporal discretization (Dormand and Prince, 1980).

3 EXPERIMENTAL TESTS AND MODEL CALIBRATION

The bridge span under investigation belongs to the Italian motorway network. It is a simply-supported, prestressed concrete girder. The girder has the trapezoidal cross-section shown in Figure 1. The cross-section is 2.3m high, with two cantilevered wings 3.85m wide, and prestressed by bonded post-tensioned tendons. A pair of piers, whose centre distance is about 40m, sustains each bridge span.

3.1 Experimental setups

The response of the considered bridge span is measured in terms of acceleration and displacement of the mid-span. The setup for the accelerations consists in two rows of seven equally-spaced Force Balance Accelerometers (FBA); the experimental equipment for the displacements consists of an easel supporting a laser sensor. The dynamic tests are carried out under the excitation of a moving two-axes vehicle with mass 3860kg (Jin et al., 2022). The modal parameters are estimated using the covariance-driven Stochastic Subspace Identification (SSI) method (Peeters and De Roeck, 2001). For each setup, the data are sampled at a 200Hz rate and used for SSI and subsequent modal analysis to derive eigenfrequencies, damping ratios, mode shapes, covariances of the modal parameters, and, as a consequence, the bending stiffness of the beam model.

3.2 Model calibration

In the analysis, the vehicle velocity and its characteristic in terms of mass and stiffness are assumed known, as well as the area of the cross section A_c , the weight per unit of volume of

Figure 1. (a) View of the bridge with the accelerometers, view (b) and scheme (c) of the experimental setup.

concrete ρ_c , and the natural frequency of the first bending mode, estimated from output-only dynamic identification, are also used as input parameter to further constraint the optimization problem. The bridge spatial discretization is assumed equal to 0.2m, approximately equal to the wheel footprint, while the sampling frequency equal to 100Hz. The remaining unknown parameters of the VBI model are the bending stiffness EI , the equivalent viscous damping of the bridge ξ_b , and the roughness level $S_d(n_0)$. The viscous damping is included in the VBI model optimization because its dynamic identification could be unreliable due to its possible underestimation (Frizzarin et al., 2010). The authors follow a three-step approach for estimating the three unknown parameters:

1. the bending stiffness (EI) is estimated from the first bending mode of the considered bridge span;
2. the bridge damping (ξ_b) is estimated from experimental displacement response using the VBI model without road roughness;
3. the bridge roughness ($S_d(n_0)$) is estimated from experimental displacement response using the VBI model with road roughness.

The first mode closely resembles that of a pinned-pinned beam. Such bending mode can be reasonably used (in terms of mode shapes and natural frequencies) to estimate the bending stiffness EI of an equivalent beam model. To estimate EI , the authors solve a nonlinear least-squares problem (He et al., 2021) that which leads to find a global minimum of the objective function for $E \approx 1.575 \text{Nm}^2$.

Conversely, the experimental displacement data are used to calibrate the bridge damping and the road roughness. The calibration is performed by using a genetic optimization algorithm (Sirrotti et al., 2021). The genetic algorithm performs iteration of parameters with the goal of minimizing the integral of the difference between experimental and simulated displacement. As anticipated, the authors assume the value of the bending stiffness EI to further constrain the optimization problem that provided $\xi_b = 0.02$ and $S_d(n_0) = 2 \cdot 10^{-5}$ as optimum values of the parameters. The damping value is consistent with that of concrete structures, while the roughness level corresponds to a profile class A, according to the ISO:8608 classification.

Figure 2 plots the experimental displacement response of the bridge span against the predictions of the moving load (labelled load-smooth) and VBI models (labelled mass-smooth). The experimental data refer to the transit of a two-axes vehicle with a 3860kg mass, moving at constant velocity approximately equal to 80km/h. Such data reveal a significant noise level. However, the maximum beam deflection is low, and close to the sensor resolution ($\approx 10^{-2} \text{mm}$). The maximum deflection is approximately equal to 0.08mm. The model predictions are in good agreement with the experimental data, especially in the first part of the response and after the vehicle has crossed the bridge. Two significant aspects arise from the observation of Figure 2:

- in case of no or negligible roughness, there is no substantial difference between the VBI and moving load models. Therefore, the two responses are almost indistinguishable.
- even a minor level of road roughness (road profile A) leads to differences between the two models because the road roughness activates a VBI phenomenon, which is evident in the second part of the transit (shaded red rectangle). The VBI model (in red) can closely

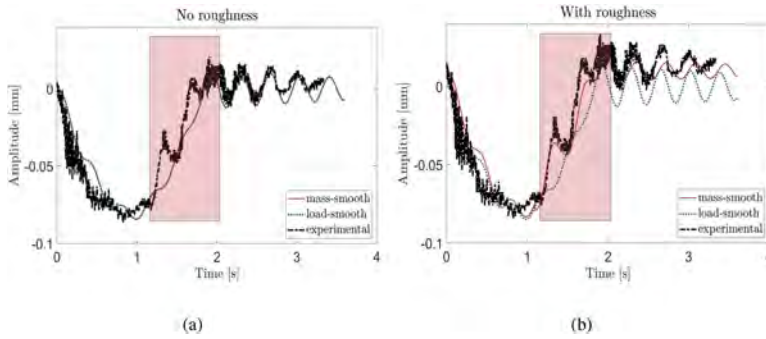

Figure 2. Experimental validation of the VBI and the concentrated force models in case of constant velocity (a) without and (b) with roughness ($S_d(n_0) = 2 \cdot 10^{-5}$).

follow the experimental data, especially the peaks arising in this part of the response. Conversely, the moving load model is not significantly influenced by the road roughness. The two models do not lead to noteworthy differences in maximum deflections, but the difference manifests as additional peaks due to the vehicle dynamics.

4 PARAMETRIC ANALYSES AND DISCREPANCY INDICATORS

A parametric analysis is performed to assess how the vehicle dynamics affects the bridge response under different roughness conditions. The parameters varied in the analyses are the vehicle velocity c , in the range 50–150 [km/h], the vehicle mass m_v , in the range 1–50 [ton], and the viscous damping coefficient of the vehicle, in the range 0.15–0.30. Such ranges reasonably represent the variation related to the variability of the vehicular traffic. Additionally, the values of $S_d(n_0)$ for the considered road roughness profiles according to ISO 8608 are $S_d(n_0) = 16 \cdot 10^{-6} \text{m}^3/\text{cycle}$ for Profile Class A, $S_d(n_0) = 64 \cdot 10^{-6} \text{m}^3/\text{cycle}$ for Profile Class B, and $S_d(n_0) = 256 \cdot 10^{-6} \text{m}^3/\text{cycle}$ for Profile Class C. The three-dimensional parameters' space is sampled following the Latin hypercube sampling scheme (Iman and Conover, 1979). The number of samples is set equal to 10000, which allowed to obtain a value of the COV ($< 0.1\%$). The authors used two discrepancy indicators to quantify the differences between the two predictions, one referred to the maximum displacement and the other to the cross-correlation, following the definition of the modal assurance criterion. Such indicators read

$$\delta = \frac{\max(|w_{vbi}|) - \max(|w_{cl}|)}{\max(|w_{cl}|)}; \text{MAC} = \frac{|w_{vbi} \cdot w_{cl}^T|^2}{(w_{vbi} \cdot w_{vbi}^T)(w_{cl} \cdot w_{cl}^T)}; \quad (8)$$

where w_{vbi} and w_{cl} collect the bridge responses from the VBI and concentrated load models. Given the roughness level, the road roughness is randomly varied in each run of the two models.

The results of the parametric analyses in terms of δ and MAC are first used to estimate the Sobol sensitivity indexes (Sobol, 1993).

Table 1. Sobol sensitivity indicators for the effects of weight, damping, and velocity of the vehicle.

Parameter	δ	MAC	δ	MAC	δ	MAC
	Class A		Class B		Class C	
Weight	0.53	0.67	0.63	0.57	0.50	0.49
Damping	0.25	0.25	0.26	0.27	0.23	0.44
Velocity	0.21	0.24	0.30	0.28	0.42	0.45

Table 1 shows the Sobol sensitivity indicators, which estimate the effects of the weight, damping, and velocity of the vehicle on δ and MAC for the three roughness classes. The weight has a dominant effect on values of δ and MAC obtained for the three road classes ($> 50\%$),

whereas, the effects of damping, and velocity are almost equal and range between 20 and 30%. Increments in the road roughness, from class A to C, cause an increment in the effects of damping and velocity on the chosen discrepancy indicators.

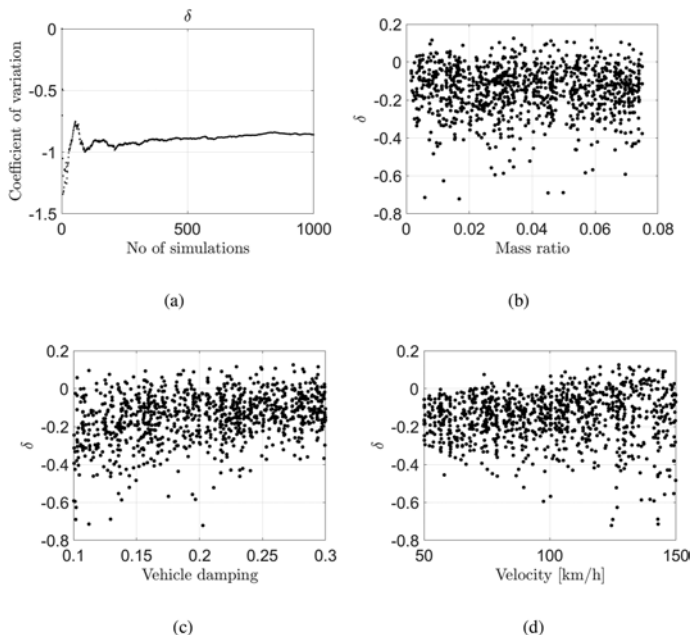

Figure 3. (a) Coefficient of variation of δ (Equation 8) as a function of the number of simulations. (b)-(d) Comparison between coupled and uncoupled models in terms of δ in Equation 8 as a function of the mass ratio, vehicle damping, velocity given a roughness class A.

Figure 2 shows the plots of δ as a function of the mass ratio (vehicle mass divided by the bridge mass), velocity and damping of the vehicle. Using these results the authors derived the probability density functions of the δ and MAC parameters as functions of the mass, damping, and velocity of the vehicle.

5 PROBABILISTIC DENSITY FUNCTIONS OF THE DISCREPANCY INDICATORS

The parameters δ and MAC obtained from the parametric analyses (Table 2) are fitted by suitable probability density functions. Specifically, it is assumed that

$$Z_i = T(Y_i) \sim N(\mu_i, \sigma_i^2), \quad (9)$$

where $T(\cdot)$ is the two-parameters Box-Cox transformation, $Y_i \in \{\delta, \text{MAC}\}$ are random variable associated to two parameters, and μ_i and σ_i^2 are unknown parameters ($i = \{\delta, \text{MAC}\}$). The posterior distribution of the parameters $\Theta = \{\mu_i, \sigma_i\}$ is derived by means of the Bayes' rule in closed form assuming a prior of the joint distribution of μ_i and σ_i^2 in the form $p(\Theta) \propto 1 \cdot \sigma_i^{-2}$. The two posterior marginal distributions are a t distribution for μ_i

$$\mu_i \sim t(\bar{z}_i, s_i^2/n, n-1), \quad (10)$$

and an Inverse-Gamma distribution for σ^2

$$\sigma^2 \sim IG((n-1)/2, s_i^2(n-1)/2). \quad (11)$$

In Equations (10) and (11), \bar{z}_i is the mean value of the realizations of the transformed random variables, s_i is the correspondent corrected sample standard deviation, and $n = 1000$ is the number of realizations of z_i . The values of \bar{z}_i and s_i^2 for the δ and MAC indicators related to each roughness class can be found in Table 5.

Table 2. Posterior statistics of the fitting probability density functions δ .

Roughness class	Descriptive parameter	λ_1	λ_2	Sample mean \bar{z}_i	Sample standard deviation s_i
A	δ	1.800	0.722	-0.344	0.006
	MAC	3.400	0.0	-0.057	0.001
B	δ	1.800	1.459	0.110	0.059
	MAC	1.700	0.000	-0.202	0.009
C	δ	1.800	3.086	1.780	0.607
	MAC	1.700	0.000	-0.622	0.065

6 ANALYSIS OF THE RESULTS

Figure 4 shows the histogram plots of the δ and MAC functions. The road roughness plays a crucial role in magnifying the VBI effects because it activates the vehicle dynamics, which interacts with the bridge significantly, especially for frequency ratios close to 1. Consequently, an increase in road roughness entails increasing the difference between the VBI and moving load models. The moving load model is not conservative: the percentage of underestimation of the beam deflection rises from nearly 14% to almost 90% as the road roughness increases from Class A to Class C. Such results shows that there are cases, and in particular those with high road roughness, where the effects of VBI cannot be neglected. Consequently, to use moving load models, which are usually easier to implement, it is necessary to separately account for the additional effect of VBI that can be estimated using the fitted probability density functions of δ .

Figure 4. Histograms of δ and 1-MAC for the considered roughness classes.

In mid-span bridges, like the one considered in this paper, especially those belonging to high-level road networks, the road roughness belongs to class A and the increase of deflection due to VBI is, on average, 14%. In design, the potential underestimation of the load effects due to moving load models is compensated by including safety factors and load values corresponding to high fractiles of given probability distributions according to national and international standards.

7 CONCLUSIONS

This paper quantifies the effect of road roughness on vehicle bridge interaction (VBI) in a mid-span prestressed concrete bridge response. The bridge is modelled as a pinned-pinned Euler

Bernoulli beam, while two vehicle models are compared to simulate the vehicle transit: a concentrated load and a sprung-mass model. The first model does not include the mutual interaction between the bridge and the vehicle dynamic. It is used as a reference model to estimate the modelling error related to the lack of VBI effects. The differences between the two models are quantified in terms of relative error (δ) and correlation (MAC) between time histories. The governing equations are solved numerically after temporal and spatial discretization. It is found that the roughness triggers VBI phenomena and leads to higher discrepancies between the VBI and load models. Averagely, the load model underestimates the load effect by 14%, 37% and 90% in roughness classes A, B, and C, respectively. Future research papers will extend this study to different bridge typologies by varying the frequency ratio, i.e. the ratio between the vehicle and bridge natural frequency and more detailed VBI models. Additionally, the authors will extend the analyses further to include the effect of roughness in VBI due to vehicle braking.

ABSTRACT: The mechanical properties of concrete-filled steel tubular (CFST) members are influenced by the possible debonding gap between the steel tube and concrete core. To investigate this phenomenon, finite element models (FEMs) of the CFST columns with different debonding types, such as the circumferential debonding gap (CDG) and spherical-cap debonding gap (SDG), were established by using ABAQUS. The accuracy of the FEMs was verified comparing the obtained results with experimental ones. The verified FEMs were used to analyze the influence of different debonding types on the mechanical performance of the axially compressed CFST stub columns with the same debonding arc-length ratio (R_D). The results showed that with an increase in R_D , the ultimate load-bearing capacity (N_u) of CFST columns decreased. However, a critical R_D (R_{D-cr}) was found, in fact when the R_D was less than or equals to the R_{D-cr} , the influence of different debonding types on the N_u and failure modes of CFST columns were basically the same. When the R_D was larger than the R_{D-cr} , with an increase in R_D , the N_u of SDG CFST columns decreased linearly, however, the N_u of CDG CFST columns decreased nonlinearly with gradually reduced decrease rates. Finally, it was found that the overall bending, inward and outward buckling in SDG CFST columns were more serious than those in CDG CFST columns.

1 INTRODUCTION

According to the inspections made in arch bridges, debonding gaps can be found between the steel tube and concrete core, which can weaken the combined effect of two materials in CFST (concrete-filled steel tube) structures (Han et al. 2016, Shen et al. 2022, Xue et al. 2010, 2012). Two different types of debonding gaps could be found, which are the circumferential debonding gap (CDG) (Figure 1a) and spherical-cap debonding gap (SDG) (Figure 1b) (Contento et al. 2022, Han et al. 2016, Shen et al. 2022, Xue et al. 2021a).

The main parameters of CDG or SDG are shown in Figures 1a, b, respectively, including the debonding thickness (T_D : T_{CDG} or T_{SDG}), debonding arc-length ratio (R_D : R_{CDG} or R_{SDG}) and debonding length (L_D : L_{CDG} or L_{SDG}). T_{CDG} or T_{SDG} is the maximum distance between the outer surface of the concrete core and the inner surface of the steel tube within the range of CDG or SDG. R_{CDG} or R_{SDG} is the ratio of the arc-length of CDG or SDG to the perimeter of the section ($\theta_{CDG}/2\pi$ or $\theta_{SDG}/2\pi$), where the θ_{CDG} or θ_{SDG} is the angle of CDG or SDG. L_{CDG} or L_{SDG} is the length of CDG or SDG along the direction of the specimen length (L).

Some experimental tests done to investigate the influence of CDG on the mechanical performance of CFST columns have been carried out by choosing the R_{CDG} as the key parameter ($R_{CDG} = 0, 0.25, 0.5$ and 0.75 (Xue et al. 2012), $R_{CDG} = 0$ and 0.25 (Xue et al. 2020, 2021b), $R_{CDG} = 0$ and 0.5 (Shao et al. 2018), $R_{CDG} = 0, 0.5$ and 1 (Xie. 2018), and $R_{CDG} = 0$ and 1 (Liao et al. 2011, Han et al. 2016)). It can be found that, with an increase in R_{CDG} , the ultimate load-bearing capacity (N_u) of CFST columns decreased, and the influence of R_{CDG} on the N_u

also decreased. Regarding the failure mode, with an increase in R_{CDG} , the number of local buckling in the range with debonding gap (DG range) increased, the outward local buckling in the range without debonding gap (NDG range) at the mid-height and the elephant-foot shaped buckling near both ends were more obvious (Liao et al. 2011, Han et al. 2016, Xue et al. 2012).

Experimental tests on the influence of SDG on the mechanical performance of CFST columns have been also carried out by choosing the gap ratio of SDG ($\chi_{SDG} = T_{SDG}/D$) as the key parameter. It can be concluded that, with an increase in χ_{SDG} , the N_u of CFST columns linearly decreased. With an increase in χ_{SDG} , the axially compressed CFST columns exhibited clearly local buckling in DG range at failure, and the number of outward local buckling increased at the mid-height; the failure mode of the eccentrically compressed CFST columns changed from inward bending to wavy inward local buckling in DG range. In the literature, there is no research on the influence of R_{SDG} on the mechanical performance of CFST columns.

The influence of CDG or SDG on the mechanical performance of CFST stub columns was analyzed separately in some references (Han et al. 2016, Liao et al. 2011, Shen et al. 2022, Xue et al. 2021). However, the results of CDG or SDG were not compared with each other in the same research. The influence of different debonding gap types on mechanical performance of axially compressed CFST stub columns with the same debonding area was studied by Xue et al. (2022). The results showed that the mechanical performance of CDG or SDG CFST columns with the same debonding area were different.

It is difficult to measure the T_D in real applications. The most accurate detection technology for the T_D is to drill holes on the steel tube, which may damage the steel tube. The knocking method is a nondestructive detection method which can be used to measure the approximate range of debonding gaps to calculate the R_D . Therefore, the R_D should be considered as the key parameter in CFST columns with CDG or SDG. However, there is few research on the influence of different debonding gap types on mechanical performance of axially compressed CFST stub columns with the same R_D based on the knowledge of authors. In this paper, the influence of CDG or SDG on the N_u and failure modes of CFST stub columns with the same R_D were analyzed.

Figure 1. Parameters of debonding gaps.

2 FINITE ELEMENT SIMULATION

2.1 Finite element modelling

The steel tube was simulated by shell elements (S4R). The core concrete was simulated by solid elements (C3D8R). The end plates were simulated by discrete rigid elements (R3D4).

The steel tube was simulated by an elastic-plastic model using a stress-strain relation that consists of five stages with Von Mises yield criterion (Han et al. 2007). The damage plasticity model

was used for modelling concrete by using the equivalent stress-strain model proposed by (Han et al. 2007). For concrete in tension, the tensile softening behaviour was set by using the fracture energy model specifying the post failure stress as a tabular function of cracking displacement.

Both the bond and friction actions were considered in the interface modeling between the steel tube and concrete core. For the interface of the cross-sectional area in NDG range, the normal behaviour was simulated with hard contact; the friction coefficient was taken as 0.6 (Xue et al 2022). For the cross-sectional area in DG range (CDG or SDG shown in Figures 1a, b, respectively), both normal contact pressure and tangential shear stress were taken as zero at the beginning. When the inner surface of the steel tube contacted with the outer surface of the concrete core due to the inward buckling in the steel tube, the normal and tangent behaviours of the interface was simulated as the same as the interface of the cross-sectional area in NDG range.

The loading history was applied by using vertical downward displacement in the z-axis at the top end plate, as illustrated in Figure 2.

Figure 2. Load applications and boundary conditions.

2.2 Verification of finite element models

The FEMs of CDG and SDG CFST stub columns information were listed in Table 1.

3 INFLUENCE OF DIFFERENT DEBONDING GAP TYPES WITH SAME RD

3.1 Parameters selection

According to GB 50923-2013 (MOHURD 2013), when the R_{CDG} is larger than 0.2 or the T_{CDG} is larger than 3 mm, it is recommended to drill holes on the steel tube in DG range and grout. Therefore, in this research the maximum R_D was set at 0.2 and T_{CDG} was set as 3 mm. T_{SDG} was changed from 0 to 21 mm with an increment of 1 mm, and the corresponding χ_{SDG} changed from 0 to 9.1%. The corresponding R_{SDG} could be calculated according to the known T_{SDG} . The D of 219 mm, t of 4 mm, L of 657 mm were chosen. The cross-sections of SDG and CDG CFST columns with $R_{SDG} = R_{CDG}$ were shown in Figure 3. For the material properties of steel, a yield strength (f_y) of 345 MPa. For the material properties of concrete, a characteristic strength (f_{ck}) of 32.4 MPa, cylinder strength (f'_c) of 41.5 MPa.

3.2 Ultimate load-bearing capacity

In order to understand the influence of debonding gap on N_u , a reduction coefficient of N_u ($K_D = N_{u-D}/N_{u-N}$) was defined (Xue et al. 2012). The N_{u-D} was the N_u of specimens with debonding gap (CDG or SDG specimen) and N_{u-N} was the N_u of specimen without debonding gap (NDG specimen).

Table 1. Experimental and numerical results of CFST stub columns with CDG or SDG.

Debonding gap type	Literature	Label	N_u (kN)		
			N_{u-EXP}	N_{u-FEM}	N_{u-FEM}/N_{u-EXP}
CDG	Xue et al. (2012)	N3-0-A	2647	2705	1.02
		D3-1-A	2433	2431	0.99
		D3-2-A	2306	2358	1.02
		D3-3-A	2281	2345	1.02
		N4-0-A	2896	2965	1.02
		D4-1-A	2602	2625	1.00
		D4-2-A	2538	2554	1.00
		D4-3-A	2503	2532	1.01
	Han et al. (2016)	N-1	1559	1428	0.92
		N-2	1544		0.92
		C1.1-1	1143	1164	1.02
		C1.1-2	1113		1.05
SDG	Liang (2008)	PX-0-0	3400	3385	0.99
		PX-0-2	3130	3010	1.04
		PX-0-5	3010	3022	1.00
	Guo et al. (2020)	A0C0	5582	5809	1.04
		A0C6.42	5476	5236	0.96
	Zhang et al. (2019)	C0-0-0a	1779	1708	0.96
		C0-0-0b	1722		0.99
		CS-6-0a	1569	1467	0.93
		CS-6-0b	1518		0.97

The N_u obtained by experimental tests (N_{u-EXP}) and FEMs (N_{u-FEM}) were compared, as listed in Table 1. The mean value of N_{u-FEM}/N_{u-EXP} was 1.001 and the standard deviation was 0.045. Therefore, the finite element simulation method could be used to simulate the mechanical performance of CDG and SDG CFST stub columns.

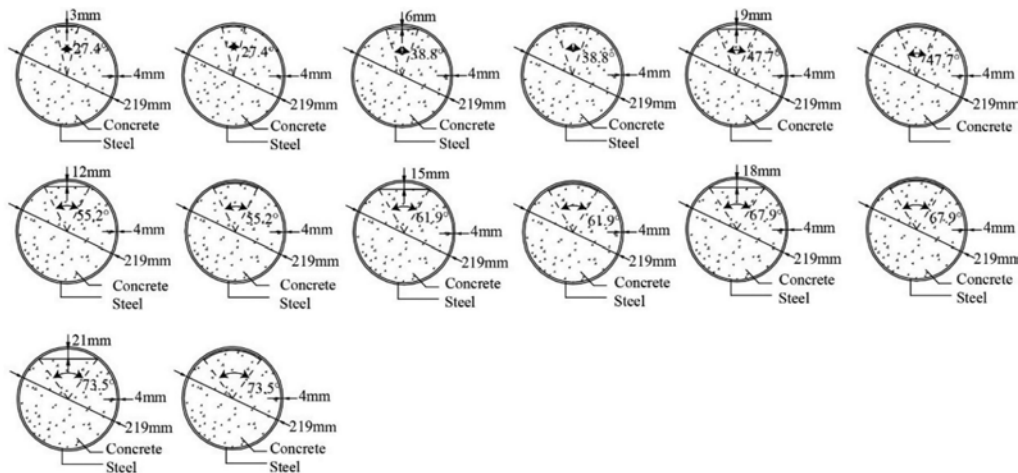

Figure 3. Cross-sections of SDG and CDG specimens with same R_D .

The influence of different debonding types with the same R_D on the N_u , K_D and the decrease rate of K_D are shown in Figure 4. It can be found that with an increase in R_D , the N_u and K_D of CDG or SDG specimens decreased. A critical R_D (R_{D-cr}) (0.12) can be found. When $R_D \leq R_{D-cr}$, with an increase in R_D , the influence of different debonding types on N_u and K_D was negligible, and the minimum K_D was 0.94. When $R_D > R_{D-cr}$, with an increase in

R_D , the influence of different debonding types on N_u and K_D was different; the N_u and K_D of SDG specimens decreased linearly, however, the N_u and K_D of CDG specimens decreased nonlinearly with gradually reduced decrease rates, as shown in Figure 4a. When $R_D = 0.2$, for CDG specimen, the N_u decreased from 3005 kN to 2674 kN and the K_D decreased to 0.89; for SDG specimen, the N_u decreased from 3005 kN to 2597 kN and the K_D decreased to 0.86. With an increase in R_D , the decrease rate of K_D for CDG or SDG specimens increased firstly until the R_D reached 0.09 and the maximum decrease rate of K_D was 0.014; when $R_D > 0.09$, the decrease rate of K_D for CDG or SDG specimens decreased, as showed in Figure 4b, the decrease ratio of K_D of CDG specimen reduced faster than that of SDG specimen.

Figure 4. Influence of different debonding gap types on N_u , K_D , and decrease rate of K_D .

3.3 Axial load-axial displacement curves

The comparisons of the axial load (N)-axial displacement (Δ) relationship curves of different NDG or DG specimens (CDG and SDG specimens) are shown in Figure 5. It can be found that when $R_D = 0.12$, the influence of different debonding gap types on the N_{u-D} and the curves was negligible. When $R_D = 0.2$, the difference of $N-\Delta$ relationship curves of CDG or SDG specimens was the descending stage after N_{u-D} . For CDG specimen, the N decreased until nearly $A_s f_y + A_c f_c'$; for SDG specimen, the descending branch of the $N-\Delta$ relationship curves was longer than that of CDG specimen, and the N decreased to a value less than $A_s f_y + A_c f_c'$. It is because even the R_D was the same (0.2), the T_{CDG} (3 mm) was less than the T_{SDG} (20 mm). Therefore, the inward buckling in CDG specimen can easier let the steel tube and concrete core in DG range contact and provide contact stress to partial concrete core in DG range from the steel tube than that of SDG specimen.

Figure 5. Comparisons of $N-\Delta$ relationship curves of NDG or different DG specimens.

3.4 Failure mode

The CDG or SDG range and NDG range in the cross-section of the specimen were defined in Figure 6.

Figure 6. Debonding or non-debonding ranges in cross-section.

The failure modes of axially compressed CDG or SDG CFST stub columns with the same R_D were showed in Figure 7. When $R_D = 0.12$, the inward buckling in DG range (CDG and SDG range), overall bending in NDG range, and lightly elephant-foot shape buckling at both ends were observed in CDG or SDG specimens, as shown in Figures 7a, b. When $R_D = 0.2$, the overall bending in NDG range and elephant-foot shape buckling at both ends can be observed in CDG or SDG specimens; however, in DG range, the inward buckling was observed in CDG specimen, while wavy inward and outward local buckling was observed in SDG specimen, as shown in Figures 7c, d.

Figure 7. Failure modes of SDG and CDG specimens with same R_D .

The lateral deflection (U) curves along the L of different specimens corresponding to N_u were illustrated in Figures 8a, c. The $R_D = 0.12$, $R_D = 0.2$ and NDG specimens were compared. The U away from the center of the specimen was defined as the positive and the U towards the center of the specimen was defined as the negative. The NDG and DG range in the specimen were illustrated in Figure 8b, where the NDG range is in the right and the DG range (DG specimen) or NDG range (NDG specimen) is in the left.

By comparing the U of DG specimens and NDG specimen, the overall bending toward to DG range can be found in DG specimen, and the outward buckling can be found in NDG specimen.

By comparing the U at the $L/2$ in DG range ($U_{L/2-D}$) of different specimens (Figure 8a), it could be found that when the R_{CDG} increased from 0.12 to 0.2, the $U_{L/2-D}$ decreased from 0.66 to 0.51 mm (by 0.15 mm). When the R_{SDG} increased from 0.12 to 0.2, the $U_{L/2-D}$ slightly increased from 0.65 to 0.70 mm (by 0.05 mm). When $R_D = 0.12$, the $U_{L/2-D}$ of CDG or SDG specimens

were nearly the same, therefore, the influence of different debonding gap types on the $U_{L/2-D}$ is small. When $R_D = 0.2$, the $U_{L/2-D}$ of CDG specimen was smaller than that of SDG specimen, it is because that the inward buckling in SDG specimen was more serious than that in CDG specimen.

By comparing the U at the $L/2$ in NDG range ($U_{L/2-N}$) of different specimens (Figure 8c), it could be found that with an increase in R_D , the $U_{L/2-N}$ decreased. When the R_{CDG} increased from 0.12 to 0.2, the $U_{L/2-N}$ decreased from 0.65 to 0.35 mm (by 0.3 mm). When the R_{SDG} increased from 0.12 to 0.2, the $U_{L/2-N}$ slightly decreased from 0.64 to 0.53 mm (by 0.11 mm). When $R_D = 0.12$, the $U_{L/2-N}$ of CDG or SDG specimens were nearly the same, therefore, the influence of different debonding gap types on the $U_{L/2-N}$ was small. When $R_D = 0.2$, the $U_{L/2-N}$ of CDG specimen was smaller than that of SDG specimens, therefore, the overall bending in SDG specimen was more serious than that in CDG specimen.

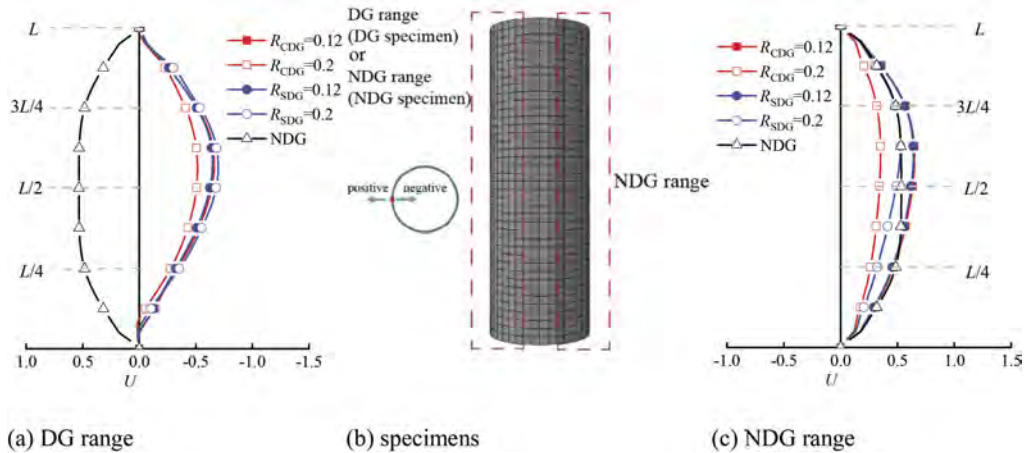

Figure 8. Lateral deflections corresponding to N_u .

4 CONCLUSIONS

Based on the finite element analyses, the following conclusions can be drawn:

- (1) With an increase in debonding parameters, the ultimate load-bearing capacity of axially compressed CFST stub columns decreased. The critical value of debonding arc-length ratio could be obtained. When the debonding arc-length ratio was less than the critical value (0.12), the influence of different debonding types on load bearing capacity was negligible. When the debonding arc-length ratio was greater than the critical value (0.12), the load bearing capacity of SDG specimen decreased linearly, however, CDG specimen decreased nonlinearly with gradually reduced decrease rates.
- (2) When the debonding arc-length ratio was 0.12, the influence of different debonding gap types on the load-displacement curve was negligible. When the debonding arc-length was 0.2, the descending stage after N_u in SDG specimen was longer than CDG specimen.
- (3) When the debonding arc-length ratio was less than the critical value (0.12), the influence of different debonding gap types on the failure mode was negligible. The failure modes of steel tubes shows that the inward buckling in debonding range, and overall bending in non-debonding range. When the debonding arc-length ratio reached 0.2, the failure mode had no obvious change in CDG specimen, but the wavy inward and outward local buckling could be observed in SDG specimen.
- (4) When the debonding arc-length ratio was less than the critical value (0.12), the influence of different debonding gap types on the lateral deflections was negligible. However, when debonding arc-length ratio was 0.2, both inward buckling in DG range and overall bending in NDG range of SDG was more serious than CDG, wavy inward and outward local buckling could be observed in DG range of SDG specimen.

- (5) The constraint effect between steel tube and concrete was the key to influence the ultimate bearing capacity of CFST axially compresses stub columns. The next step of the research is to analyze the influence of different debonding types on the constraint effect between steel tube and concrete.

ABSTRACT: Vibration-based structural health monitoring is an efficient technique for dynamic assessment of the structures. Based on the identified dynamic characteristics, the condition of a bridge can be assessed by means of structural identification through the finite element model updating procedure. The modal parameters are generally the indicators that reflect the changes of the global performance of the bridges. As the supplement, non-destructive evaluation methods can be employed to provide more detailed information about the local condition of the structure. In this study, operational modal analysis was performed on a butterfly-arch pedestrian bridge at Fuzhou University, which was based on an innovative design concept, known as the stress-ribbon bridge. The uncertain model parameters of the structure were identified by updating the refined FE model in reference to the experimental modes. The ultrasonic instruments and rebound hammers were used to determine the debonding condition of the concrete-filled steel tubular sections of the main arches and the elastic modulus of the concrete slabs, respectively. Both of them play an important role to influence the dynamic behaviour of the bridge. The key structural parameters that were identified by the FE model updating procedure are compared to the nondestructive testing results. It's found that the nondestructive testing methods provide important supplementary information to the SHM for condition assessment of the structure.

1 INTRODUCTION

In vibration-based structural health monitoring (VBM), operational modal data is usually extracted by ambient vibration tests (AVT) to investigate the initial state of the bridges and structures. On the basis, the baseline model can be built by model calibration for long-term monitoring of the structure with good accuracy and high fidelity. The modal information (e.g., natural frequencies and mode shapes) are however the indicators of global dynamic characteristics of the structure, which sometimes have difficulties to reflect minor structural degradation or localized deterioration of the materials (Aktan et al. 2000). On the other hand, non-destructive evaluation (NDE) technique focuses on the local condition of the structures. Verma et al. (2013) provided a comprehensive review of nondestructive testing methods for condition monitoring of concrete structures. It's concluded that NDE methods have been used for more than three decades for monitoring concrete structures, which has currently

reached a mature status for condition evaluation of existing RC structures. However, as the local approach of structural evaluation the application of the NDE on site can be very time-consuming and require heavy labour works. The advantages and disadvantages of the SHM and NDE suggest that both approaches can be supplementary to each other. Aldrin et al. (2016) presented a comprehensive approach that integrates the VBM and NDE under the framework of probability of detection (POD) evaluation procedure for aerospace structures. By using a model-based method, they discovered that justification of the underlying assumptions of the statistical model choices was the key to the success of condition-based maintenance for the real applications. In this regard, development of a comprehensive approach of SHM and NDE is highly anticipated by civil engineers. Patil & Reddy (2020) presents a combination of the vibration-based method and non-destructive method for damage assessment of carbon composite fiber reinforced structure. Changes of the frequency response functions are used as the damage indicator to distinguish the intact and damaged specimens. Following that, the ultrasonic C-scanning method is used to locate and quantify the damage in the specimen. Vandecruys et al. (2022) presents a case study of acoustic emission and vibration-based monitoring of locally corroded reinforced concrete beams. Their findings suggested that the local (NDE) and global (VBM) monitoring techniques supplemented each other. The proposed comprehensive approach increased the sensitivity and efficiency of damage detection method in different phases of corrosion damage progress.

In the current study, an onsite investigation of an arch pedestrian bridge is performed by using VBM and NDE. The current study follows a previous research work on the same structure (He et al. 2022). The local defects of the main arches, known typically as debonding/void of the concrete core is the focus of the current work. Ultrasonic testing was implemented to assess the condition of the Concrete-Filled Steel Tubular (CFST) composite sections. In addition, the deck system of the bridge, known as the stress ribbon, is composed of several precast concrete segments. Evaluation of the compressive strength and hardness of the concrete slab is conducted by the rebound hammer testing. The results of structural identification obtained by the FE model updating method are then presented. Fidelity of the updating results will be addressed in reference to the findings of NDE for the identified model parameters.

2 EXPERIMENTAL PROGRAM

2.1 *Description of the bridge*

As shown in Figure 1, the stress-ribbon deck of the pedestrian bridge is supported by the cross beams between the outward inclined CFST arches, also known as the butterfly arches. Since the stress ribbons were anchored to the abutment where the springs of the arches were rooted, the whole structure consists of the self-anchored system, which loads the foundations mainly in the gravity direction. The span of the main arches is 25 meters with the rise of 5.5 meters. See Figure 2. They are made of the 42.6cm-diameter steel pipes with the thickness of 1.6 cm. The angle between the inclined arches and the ground is 60 degrees. The span of the secondary arches is 16.8 meters. They are made of the 37.7cm-diameter steel pipes with the thickness of 1.6 cm. The connections between the main and the secondary arches are welded. They are also interconnected by seven rigid hangers on each side. The stress-ribbon deck was assembled from the precast concrete segments by using two pre-stressed tendons. Each of the precast segment is 6 meters in width, 1.15 meters in length and 14 cm in thickness. The tendons are formed by two bundles of 12×Φ15.2mm monostrands grouted inside the galvanized steel pipes. The middle part of the bridge deck simply rests on the cross beams, whereas the side parts of the bridge deck are supported by the pre-stressed tendons. See Figure 3.

2.2 *Ultrasonic testing*

2.2.1 *Working principle*

Debonding is the common structural defect of the CFST members in an arch bridge (Chen et al. 2022). They can usually be assessed by using the ultrasonic testing method. Shown in Figure 4 is a typical sound wave transmission detector for quality testing of the CFST construction.

Figure 1. A stress-ribbon CFST arch pedestrian bridge at Fuzhou university.

Figure 2. Front view of the bridge with the measurement nodes of AVT labeled (units in mm).

Figure 3. Top view of the bridge with the measurement nodes of AVT labeled (units in mm).

The propagation speed of ultrasonic waves in solid is a function of the Young's modulus E and the density ρ of the materials, $V_{solid} = f(E/\rho)$. The ultrasonic wave speed in steel and concrete is generally 4000–6000 m/s (Li et al. 2020). Under a certain ambient condition, the following relationship applies for the ultrasonic wave speeds,

$$\frac{V_s}{V_c} = p_c \quad (1)$$

where V_s = the wave speed in steel; V_c = the wave speed in concrete; and p_c = a constant to be determined. For a CFST section without defects, the ultrasonic time-of-flight T_f equals to,

$$T_f = \frac{2 \cdot t}{V_s} + \frac{D - 2 \cdot t}{V_c} \quad (2)$$

where t = the thickness of steel pipe; D = the diameter of steel pipe. Once p_c is obtained by the CFST specimen tests, both V_s and V_c can be obtained by solving Equation (2). On the basis, for the CFST sections with debonding/void, the ultrasonic time-of-flight T_f can be estimated by

Figure 4. Ultrasonic instrument: WE-520 sound wave transmission detector (operating at 50 kHz).

$$T_f = \frac{2 \cdot t}{V_s} + \frac{D - 2 \cdot t - \Delta h}{V_c} + \frac{\Delta h}{V_a} \quad (3)$$

where Δh = the thickness of void or debonding in the concrete core on the path of the wave passage and V_c = the wave speed in air, which can be assumed as a constant of 340m/s.

2.2.2 Testing scheme

As shown in Figure 5, on each cross section of the CFST the ultrasonic tests were repeated in four different directions. They were equally distributed around the perimeter and all go through the center of the cross section. The values of the ultrasonic time-of-flight T_f were read from the device. And the thickness of debonding Δh can be determined by Equation (3). A linear interpolation is then applied to the discrete values of Δh along the perimeter of the section to estimate the total debonding area at the concrete core. On the main arches, eleven cross sections were tested at each side. See Figure 6. In addition, before the ultrasonic testing, the traditional testing method of hammer impacts was also applied in order to quickly evaluate the severity of the debonding condition. The results of the hammer impact tests were indicated by the quality number N_q . For instance, $N_q=10$ for the arc-length ratio of debonding $R_d < 5\%$, $N_q=9$ for $R_d = 5\sim 10\%$, $N_q=8$ for $R_d = 10\sim 20\%$, and $N_q=7$ for for $R_d = 20\sim 30\%$ (Xue et al. 2012).

Figure 5. Placement of the probes at the cross section in the ultrasonic testing.

Figure 6. Top view of the bridge with the cross sections of ultrasonic testing labeled (units in mm).

2.3 Rebound hammer testing

2.3.1 Working principle

A rebound hammer is a handheld device for non-destructive testing of concrete. It helps determine the compressive strength and hardness of concrete by measuring the rebound height of a steel ball dropped onto the surface. The relevant technical specification (MOHURD 2011) in China provides the detailed requirements and process to perform the rebound hammer testing. In particular, the depth of the carbonation at the concrete surface has to be identified, which influences the results of the rebound hammer tests. To convert the cubic strength of concrete $f_{cu,k}$ to the corresponding Young's modulus of concrete $E_{c,s}$, the Chinese Code for design of concrete structure (MOHURD 2015) suggests the following formula:

$$E_{c,s} = \frac{10^5}{2.2 + \frac{34.7}{f_{cu,k}}} \text{ (MPa)} \quad (4)$$

The values $E_{c,s}$ above are however the static elastic modulus of concrete. Memory et al. (1995) suggests the following equation to calculate the dynamic elastic modulus of concrete $E_{c,d}$:

$$E_{c,s} = 1.25E_{c,d} - 19 \text{ (GPa)} \quad (5)$$

2.3.2 Testing scheme

Since the concrete deck is fully covered with the ceramic pavement, the rebound hammer tests were only applied from underneath the bridge. By considering the accessibility, the two segments of the precast concrete slab next to the east and west abutments were tested.

2.4 Ambient vibration testing

Ambient vibration tests were performed for twenty-two measurement nodes distributed on the bridge deck across the span. The acquisition system consisted of four wireless accelerometers. The signals of three-dimensional records were highly synchronized. As shown in Figure 3, the nodes No. 2 and No. 16 were the reference nodes, which are used to glue the separate mode shape vectors from each individual testing setups. In detail, the tests included 11 setups.

System and modal parameters are extracted from the ambient data with the output-only reference-based stochastic subspace identification algorithm (Peeters et al. 1999). The reference channels were those of the reference sensors. Data processing and system identification process was accomplished by using the MACEC toolbox (Reynders et al. 2014).

3 EXPERIMENTAL RESULTS

3.1 Ultrasonic testing

By the tests of the CFST specimens in laboratory, p_c in Equation (1) is found to be 1.18. Correspondingly, $V_s = 7,778$ m/s and $V_c = 4,896$ m/s by solving Equation (2). On the basis of the working principle in Section 2.2.1, the debonding/void rate k_d can be obtained, which defines the ratio between the debonding/void area and the circular area of the concrete core at the CFST cross section. On the basis of the formulas to calculate the design values of the compressive and flexural stiffness of the CFST members (Chen et al. 2022), the following equation is proposed herein for the equivalent stiffness of the CFST members:

$$(EA)'_{\text{equivalent}} = E_s A_s + k E_c A_c \quad (6)$$

$$(EI)'_{\text{equivalent}} = E_s I_s + 0.6 k E_c I_c \quad (7)$$

where the subscripts s and c stand for the steel pipe and concrete core, respectively. The reduction factor of 0.6 to the flexural stiffness of the concrete core $E_c I_c$ takes into account the cracking of the concrete core under tension (Chen et al. 2022). By considering the effects of debonding, the

values of the compressive and flexural stiffness of the CFST section can be modified by introduction of the reduction factor $k (= 1 - k_d)$. The experimental results of the ultrasonic testing are given in Figure 7 in terms of the k factors. The mean values of k are similar of the two main arches, around 0.98. The minimum values of k are found at the springs of the arches, around 0.97. In particular, the experimental results obtained from the ultrasonic testing are usually in agreement with the findings of the hammer impact tests. The crown sections are labeled by 10, suggesting an almost zero debonding rate. And the spring sections are labeled by $N_q=7$, suggesting the most severity of the debonding condition.

Figure 7. Stiffness reduction factors k identified at the CFST cross sections by ultrasonic testing.

3.2 Rebound hammer testing

Totally 16 rebound hammer tests shall be repeated on an individual test area (MOHURD 2011). In Table 1, the results of the hammer tests are provided in detail. The two deck segments being tested are, repetitively, next to the east and west abutments. The cubic strength of the concrete was obtained in reference to the specification. The static elastic modulus of concrete $E_{c,s}$ is then estimated by Equation (4). Finally, the dynamic elastic modulus of concrete $E_{c,d}$ is obtained by Equation (5). Figure 8 illustrates the variation of the rebound values on each test area for the 4 by 4 test points in the gray colour scale.

Table 1. Results of rebound hammer testing.

Test area	Rebound value (mm)				Average value (mm)	Carbonization depth (mm)	Cubic strength (MPa)	Static $E_{c,s}$ (MPa)	Dynamic $E_{c,d}$ (MPa)
East side	52	52	58	49	54.1	3.0	57.8	35,709	43,767
	56	42	57	57					
	54	58	54	46					
West side	56	56	52	52	45.4	1.5	46.6	33,960	42,372
	44	45	36	47					
	46	48	39	46					
	42	46	48	45					
	52	63	44	54					

3.3 Ambient vibration testing

The results of the ambient vibration tests were provided in Table 2 concerning the identified experimental modes. They included five vertical bending modes and three torsion modes. No lateral modes were identified under the current ambient vibration conditions. The identified damping ratios were generally around 1% except of the second mode. Significant modal deformation was observed in the 2nd mode for the main arches, whereas the other bending or torsion modes were

Figure 8. Rebound values at the slabs of the west side (left) and east side (left).

characterized with the deformation mainly for the slab. The composite action of CFST cross sections is considered to influence the energy dissipation mechanism for the the 2nd vibration mode.

Table 2. The identified experimental modes.

No.	Nature frequency f (Hz)	Damping ratio ξ	Type of the vibration modes
1	3.59	0.7%	1st Vertical bending mode
2	5.28	3.9%	2nd Vertical bending mode
3	6.91	1.6%	1st Torsion mode
4	7.79	1.2%	3rd Vertical bending mode
5	9.17	1.1%	2nd Torsion mode
6	10.98	1.0%	3rd Torsion mode
7	14.45	0.8%	4th Vertical bending mode
8	14.92	0.6%	5th Vertical bending mode

4 RESULTS OF MODAL-BASED FE MODEL UPDATING

Structural identification was performed by using parametric updating of the refined reference model of the bridge (He et al. 2022). In the refined FE model, the bridge deck was modeled with the shell elements. Four rigid links were introduced between the anchors of the prestressed tendons and the springs of the main arch to simulate the abutments. The numerical solution process of the FE model updating was formulated into the nonlinear least square problem, which intends to minimize the relative differences between the experimental and numerical natural frequencies. The stiffness of the soil springs at the abutments, the elastic modulus of the concrete deck E_C and the elastic modulus of the tendons E_t were chosen as the updating parameters for a total of eight parameters. Under the optimal solution, E_C of the concrete deck is identified as 57,598 MPa. E_C of the concrete core of the CFST sections is 42,000 MPa and the E_s of the steel pipe of CFST is 210,000 MPa. In particular, both of them were not included into the updating parameters and kept as the constants in the updating process.

5 DISCUSSION

The results of ultrasonic testing show that the average debonding/void rate k_d is 2% for all the 22 cross sections along the main arches. Xue et al. (2012) found that if the debonding/void rate k_d is less than 1.2%, its influence on the ultimate load capacity and stiffness of CFST columns can be neglected. Therefore, for the current CFST bridge, it might be necessary to consider the uncertainty of E_C of the concrete core of the CFST main arches by taking it as one of the updating parameters. In addition, with respect to the variation of k (Figure 6), the assumption for a uniform value of E_C for the main arches is acceptable. Besides, both hammer impact tests and ultrasonic tests found almost zero debonding rate on the secondary arches. Therefore, the stiffness of the secondary arches need not be updated, since the initial estimation of the material properties are sufficiently accurate.

The results of rebound hammer testing showed the variation of E_C of the concrete deck between the selected two segments. The absolute value of the relative difference is 3.2%. In this regard, it is reasonable to assume a constant E_C of the concrete deck in the FE model updating. The identified value by FE model updating is found to be almost 30% greater than those identified by NDE. The non-structural elements, including the hand-rails and ceramic pavement should contribute to the increased value of E_C , as well as the influence of pre-stressing forces at the tendons. Nevertheless, further investigation remains open for any future research.

6 CONCLUSION

In this study, a butterfly-arch pedestrian bridge was investigated by both VBM and NDE methods. The uncertain model parameters of the structure were identified by updating the refined FE model in reference to the experimental modal data. The ultrasonic instruments and rebound hammers are used to determine the debonding condition of the CFST members of the main arches and the elastic modulus of the concrete slabs, respectively. Both of them play an important role to influence the dynamic performance of the self-anchored structural system. Accuracy and variability of the key structural parameters that were identified by the FE model updating process is investigated in comparison to the NDE results. It is found that the NDE methods serve as an important supplementary technique to the SHM technique for condition assessment of the studied structure.

Bridge maintenance prioritization by using multi-criteria decision analysis

H. Silimanotham & M. Henry

Shibaura Institute of Technology, Tokyo, Japan

ABSTRACT: Bridges are one of the essential components of road infrastructure, however, if they are not maintained, their rehabilitation causes huge burdens on the country's economy. In Lao PDR, due to the absence of a maintenance management plan, the prioritization of the bridges for the maintenance plan does not depend on technical factors, due to which the important structure gets neglected. The research explores the application of Fuzzy-Analytic-Hierarchy-Process (FAHP) and Linear-Aggregation methods (LAM), the multi-criteria-decision-making techniques, on a database obtained from the Ministry of Public Works and Transport, to solve bridge maintenance prioritization problems. Both methods involved determining the weight of criteria on the three bridge characteristics i.e., condition, aging, and maximum loading. FAHP was found suitable if the bridge prioritization can be done relative to the characteristics of all the other bridges, whereas LAM can be applied if the priority is determined just by the characteristics of the bridge itself.

1 INTRODUCTION

Efficient road transport is the backbone of a country's economy, and bridges are one of the essential components of road infrastructure. However, bridges deteriorate with the passage of time due to a variety of factors that include traffic loading, aging, and various environmental impacts. Special attention should be given to the maintenance plan of these expansive structures (Leonovich & Kashevskaja, 2007). If their maintenance is ignored due to any reason, the rehabilitation of these structures becomes a huge burden on the country's economy.

Lao PDR has 3,580 bridges with 6 classifications i.e., national, provincial, district, urban, rural, and specific road bridges. However, the Ministry of Public Works and Transport (MPWT) has only 1 percent of the road budget for the bridges' maintenance which also includes site inspection and surveying. Due to the absence of a maintenance management strategy in Lao PDR, the selection of a bridge for the maintenance plan is normally determined by coordination meetings between relevant agencies without considering and evaluating technical factors. Due to this, the maintenance budget is usually spent on urgent cases only and routine and periodic maintenance is generally ignored. Yet, there is no proper bridge maintenance management system exists to deal with such a problem. There is a need to develop the bridge maintenance system for prioritizing the bridge to be included in the maintenance plan.

Over the last few decades, a lot of research has been made to develop the technique for assessing the bridge condition for prioritizing it for the maintenance plan. It includes the deterministic approach (Frangopol et. al., 2001), the stochastic approach (Val & Melchers, 1997), and the fuzzy logic-based approach. Tee et. al. (1988) suggested a fuzzy approach for the evaluation of bridges, and Sasmal et. al. (2006) suggested the fuzzy AHP approach for the condition rating of existing concrete bridges. This research was focused to utilize the existing data of bridges with MPWT for developing and comparing the weighted rating criteria for bridge prioritization, based on Linear Aggregation Method (LAM), and the Fuzzy Analytic Hierarchical process (FAHP). However, the data obtained from MPWT was incomplete due

to the lack of bridge characteristics and year of construction for some of the bridges. Therefore, the research was focused on bridge maintenance prioritization on small scale in a Luang Prabang province that belongs to the national road and has complete data.

2 METHODOLOGY

2.1 *Data and evaluation criteria*

The data for the research was collected from the MPWT. It was observed that most of the bridges were located on the national road, followed by provincial, district, urban, rural, and specific roads. The national road network consists of around 34% of the total bridges (3580). However, the research was focused on one road section of the national road network i.e., road number 13th North section in Luang Prabang province. This road section has around 671,700 meters of road distance and has 21 bridges. The bridge's characteristics are shown in Table 1. Due to data limitations, the analysis was done based on three bridge characteristics i.e., bridge condition, bridge aging, and bridge capacity in terms of maximum loading. The bridge conditions were classified into 5 categories in the data obtained, with 1 showing "no damage" to the 5 representing the "severe damage" of the bridge. Two Multi-Criteria Decision Making (MCDM) techniques i.e., Fuzzy Analytic Hierarchy Process (FAHP), and Linear Aggregation Method (LAM) were applied to the data. The weight criteria for prioritization were selected as equal weighting, in which the three bridge characteristics (criteria) were considered equally important, and strong importance for each characteristic individually (condition strongly more important, aging strongly more important, and maximum loading strongly more important as shown in Table 2) for both methods (FAHP, LAM). The first step for both the methods involved categorization of the bridges. The bridges were classified into 5 categories based on bridge aging data by following the Laos MPWT bridge maintenance frequency and on the maximum loading data following the concept proposed by Paeglitis (Paeglitis & Paeglitis, 2010).

Table 1. Actual bridge characteristics of 21 bridges.

2.2 *Fuzzy Analytic Hierarchy Process (FAHP)*

The Analytic Hierarchy Process (AHP) is one of the methods of Multi-Criteria Decision Making (MCDM) that is applied to decision-making problems with different evaluation criteria

and conditions for assisting in decision-making by using a pairwise comparison matrix. Saaty elaborated in detail on the basic principles and stages of decision-making (Saaty, 1980; Laarhoven & Pedrycz, 1983). Many researchers propose this method as an easy approach that can be used for decision-making. However, the AHP has some limitations, i.e., the dependence of the AHP model on its main input, or when an expert perception is subjective. Triangular Fuzzy Numbers (TFN) and linguistic variables can overcome the weaknesses of the AHP method in determining priorities from the decision-making of vague decision-makers (Yossysfra et al., 2019). Therefore, the research utilizes Fuzzy Analytic Hierarchy Process (FAHP) for decision-making for prioritizing the bridges for the maintenance plan (Zadeh et al., 1965). The method of FAHP assists in avoiding decisions that are detrimental to the surroundings (Pan, 2008). The structure of FAHP is the combination of AHP and the Fuzzy concept that elaborate the standard AHP method into the fuzzy domain by utilizing the fuzzy number instead of the real number for calculations (Petkovic et al., 2012). The process starts with data normalization. Once the data is normalized, the weightage of all the criteria is determined by using a fuzzy number. Therefore, based on the Chang scale, the intensity of criteria importance was transformed into the TFN comparison scale (Fuzzy number) that consisted of three values i.e., l (lowest value), m (middle value), and u (highest value) (Chang, 1996) as shown in Table 2. Once the weightage for all the criteria was established, the geometric mean and local weight for all the criteria were calculated. Then the bridge maintenance prioritization by using a pair-wise comparison matrix was developed and finally, the bridges were ranked for maintenance prioritization by averaging the three fuzzy numbers (l, m, and u). The results of FAHP were then compared with the Linear Aggregation Method. The stepwise equations for the FAHP process are mentioned below for bridge maintenance prioritization (Guzman, 2001).

$$\text{Inverse triangle fuzzy: } (l, m, u)^{-1} = \left(\frac{1}{u}, \frac{1}{m}, \frac{1}{l}\right) \tag{1}$$

$$\text{Fuzzy multiplication: } (l_1, m_1, u_1) \times (l_2, m_2, u_2) = (l_1 \times l_2, m_1 \times m_2, u_1 \times u_2) \tag{2}$$

$$\text{Geometric mean of criteria i: } g_i = \left(\prod_{j=1}^n r_{ij}\right)^{\frac{1}{n}} \tag{3}$$

$$\text{Local weight of criteria i: } W_i = g_i / \sum_{i=1}^n g_i \tag{4}$$

$$\text{Final priority weight of bridge i: } PW_i = \sum W_{overall} \times W_{local} \tag{5}$$

Where g_i is the geometric mean of criteria, r_{ij} is the pair-wise comparison matrix, $W_{overall}$ is the weight per criteria, and W_{local} is the local weight of criteria.

Table 2. Definition and membership function of fuzzy number.

Intensity of importance	Definition	Fuzzy number (l, m, u)
1	Equally important	(1,1,2)
3	Moderately more important	(2,3,4)
5	Strongly more important	(4,5,6)
7	Very strongly more important	(6,7,8)
9	Extremely more important	(8,9,9)

2.3 Linear Aggregation Method

The Linear Aggregation Method (LAM) is one of the methods of MCDM for decision-making that uses the relations between the criteria and the weighting of criteria from the decision-makers' perceptions for finding the highest priority criteria (Yager, 2009). The Linear Aggregation Method (LAM) was applied to the same data to prioritize bridge maintenance by comparing the bridge characteristics in four different weightings. LAM analyzes the bridge priority weight by combining LAM and FAHP as the local weight of all criteria via equation 6 (Yager, 2008). The first step for performing LAM is to normalize data for calculating the linear aggregation. Then the data normalization was done based on the range from 0 to 1 scale for calculating the

linear aggregation for all criteria. Once the data were normalized, the local weights of FAHP for all the criteria were used to calculate the LAM. Finally, the bridge ranking was done for maintenance prioritization. The following equations were used for the LAM process.

$$\text{Linear aggregation: } LAM = \sum C_i \times W_i \quad (6)$$

Where C_i is the criteria data (condition, age, and maximum loading), and W_i is the local weight of all criteria from FAHP in 4 weighting cases (equal weighting, condition strongly important, aging strongly important, and maximum loading strongly important).

3 RESULTS AND DISCUSSIONS

3.1 Effect of weighting

3.1.1 Fuzzy Analytic Hierarchy Process

The results of the FAHP are shown in Table 3 which illustrated the bridge maintenance prioritization weight by using a pairwise comparison matrix for all 21 bridges for equal weighting, and for each bridge characteristic individually i.e., condition strongly more important, aging strongly more important, and maximum loading strongly more important. The results obtained prioritized the 21 bridges in 6 categories of ranking in 4 different weights (equal weight, condition, aging, and maximum loading). It was observed that bridge B15 has the highest priority (rank 1) on the equal weight, the bridge condition strongly more important, and the maximum loading strongly more important criteria, but it has 2nd priority in case of aging strongly more important for the maintenance plan. On the other hand, bridges B1, B2, and B3 are the highest priority for the bridge maintenance plan on the aging strongly more important criteria. They are the second rank for bridge maintenance on equal weighting and maximum loading strongly more important and the third rank on condition strongly more important. On the contrary, bridges B6, B8, B9, B10, and B12 are the least ranked or lowest priority bridges for the maintenance plan.

Table 3. Result of Fuzzy Analytical Hierarchy Process.

Bridge No	Equal weight		Condition strongly more important		Aging strongly more important		Max_Load strongly more important

B17	0.048	4	0.047	4	0.049	4	0.048	4
B18	0.057	3	0.066	2	0.052	3	0.052	3
B19	0.048	4	0.047	4	0.049	4	0.048	4
B20	0.048	4	0.047	4	0.049	4	0.048	4
B21	0.048	4	0.047	4	0.049	4	0.048	4

3.1.2 Linear Aggregation Method (LAM)

The results of linear aggregation methods are presented in Table 4 for the bridge maintenance priority weight for all 21 bridges in four weighting cases. The LAM results ranged between 0 and 1, with higher values signifying higher priority and lower values signifying lower priority.

Table 4. Result of Linear Aggregation Method.

Bridge No	Equal weight	Rank	Condition strongly more important	Rank	Aging strongly more important	Rank	Max_Load strongly more important	Rank
B1	0.733	1	0.544	3	0.885	1	0.771	1
B2	0.733	1	0.544	3	0.885	1	0.771	1
B3	0.733	1	0.544	3	0.885	1	0.771	1
B4	0.600	3	0.487	4	0.600	4	0.713	3
B5	0.600	3	0.487	4	0.600	4	0.713	3
B6	0.400	5	0.287	6	0.287	6	0.627	5
B7	0.533	4	0.344	5	0.571	5	0.685	4
B8	0.400	5	0.287	6	0.287	6	0.627	5
B9	0.400	5	0.287	6	0.287	6	0.627	5
B10	0.400	5	0.287	6	0.287	6	0.627	5
B11	0.600	3	0.487	4	0.600	4	0.713	3
B12	0.400	5	0.287	6	0.287	6	0.627	5
B13	0.600	3	0.487	4	0.600	4	0.713	3
B14	0.600	3	0.487	4	0.600	4	0.713	3
B15	0.733	1	0.771	1	0.658	2	0.771	1
B16	0.667	2	0.629	2	0.629	3	0.742	2
B17	0.600	3	0.487	4	0.600	4	0.713	3
B18	0.667	2	0.629	2	0.629	3	0.742	2
B19	0.600	3	0.487	4	0.600	4	0.713	3
B20	0.600	3	0.487	4	0.600	4	0.713	3
B21	0.600	3	0.487	4	0.600	4	0.713	3

Table 4 shows that bridges B1, B2, and B3 have the first rank for maintenance prioritization in equal weight strongly more important, aging strongly more important, and maximum loading strongly more important characteristics. However, for condition strongly more important, these bridges ranked 3rd for prioritization. While bridge B15 also ranked 1st for prioritization based on equal weight, a condition strongly more important and maximum loading strongly more important but ranked 2nd for aging strongly more important. But the same bridges i.e., B6, B8, B9, B10, and B12 that were ranked lowest with FAHP were also observed to be ranked lowest in LAM. It was observed that among four different weights of criteria, the most critical weight of criteria were condition strongly more important, and aging strongly more important in the LAM process because the ranks for the bridges were found highly changing than other weights of criteria.

3.2 Comparison of the results of FAHP and LAM

For comparison purposes, the results of FAHP were multiplied by 10 and the graphs were generated for both methods for all criteria.

3.2.1 Equal weighting

Figure 1 shows the comparison of equal weighting for both cases (FAHP, LAM). The results of the two methods were found slightly different. In LAM, the highest priority weight (ranking) was found for four bridges i.e., B1, B2, B3, and B15 but for the FAHP, only one bridge i.e., B15 was found the top-ranked bridge for prioritization for equal weighting cases. B1, B2, and B3 were the oldest bridges (50 years old) with insignificant damages (condition-2) and with a maximum loading capacity of 40 tons. However, bridge B15 was found 28 years old, with severe damage (bridge condition-4) and 40 tons maximum loading as shown in Table 1. It shows that in LAM, the bridge ranking was done by taking the combined effect of aging, condition, and maximum loading

individually for each bridge but in FAHP, the bridge characteristics were involved separately in bridge ranking among all 21 bridges.

Figure 1. The results comparison of equal weighting between FAHP and LAM.

3.2.2 Maximum loading strongly more important

Figure 2 shows the comparison of the results of FAHP and LAM for the maximum load characteristic strongly more important for the 21 bridges. In LAM, four (4) bridges B1, B2, B3, and B15 were found highest rank for the prioritization for maintenance planning in case of maximum loading strongly important but for FAHP, only one bridge B15 was found the top ranking. From Table 1, it was observed that the maximum loading was found similar for all bridges (40 tons) but the ranking was done based on the other characteristics i.e., condition and aging.

Figure 2. The results comparison of maximum loading strongly more important between FAHP and LAM.

3.2.3 Bridge condition strongly more important

Figure 3 shows the results comparison of the LAM and FAHP for the bridge condition strongly more important characteristic only. It was observed that for both methods the bridge ranks are similar for prioritization based on bridge condition strongly more important for the maintenance plan. Bridge B15 was found the first rank for both the methods (LAM, and FAHP) having severe damage (condition-4) whereas bridges B6, B8, B9, B10, and B12 were having the least rank for prioritization by both methods having condition-1 (No damage).

3.2.4 Aging strongly more important

The comparison of the result of both methods for aging strongly more important are shown in Figure 4. The results show that bridges' ranks are similar for both methods (LAM and FAHP) for considering the aging characteristic only. Three bridges B1, B2, and B3 were

Figure 3. The results comparison of condition strongly more important between FAHP and LAM.

found with the highest rank having maximum age (50-years old) and bridges B6, B8, B9, B10, and B12 having age 3-years old were found the least important to be consider for prioritization for the maintenance plan based on aging strongly more important as shown in Table 1.

Figure 4. The results comparison of aging strongly more important between FAHP and LAM.

4 CONCLUSIONS

The research was carried out to develop the method for bridge maintenance prioritization based on the available data with MPWT in Luang Prabang province of Laos. Two different methods of the MCDM technique i.e., Linear Aggregation Method (LAM) and Fuzzy Analytic Hierarchy Process (FAHP) were applied to the four different weighting selection criteria for prioritizing the bridges for the maintenance plan. The results of both methods were analyzed and compared. It was found that for prioritizing the bridge for the maintenance plan, the rankings of the bridges were found similar in the case of bridge condition as strongly more important and aging strongly more important for both the methods (FAHP, LAM).

From the bridge maintenance perspective, both methods were found useful for bridge maintenance planning. However, if the road agency has to select the bridges for prioritization based on bridge characteristics individually for each bridge, the LAM may be the better approach. However, if the bridge selection is to be done among the number of bridges, then FAHP can be the suitable approach for the prioritization of the maintenance plan. The LAM approach was also found easier and can be useful in case of time constraints as it does not need much detail analysis as compared to FAHP which is a deep detail analysis.

ACKNOWLEDGEMENT

The Authors would like to extend their gratitude to Mr. Azam AMIR for helping me with the paper writing, to Japan International Cooperation Agency (JICA) for their support through the Road Asset Management Program, to Shibaura Institute of Technology (SIT), Tokyo for providing the environment for the research, and to Ministry of Public Works and Transport (MPWT) in Lao PDR, for sharing the data and information needed.

Freeze/thaw effects on the performances of FRCM strengthened reinforced concrete beams

S. Verre

Università eCampus, Novedrate (CO), Italy

M. Guglielmi

Department of Civil Engineering, University of Calabria, Arcavacata di Rende, Italy

ABSTRACT: Nowadays, the use of FRCM (Fabric Reinforced Cementitious Mortar) systems is largely adopted in the field of structural retrofitting. Nonetheless, the durability issue is a lightly investigated phenomenon, even if it is important for the long-term effects on external reinforcement effectiveness. This paper presents the results of freeze/thaw cycles and low temperature on the mechanical response of concrete members strengthened with a PBO-FRCM system consisting of Polyparaphenylenebenzo-bisoxazole fiber meshes embedded into an inorganic mortar. In particular, the experimental investigation was performed on small RC-beams (1000 mm long), on FRCM specimen and FRCM-concrete joints. Test results were reported and discussed in the paper.

1 INTRODUCTION

New techniques based on the use of innovative materials, commonly known as Fabric Reinforced Cementitious Matrix (FRCM) or Textile Reinforced Mortars (TRM), have been developed in the last decades for strengthening existing masonry or concrete structures. This alternative strengthening method uses fiber grids embedded in cement-based mortars; the function of the fibers is to bear the tensile stresses, while the mortar should be able to contain and protect the textile also providing to the stress transfer from the substrate to the fiber. This phenomenon is accomplished through the bonding between the substrate and the mortar and the mechanical interlocking between the fabric and the mortar. The use of FRCM reinforcements has the following main advantages: *i*) less sensitivity to debonding phenomena because of the lower stress concentrations related to the larger bonded area of the grid; *ii*) simplicity of application; *iii*) workability assured in a wide range of temperatures and *iv*) less sensitivity to modified environmental conditions. These features make the use of FRCM effective in the strengthening of concrete structures (Awani et al. 2017). As for tensile behavior, the bond behavior of FRCM systems is also influenced by cracking of the cement-based matrix and friction phenomena between rovings and mortar. It was demonstrated that the treatment of the substrate surface and the use of a matrix with controlled shrinkage reduced the possibility of reinforcement detachment even if several aspects are involved, such as the arrangement of the fibers in the fabric mesh, the matrix impregnating capacity and the non-uniform distribution of the stress among the fibers. Moreover, several experimental tests (Carozzi & Poggi 2015) showed that for FRCM materials, different debonding mechanisms also involving the fiber–matrix interface may occur in addition to the “telescopic” tensile failure of the fibers. The well-known benefits of these materials have to be balanced with the sensitivity of such a strengthening technique to debonding phenomena and to environmental conditions different from the standard ones. Because of the inorganic origin of the mortar, FRCM systems seem to be less sensitive to modified environmental conditions. Although the mechanical characterization and the effectiveness of FRCMs as externally bonded reinforcement systems have been deeply investigated (Koutas et al. 2018), their ability to withstand the

exposure to service environments is relatively unknown. At present, very few works concerning the performance of FRCM systems under various environmental exposure conditions have been conducted. Moreover, the long-term behavior of FRCM systems also concerns all the degradation mechanisms typical of cementitious materials. For example, alkali aggregate reaction, sulphate attack and freeze–thaw cycles represent chemical-physical conditions that may promote the formation of expansive compounds usually responsible for crumbling or spalling of cementitious materials. The decay of mechanical properties due to freeze–thaw cycles and salt attack is more noticeable in matrices with high porosity and low strength (Verre 2021). Thus, in the case of FRCM systems made of lime-based matrices, the effects of artificial exposure could be more compromising than in the case of cementitious matrices. Recent guidelines (CNR-DT 215 2020; ACI549.4R 2013), provide durability tests to evaluate the residual mechanical properties of FRCM systems after being subjected to different environmental exposures. These tests include aging in water vapor, immersion in saltwater and alkaline solution at 23°C up to 3000h, freezing–thawing cycles, fuel resistance and thermal tests. These guidelines provide for mechanical tests on FRCM coupons, constituted by the coupling of fabric reinforcement and inorganic matrix. However, beside the importance of investigating the effect of different aging protocols, a deep understanding of the factors affecting the durability of FRCM composite systems should also consider the behavior of each of its components subjected to environmental stresses. In this study, the effects of freeze/thaw cycling exposure on the mechanical properties of an FRCM system constituted by a bidirectional fabric, made of PBO (short for Polyparaphenylenebenzo-bisoxazole) fibers coupled with a cement-based matrix have been investigated. Experimental tests have been conducted on the individual materials (PBO fiber fabrics, matrix) and on FRCM coupons, in order to assess the structural efficiency of the whole composite system subjected to the detrimental environmental actions of freeze–thaw cycles from 18°C to +38°C. The number of cycles, the exposure time and temperature/exposure time before the conditioning were the investigated parameters. In detail, single bundles and dry textile mechanical properties were evaluated in accordance to different guidelines, while both flexural tensile and compressive strength were considered for the mortar. A total of six direct tensile (DT) tests were carried out on PBO-FRCM coupons to evaluate the mechanical response of the composite systems, according to CNR-DT 215 (2020). Moreover, six direct single-lap shear tests (DS) were performed on PBO-FRCM concrete joints following the recommendations of CNR-DT 215 (2020) in order to provide further insights on their bond properties. Since information about the long-term behavior of concrete elements bonded with FRCM systems and exposed to temperatures and a wet environment corresponding to serviceability conditions are lacking, the experimental program presented in this paper is aimed to partially fill such a gap. In order to investigate the effect of low temperature and freeze/thaw cycles on the mechanical response of concrete members strengthened with the PBO-FRCM system, all the tests were carried out in a chamber able to replicate the same values of temperature applied during the conditioning phases.

2 EXPERIMENTAL INVESTIGATION

The experimental investigation was performed on four rectangular RC beams, six FRCM specimen and six FRCM-concrete joints subjected to freeze–thaw cycles and freeze temperature. All the beams had a cross section of 150x150 mm and a length of 1000 mm. The geometry and the internal reinforcement of the beams were reported in Figure 1a. The internal reinforcement was composed by two steel bars (dia. 8 mm) on the tension side of the beams, two steel bars (dia. 8 mm) on the compression side of the beams and five steel stirrups (dia. 8 mm). The concrete cover adopted with respect to the transversal reinforcement was equal to 20 mm for all sides. All the beams were tested as simply supported in symmetrical three-point bending. All concrete prisms had a rectangular cross section equal to 200x150 mm and a height of 400 mm (Figure 1b). Three beams were strengthened, and one un-strengthened beam used as the reference beam (called B-Control). All the specimens were named according to the following notation: B (DT or DS)-FRCM-U (FT or T)- η L-Z, where B indicates beam specimen, DT and DS indicates the FRCM and FRCM-concrete joint, respectively, FRCM is used to

identify the strengthened beam, U indicates the unconditioned specimen, FT and T indicate the Freeze/Thaw or low temperature conditioning, respectively, ηL indicates the number of fiber layers (1 layer in this study) and Z is the specimen number.

Figure 1. Geometry: a) for the RC beam with internal reinforcement and b) DS specimen.

2.1 Materials

The compressive strength f_{cm} of the ready-mix concrete evaluated at 28 days after the casting (evaluated on three specimens) was equal to 30.5 MPa (CoV=0.01). The mechanical properties of the longitudinal rebar and the stirrups were evaluated under the tensile test. For the 8-mm bars, the yielding and ultimate strength obtained on three specimens were 525.5 MPa (CoV= 0.01) and 628.5 MPa (CoV= 0.02), respectively. The fabric mesh adopted in the FRCM system presents a bi-directional development of fiber bundles and different fiber density; in particular, the fiber bundles along two orthogonal directions was unbalanced ($70\text{-}18 \text{ g/m}^2$). The mechanical properties of the PBO fibers in terms of the tensile strength, ultimate strain and elastic modulus, evaluated according to CNR-DT 215 (2020) guidelines, were 3375 MPa (CoV= 0.04), 2.5 % (CoV= 0.09) and 211 GPa (CoV.= 0.05), respectively. The mortar was a stabilized mono-component inorganic cementitious matrix (Ruregold 2022). Three specimens were tested, the load was applied with a rate equal to 100 N/s and 500 N/s for the flexural tensile and compressive test, respectively, in accordance to UNI 1015 (2007). The mechanical properties (compressive and flexural strength) in terms of average values were equal to 43.11 (CoV= 0.03) and 6.73 (CoV= 0.05), respectively.

2.2 Specimen preparation

The technique adopted in the application of the composite strips for the single-lap direct shear (DS), direct tensile (DT) specimens and the strengthening beams is similar, and it is organized in three steps. The first step consists of the realization of a formboard of 3 mm thickness, attached on the concrete surface and a wood planer, respectively. The shape used to strengthen the RC-beam of the formboard, having a bonded length (L_{beam}) of 900 mm and a width of 100 mm, was cut out of the in order to accommodate the composite strips (Figure 2a). Each composite strip was made individually and it was applied along the centerline of the tension for RC beams, while for the DS specimen, shape of the formboard having a bonded length ($L_{b,DS}$) of 260 mm and 50 mm, respectively. Lastly, the shape of the formboard used to for the DT specimens having a bonded length ($L_{b,DT}$) of 500 mm and 50 mm, respectively. The DT specimens were casted on the wood planer surface to ensure the planarity of the surface. In the second step, the mortar (called the internal layer) was applied by mold with light pressure and subsequently the textile was placed on the internal layer. However, the second step is the most critical one, where the perfect alignment of the fibers and impregnation with the matrix must be ensured (Figure 2b). Finally, in the third step the same operation as in step one is repeated (Figure 2c). During the casting of the strengthened beams, K-type thermocouples (0.3 mm of conductor diameter) were glued to the concrete-internal mortar layers and fiber interfaces. In all applications of the composite strips on the DS specimens, the bonded area was started at 20 mm of the edge of the top face of the concrete prism, while for the strengthened beams the bond area was centered with respect to the middle of the beam (Figure 1b). Finally, all specimens were stored and cured in laboratory for 28 days, while for the

DT specimens were demolded from the respective formboards after about 7 days. Specimens were all left to cure at room condition (temperature $T=20^{\circ}\text{C}$ and relative humidity $\text{RH}=65\%$).

Figure 2. Specimen preparation: a) apply the formboard and internal layer of mortar, b) PBO-fibers and c) external matrix layer.

2.3 Freeze/Thaw protocol (FT) and Low Temperature (LT)

All the specimens subjected with the Freeze/Thaw regime were conditioned in a chamber for one week at a relative humidity of 90% and a temperature of $38^{\circ}\text{C} \pm 2^{\circ}\text{C}$. Subsequently, the specimens were subjected to freeze-thaw cycles (20 in total). Each cycle consisted of 4 hours at $-18^{\circ}\text{C} \pm 2^{\circ}\text{C}$, then, 12 hours at 90% humidity and a $38^{\circ}\text{C} \pm 2^{\circ}\text{C}$ temperature, in accordance with CNR-DT 215 (2020). In Figure 3 the environmental conditioning regime was reported.

Figure 3. Environment conditioning regime.

The B-FRCM-T-1L-1 was cooled at a temperature of $-18^{\circ}\text{C} \pm 2^{\circ}\text{C}$ in a chamber until the fiber interface reaches the same temperature present in the climatic chamber, in order to evaluate the effects of freeze.

2.4 Direct Tensile (DT), single lap Direct Shear (DS) and flexural test protocol

Direct tensile tests carried out on six FRCM specimens (three unconditioned and three subjected to conditioning). The test setup adopted is shown in Figure 4a. The gauge length and the tabs used were 300 mm in length and 100 mm in width. The strain measurements between the ends of the tab were acquired by LVDT a and b, that were fixed lengthwise at the side of the specimen by aluminum supports. Six FRCM-concrete joints specimen (control and subjected to conditioning) were tested by single-lap direct shear test set-up using the push pull configuration (Carloni et al. 2022). The test setup used (Figure 4b) is the classic push pull configuration. The steel frame was bolted by four steel bars to the machine used for the test. In addition, the shape of the steel frame was realized to restrain the movement of the concrete prism during the test and to allow the composite strip to be housed on the sides of the prism not involved in the test.

The load was applied through a couple of aluminum tabs glued by thermosetting epoxy on the dry fiber at the top of the fibers. An L shape aluminum plate was attached to the dry fiber at the top of the concrete prism near the bonded area. The reaction of the latter was measured by two linear variable displacement transformers (LVDTs) attached at both sides of the composite strip, called LVDT “a” and “b”.

Figure 4. Test setup adopted for: a) tensile test for DT and (b) single-lap shear test for specimen.

Figure 5. Test setup adopted for reinforced concrete beam.

All the beams were tested in symmetric three-point bending under displacement control. The midspan displacements were measured through the LVDTs positioned on both sides at the middle of the beams and in correspondence of the load point (Figure 5). On the longitudinal internal bar, two strain gauges were attached close the applied load point. All the tests were conducted under displacement control using the rate of 0.2 mm/min; this loading rate value was already used for RC beams strengthened with FRCM composites (Sneed et al. 2016).

3 RESULTS AND DISCUSSION

3.1 Direct Tensile (DT), single lap Direct Shear (DS) and flexural test protocol

After FT treatment, the majority of the FRCM composites didn't show any crack patterns on the surface of the specimens or at the matrix-to-substrate interface. After the FT treatment, the flexural and compressive strength of the mortar were 7.59 MPa (CoV= 4%) and 46.09 MPa (CoV= 3%), respectively. Therefore, after the FT treatment, there was a slight increase of the mechanical properties of the mortar; with reference to the initial values, the flexural strength and the compressive strength increase of 13%, and 7%, respectively. The results of the DS tests are reported in Table 1 in terms of peak load P^* , average value of P^*_{avg} evaluated for each group of specimens (unconditioned and conditioned) and the ratio between the average value of unconditioned and conditioned specimen Δ^* .

Table 1. Experimental results of DS specimens.

	P^* (kN)	P^*_{avg} (kN)	Δ^*
DS-FRCM-U-1L-1	4.60		
DS-FRCM-U-1L-2	4.70	4.62	-
DS-FRCM-U-1L-3	4.56		
DS-FRCM-FT-1L-1	4.61		
DS-FRCM-FT-1L-2	4.83	4.74	1.03
DS-FRCM-FT-1L-3	4.78		

For all tested specimens, the debonding failure at the fiber–matrix interface was observed. The experimental curves applied load-global slips of the unconditioned and conditioned specimens are reported in Figure 6a. It should be noted that, after the FT treatment, the peak load values of strengthened specimens increased slightly (3%) with respect to the untreated specimens. In addition, all conditioned specimens showed an initial stiffness increment due to the environment conditioning. In Figure 6b the stress-strain curves for both unconditioned and conditioned specimens subjected to tensile test are reported.

Figure 6. Comparison between experimental curves (unconditioned and conditioned): a) DS specimen and b) DT specimens.

Table 2 reports the values of the ultimate stress (σ), the corresponding strain (ϵ) and the cracked modulus of elasticity (E) for all tested specimens. The analysis of the results evidences a small increase of the ultimate stress for conditioned specimens with respect to the unconditioned one. Comparing the experimental curves shown in Figure 6b, the global behavior in the cracked stage of the conditioned specimens shows similar stress values but a smaller strain range. The cracked elasticity modulus of conditioned specimens increases of 6.8% with respect to that of the unconditioned one.

Table 2. Experimental results of DT specimens.

	σ (MPa)	ϵ (‰)	E (GPa)
DT-FRCM-U-1L-1	3111.30	26.6	108.9
DT-FRCM-U-1L-2	3041.72	24.5	121.7
DT-FRCM-U-1L-3	2931.57	24.6	119.9
DT-FRCM-FT-1L-1	2920.58	16.7	122.6
DT-FRCM-FT-1L-2	3155.39	17.1	126.6
DT-FRCM-FT-1L-3	2899.08	19.6	125.0

The increase of the capacity in terms of ultimate stress and modulus of elasticity should be attributed to an extended curing time of one week at relative humidity of 90% and a temperature of $38^{\circ}\text{C} \pm 2^{\circ}\text{C}$ in the conditioned environment. Furthermore, the compatibility of the mortar with the substrate (concrete), high strength (mortar), and the low permeability of the materials (concrete and mortar) contributed to the increase of performance of the reinforcement (Arboleda et al. 2014). Table 3 reports the results obtained in the flexural tests

Table 3. Summary of the results obtained in the flexural tests of RC beams.

	P_{yie} (kN)	δ_y (mm)	P_{max} (kN)	δ_{max} (mm)	δ_{max}/δ_y (-)	ϵ_{frcm} (-)	$P_{max}/P_{max-B-control}$ (-)
B-Control	28.19	3.32	34.20	13.06	3.93	-	-
B-FRCM-U-1L-1	33.52	4.10	42.30	11.21	2.73	0.015	1.24
B-FRCM-FT-1L-1	41.93	5.03	47.43	9.62	1.91	0.016	1.39
B-FRCM-T-1L-1	45.56	5.32	45.06	7.61	1.43	0.014	1.32

on the strengthened and un-strengthened reinforced concrete beams in terms of yielding load (P_{yie}), yielding displacement, δ_y , maximum load, P_{max} , maximum displacement, δ_{max} , the ductility index δ_{max}/δ_y , the strain at failure in the FRCM system ϵ_{frcm} and the ratio $P_{max}/P_{max-B-control}$ of the ultimate load between strengthened beam and B-control were summarized.

The experimental load-midspan deflection curves reported in Figure 7 can be divided in three stages: (i) linear elastic, followed by a second stage (ii) almost linear branch, in which the concrete starts cracking and then (iii) a non-linear ascending branch corresponding to the post-yielding stage until reaching the peak load. The beam B-FRCM-U-1L reached a higher ultimate applied load (P_{max}), with an increment equal to 24% with respect to the B-Control.

Figure 7. Load– midspan displacement response of beam specimens.

The conditioned beams showed an increase between 32 and 39% in terms of P_{max} , while the initial stiffness was unchanged. The conditioning effect, as reported for the DT and DS specimens, is evident in the post peak behavior of the beams where the midspan displacement is reduced compared to the B-FRCM-U-1L-1.

Figure 8. Typical failure mode for the strengthening beams.

The un-strengthened beam (B-Control) exhibited the typical flexural behavior of a flexure-dominant with the gradual occurrence and progression of flexural and flexure-shear cracks and a significant amount of deflection. For the strengthened beams, the flexural cracks first appeared near the applied load point and progressed in length and number with increasing load. Flexural and flexure-shear cracks also appeared within the shear span regions on each end of the beam. The cracks in the concrete beam extended through the thickness of the matrix and were observed on the external surface of the composite. Interfacial cracks formed within the composite at the level of the fibers between the load point and the support at the localized locations of flexural cracks as shown in Figure 8.

4 CONCLUSIONS

The paper presented the results of the experimental investigation on the effect of the Freeze/Thaw and low temperature FRCM composite systems. Based on the results, the following conclusion can be drawn:

- The mechanical characteristics of the mortar in terms of flexural tensile and compressive strength showed an increase of 13 and 7% for the specimens subjected at Freeze/Thaw;
- The Freeze/Thaw environment had no significant influence on the behavior of the FRCM composite;
- The DS conditioned specimens showed an increase of initial stiffness and in terms of peak load;
- The behavior of DT conditioned specimens in the third stage showed an increase in terms of tensile modulus equal to 6.8%;
- The beams strengthened unconditioned and conditioned showed an increment between the 24 and 32% to 1.32 with to respect the conditioned beam.

Additional studies are needed to better understand the role of F-T cycles and low temperatures on the mechanical properties of PBO-FRCM systems.

Interface experimental behavior between basalt-FRCMs and natural stones

G. Bramato, M. Leone & M.A. Aiello

Department of Engineering for Innovation, Campus Ecotekne, University of Salento, Lecce, Italy

ABSTRACT: The issue of environmental sustainability is central to several areas of research; in fact, the reduction of polluting emissions and concentration of CO₂ in the atmosphere is a key objective for both private and public institutions. In structural engineering, the sustainability goal involves the design stage, the construction technologies and materials, the maintenance. Specifically referring to structural materials, the research effort is very relevant, as the production of many materials currently used is particularly energy intensive. In the last years, innovative materials have been developed by replacing some components with recycled ones or from industrial processing waste. For example, innovative geopolymers mortars are made with lightweight components, blast furnace or fly ashes (a residue from coal combustion in electricity generation) that replace traditional binder. This new kind of materials can be used as inorganic matrix in case of FRCM (Fiber Reinforced Cementitious Matrix) applications to restore and strengthen existing buildings. The object of the experimental campaign, whose results are reported in this paper, is to study the shear-bond behavior between basalt-FRCM reinforcement system and masonry varying the binder in the mortar: two traditional (cement and lime-based, both with short fibers inside) and an innovative geopolymer matrixes. Two different types of substrates representative of the historical and artistic heritage of Southern Italy are also used: a compact calcareous stone, called *Pietra Leccese*, and a porous calcareous stone, called *Calcarenite*. The results obtained evidenced that the mechanical properties of inorganic matrix always influence the shear bond behavior of the samples, similar conclusion cannot be drawn referring to the mechanical properties of substrates.

1 INTRODUCTION

The Kyoto Protocol was adopted in December 1997 by the Conference of Countries to the United Nations Convention on Climate Change and entered into force in February 2005, following its ratification by the 55 countries responsible for 55% of carbon dioxide emissions. It aims to reduce emissions of six gases (carbon dioxide, nitrous oxide, methane, hydrofluorocarbons, perfluorocarbons and sulphur hexafluoride) considered to be the main causes of climate change and promotes, with the same scope, the protection and expansion of forests to absorb carbon dioxide. Following the entry into force of the Protocol, different solutions have been sought in several areas, including electricity generation, transport, agriculture, waste management and productions of building materials. In fact, the manufacturing of materials like cement, bricks, ceramics, etc. is particularly energy intensive. In addition, with the advent of Environmental Criteria, building materials must have a variable percentage of recycled components and the reuse of materials must be encouraged. Taking all this into account, in the last years new materials have been developed replacing some components with waste from industrial processes. Longo et al (2020) developed a new *Geopolymer Matrix* (GPM) made of dry binders (fly ash and metakaolin), alkali activators and LWA (i.e., expanded glass aggregate). This innovative inorganic matrix therefore involves the use of recycled components (waste from the processing of a coal-fired power plant) and also has further energy benefits in

terms of conductivity, as it results lower than that of a traditional mortar. Nonetheless, the proposed GPM has proper mechanical characteristics for being used in FRCM systems to restore existing building. FRCMs are composite materials made by inorganic matrix and dry fibers meshes. The composite is an externally bonded system, so its effectiveness is influenced by stress transfer mechanisms between fibre mesh and inorganic matrix and between composite and substrates. With the aim of investigating the parameters most influential on the shear bond behavior, Raof et al (2016) analyzed different aspects: the bond length, the number of layers, the concrete surface preparation, the substrate compressive strength. Eighty shear bond concrete samples reinforced with carbon fibers different kinds of matrix were fabricated and tested under double-lap direct shear. The results evidenced that:

- increasing the bond length, the bond capacity increases in a non-proportional way for all the number of layers;
- increasing the number of layers for the same bond length, the bond capacity increases in a non-proportional way;
- the number of layers has a significant effect on the failure mode;
- different concrete surface preparation methods did not influence the bond characteristics between TRM and concrete; the use of lower concrete compressive strength marginally affected the bond strength of the TRM to concrete.

In Askouni et al (2019) et al the bond between (AR) glass FRCM and solid clay bricks was studied testing 37 specimens under double lap shear configuration. The matrix of the reinforcement was polypropylene fiber-reinforced cement-based mortar. The chosen variable parameters were bond length, bond width, number of layer and number of yarns. The results evidenced that the maximum axial stress increases almost linearly with the bond width because of the transversal yarns provide improved anchoring conditions for the longitudinal yarns and improved mechanical interlocking between mortar and meshes. Moreover, different textile configurations exhibit different shear bond behaviors.

The present work aims to investigate the stress transfer mechanism between Basalt FRCMs and masonry substrates typical of Southern Italy. Three different kind of mortar (two traditional, cementitious and lime-based, and the new GPM) and two types of substrates (Calcarenite – a calcareous porous stone - and Pietra Leccese – a calcareous compact stone) were considered.

2 EXPERIMENTAL PROGRAM AND SET-UP

The work is part of a research project, whose first results can be found in Bramato et al (2022). The experimental program discussed in the present paper is reported in Table 1 and included 18 samples divided into 6 series of 3 samples made by varying the type of substrate and matrix.

Table 1. Experimental program.

	#	Substrate	Matrix	Fibre
<i>PL_B_R</i>	3	Pietra Leccese	Lime-based	Basalt
<i>PL_B_M</i>	3		Cementitious	
<i>PL_B_G</i>	3		Geopolymer	
<i>C_B_R</i>	3	Calcarenite	Lime-based	
<i>C_B_M</i>	3		Cementitious	
<i>C_B_G</i>	3		Geopolymer	

The used nomenclature *W_X_Y_Z* indicated: W the type of substrate (C=Calcarenite, PL=Pietra Leccese), X the type of dry mesh (B=Basalt), Y the kind of inorganic matrix (R=lime-based, M=cementitious and G=Geopolymeric) and Z the progressive number of samples (i.e. 1 to 3). The mechanical properties of the constituent materials were reported in previous papers – Longo et al (2020) and Bramato et al (2022) - and the utilized geopolymer

matrix was developed in Longo et al (2020). The experimental mechanical strength (compressive and flexural strength) for the traditional mortars (lime-based and cementitious) are those reported in manufacturer technical sheet Bramato et al (2022). In Longo et al (2020) the characteristics of the innovative GPM are reported in terms of energetic and mechanical properties. Comparing the GPM with an equivalent traditional NHL mortar, better performance in terms of conductivity but worse mechanical properties were found. The Geopolymeric matrix exhibited 73% lower values of conductivity if compared with a traditional NHL according to the experimental data reported in Longo et al (2022).

The substrate used is a calcareous compact stone called *Pietra Leccese*, and a calcareous porous stone called *Calcarenite*. The mechanical properties of the natural stones were evaluated according to the current guidelines in terms of flexural and compressive strength and discussed in Bramato et al (2022).

All the tests were performed in displacement control with a rate of 0.2 mm/min by using the same universal machine and test set-up (Figure 1) reported in Bramato et al (2022).

Figure 1. Test set-up.

2.1 Experimental results

The experimental results are reported in Table 2 in terms of peak axial force, exploitation rate and global displacement average values. The exploitation rate was calculated as the ratio between the peak axial stress obtained by the shear bond test and the tensile strength of the dry mesh, while the global displacement was set equal to the relative shift of the universal machine transverses, in the following called “global displacement”. The peak axial stress (σ_{\max}), was calculated according to the following equations.

$$\sigma_{\text{peak}} = F_{\text{peak}} / (A_{\text{y}} * n) \quad (1)$$

where:

σ_{peak} = Peak axial stress [MPa];

F_{peak} = Peak axial load [N]

A_{sy} = Single yarn section area [equal to 0.23 mm², according to data sheet provided by the supplier]

n = Number of yarns [equal to 15]

Table 2. Average experimental results.

Label	F_{peak} [kN]	$\sigma_{\max} / f_{\text{tf}}$ [%]	s [mm]	Label	F_{peak} [kN]	$\sigma_{\max} / f_{\text{tf}}$ [%]	s [mm]
<i>C_B_R</i>	3269.85	72.24	10.98	<i>PL_B_R</i>	2897.04	64.00	7.78
<i>C.o.V.</i>	5.48%	5.48%	6.58%	<i>C.o.V.</i>	20.74%	20.74	20.20%
<i>C_B_M</i>	4167.35	92.07	9.79	<i>PL_B_M</i>	4738.64	104.69	10.16
<i>C.o.V.</i>	11.69%	11.69%	11.55%	<i>C.o.V.</i>	7.77%	7.77	10.20%
<i>C_B_G</i>	1037.63	22.92	4.67	<i>PL_B_G</i>	1513.54	53.68	2.65
<i>C.o.V.</i>	11.66%	11.6%	25.22%	<i>C.o.V.</i>	-	-	-

Three different kinds of failure mode were observed and reported in Figure 2:

- FM type “C”: debonding at the matrix-fibre interface;
- FM type “F”: widespread tensile failure of the dry fibre at the unbonded zone of the reinforcement;
- FM type “F*”: tensile failure of the dry fibre at the fibre-reinforcement interface.

In case of samples reinforced with lime-based mortar, about 83% of the specimens failed for debonding at the matrix-fibre interface, while half of the samples reinforced with cementitious matrix failed for debonding at the matrix-fibre interface, the other half failed because of a diffuse tensile failure at the unbonded zone of the reinforcement. All samples reinforced with geopolymer matrix were characterized by a tensile rupture at the dry fibre-reinforcement interface.

Figure 2. Typical Failure Modes observed: (a) Type “C”; (b) Type “F”; (c) Type “F*”.

For samples reinforced with geopolymeric mortar, the exploitation rate is very low even if a fibre rupture was observed. It seems that there is a possible compatibility problem between the basalt mesh utilized and the innovative geopolymer matrix. With the aim to understand these experimental results, a deep microscopic analysis of the tested specimens has been performed, that evidenced the absence of fibre damage or matrix cracking. Moreover, the lower values of coefficient of variation of both series confirmed the absence of possible experimental error. However, further tests are suggested for validating the data obtained and deepen the problem of the fibre-geopolymeric matrix compatibility. In fact, different studies evidenced that basalt fibers have good chemical stability, chemical resistance, corrosion resistance and water resistance [6-10], however studies devoted to the compatibility between Basalt fibers and geopolymeric matrix are still limited.

Figure 3 shows the average curves axial stress-displacement and the variability range for each of the six series of tested specimens. It can be observed that the variability range is very small as confirmed by the values of the coefficient of variation reported in Table 2. All the average curves show a similar trend and almost the same slope of the first phase (except for C_B_G series), even if the average peak axial stress obtained by samples reinforced with the innovative geopolymer mortar is lower with respect to that obtained in case of traditional mortar. The comparison between the experimental average curves, shown in the Figure 4, evidences and confirms that the mechanical properties of the inorganic matrix influenced the results in terms of peak axial force for both type of substrates (i.e. PL and C stone). In fact, based on this experimental data, increasing the compressive strength of inorganic matrix the maximum axial stress increases as well. In particular, comparing data obtained in case of cementitious and based-lime mortar an increase of 27% and 63% has been registered in case of *Calcarenite* and *Pietra Leccese* samples, respectively.

Figure 5 evidences the effect of substrate on the experimental results. The average curves and the relative scatter areas of series reinforced with lime-based (a), cementitious (b) and geopolymer (c) mortar are drawn. It can be observed that experimental results in terms of average peak axial stress of samples reinforced with lime-based mortar are influenced by the kind of substrates. In this case, the mortar and both the substrates have similar mechanical properties. Contrariwise, in case of cementitious samples, the influence of substrates seems negligible,

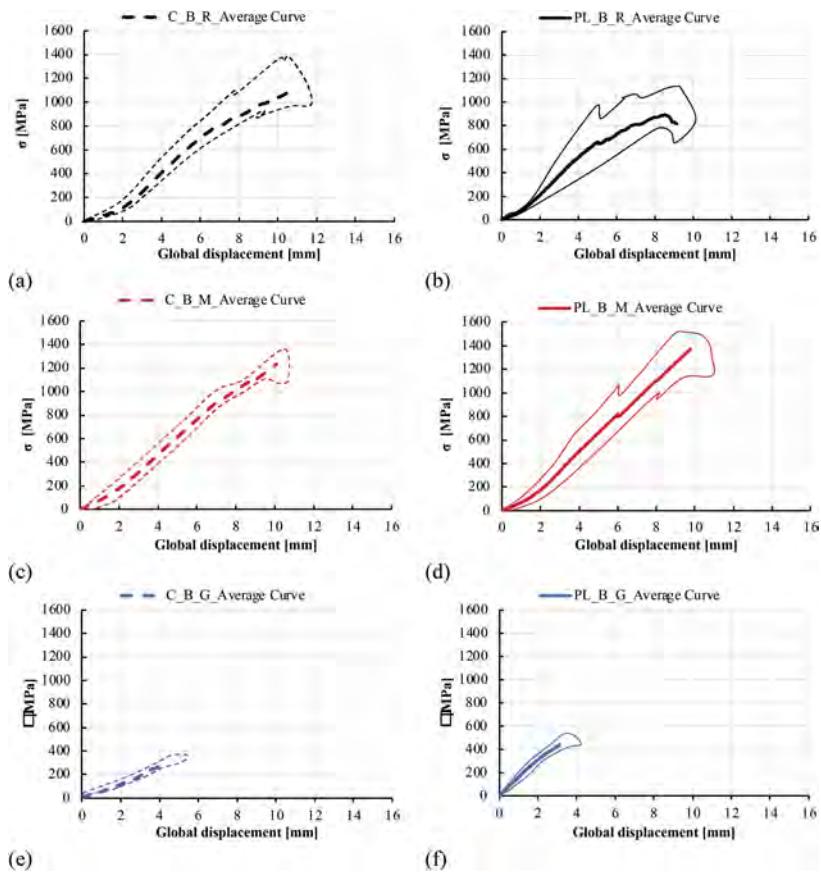

Figure 3. Shear bond specimens global displacement-stress curves: a) C_B_R series; b) PL_B_R series; c) C_B_M series; d) PL_B_M series; e) C_B_G series; f) PL_B_G series.

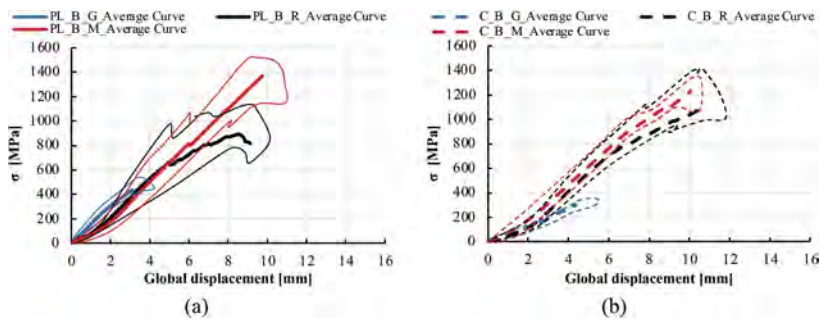

Figure 4. Shear bond specimens global displacement-stress curves: a) *Pietra Leccese* substrates; b) *Calcarenite* substrates.

probably because, the mortar has flexural and compressive strength higher than both the substrates. The analysis is still in progress to understand if the recorded percentage difference could be also attributed to the physical properties of the substrates. In case of samples reinforced with geopolymer matrix, a reduction of the slope of the curve was observed passing from *Pietra Leccese* to *Calcarenite*. A reduction in average peak axial force was also recorded. However, this data are still under investigation.

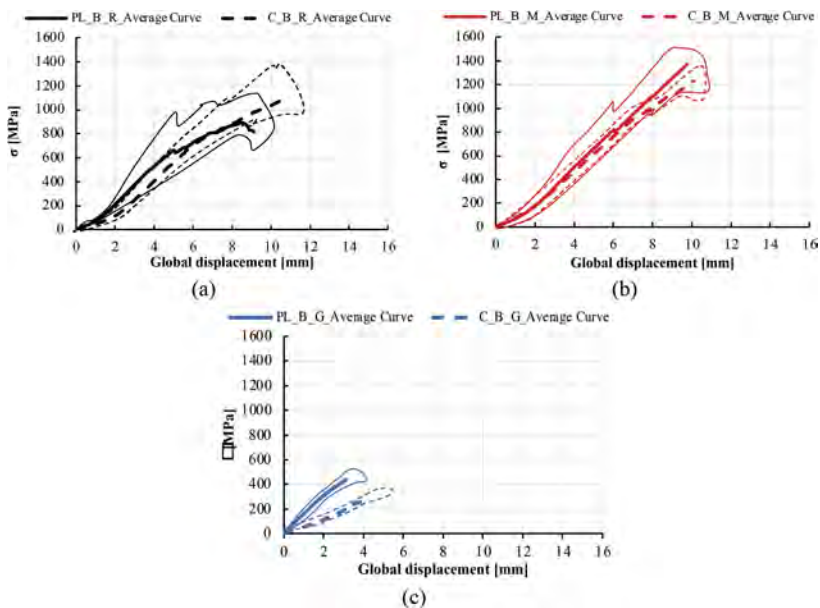

Figure 5. Shear bond specimens global displacement-stress curves: a) C_B_R series; b) PL_B_R series; c) C_B_M series; d) PL_B_M series; e) C_B_G series; f) PL_B_G series.

Billotta et al (2017) tested 10 clay bricks prisms with mechanical properties similar to natural stone used in the reported investigation and reinforced with almost the same Basalt open grid dry mesh and matrix. In detail, a natural hydraulic lime mortar with short fibers inside was used. In this case, an average peak axial force equal to 4.6 kN was recorded, a value 41% and 58% higher than in case of C_B_R and PL_B_R series, respectively. Two different failure mode were observed: tensile failure at unbonded zone of the reinforcement and a mix of tensile failure at unbonded zone of the reinforcement and slippage between fibre and matrix without matrix cracking.

Lignola et al (2017) carried out a large experimental campaign in order to investigate the performance of Basalt FRCMs in retrofitting applications by making single lap shear bond test. Some samples made had geometry and mechanical properties of fibre, substrate and matrix similar to those reports in this paper. In detail, 16 coupons were realized with clay bricks prisms with compressive strength equal to 14.6 MPa reinforced with lime-based mortar with 15 MPa compressive strength and almost the same open grid dry mesh. The results obtained was average peak axial force equal to 3.75 kN, a value 15% and 29% higher than in case of C_B_R and PL_B_R series, respectively. Moreover, Lignola et al recorded two different types of Failure Mode: type “E” – slippage between fibre and matrix with mortar cracking; type “F” – tensile failure of fibre at unbonded zone of the reinforcement.

The diversity of the results obtained in terms of axial peak strength and failure mode highlights the need to further deepen the experimental and theoretical investigation.

3 CONCLUSION

The present paper reports the main experimental results of shear bond tests on masonry samples reinforced with different Basalt-FRCM systems. In detail, three different mortars (lime-based, cementitious and an innovative geopolymer mortar) were used with the same Basalt open mesh grid. Two different substrates typical of Southern Italy were considered. The following conclusions can be drawn:

- The types of substrates influence the experimental results when their mechanical properties are similar to those of inorganic matrix;
- The mechanical properties of inorganic matrix strongly influenced the experimental results. In fact, increasing the mortar strength, a higher experimental peak stress was found;
- A possible compatibility problem between the basalt mesh and the innovative geopolymer matrix utilized in the reported investigation was observed. The progress of the research aims to deepen this issue.

ACKNOWLEDGEMENTS

The study object of this test was founded by the Italian Ministry of Education, University and Research in the framework of PRIN 2017 – SURMOUNT (Innovative systems on inorganic mortar non-metallic reinforcement for the upgrade of masonry structures and non-structural elements). The authors would acknowledge also Mapei s.p.a for materials supply.

Tensile behavior of a glass FRCM composite with textile lap splice exposed to freeze-thaw cycles

A.S. Calabrese, V. Bertolli, P. Colombi, T. D'Antino & C. Poggi

Department of Architecture, Built environment and Construction engineering, Politecnico di Milano, Milan, Italy

ABSTRACT: Fiber-reinforced cementitious matrix (FRCM) composites represent a valid alternative to fiber-reinforced polymer (FRP) composites for the strengthening of existing reinforced concrete and masonry members. FRCM composites are comprised of high strength textiles embedded within inorganic matrices and can be either applied with a discontinuous (i.e., discrete strips) or continuous layout, such as in the case of masonry elements with large surfaces (e.g., walls and vaults). Continuous applications require textile lap splices to guarantee the continuity of the composite mechanical performance. Recent investigations of the long-term behaviour of FRCM composites showed that aggressive conditions can affect the stress-transfer mechanism between fiber and matrix, determining possible reductions of the composite mechanical properties. This issue can be particularly critical in the lap splice zone due to the complex stress-transfer mechanism. Thus, the behavior of FRCM with textile lap splice under the effect of aggressive environments should be properly investigated. In this paper, the tensile behavior of a glass FRCM with continuous and overlapped textiles is studied using clamping-grip tensile tests. The effect of freeze-thaw cycles on the mechanical properties of the FRCM composite with textile lap splice is studied by comparing the results of specimens exposed to 20 freeze-thaw cycles with those of corresponding control specimens. The results obtained are analyzed in terms of maximum stress, corresponding strain, and slope of the axial stress-axial strain curve.

1 INTRODUCTION

Inorganic-matrix composites have been increasingly employed as externally bonded reinforcement (EBR) for concrete and masonry members due to their advantages with respect to organic-matrix composites (Peled et al. 2017). Among inorganic-matrix composites, fiber-reinforced cementitious matrix (FRCM) (ACI Committee 549 2020 549, Consiglio Nazionale delle Ricerche 2019 215), also referred to as textile-reinforced mortar (TRM) (Papanicolaou et al. 2008), are particularly attractive to reinforce masonry members, where the compatibility of the matrix with the masonry substrate and the reversibility of the application make these systems a valid alternative to traditional reinforcing techniques (Ferrari 2019). FRCMs comprise high strength open-mesh fiber textiles, usually made with carbon, glass, basalt, polyparaphenylene benzobisoxazole (PBO), or steel fibers, embedded within an inorganic matrix, usually a cement- or a lime-based mortar. Each FRCM composite has peculiar mechanical properties, which depend, among others, on the textile and matrix physical and mechanical properties, textile layout, and bond between matrix and fibers. Acceptance criteria are available in Italy (CSLLPP - Servizio Tecnico Centrale 2022) and in the United States (International Code Council Evaluation Service (ICC-ES) 2018) to assess the tensile behavior of FRCM composites using clamping-grip (Calabrese et al. 2020) and clevis-grip (Focacci et al. 2022) tensile tests, respectively. In addition, the Italian acceptance criteria require bond test to determine the maximum load that can be transferred between the externally bonded FRCM and a certain substrate (Bertolli and D'Antino 2022).

When applied to large surfaces, such in the case of masonry walls and vaults, textile lap splices are needed to ensure continuity of the FRCM reinforcement. Thus, both the Italian and US

acceptance criteria require tensile tests on FRCM coupons including textile lap splice, where the lap splice length l_s shall be sufficient to obtain the same tensile strength in coupons with continuous textile and with textile lap splice. Limited studies regarding the stress-transfer between lap spliced textiles in FRCM composites can be found in the literature. In (Thermou et al. 2018), steel reinforced grout (SRG) coupons with textile lap splice and different l_s were tested, observing a clear influence of l_s on the tensile strength obtained with clamping-grip tests. Carbon and glass FRCM coupons tested in (Truong et al. 2019) and (Donnini et al. 2019), respectively, using the clevis-grip test showed failure due to textile rupture. Corresponding FRCM coupons with textile lap splice showed the same failure mode and tensile strength when a lap splice length equal to 200 mm and 150 mm, respectively, was adopted. Based on numerical results of a PBO FRCM composite with textile lap splice tested using the clevis-grip set-up, a method to estimate the minimum lap splice length needed to obtain the composite load carrying capacity (or debonding load P_{deb}), i.e., the effective lap splice length $l_{s,eff}$, was proposed in (D'Antino et al. 2022). This method was then validated and confirmed comparing experimental results of PBO FRCM coupons with five different l_s with corresponding non-linear numerical models that accounted for the non-linear behavior of matrix and matrix-fiber interface (D'Antino et al. 2023).

Although these studies helped improving the state of knowledge regarding the stress-transfer mechanism between lap spliced textiles, no information is available regarding the long-term behavior of FRCM coupons with textile lap splice. In fact, exposure of FRCM composites to aggressive environments could affect their physical and mechanical properties (Ceroni et al. 2018, Calabrese et al. 2022b) and this effect could be even more important where textile lap splice are located, due to the reduced thickness of the embedding matrix that also works as a textile protection (Signorini and Nobili 2021, Ombres et al. 2020).

In this paper, the tensile behavior of a glass FRCM composite with textile lap splice under the effect of aggressive environments is investigated using clamping-grip tensile tests. Nine FRCM coupons with three different lap splice lengths are subjected to 20 freeze-thaw cycles and their response is compared with that of corresponding control, i.e., not conditioned, specimens. The effect of freeze-thaw cycles on the maximum stress, corresponding strain, and slope of the cracked portion of the axial stress-axial strain curve are analyzed and discussed.

2 EXPERIMENTAL STUDY

In this study, FRCM coupons with three different lap splice lengths (l_s) were subjected to clamping-grip tensile tests after being exposed to 20 freeze-thaw cycles. The lap splice lengths were $l_s=120$ mm, 180 mm, and 200 mm. For each l_s , three specimens were not conditioned and tested as control while three were subjected to the freeze-thaw cycles protocol, which resulted in 18 tensile tests. The tensile behavior of the glass FRCM considered in this study was previously investigated by the authors testing five specimens with a single continuous textile layer (Calabrese et al. 2022a). In (Calabrese et al. 2022a), the effect of the same freeze-thaw cycles protocol considered in this paper on the FRCM tensile behavior was also investigated.

The 18 specimens presented in this study were named following the notation $LT_{xxx}_L_W_{NC(or F/T)}_n$, where LT (=lap tensile) is the type of test, xxx (=120, 180, or 200) is the lap splice length (in mm), L and W are the specimen length and width (in mm), respectively, NC (=control) or F/T (=freeze/thaw) indicate control and conditioned specimens, and n is the specimen number.

2.1 Materials

The mechanical properties of the alkali-resistant (AR) glass FRCM composite investigated in this study and those of its constituent materials are reported in Table 1. The open-mesh bidirectional AR glass textile was coated with a styrene butadiene rubber (SBR) and had yarns spaced at 17 mm on center in both directions (Sika Italia SpA 2020). Its mechanical properties were experimentally obtained by testing textile strips comprising 3 longitudinal yarns (i.e., aligned with the load direction), according to (CSLLPP - Servizio Tecnico Centrale 2022). The AR glass FRCM properties reported in Table 1 were experimentally obtained in

(Calabrese et al. 2022a) by testing rectangular FRCM coupons with nominal dimensions equal to 450 mm (length) \times 50 mm (width) \times 10 mm (thickness), comprising one textile layer, including 3 longitudinal yarns, embedded within two 5 mm thick cementitious mortar layers. The mechanical properties of the cement-based matrix employed for the FRCM composite were declared by the manufacturer (Sika Italia SpA 2021).

Table 1. Mechanical properties of the FRCM and its components.

Property	AR glass textile	Cement matrix	FRCM
Tensile strength f_f	756 [MPa]	-	-
Elastic modulus E_f	52 [GPa]	-	-
Yarn area A_f	1.05 [mm ²]	-	-
Tensile strength σ_u	-	-	828 [MPa]
Ultimate strain ε_u	-	-	1.75 [%]
Cracked-stage slope E_3	-	-	51 [GPa]
Matrix cracking stress σ_{T1}	-	-	128 [MPa]
Compressive strength f_c	-	22* [MPa]	-
Elastic modulus E_c	-	7.6* [GPa]	-
Flexural strength f_r	-	6.0* [MPa]	-

*Declared by the manufacturer (Sika Italia SpA 2021).

2.2 Specimen geometry and test set-up

Figure 1a shows the geometry of lap splice specimens considered in this study. The FRCM coupons were comprised of two textile layers and three matrix layers and had an overall nominal thickness of 10.5 mm. Each textile layer included 3 longitudinal yarns, resulting in an overall fiber cross-sectional area $A=3.15 \text{ mm}^2$. Textile layers were overlapped in the specimen central portion considering a lap splice length l_s equal to 120 mm, 180 mm, and 200 mm. The clamping-grip tensile test set-up adopted in this study is shown in Figure 1b. The specimen ends were reinforced with epoxy-bonded GFRP tabs of dimensions 80 mm (length) \times 50 mm (width), which were clamped by the machine wedges applying an adequate clamping pressure to minimize matrix-fiber slippage at the specimen ends. Tests were conducted in displacement control, according to the indications of (CSLLPP - Servizio Tecnico Centrale 2022), monotonically increasing the machine stroke at a rate of 0.2 mm/min. A 200 mm gauge length extensometer was applied to the central portion of the specimen to measure the longitudinal strain, as provided by the Italian acceptance criteria (CSLLPP - Servizio Tecnico Centrale 2022).

2.3 Freeze-thaw cycles

The freeze-thaw cycles protocol adopted in this study followed the indications of (CSLLPP - Servizio Tecnico Centrale 2022). It comprised first 7 days of exposure to 92% RH and 38 °C and then 20 freeze-thaw cycles, each consisting of 4 hours at -18 °C followed by 12 hours at 92% RH and 38 °C. A 2.5 °C/min heating and cooling rate was adopted for the freeze-thaw cycles.

3 RESULTS AND DISCUSSION

3.1 Control specimens

Figures 2a,b, and c provide the axial stress σ – axial strain ε responses of control specimens, where σ is computed as $\sigma=P/A$, being P and A the load applied by the testing machine and the overall fiber cross-sectional area, respectively. Since for most of the specimens tested matrix cracks occurred outside the extensometer gauge length (see Figure 2d), the strain measured by the extensometer represents and underestimation of the actual specimen longitudinal strain. Accordingly, for all specimens considered in this paper the axial strain ε was computed as $\varepsilon=\delta/L_0$, being δ and L_0 the machine stroke and the length of the specimen portion included between the machine wedges (referred to as the specimen free length), respectively.

Figure 1. Specimen geometry (a) and test set-up (b).

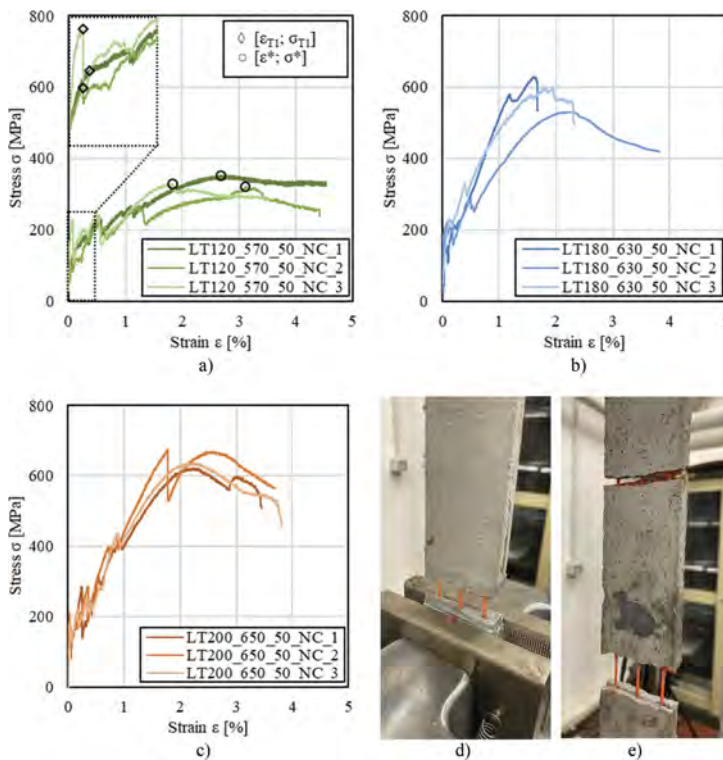

Figure 2. Stress-strain responses of control specimens: a) specimens LT120_570_50_NC; b) specimens LT180_630_50_NC; and c) specimens LT200_650_50_NC. Representative failure modes: d) specimen LT180_630_50_NC; and e) specimens LT120_570_50_NC.

As shown in Figure 2a, b, and c, the σ - ϵ response of control specimens was characterized by an initial linear branch associated with the specimen uncracked stage. This stage ended when the matrix tensile strength was reached (stress σ_{T1} in the σ - ϵ curve, see Figures 2a). Beyond this point, matrix cracks progressively occurred and widened with increasing the machine stroke δ (cracking stage). Matrix cracks occurred in different places in the three groups of specimens,

with LT120_570_50_NC specimens showing cracks at the edges of the lap splice length (see Figure 2e), whereas for specimens of groups LT180_630_50_NC and LT200_650_50_NC cracks occurred both at the edges of the lap splice length and close to the specimen gripped portion (see Figure 2d). When no further matrix cracks occurred, the specimen cracked stage began. During this stage, specimens of group LT120_570_50_NC ($l_s=120$ mm) were characterized by a non-linear response associated with the relative slippage between fiber and matrix along the lap splice length. For specimens LT180_630_50_NC and LT200_650_50_NC, the cracked stage response was initially characterized by an approximately linear branch associated with the elastic behavior of textile. With increasing the machine stroke, relative slippage between textile and matrix occurred and the response became non-linear. The transition from the linear to the nonlinear branch was recognizable in some specimens by a stress drop in the σ - ϵ response, which could be associated with the onset of debonding at the matrix-fiber interface. For some specimens (e.g., LT180_630_50_NC_1 and LT200_650_50_NC_2), the extent of the linear branch was more pronounced, which was attributed to the randomly distributed matrix-fiber interface properties and to a more uniform stress distribution among the textile yarns with respect to that of other specimens. In all specimens the maximum stress σ^* was attained during the cracked stage and was associated with the strain ϵ^* . Specimen failure eventually occurred due to the wide opening of one of the matrix cracks due to high relative slippage between fiber and matrix. In specimens LT120_570_50_NC, textile slippage occurred within the lap splice length (see Figure 2e), whereas for specimens LT180_630_50_NC and LT200_650_50_NC it occurred close to the specimen end and was eventually followed by textile rupture (Figure 2d).

Significant test response parameters of control specimens are reported in Table 2, alongside with corresponding average values and coefficient of variation (CoV). These parameters include the peak stress σ^* and corresponding strain ϵ^* , the matrix cracking stress σ_{T1} and corresponding strain ϵ_{T1} , and the post-cracked stage secant slope K , computed according to Equation 1.

$$K = \frac{\sigma^* - \sigma_{T1}}{\epsilon^* - \epsilon_{T1}} \quad (1)$$

Parameters reported in Table 2 (except K) are shown in Figure 2a for specimens LT120_570_50_NC. The maximum stress exhibited by specimens LT120_570_50_NC was on average 43% and 48% lower than that of specimens LT180_630_50_NC and LT200_650_50_NC, respectively (Table 2). This was attributed to the higher lap splice length of the latter specimens ($l_s=180$ mm and 200 mm), which prevented the textile slippage along the lap splice length, thus guaranteeing the reinforcement continuity. However, ϵ^* was 31% and 21% higher for specimens with

$l_s=120$ mm compared to that of specimens with $l_s=180$ mm and 200 mm, respectively, due to the higher textile slippage occurred along their lap splice length, which also resulted in 68% and 69% lower K values, respectively.

3.2 Specimens subjected to freeze-thaw cycles

All specimens exposed to freeze-thaw cycles provided the same failure modes of corresponding control specimens, which indicated that the conditioning protocol did not affect the specimen failure mode. The σ - ε responses of conditioned specimens are shown in Figure 3 where the envelopes of corresponding control specimens are also provided for comparison. Conditioned specimens provided σ - ε responses consistent with those of control specimens, as they were characterized by three subsequent stages: uncracked, cracking, and cracked stages. It should be noted that specimen LT120_570_50_F/T_2 prematurely failed due to improper fabrication and is not shown in Figure 3. Calabrese et al. (2022) investigated the effect of the same freeze-thaw cycles protocol on the tensile behavior of single textile layer coupons of the same AR glass FRCM considered in this study, observing a 12.4% reduction of the average tensile strength after conditioning. This reduction was attributed to the possible degradation of the textile SBR coating due to temperature cycles, which in turn altered the matrix-fiber stress-transfer mechanism and thus the conditioned specimen tensile capacity.

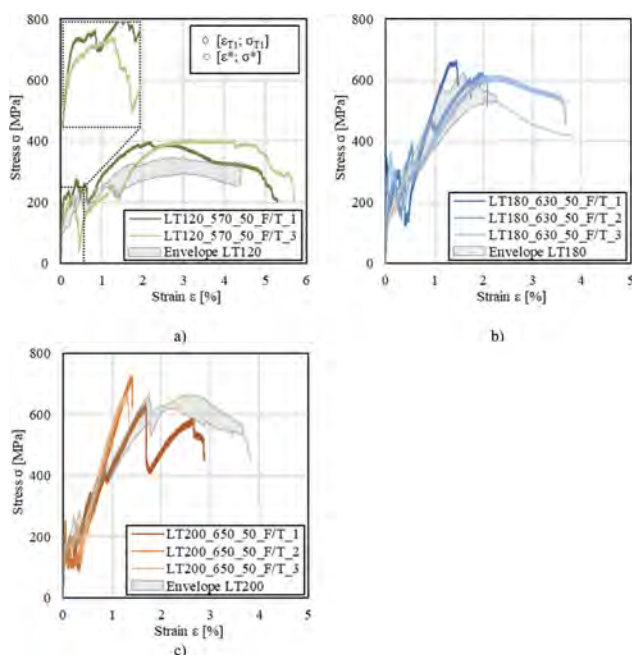

Figure 3. Stress-strain responses of specimens subjected to freeze-thaw cycles: a) specimens LT120_570_50_F/T; b) specimens LT180_630_50_F/T; and c) specimens LT200_650_50_F/T.

Table 3 collects the relevant parameters of the σ - ε response for all conditioned specimens, alongside with average values, CoV, and percentage of average retained stress, strain, and secant modulus, with respect to the corresponding average parameters provided by control specimens (Table 2). As inferred by Table 3, σ_{T1} was between 4% and 63% higher for conditioned specimens in comparison with that of control specimens. This was attributed to the specimen exposure to a high moisture environment, which promoted the continuous curing of the cement-based matrix. A similar finding was reported by (Calabrese et al. 2022a, Calabrese et al. 2022b) on cement-based matrix composites subjected to various ageing protocols.

Despite of a same failure mode, the σ^* of conditioned specimens was on average 5% to 20% higher than that of corresponding control specimens. It can be postulated that the prolonged matrix curing improved the matrix-fiber stress-transfer mechanism resulting in a higher tensile strength of conditioned than of control specimens. Furthermore, 2% and 30% lower ϵ^* average values were recorded on specimens of groups LT180_630_50_NC and LT200_650_50_NC, respectively. The different matrix-fiber stress-transfer is also confirmed by specimens showing a long linear branch in the cracked stage.

†Premature failure.

4 CONCLUSIONS

This paper investigated the effect of freeze-thaw cycles on the tensile behavior of AR glass FRCM specimens with textile lap splice. Three different lap splice lengths were considered, namely $l_s=120$ mm, 180 mm, and 200 mm. The results showed that low a lap splice length led to high slippage at the matrix-fiber interface along the lap splice length, which in turn resulted in 43% and 48% lower average tensile strength of specimens with $l_s=120$ mm with respect to that of specimens with $l_s=180$ mm and 200 mm, respectively. The freeze-thaw cycles protocol considered in this study did not affect the specimens failure mode. The average cracking stress of conditioned specimens resulted higher than that of control specimens, which was attribute to the continuous matrix curing. Similarly, matrix curing improved the matrix-fiber stress-transfer mechanism, determining a slight ϵ increase in the specimen tensile strength after conditioning.

Effect of salt crystallization on the bond behavior of glass FRCM-masonry joints

V. Bertolli, A. Cagnoni, A.S. Calabrese, P. Colombi & T. D’Antino

Department of Architecture, Built environment and Construction engineering, Politecnico di Milano, Milan, Italy

ABSTRACT: The use of fabric-reinforced cementitious matrix (FRCM) composites for reinforcement of existing masonry members has attracted an increasing interest in recent years. FRCM composites are particularly suitable for masonry strengthening and retrofitting due to their ease of installation, reversibility, excellent compatibility with the substrate and vapor permeability. Tensile mechanical properties and bond behavior of FRCM composites were extensively studied. However, limited information is available regarding the durability of FRCM and FRCM-strengthened members, which may represent a critical issue for the effectiveness of the strengthening system. Indeed, existing masonry structures suffer from the presence of moisture, which can come from rising damp, condensation, infiltration of rainwater, etc. Water is often responsible for the presence of salt within the element, which represents a major cause of masonry damage. When the salt crystallization takes place at the interface between the FRCM and the substrate, a possible reduction of the FRCM bond capacity can be observed.

In this paper, the effect of salt crystallization on the bond behavior of an FRCM applied onto a masonry substrate is experimentally investigated. The FRCM composite employed comprises a glass open mesh reinforcing textile and a cementitious matrix. FRCM-masonry joints were conditioned in a saline solution to induce salt crystallization in the FRCM, i.e., within the composite strips and at the FRCM-masonry interface. The bond behavior of the FRCM composite before and after the conditioning is investigated with single-lap direct shear tests. The results obtained provide information on the long-term behavior of the glass FRCM composite considered.

1 INTRODUCTION

Fabric-reinforced cementitious matrix (FRCM) composites have gained large popularity in recent years as externally bonded reinforcement (EBR) for masonry (Carozzi and Poggi 2015) and reinforced concrete (RC) structures (Täljsten and Blanksvärd 2007), where they proved to be effective as in-plane (de Felice et al. 2014) and out-of-plane (Papanicolaou et al. 2008) reinforcement for walls and flexural, shear, and torsional reinforcement for RC beams (Bencardino et al. 2018, Triantafyllou and Papanicolaou 2006, Alabdulhady et al. 2017). They comprise different high strength fibers arranged in open-mesh textiles embedded within inorganic matrices. FRCMs overcome some of the main drawbacks related to the use of fiber-reinforced polymers (FRP) composites, such as irreversibility of the application and absence of vapor permeability (Ombres 2015, Del Prete et al. 2015). Furthermore, recent studies on FRCM long-term behavior showed that these inorganic matrix composites have better resistance to high temperatures (Ferretti et al. 2022) and to aggressive environments (Franzoni et al. 2019, Al-Lami et al. 2021) than FRPs (Trapko 2013, Tedeschi et al. 2014). However, the inorganic matrix of FRCMs is not able to uniformly impregnate fiber filaments as the organic resin of FRP composites does, due to the dimension of the components of the mortar matrix. In FRPs, an even stress distribution among fiber filaments can be assumed thanks to the use of organic resins and this leads to different resisting mechanism developing in FRP and FRCM when subjected to external loads. FRCM mechanical properties are determined with tensile tests (i.e., clamping- (CSLLPP 2022) or clevis-grip (International Code Council Evaluation Service (ICC-

ES) 2018) tests) and single- or double-lap direct shear tests (European Organization for Technical Assessment (EOTA) 2018), which allows for assessing the composite tensile strength and the FRCM-substrate interface debonding mechanism, respectively (Focacci et al. 2022). When failure occurs due to debonding, direct shear tests provide information on the bond behavior of the interface where debonding occurs and allow the evaluation of the bond capacity and cohesive material law (CML) of this interface (Bertolli and D'Antino 2022, D'Antino et al. 2020).

Moreover, durability of FRCMs is a fundamental aspect to be considered when dealing with their application on external surfaces of existing structures, where they can be exposed to humidity, rainfall, and to saline and alkaline environments (Al-Lami et al. 2020). Among different detrimental effects of atmospheric processes, salt attack is the most common cause of weathering in masonry structures (Donnini 2019). There are limited studies in the literature focused on the effects of aggressive saline environment on the mechanical behavior of FRCM composites. Long-term tensile behavior of FRCM was evaluated by Arboleda (2014) and the results indicated a slight increase in tensile capacity of FRCM conditioned in saline and alkaline solution and with freeze-thaw cycles. Similarly, Nobili (2016) assessed FRCM durability against alkaline and saline environments through tensile tests on alkali-resistant (AR) glass FRCM coupons. The saline solution employed comprised 3.5 wt% of sodium chloride (NaCl). Even though not as high as that obtained for the alkaline solution, a reduction of the peak stress attained by the specimen conditioned in saline environment was observed. Tensile behavior of FRCM conditioned in saltwater was also investigated by Donnini et al. (2020), in which it is shown that the tensile strength slightly increased after conditioning, due to curing of the mortar matrix.

Long-term bond behavior of FRCM was investigated by Franzoni et al. (2017), which carried out direct shear tests on steel reinforced grout (SRG) composites aimed at defining an accelerated conditioning procedure able to reproduce the actual environmental conditions to which FRCM are subjected in real applications. The conditioning consisted in four wet-dry cycles, composed of 2-day wetting phase in a sodium chloride (NaCl, 2 wt%) and sodium sulfate decahydrate ($\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$, 8 wt%) solution, followed by a 3-day drying phase in a ventilated oven at 60 °C. The duration of wetting and drying phases was selected to allow for water saturation and evaporation, respectively. Moreover, to avoid possible effects due to the presence of water within the specimen (i.e., water saturation effect (Franzoni et al. 2015)) on the bond behavior of the specimens (Franzoni et al. 2018), they were oven dried at 60 °C for 2 days before testing. This accelerated procedure was modified by Franzoni et al. (2018), where six wet-dry cycles were performed on SRG-masonry joints. Then, the same conditioning procedure was performed in Franzoni et al. (2019), where different mortar matrices were adopted to investigate the matrix role on the bond behavior of SRG composites. Results showed a reduction of the peak stress attained in direct shear tests in all the conditioned specimens, with lower strength reduction for specimen with cement-based matrix. In Donnini (2019), the same saline solution of Franzoni et al. (2019) was employed for the conditioning of 12 glass FRCM DS test specimens that were subjected either to 1000 hour immersion in saline solution or to wet-dry cycles. Results showed higher strength reduction for the specimens immersed in the saline solution. The effect of salt crystallization on FRCM-masonry joints was also investigated by Garavaglia et al. (2020) by means of pull-off tests. The conditioning procedure was selected according to (RILEM TC 127-MS 1998), and the specimens were inserted in a dry gravel layer filled with water saturated with a 10 wt% of Na_2SO_4 solution for 11 months. Pull-off test showed strong reduction on the bond strength (ASTM International 2004) of conditioned specimens.

The number of studies available in the literature assessing the long-term bond behavior of FRCM is quite limited. US and Italian acceptance criteria (AC 434-13 2013, CSLLPP 2022) evaluate FRCM durability by means of clamping- or clevis- grip tensile tests on specifically conditioned specimens. For example, (International Code Council Evaluation Service (ICC-ES) 2018) prescribes conditioning procedure for 1000 or 3000 hours in water, saltwater (immersion in a solution at 22 °C), alkaline solution, and freezing and thawing cycles. However, as also evidenced in (Franzoni et al. 2019), a common conditioning procedure for the evaluation of the effect of salt crystallization on the bond behavior of different FRCM composites is not yet defined.

In this paper, the effect of salt crystallization on the bond behavior of FRCM-masonry joints is investigated considering a coated glass FRCM embedded within a cement-based

mortar matrix. Four specimens were exposed to three wet-dry cycles in saline solution and then tested using a single-lap direct shear test set-up. The results obtained were compared with those of four corresponding control (i.e., unconditioned) specimens highlighting the detrimental effect of the conditioning procedure on the FRCM bond behavior.

2 MATERIALS AND METHODS

2.1 *Materials*

To evaluate the effect of salt crystallization on the bond behavior of FRCM-masonry joints, an experimental campaign was carried out on eight FRCM composite strips applied to masonry wallettes, tested with a push-pull single-lap direct shear set-up. Four out of eight specimens were subjected to an accelerated conditioning procedure whereas the remaining four were used as control specimens.

The FRCM composite comprised a coated glass open-mesh textile and a cementitious matrix. The textile employed was made with alkali-resistant glass fibers arranged in discrete bundles, each coated with styrene butadiene rubber (SBR). The textile was embedded within a commercial M20 (EN 998-2 2016) cementitious matrix (Sika Italia SpA 2021). The textile cross-sectional area was determined by the calcination method (EN 1172 1999) on eight bundle specimens and was $A^*=1.05 \text{ mm}^2$ (CoV 0.8%) for a single longitudinal bundle (warp direction) and $A_t^*=0.99 \text{ mm}^2$ (CoV 0.4%) for a single transversal bundle (weft direction). The equivalent thickness of the textile in longitudinal direction was $t_f=0.063 \text{ mm}$. Tensile tests of nine bare textile strips (i.e., not impregnated with the mortar) including 3 longitudinal bundles provided a tensile strength, ultimate strain, and modulus of elasticity of 756 MPa (CoV 6.1%), 1.48% (CoV 15.6%) and 52 GPa (CoV 6.1 %).

Each masonry wallette was made of seven solid clay UNI bricks and six 10 mm-thick mortar joints. The masonry wallettes total height was 480 mm, and their width and depth 240 and 110 mm, respectively. The bricks had nominal dimensions 240×110×60 mm and compressive strength ranging from 15 to 25 MPa, according to information provided by the manufacturer (Danesi srl 2020). The mortar used for the joint was a commercial pre-mixed mortar (Fassa Bortolo srl 2020, EN 998-2 2016). The FRCM strips were applied to the 240 mm-wide side of the wallettes with the loaded end placed 30 mm below the upper edge of the masonry wall. The strips had bonded width $b_f=50 \text{ mm}$ and bonded length $L=300 \text{ mm}$ (CSLLPP 2022). The specimens were cast with the following procedure:

- A first 5 mm-thick layer of mortar was applied to the surface of the wallette using a mold to accurately control the strip geometry.
- The open-mesh textile, which comprised $n=3$ bundles longitudinal bundles, was gently pressed onto the first mortar to assure proper impregnation. A portion of the textile with length 270 mm was left bare beyond the loaded end.
- A second 5 mm-thick layer of mortar was applied as finishing layer. Thus, the total thickness of the FRCM strip was 10 mm.

2.2 *Accelerated conditioning procedure*

After being left to cure for at least 28 days, four FRCM-masonry joints were subjected to an accelerated weathering procedure. The conditioning comprised three wet-dry cycles in which the specimens were first immersed in a saline solution for 48 hours and then dried in a controlled environment characterized by a $23 \pm 2 \text{ }^\circ\text{C}$ temperature and a $50 \pm 10 \%$ relative humidity for 72 hours. As reported by (Franzoni et al. 2017), at least 8h immersion is necessary to obtain a complete saturation of masonry walls by capillarity adsorption. However, the amount of time required depends on the type of brick and mortar employed and 48 hours were selected in this work for the wetting phase. During the 72 hours drying phase, specimens were stored at room conditions and water evaporated from the masonry substrate, promoting salt crystallization. Dry conditions of the specimens were essential to guarantee the absorption of saline solution during the following cycle.

During the wetting phase, the specimens were partially immersed in a 20 mm-head Na_2SO_4 (10 wt%) solution for 48 hours, to allow capillary absorption of the saline solution. In each cycle, during the first 24 hours the specimen was immersed in the solution on one 480×110 mm side and then was turned and immersed on the opposite side for the remaining 24 hours (Figure 1a). During immersion, the masonry wallettes were placed on a composite grid to promote a homogeneous solution absorption. Duct tape was applied to every side of the masonry wall (except for the two alternatively immersed in the solution), including the side where the composite strip was applied, to induce salt crystallization through the FRCM strip. The level of the solution was kept constant through the cycles. At the end of the conditioning procedure, a considerable amount of salt crystallized in the free (i.e., not covered by the duct tape) surfaces of the masonry wallettes. Salt crystallization was also observed in the FRCM strip, with most of the crystallized salt located on the strip sides and in correspondence of the mortar joints (Figure 1b). At the end of the conditioning cycles, the duct tape around the wallettes was removed and the specimens were left to cure for additional 48 hours before testing (Figure 1c).

The conditioning applied in this work was an accelerated procedure (see (Franzoni et al. 2018)) aimed at inducing a realistic damage in a relatively short period of time without changing the masonry deterioration process. The end of the conditioning procedure was determined by visual inspection when a remarkable amount of efflorescence was obtained on the wall free surfaces.

Figure 1. A) Specimen immersed in salt solution during the second wet-dry cycle. b, c) Specimens 48 hours after the end of the conditioning procedure.

2.3 Direct shear tests

After the conditioning procedure, single-lap direct shear tests were performed on control and conditioned specimens to study the debonding mechanism of the glass FRCM composite. Experimental tests were carried out in displacement control at a rate of 0.0034 mm/s using a servo-hydraulic testing machine. GFRP tabs (with dimensions 50×80 mm) were epoxy bonded at the end of the bare textile beyond the loaded end to promote uniform stress distribution among the bundles and allow for clamping by the testing machine. During the test, fibers were pulled whereas the masonry wallette was restrained with a steel frame (Figure 2a, b).

Two linear variable displacement transducers (LVDTs) with measurement range of 200 mm were employed to measure the relative displacement, i.e., slip, between the masonry wallette and the textile. They were attached to the masonry surface at the loaded end and reacted off of an aluminum L-shaped plate fixed to the bare fibers immediately outside the FRCM strip. The average of the measurements of the two LVDTs (*LVDTa* and *LVDTb*) was named global slip g in this paper. During the test, the applied load, P , and the stroke of the testing machine, δ , were recorded with a frequency of 5 Hz. The stress in the textile, σ , was obtained as the ratio between the load recorded by the testing machine, i.e., the applied load P , and the textile cross-sectional area in warp direction, $A_f = t_f b_f = n A^* = 3.15 \text{ mm}^2$.

3 RESULTS AND DISCUSSION

Specimens were named DS_X_Y_C_S_N, where DS = direct shear (type of test), X = bonded length [mm], Y = bonded width [mm], C = clay brick masonry (type of support), S (if present) =

Figure 2. Single-lap direct shear test set-up: a) sketch and b) specimen DS_300_50_C_S_1 before testing.

indicates the salt conditioned specimens, and N = specimen number. The applied stress σ – global slip g curves for the FRCM-masonry joints studied are reported in Figure 3a, b for control and conditioned specimens, respectively. All specimens failed due to rupture of the fibers at the loaded end, either inside the FRCM strip or immediately outside it. Failure occurred first in one bundle and then in the remaining, which indicated the non-uniform stress distribution among the different bundles in the FRCM strip (see Figure 4a, b). However, fibers within each bundle failed approximately at the same time (i.e., no telescopic behavior (Hegger et al. 2006) was observed) due to the presence of the SBR coating that promoted the uniform distribution of stresses among fibers within the bundle.

Figure 3. Applied stress σ – global slip g curves for a) control and b) conditioned specimens.

The main parameters obtained by direct shear tests on control and conditioned specimens are reported in Table 1. P^* is the peak load, σ^* the corresponding peak stress, and g^* the global slip associated with the peak stress. Average values and coefficient of variations of nominally equal specimens are also reported. The average peak stress of control specimens was $\sigma^* = 742$ MPa, while that of conditioned specimen was $\sigma^* = 645$ MPa. Thus, an average reduction of 13.1% was observed for specimens subjected to the conditioning procedure. Moreover, a reduction of 11.8% in the average value of the global slip associated with the peak stress, g^* , was also observed for conditioned specimens.

Figure 4c shows the comparison between the envelope curves of control and conditioned specimens. The conditioning procedure caused a modest decrease in the peak stress attained in direct shear tests and had no influence in the failure modes of the specimens. It is worth noting that a direct evaluation of the effects of the salt crystallization on the bond behavior of the FRCM-masonry joints could not be performed since failure was attained right outside the FRCM strip. Indeed, the only conclusion that could be drawn is that the bond behavior of the joint was not adversely affected enough by the conditioning procedure to induce failure at the matrix-substrate or matrix-fiber interfaces before fiber rupture occurred (due to hierarchy of interface failures (Carloni et al. 2018)). Moreover, visual observation of the crystallized salts suggested a lower porosity of the cementitious matrix employed with respect to the masonry

bricks or mortar layers (salt crystallized mostly in correspondence of the mortar joints and on the FRCM strip sides). Thus, salt crystallization could be expected at the FRCM-masonry interface. These aspects will be clarified with the investigations on porosity and salt migration pattern of the different materials involved in the bond behavior.

Table 1. Results of direct shear tests on control and conditioned specimens.

Samples Name	P^* [kN]	σ^* [MPa]	g^* [mm]	Samples Name	P^* [kN]	σ^* [MPa]	g^* [mm]
DS_300_50_C_1	2.39	759	2.96	DS_300_50_C_S_1	2.03	643	2.66
DS_300_50_C_2	2.26	717	2.09	DS_300_50_C_S_2	1.98	627	2.26
DS_300_50_C_3	2.36	749	3.63	DS_300_50_C_S_3	2.11	670	3.14
DS_300_50_C_4	2.18	691	4.14	DS_300_50_C_S_4	2.01	639	2.12
Avg	2.34	742	2.89	Avg	2.03	645	2.55
CoV [%]	2.4	2.4	21.9	CoV [%]	2.8	2.8	18.0

It is worth noting that a clear conditioning procedure for the evaluation of the effect of salt crystallization on FRCM-masonry joints is not yet defined in the literature. Further experimental results are needed to improve our knowledge on the joint bond behavior of conditioned specimens and to define a shared conditioning procedure.

4 CONCLUSIONS

In this paper, an accelerated conditioning procedure was performed on direct shear test specimens to evaluate the effect of salt crystallization on the bond behavior of glass FRCM-masonry joints. The FRCM comprised a cementitious mortar and a coated glass fiber textile. The results obtained for conditioned specimens were compared with those of corresponding control specimens and allow for drawing the following conclusions:

- the detrimental effect of the conditioning procedure performed resulted in a slightly lower average peak stress attained by conditioned than by control specimens;
- all specimens tested failed due to tensile rupture of the textile either inside the FRCM strip or right outside it;
- physical and chemical investigations on the microstructure of the materials and interfaces will provide additional information on the long-term behavior of the FRCM reinforcement and of FRCM-masonry joints;
- considering the limited number of tests performed and available in the literature, more investigation is needed to clarify the effect of salt crystallization on the behavior of FRCM-

masonry joints. To this aim, a commonly accepted conditioning procedure should be defined for the determination of the salt crystallization resistance of FRCM composites.

On the behaviour of FRCM fibres in saturated alkaline solution

M. Canestri, F. Ferretti, E. Sassoni & C. Mazzotti

DICAM Department, University of Bologna, Bologna, Emilia Romagna, Italy

ABSTRACT: The main objective of this work was to study the behaviour of fibre grids, usually employed in FRCM (Fibre Reinforced Cementitious Matrices) systems, when exposed to an alkaline solution. Three basalt and a glass fibre textiles were conditioned in a saturated solution of calcium hydroxide and distilled water at 23°C. The total exposure time was chosen equal to 1000h. To monitor the conditioning process, alkalinity levels were periodically controlled for the whole exposure time. Subsequently, tensile tests were conducted on textile samples, including multiple longitudinal strands. A series of preliminary SEM (Scanning Electron Microscopy) analyses was also conducted to verify the integrity of the organic coating applied to the fibres. The coating, indeed, has the fundamental role of preventing or delaying the degradation process. The obtained results are discussed in terms of ultimate strength and elastic modulus reductions, showing significant detrimental effects of the alkaline environment especially for the basalt fibres.

1 INTRODUCTION

In recent years, retrofitting systems such as FRCMs (Fibre Reinforced Cementitious Matrices) have been extensively applied to recover damages caused by earthquakes or to improve the structural capacity of existing constructions. These externally bonded solutions have shown excellent mechanical performances and a good compatibility with the masonry substrates. Many authors have already proven the retrofitting potential and efficiency of these composite materials in several experimental studies, where the behaviour of strengthened elements was compared with the behaviour of unreinforced ones (Feo et al. 2016, Angiolilli et al. 2020, Garcia Ramonda et al. 2021, Ferretti et al. 2021a,b). However, still limited studies have examined their behaviour when exposed to temperature variations (Ferretti et al. 2022a, b), freeze and thaw cycles, or to aggressive environmental actions.

Composite systems can be affected by alkaline and saline environments, which can have significant effects on their mechanical properties, as demonstrated by recent studies. Nobili (2015) studied the effect of 1000h of exposure in saline and alkaline environment on the two components characterising a glass-FRCM system, i.e., fibres and mortar, both showing reduced strength values after the conditioning process. Hristozov et al. (2016) organised a large experimental campaign, with 490 samples in total, to study the effect of four environmental conditions (dry heat, distilled water, salt water and alkaline) for 4 total durations (500, 1000, 2000, 3000h) on flax and glass fibers. Tensile properties of both fibre typologies significantly decreased with the conditioning process, with flax composite showing slightly higher strength retention rates. Donnini et al. (2020) examined the effects of saline, alkaline environments and freeze thaw cycles on the mechanical properties of carbon and AR (Alkali Resistant) glass fibres. Alkaline exposure was demonstrated to be the most detrimental condition for glass yarns, characterised by a final strength reduction of about 25%. Micelli & Aiello (2019) focused their work on examining the residual mechanical properties of glass, basalt, PBO (polyparaphenylene benzo-bisoxazole) and steel fibers when exposed to alkaline environment. They carried out an interesting literature review, leading to the definition of four different aging aqueous solutions, aiming at representing the spectrum of

different possible combinations of inorganic matrix. Tests demonstrated that fibers were more susceptible to cementitious environments than to lime-based ones, especially in the case of glass and basalt materials, with strength loss up to 86% and full deterioration achieved in some cases. Some of the aging protocols defined in this experimental work were then reproduced and used (Rizzo et al. 2020, Micelli et. al. 2021) to further demonstrate the efficiency of the methodology and its effectiveness in studying the deteriorating effect on glass fibres based FRCM systems.

The objective of this research is the study of the behaviour of different types of fibre grids, when exposed to an alkaline solution. Conditioning protocols, such as solutions and exposure time, were selected considering the indications found in the cited literature, as will be specified in the following.

2 MATERIALS AND METHODS

2.1 Materials

In this experimental campaign, four different textiles, adopted as reinforcements in lime-based FRCM systems, were conditioned in alkaline solutions and then tested to verify material degradation. According to the manufacturer's indications, geometrical and technical specifications of the investigated reinforcing fibres are the following:

- B1 (Figure 1a): a balanced bidirectional basalt grid, characterised by a total weight density of 304 g/m², a bundle spacing of 20 mm and an equivalent thickness of 0.035 mm. As a result, an area of 0.7 mm² was considered for each bundle;
- B2 (Figure 1b): a balanced bidirectional basalt grid, characterised by a total weight density of 210 g/m², a bundle spacing of 16 mm and an equivalent thickness of 0.034 mm. As a result, an area of 0.544 mm² was considered for each bundle;
- B3 (Figure 1c): a balanced bidirectional basalt grid, characterised by a total weight density of 200 g/m², a bundle spacing of 17 mm and an equivalent thickness of 0.032 mm. As a result, an area of 0.544 mm² was considered for each bundle;
- G1 (Figure 1d): a balanced bidirectional glass grid, characterised by a total weight density of 240 g/m², a bundle spacing of 25 mm and an equivalent thickness of 0.036 mm. As a result, an area of 0.9 mm² was considered for each bundle.

Figure 1. Reinforcing textiles: (a) B1; (b) B2; (c) B3; (d) G1.

2.2 Conditioning protocols

Experimental tests to investigate the potential capacity reduction of textiles or FRCM systems when exposed to alkaline environments are usually carried out without shared and recognised procedures or standards to be followed, both in terms of type of solutions in which samples should be immersed, temperature levels and exposure times. However, based on the experimental works currently available in the literature, some of which are reported in Section 1, one possibility is to simulate the alkaline environment, which can be potentially found in lime-based mortars, by dissolving a specific content of calcium hydroxide (Ca(OH)₂) in distilled water. In this research, the 0.16% content, in weight, of Ca(OH)₂ was adopted to obtain a saturated solution with a pH approximately equal to 12. The solution was poured inside High-Density PolyEthylene (HDPE) tanks. Subsequently, the grid samples were submerged

inside the solution at 23°C for a total exposure time equal to 1000h. To control the conditioning process, the alkalinity level was periodically monitored through a standard pH sensor, while the temperature stability was ensured by means of a room with a controlled temperature and humidity environment. The values of the registered pH levels are reported in Figure 2b.

Figure 2. pH sensor (a) and pH level of the alkaline solution for 1000h (b).

A mean pH value of 12.4 was found during the 1000h of the conditioning process, while its value was almost constant with minimal variation (i.e., ± 0.2). As a result, the quality of the conditioning setup, achieved after a series of preliminary tests, was confirmed. In fact, one of the main issues that can occur is the undesired reaction of the calcium hydroxide with the carbon dioxide (CO_2) contained in the air, which could potentially lead to the precipitation of calcium carbonate (CaCO_3) and, consequently, to the reduction of the pH, therefore nullifying the conditioning process. In order to avoid this effect, airtight tanks were used with a high height-to-width ratio, to minimize the free surface of the solution, where this reaction could take place, and reduce the air intake.

2.3 Tensile test setup

The preparation of the specimens was performed following the indications and prescriptions provided by the *Italian Guidelines for the identification, qualification and acceptance control of FRCM composites to be used for the structural strengthening of existing constructions* (2018). In particular, 500 mm long textile samples were cut out of rolls, including 4 longitudinal bundles for the three basalt-based systems and 3 for the glass one (Figure 1). A total of 6 specimens for each grid type were prepared, half of which were directly tested. The remaining ones were conditioned as described in Section 2.2 and tested afterwards. The extremities of the samples were reinforced with $7 \times 7 \text{ cm}^2$ GFRP (Glass Fibre Reinforced Polymer) tabs, applied to the textiles by means of a bi-component epoxy resin. This solution was adopted to avoid an uneven stress distribution between the longitudinal bundles during the tensile tests. The tests were performed using a servo-hydraulic testing machine (Figure 3), equipped with a 0.5 load cell, with a maximum load capacity of 100 kN. Particular attention was paid to ensure the verticality of the samples inside the testing apparatus to avoid potential parasitic effects. Subsequently, all the tests were conducted under displacement control, with a constant rate of 0.5 mm/min. Strain values were recorded alongside load ones by means of an extensometer, which was firmly clipped to the central part of the specimens, with a gauge length of 100 mm.

3 EXPERIMENTAL RESULTS AND DISCUSSION

3.1 Stress vs strain curves

The results of the tensile tests are reported in this section both for the unconditioned and the conditioned samples. A total of 24 tests were carried out, considering the 4 fibre grid types analysed. Samples are identified in the following by the notation “TT_XX_AK_n”, where the

Figure 3. Setup of the direct tensile tests.

first two letters indicate the test type (Tensile Test), XX the material, AK the alkaline conditioning process (when applicable), and n is the specimen number. The obtained results are shown in Figures 4-7 in terms of axial stress *vs* strain. Stress values were derived from the axial load ones by dividing them for the cross-section area of the textiles, as indicated in Section 2.1. Deformation values were derived by dividing the registered displacement values by the gauge length of the extensometer, equal to 100 mm.

Figure 4. Stress *vs* strain curves for material B1 (a) and representative failure mode obtained for the sample TT_B1_1 (b).

The stress *vs* strain behaviour observed in all the tests was linear elastic up until the failure, which occurred due to fibres rupture inside the free length of the samples in all cases. This was detected for both material types (basalt or glass) and for both the unconditioned and the alkaline conditioned samples. In addition, for B1 and B3 materials, the rupture always occurred locally along the bundles of the textile, with minimal diffusion in the length of the specimens. On the other hand, for B2 specimens, the failure developed involving longer portions of material, with a complete shattering of the yarns (Figure 5). G1 samples showed a progressive failure and detangling of the strands that form the single bundles (Figure 7). Finally, it is worth highlighting that the exposure in the aggressive environment did not affect the obtained failure modes.

Figure 5. Stress vs strain curves for material B2 (a) and representative failure mode obtained for the sample TT_B2_3 (b).

Figure 6. Stress vs strain curves for material B3 (a) and representative failure mode obtained for the sample TT_B3_2 (b).

Figure 7. Stress vs strain curves for material G1 (a) and representative failure mode obtained for the sample TT_G1_2 (b).

3.2 Mechanical properties and capacity retention rates

The mechanical properties obtained from the 24 tensile tests are reported in Table 1: mean values of the maximum tensile strength σ_{uf} are displayed alongside the corresponding ultimate

strain values ε_{uf} and the elastic modulus E_f (evaluated in a range of 20%-50% of the tensile capacity). Moreover, following the indication of the International standard ISO10406-1, capacity retention rates were evaluated for the tensile strength (R_σ) and the elastic modulus (R_E), according to the following expressions:

$$R_\sigma = \left(\frac{\sigma_{uf,AK}}{\sigma_{uf,0}} \right) \cdot 100 \quad (1)$$

$$R_E = \left(\frac{E_{f,AK}}{E_{f,0}} \right) \cdot 100 \quad (2)$$

where $\sigma_{uf,AK}$ and $E_{f,AK}$ are the tensile capacity and elastic modulus of the conditioned specimens, respectively, while $\sigma_{uf,0}$ and $E_{f,0}$ are the corresponding reference values for unconditioned ones.

Table 1. Mechanical properties obtained from the tensile tests.

Specimen	σ_{uf} MPa	ε_{uf} %	E_f GPa	R_σ %	R_E %
TT_B1	1817 (6.74)	1.79 (8.26)	103.42 (1.22)	100.0	100.0
TT_B1_AK	924 (3.31)	0.93 (7.33)	103.00 (7.45)	50.9	99.6
TT_B2	1333 (4.10)	1.7277.15 (4.95)	100.0 (0.37)	100.0	TT_B2
TT_B2_AK	951 (10.7)	1.46 (10.0)	65.42 (1.25)	71.3	84.8
TT_B3	1244 (3.70)	1.57 (3.37)	78.81 (0.86)	100.0	100.0
TT_B3_AK	724 (5.17)	1.09 (2.43)	64.93 (0.72)	58.2	82.4
TT_G1	1490 (0.78)	2.03 (1.37)	73.91 (0.98)	100.0	100.0
TT_G1_AK	1339 (3.69)	1.80 (3.72)	74.34 (2.20)	89.9	100.6

(CoV % values are reported in parenthesis)

A strong reduction in terms of tensile capacity was clearly observed in all the basalt fibres systems (B1-B2-B3), with retention rates varying from 50.9% to 71.3%. On the other hand, the effect of the alkaline environment on the tensile behaviour of glass fibres was less prominent, with a retention rate equal to 89.9%. At the same time, elastic modulus values remained almost unchanged for the B1 and G1 materials; conversely B2 and B3 specimen showed affected retention values of 84.8% and 82.4%, respectively.

3.3 SEM analyses

Considering the results obtained in the tensile tests, a series of SEM analyses was carried out using a Tescan Mira 3 FEG-SEM, trying to explain the experimental outcomes and the degradation experienced by the conditioned materials. For this purpose, during the specimen preparation phase, additional textile samples of B1 and G1 materials (denoted as B1_AK and G1_AK in the following) were prepared and cured inside the same conditioning tanks. Subsequently, after making both unconditioned and conditioned samples conductive by sputtering with graphite, they were examined at 100x of magnification.

Figure 8. SEM images of B1 sample at 100x (a) and B1_AK sample at 100x (b).

Figure 9. SEM images of G1 sample at 100x (a) and G1_AK sample at 100x (b).

For the B1 sample, the images (Figure 8a) clearly show that the external coating was already fractured in multiple positions and evident cracks were already present. In these positions, the aggressive attack of the alkaline environment could concentrate its major effects (Figure 8b), causing widespread damage also to the nearby intact surface. This observation can explain the reason why the basalt fibres showed the lowest retention rates after 1000h of conditioning time. On the contrary, the organic coating covering the glass fibres in the unconditioned G1 samples (Figure 9a) seemed almost intact, with some small holes which started developing on the G1_AK sample only (Figure 9b). For this reason, the detrimental effect of the alkaline environment on the glass fibres was mitigated, with medium-high level of capacity retention rate from the tensile tests after 1000h.

4 CONCLUSIONS

In this work, an experimental study was presented on the mechanical behaviour of fibres, commonly used in FRCM systems, when exposed to an alkaline solution. After a series of preliminary tests, the aging solution was chosen and prepared introducing 0.16% of calcium hydroxide, in weight, in distilled water at 23°C. Then, samples made of three different basalt and one glass textiles were cut and immersed inside the solution. The level of alkalinity was controlled periodically to monitor the conditioning process. Tensile tests were then executed,

following standard setup configuration from Italian Guidelines, both on conditioned samples and unconditioned ones, used as reference. A comprehensive comparison was reported, in terms of stress vs strain curves, failure modes and retention rates of strength and deformability values. The strongest effects due to alkaline exposure were observed in the basalt fibres specimens, with reduced capacity retention rate up to 50.9%. On the other hand, glass fibres were less affected and showed higher retention rates after the detrimental exposure. SEM observation of the samples suggested the pivotal role of the coating integrity in influencing the degradation process.

ABSTRACT: The use of inorganic matrix fiber-reinforced systems has been investigated and promoted in the last years for the structural repair and rehabilitation of historical masonry constructions. Fabric Reinforced Cementitious Matrix (FRCM) and Composite Reinforced Mortar (CRM) are the two families of materials that have been studied and put into practice. The high physical-mechanical compatibility with masonry and ease of installation are the key points that made these systems suitable for structural engineering practice. Durability issues related to the presence of an alkaline matrix and aggressive agents in harsh environments are the actual frontier of the research in the field. This experimental study allowed to investigate the mechanical behavior and durability of a Glass Fiber Reinforced Polymer (GFRP) grid and GFRP pultruded bar used respectively as reinforcement and connectors in a new CRM system. Tensile tests were performed before and after aging consisting of separate exposure to moisture, alkaline solutions, freeze-thaw cycles, and marine water. Different exposure times were investigated. Pull-out from different substrates and lap splice tests were also performed on the GFRP connectors. Measurements of the glass transition temperature and electronic microscopy completed the experimental protocol. The results in terms of mechanical comparison between the control and aged specimens are provided and discussed in the paper.

1 INTRODUCTION

Composite materials, constituted by fibers of various nature (carbon, steel, basalt, glass, aramid, PBO or natural fiber) embedded in a matrix constitute a modern generation of strengthening systems widely used in civil engineering. In this scenario two families of fiber reinforced materials are used: FRP (Fiber Reinforced Polymers) that have an organic matrix, and inorganic matrix composites. The materials used in existing masonry are called FRCM (Fabric Reinforced Cementitious Matrix) or CRM (Composite Reinforced Mortar). FRCM and CRM systems are successfully used in masonry construction because of their mechanical compatibility with masonry substrates and the high vapor permeability of mortar. Unfortunately only few works are available in literature on the durability of FRCM and CRM materials. The first studies were related to the use of carbon fibers (Nobili & Signorini 2017; Donnini et al. 2017) and AR-Glass FRCM (Nobili 2016), and others include the study of the durability of the constituent materials, fibers (Micelli & Aiello 2017) and mortar (Nobili 2016). A recent work (Arczewska et al. 2021) put in evidence the essential role of the resin in Glass FRP products, as a protection against the ingress of alkaline

fluids. In this perspective the matrix has also an important role to prevent degradation in terms of inter-laminar shear strength (Pan & Yan 2021; Yu et al. 2021). Another recent study (Wang et al. 2022) illustrated that a small drop in the pH values from 13 to 11 could significantly reduce the alkali-induced fiber erosion and thereby greatly alleviate the tensile strength degradation of conditioned GFRP. In this study the mechanical properties and the durability of the GFRP reinforcements and connectors of a CRM system were investigated. Short and long-term properties were measured and compared by performing different ageing protocols that include immersion in artificial seawater (saline solution), high humidity and alkaline solutions. Connectors were also tested in lap splice and pull-out configurations. The obtained results, in terms of residual mechanical properties are discussed in the paper in order to highlight the influence of potential aggressive environments on the engineering properties of the tested specimens.

2 EXPERIMENTAL PROGRAMME

2.1 Materials and specimens

A new GFRP grid made by glass fibers and epoxy matrix was investigated, named MR44, with a spacing of 40x40 mm. Transversal connectors made by GFRP bars having a nominal diameter of 7 mm were also tested. The GFRP grids were tested under direct tensile force in the two directions, as illustrated in Figure 1. The two directions show a different configuration of the fibers: twisted and flat. Twisted bars are named “warp”, while the flat bars are called “weft”. Specimens were cut from the grid and tested according to ISO 10406-1:2015, as same as done for the connectors that have a cross-section area of 52.28 mm², obtained from experimental tests by weighting. Lap splice tests were also performed for the connectors, by using an overlap length of 100 mm. GFRP connectors were also tested for measuring the highest pull-out force causing the extraction of the connector from a substrate. Four different substrates were used, concrete, limestone masonry, clay bricks masonry and hard stone blocks masonry. An embedded length of 100 mm was used. In Figure 2 the geometry of the specimens is shown: LxBxH are 250x250x350 mm (concrete), 380x380x270 mm (clay), 370x350x230 cm (limestone), 340x250x260 cm (hard stone). In addition to tensile tests, joint-shear tests were performed on specimens that are shown in Figure 2.

Figure 1. GFRP grids and geometry of the tensile specimens - GFRP rebar connector.

Figure 2. Pull-out connectors specimens – joint shear test specimens - lap splice specimens.

2.2 Ageing and test set-up

The durability of the composites materials described above (grids and connectors) was investigated by using protocols of accelerated ageing. Freeze and thaw cycles: the samples were conditioned in a humid chamber for one week (RH > 90%, T= 38±2°C); then they were subjected to 20 cycles of freezing and thawing. Each cycle includes four hours at -18±1 °C, followed by 12 hours in a humid chamber (RH > 90%, T= 38±2°C). Humid environment: conditioning was carried out for 1000 and 3000 hours by immersing the samples in chemically inert water at a temperature of 38±2°C assuring a relative humidity > 90% (ASTM D 2247-11, ASTM E104-02). Saline environment: the conditioning was carried out for 1000 and 3000 hours by immersing the samples in a solution made of 245 g of NaCl and 40.94 g of Na₂SO₄ per 10 liters of distilled water, at a temperature of 23±2 °C (ASTM D1141-98, ASTM C581 -03). Alkaline environment: conditioning was carried out for 1000 and 3000 hours by immersing the samples in a solution composed of Ca(OH)₂ (0.83 g/litre) and distilled water with pH=12.5 (periodically monitored by pH-meter), at a temperature of 23± 2°C.

In Table 1 the total number of specimens and tests are shown.

Table 1. Experimental tests.

Test type	Specimen type and repetitions		
	grid MR44 warp	grid MR44 weft	Connector
Tensile Control specimens	15	15	10
Tensile Freeze-thaw	5	5	5
Tensile Humidity 1000 hrs	5	5	5
Tensile Humidity 3000 hrs	5	5	5
Tensile Saline 1000 hrs	5	5	5
Tensile Saline 3000 hrs	5	5	5
Tensile Alkaline 1000 hrs	5	5	5
Tensile Alkaline 3000 hrs	5	5	5
Pull-out from four substrates	-	-	20
Lap splice	-	-	3
Joint strength	10	10	-

During the ageing period small specimens of GFRP grids were immersed in water at 40°C and the increase of weight was measured twenty times in a period of 2000 hours.

3 TEST RESULTS AND DISCUSSION

All the composites specimens that were subjected to tensile tests until failure exhibited a linear elastic behaviour, as expected from theory. In the following sub sections the results will be presented for each type of material. The values of the elastic modulus reported herein were those measured in the range between 20% and 50% of the ultimate load.

3.1 GFRP grids MR 44

Failure modes of warp and weft specimens were caused by fibers breakage. There were not significant differences in failure modes observed for control and conditioned specimens. The typical circumstances described above are illustrated in Figure 3.

The average values of the tensile strength and elastic modulus are reported in the following Table 2, where A_n is the cross-section area. When the residual properties of conditioned specimens, after ageing, exceed the reference specimens (due to the statistical error), they are reported as 100%.

As reported in the Table 2 the ageing in the different environments did not produce severe reduction of the engineering properties such as ultimate strength and longitudinal stiffness (modulus E).

Figure 4. Absorption curve after 2000hrs in hot water for MR 44 GFRP grid.

This results was observed either after 1000 hours or 3000 hours of immersion. The specimens after ageing were covered by a white film made of solid particles produced by deposition, but at the same time no microcracks or detachments were visible on the matrix surface.

The most important result is that related to the ageing in alkaline environment, since it was potentially the most detrimental condition for glass fibers. It is well known in fact that alkaline attack may produce a chemical degradation of the fibers which causes a physical dissolution due to the hydrolysis. Different degradation mechanisms were observed in literature in presence of alkaline solutions, they include: an effect of the $(OH)^-$ ions which produce corrosion of the fibers; a second effect due to the precipitation of hydration products, which may reduce the flexibility of the fibers and change the behavior at the interface with the inorganic matrix; the presence of chemical products which cause a densification of the matrix at the interface level which may produce a bending effect in the fibers. These effects are avoided by using alkali resistant glass and at the same time when the physical protection provided by the matrix is able to strongly reduce the penetration of fluids also at the interlaminar level. In the case studied herein it was measured that the presence of the alkaline solutions did not produce any effect on the tested GFRP grids, in both directions. In Figure 4 the absorption diagram is shown for the GFRP specimens immersed in hot water for 2000 hours, after twenty weight measurements. From the diagram it is observed that at the early stages

the weight increase follows a pseudo linear trend, which is typically described by the Fick's law. After 1500 hours a knee-point is visible, where the slope of the curve lies in a horizontal branch, which indicates that absorption process is almost complete and the weight increase is not expected to develop in a significant way. The weight increase remained lower than 2.5% which is a measure of the very low permeability of the epoxy resin used as matrix in the studied reinforcement. This confirms the high values of the retained strength after ageing in the moist environments used for the studied durability protocols. The tests performed to measure the joint shear strength on MR 44 grid revealed a maximum load of 2.08 kN and 0.99 kN, as average values respectively for warp and weft specimens. Coefficient of variations were respectively 7.7% and 13.1%, thus the results can be considered free from significant experimental errors. The high difference between the two directions is due to the different technology used to join the two filaments, as visible in Figure 1. The warp filament is glued to the weft filament which is inserted into a sort of buttonhole created inside the warp filament. This produced a sort of mechanical interlock along the warp direction under tensile forces. While along the weft direction the failure is due to the sliding of the weft filament inside the buttonhole. Three DSC tests (Differential Scanning Calorimetry) were performed on the epoxy resin before and after ageing in hot water. The control specimens have shown an average glass transition temperature of 75.3 °C which was almost the same for the aged specimens. This confirmed that no significant changes were produced at the matrix level. In order to detect possible damages on the glass fibers scanning electronic microscopy (SEM) was applied to MR 44 specimens aged after 3000 hours in alkaline bath. A SEM view of the aged fibers is shown in Figure 5. Some solid precipitates are visible on the surface of the glass fibers, but no damage is detectable. This confirms the good durability of the composite reinforcement, as measured through the mechanical tests.

Figure 5. SEM microscopy after ageing in alkaline solution (3000 hrs) - GFRP grid MR44.

3.2 GFRP connectors

GFRP connectors are made by GFRP pultruded bars, by using the same glass fibers and resin of MR 44 grids. The alignment of the fibers and good impregnation are the most important technological parameters that may assure a good mechanical response in terms of engineering properties. When subjected to tensile forces up to the ultimate strain value, the failure modes of GFRP connectors were characterized by fiber rupture far from the gripping area, which was accompanied, in some cases, to an intralaminar failure inside the resin or at the fiber/matrix interface. Typical failure modes of the tested GFRP rods are shown in Figure 6. In this kind of specimens the failure of aged specimens evidenced in more cases a failure mode characterized by the presence of a delamination mechanism, accompanying the fiber breakage, as evident in the last picture of Figure 6.

The results of the tensile tests on GFRP connectors are reported in Table 3.

Freeze-thaw cycles did not produce a reduction of the engineering properties that could be considered meaningful for design applications. The same conclusion can be addressed to the aged specimens in saline solution, after 1000 hours. A reduction of about 12% in ultimate strength was observed after 3000 hours of immersion in saline solution. The aged rods demonstrated to be more sensitive in presence of humidity and alkaline solutions, especially after 3000 hours. The reduction in ultimate strength was respectively about 12% and 18% after ageing in humid and alkaline bath.

Three DSC tests (Differential Scanning Calorimetry) were performed on the epoxy resin of the connectors before and after ageing in hot water. Aged and unaged specimens have shown the same behavior (average $T_g=77.1$ °C). The tensile tests on the lap splice configuration, with a superposition of 100 mm, exhibited an ultimate force that was about 5 times lower than the average ultimate tensile force. A maximum force of 6.51 kN was recorded as average value of the tested bars, corresponding to a maximum tensile stress of 124.53 MPa. The maximum force of extraction from different substrates varied, in relationship to the single material that was considered. This because the mechanical properties of the substrates were very different from each other. The compressive strength of the four substrates was measured by performing uniaxial compression tests that

evidenced the following average values: $f_m=12.2$ MPa for clay bricks masonry with cement mortar joints; $f_c=34.3$ MPa for concrete; $f_m=4.8$ MPa for masonry made with soft limestone squared blocks and lime based mortar; $f_m=4.8$ MPa for blocks of hard stone and lime based mortar. In this last case failure was governed by cracks along the irregular mortar joints. The test typical failure modes of the pull-out tests are shown in Figure 7.

Figure 7. Set-up and failure modes of pull-out tests.

Concrete elements with embedded GFRP did not present any crack, and the failure was due to tensile breakage of the fibers at an average ultimate load of 27.9 kN which is fully comparable to the values of the tensile tests. Therefore the length of 100 mm inside concrete provided a full anchorage of the bar. For GFRP connectors glued inside soft limestone masonry blocks, the pull-out load was the lowest (average value equal to 12.9 kN), respect to the other substrates. In this case the failure was caused by an adhesive debonding, as visible in Figure 7. For hard stone and clay bricks the failure modes were similar (splitting failure), as visible in Figure 7. The ultimate load for clay bricks was 21.2 kN, higher than hard stone that recorded an average ultimate load of 16.4 kN.

4 CONCLUSIONS

An experimental study has been presented on GFRP reinforcements and connectors used in a Composite Reinforced Mortar system, commonly applied for the structural strengthening of masonry construction. The mechanical properties have been investigated in the short term, and after ageing in different aggressive solutions. The results confirmed that the presence of a good polymeric matrix can act as a protective agent for the impregnated fibers. The residual mechanical properties after ageing were very high in all cases. The maximum reduction of 18% for GFRP connectors was observed after immersion in alkaline solutions for 3000 hours.

Performance and environmental analysis of Reclaimed Asphalt Pavement (RAP) concrete produced in industrial environment

G. Masi, A. Michelacci, S. Manzi, A. degli Esposti, B. De Pascale, A. Bonoli & M.C. Bignozzi

Department of Civil, Chemical, Environmental and Materials Engineering, University of Bologna, Bologna, Italy

ABSTRACT: This study aims at evaluating the performances of reclaimed asphalt pavement (RAP) as concrete aggregate replacement in terms of mechanical and physical properties and environmental analysis. RAP concrete production was scaled up and it occurred in an industrial environment (CTI, Imola, Italy) by preparing a 3.5 m³ concrete casting. A partial aggregate replacement of 40% of RAP was fixed to ensure acceptable workability and mechanical performance. For comparison's sake, the same concrete mix with 100% natural aggregates was also tested. Concrete performances in terms of mechanical and physical properties were checked initially after 7 and 28 days of curing. Environmental analysis of RAP concrete was also carried out using Life Cycle Assessment (LCA) analysis applying a “cradle-to-gate” approach. All the realistic input data collected from the industry plant were considered. Durability tests are ongoing and freezing-thawing resistance and exposure to salt spray chamber on unreinforced and reinforced concrete specimens will be evaluated. As main outcomes, even if inferior mechanical properties were obtained in terms of compressive, tensile strength and elastic modulus values, a relevant reduction (average value of 15%) of environmental impacts was found especially related to global warming potential, terrestrial ecotoxicity, human non-carcinogenic toxicity and fossil resource scarcity. This study is set in the framework of “Sustainable concrete made with recycled asphalt pavement (RAPCON)” project (2020–2023), funded by Cariplo Foundation under the “Circular Economy for a sustainable future” call (2019).

1 INTRODUCTION

In order to improve the environmental sustainability of concrete, several routes have been and are currently investigated. Mainly the use of supplementary cementitious materials (SCMs) or alkali activated binders as cement replacement or the recycling of construction and demolition waste (CDW) as aggregate replacement, as well as the combination of these strategies, have shown promising results (Boobalan *et al.*, 2022). As aggregates usually represent about the 80% of a concrete mix and are the mostly used materials after water, using recycled aggregates from CDW is a promising route to improve concrete sustainability (de Brito and Kurda, 2021). Among the others, reclaimed asphalt pavement (RAP) has been widely studied as potential concrete aggregate from CDW (Debbarma, Selvam and Singh, 2020; Nandi and Ransinchung, 2021). RAP consists of natural aggregates covered by a bituminous layer and dust film, and it is derived from demolition and milling processes during asphalt pavement maintenance (Singh, Ransinchung and Kumar, 2017). A recent study has highlighted the suitability of RAP as recycled concrete aggregate thanks to its good dimensional stability and freezing and thawing resistance (Masi *et al.*, 2022). However, the presence of the bituminous layer can hinder the overall performances of concrete at the fresh and hardened state.

Increasing the RAP content in concrete mix induces a decrease in the mechanical performance due to moderate adhesion between the bituminous layer and the cement binder (Huang, Shu and Li, 2005; Al-Oraimi, Hassan and Hago, 2009; Hossiney, Tia and Bergin, 2010; Brand and Roesler, 2017). Other studies have highlighted the negative effect of RAP in the workability of fresh concrete (Huang, Shu and Burdette, 2006; Al-Oraimi, Hassan and Hago, 2009). Thus, a preliminary characterization protocol of RAP as concrete aggregate is fundamental to ensure the final concrete performance (Masi *et al.*, 2022). On the other hand, the use of RAP as concrete aggregate can improve some mechanical and durability properties, such as toughness and freezing and thawing resistance, respectively, due to different pore size distribution and the presence of the bituminous layer (Huang, Shu and Li, 2005; Huang, Shu and Burdette, 2006; Abraham and Ransinchung, 2019). The limited use of this type of CDW as recycled concrete aggregate is surely related to the lack of specific guidelines and standards and also to limited systematic information related to the environmental sustainability of RAP when used as concrete aggregate replacement (i.e., life cycle assessment (LCA)). Few studies are currently available in literature reporting LCA analyses and are mainly related to specific applications such as concrete slab production (Shi, Mukhopadhyay and Zollinger, 2018), precast concrete blocks (Nandi and Ransinchung, 2021) and cement-based pavement layers (Bressi, Primavera and Santos, 2022).

So, this study investigates the mechanical performances (i.e., compressive, tensile strength and elastic modulus) and their correlation with some physical properties (i.e., geometric density and open porosity) of a concrete mix produced by 40% RAP as replacement for concrete aggregates. A reference concrete mix (with 100% natural aggregates) was also prepared and tested for comparison purpose. All concrete mixes were prepared in a real industrial environment (CTI, Imola, Italy) by formulating 3.5 m³ for each investigated mix. In addition, the main environmental impacts for both the investigated concrete are studied using LCA analysis, applying a “cradle-to-gate” approach and considering 3.5 m³ concrete mix as the functional unit. All the input data for the LCA analysis have been kindly provided by CTI industrial plant, so as to build a realistic case study that well simulates the production of RAP-based concrete. This study reports the first results of the task related to the “validation in industrial relevant environment” of the project “Sustainable concrete made with recycled asphalt pavement” (RAP-CON, 2020-2023) granted by Fondazione Cariplo (“Circular Economy for a sustainable future” call, 2019).

2 MATERIALS AND METHODS

2.1 Materials

For preparing concrete mixes, CEM III/A 42.5 R was used together with superplasticizer (MasterEase 7007, Master Builder solution) as admixture. Natural siliceous aggregates were used with a maximum diameter of 16 mm. The applied RAP was kindly provided by CTI with a maximum diameter of 16 mm. Figure 1 reports images of RAP stored in the CTI plant and their particle size distribution.

Figure 1. Images of RAP in the industrial plant and particle size distribution of the used RAP.

2.2 Mix design and sample preparation

Concrete mixes were prepared in CTI industrial plant located in Imola (Bologna, Italy). Two different concrete mixes were formulated by using 100% natural aggregates (CNAT used as reference mix) and a 40% RAP replacement (CRAP). Both these mixes were prepared in order to produce 3.5 m³ concrete using the mix design reported in Table 1. The material dosage was designed in order to produce both CRAP and CNAT characterized by C32/40 strength class and a S4 slump class. For both the mixes, the water (considering both the added water and the humidity of the aggregate) to cement ratio (W/C) was kept constant and equal to 0.448. After mixing procedures, slump test was carried out to validate the targeted slump class (S4) and values of 170 and 185 mm were measured for CRAP and CNAT, respectively. Then, fresh concrete was cast in sample holders and compacted by using concrete vibrator. Lastly, curing was performed for 7 and 28 days at 20 °C with a relative humidity of 95%. For this study, the following samples were used for each mix and curing time: 10 cubic samples (with the edge of 150 mm) for compressive strength and geometric density measurements, 3 cylindrical sample (with 150 mm diameter and 300 mm height) for tensile strength and other 3 cylindrical samples (with the same dimensions) for elastic modulus determination.

Table 1. Mix design for producing 1 m³ of concrete.

	Material dosages (kg/m ³)					
	Cement	Water	Additives	Gravel	Sand	RAP
CNAT	375	127	3.86	971	840	-
CRAP	380	137	3.58	461	628	696

2.3 Characterization

Geometric density was calculated by dividing the dry mass of cubic sample by its geometric volume. The reported results are an average of at least 3 repeated measurements.

Mechanical performances of CRAP and CNAT samples were evaluated in terms of compressive, tensile splitting strength and elastic modulus measurements. Compressive strength was determined in accordance with the EN 12390-3 standard (*EN 12390-3 Testing hardened concrete: compressive strength of test specimens*, 2019) as the ratio of the maximum load at failure and cross-sectional area of the cubic specimen. The reported results are the average of 10 measurements on cubic samples (L=150 mm). Tensile splitting strength was performed on 2 cylindrical samples (D=100 mm and H=200 mm) according EN 12390-6 standard (*EN 12390-6 Testing hardened concrete: tensile splitting strength of test specimens*, 2009). Elastic modulus was measured in accordance with EN 12390-13 (*EN 12390-13 Testing hardened concrete: determination of secant modulus of elasticity in compression*, 2013) on 3 cylindrical samples (D=150 mm and H=300 mm).

Lastly, to determine the open porosity and the average pore diameters of the two concrete mixes at the different curing time, mercury intrusion porosimetry (MIP) using Pascal 140 and 240 instruments (Thermo Fisher Scientific). MIP analyses were performed onto concrete samples of about 1 cm³ (avoiding external surfaces) in triplicate.

2.4 Life Cycle Assessment (LCA)

LCA analysis was carried out using Simapro 9.2 software in accordance with ISO 14040 standard series (*ISO 14040 Environmental management - life cycle assessment - principles and framework*, 2006th ed., 2020). The objective of the analysis is the evaluation of the environmental impact of a cement mix produced in an industrial scenario applying 40% RAP as replacement for natural aggregate, compared with a control mix made with 100% natural aggregate. The system boundary is set on a “cradle-to-gate” approach (i.e., from materials extraction/production to concrete production at the batching plant). In details, the RAP

production phases take into account the impacts related to the treatments (crushing and screening) at the CTI plant, while milling and transportation to the CTI plant of asphalt waste are not considered in the analysis because they are part of the previous product system (Santos, Flintsch and Ferreira, 2017; Vandewalle *et al.*, 2020). The functional unit (FU) used in the present study is 3.5 m³ of concrete. Data on the impacts generated by extraction/production of materials commonly used in concrete (i.e., cement, water, natural aggregates, and plasticizers) were obtained from the Ecoinvent 3.8 database available on the SimaPro software. The transportation conditions considered for each material are based on CTI suppliers. Materials were modeled starting from the inventory data and some specific data were implemented using information from CTI, as reported in Table 2.

Table 2. Materials used in investigated concrete mixes and their transportation distances considered in the analysis.

Material	Material dataset	Origin	Destination	Transportation dataset	Distance (km)
CEM III/A 42.5 R	Cement, blast furnace slag 36-65%	Cement supplier	CTI Batching plant	Transport, freight, lorry	60
Water	Tap water	-	CTI Batching plant	-	-
Plasticizer	Polycarboxylates, 40% active substance	Supplier	CTI Batching plant	Transport, freight, lorry	214
Gravel	Gravel, crushed	Quarry	CTI Batching plant	Transport, freight, lorry	18
Sand	Sand	Quarry	CTI Batching plant	Transport, freight, lorry	18

Since CTI also operates in the field of pavements, the company directly recovers waste generated from the milling of pavements following maintenance work. Waste is crushed and screened with a diesel-powered machinery (CAMS CENTAURO 100/32) consuming 0.325 L/t_{RAP} of diesel under conditions of high productivity. The processed waste is known as RAP, ready to be used as recycled aggregate. Both RAP processing and concrete production take place in the CTI plant. To enhance the use of RAP as natural aggregate replacement for concrete production, a credit for the designed system has been considered (Pantini, Borghi and Rigamonti, 2018) as shown in Table 3. More specifically, the use of 40% of RAP in concrete mixture avoids not only the use, but also the production of 2356 kg of natural aggregate (1614 kg of gravel and 742 kg of sand) for 3.5 m³ of concrete and its transportation from the quarry to the CTI plant.

A mixing plant working with about 10 kWh for 3.5 m³ of concrete was considered as the last step in concrete production. The method used for the analysis is ReCiPe 2016 at the mid-point level in hierarchist (H) perspective, which addresses 18 impact categories.

3 RESULTS AND DISCUSSION

3.1 Concrete properties

First results of mechanical performance and physical properties of CRAP and CNAT after 7 and 28 days of curing are reported in Table 3.

In general, CRAP exhibits inferior mechanical properties in terms of compressive, tensile strength and elastic modulus compared to CNAT. This is related to the porosity of the samples, as shown by the reduction in geometric density related to the use of RAP as aggregate replacement. On the other hand, considering the different curing time, while CNAT reaches compressive strength slightly higher than 40 MPa (the strength target of the mix design)

Table 3. Mechanical and physical properties of concrete made with natural and RAP aggregates after 7 and 28 days of curing.

Sample	Geometric density (ρ , g/cm ³)	Compressive strength (R_c , MPa)	Elastic modulus (E_d , GPa)	Tensile strength (f_t , MPa)	Open porosity (%)	Median pore diameter (μ m)
CNAT-7	2.21±0.04	41±2	29.2±0.5	3.2±0.2	10.9±0.5	0.025±0.001
CRAP-7	2.03±0.01	25±2	21.6±0.1	2.6±0.3	19±4	0.17±0.06
CNAT-28	2.20±0.03	52±3	43±3	2.9±0.4	9.8±0.2	0.021±0.001
CRAP-28	2.02±0.01	34±1	26±5	2.3±0.2	18±2	0.09±0.06

already after 7 days of curing, CRAP shows slightly lower values than expected even after 28 days. This result is also partly related to a small addition of water (about 30 L for the whole 3.5 m³ mix) during the concrete preparation for workability reasons even if the overall W/B ratio (considering both the added water and aggregate humidity) does not change. More in detail, while tensile strength values can be considered constant for both the concrete mixes and considered curing time, compressive strength and elastic modulus values exhibit a significant increase for both CRAP and CNAT passing from 7 to 28 days of curing: CRAP exhibits a compressive strength of 25 MPa after 7 days and 34 MPa after 28 days, representing an increase of 36%, and an elastic modulus of 22 GPa and 26 GPa after 7 and 28 days, respectively, representing a 20% increase. CNAT shows compressive strength values of 41 and 52 MPa for 7 and 28 days, respectively (a correspondent increase of 27%) and elastic modulus values of 29 GPa after 7 days and 43 GPa after 28 days, representing a 47% increase. These inferior mechanical performances measured for this mix where 40% RAP has been used are quite expected results based on the literature analysis (Huang, Shu and Li, 2005; Al-Oraimi, Hassan and Hago, 2009; Hossiney, Tia and Bergin, 2010).

More interestingly, Table 3 also reports the outcomes of the MIP measurements in terms of open porosity and median pore diameters. For both 7 and 28 days of curing, open porosity measured for CRAP is higher than the ones measured for CNAT. These results well highlight that CRAP is more porous and characterized by larger pores. This difference in pore size distribution is an important key in terms of durability. In fact, pore size distribution towards larger pores induces a decrease in the crystallization pressure of water or salts when samples are exposed to freezing and thawing or salt crystallization cycles (Scherer, 1999). Therefore, these results are quite encouraging regarding durability tests in terms of frost resistance that are currently ongoing, indicating that probably CRAP will show good durability performance in this regard (Thomas, Fellows and Sorensen, 2018). However, due to the fact that RAP is partially replaced as concrete aggregate and is distributed more or less evenly throughout the concrete, a dedicated investigation is currently ongoing to validate the durability performance in terms of frost resistance.

3.2 LCA analysis

The environmental impacts related to both the analyzed mixes are reported in Table 4.

Four categories show significant impact values: global warming potential (GWP), terrestrial ecotoxicity (TE), human non-carcinogenic toxicity (HNCT) and fossil resource scarcity (FRS). CRAP exhibits variations equal to -5% in GWP, -18% in TE, -15% in HNCT and -12% in FRS compared to CNAT. Generally, the production of 3.5 m³ of CRAP shows lower values than CNAT for each of the considered impact categories, with an average reduction of about 15%. Thus, the 40% of RAP in the concrete mix brings significant benefits, as remarked in Figure 2.

The impact related to each input data was evaluated for both CNAT and CRAP for the 4 categories in which concrete is most impactful (Figure 3): raw material production, power consumption (electricity) for concrete mixing, all the considered transportation phases and the credits related to avoided use of natural aggregates.

Table 4. Results of LCA analysis in terms of the 18 impact categories addressed by the Recipe midpoint (H) method for 3.5 m³ of concrete made with natural aggregate (CNAT) and concrete containing 40% of RAP in mixture (CRAP).

Impact category	Unit	CNAT	CRAP
Global warming potential (GWP)	kg CO ₂ eq	7.71×10 ²	7.33×10 ²
Stratospheric ozone depletion (SOD)	kg CFC11 eq	1.30×10 ⁻⁴	1.09×10 ⁻⁴
Ionizing radiation (IR)	kBq Co-60 eq	4.23×10 ¹	3.67×10 ¹
Ozone formation - Human health (OF1)	kg NO _x eq	1.49×10 ⁰	1.30×10 ⁰
Fine particulate matter formation (FPMF)	kg PM2.5 eq	6.40×10 ⁻¹	5.60×10 ⁻¹
Ozone formation - Terrestrial ecosystems (OZ2)	kg NO _x eq	1.51×10 ⁰	1.32×10 ⁰
Terrestrial acidification (TA)	kg SO ₂ eq	1.67×10 ⁰	1.51×10 ⁰
Freshwater eutrophication (FE)	kg P eq	1.50×10 ⁻¹	1.30×10 ⁻¹
Marine eutrophication (MEu)	kg N eq	1.00×10 ⁻²	1.00×10 ⁻²

Figure 2. Impact categories addressed by the Recipe midpoint (H) method for 3.5 m³ of concrete made with natural aggregate (CNAT) and concrete containing 40% of RAP in mixture (CRAP). Results are shown according to internal normalization.

Firstly, cement production is the most critical stage for most of the total impact of each category: it is responsible of about the 90% of CO₂ emissions for both concrete mixes, where a 5% reduction of GWP category was measured in CRAP due to RAP incorporation. Transportation is the most relevant stage after cement production. Thus, a unique RAP processing and concrete batching plant is a favorable condition (as in the considered industrial plant). In addition, the advantage associated with the reduction of natural aggregate in mixture is greatly appreciated in TE category. In HNCT and FRS categories, natural aggregate production follows cement in impact. Water and RAP production exhibit almost no impact, but they were still reported for completeness. Lastly, the registered impact reduction for CRAP is mainly due to the avoided use of natural aggregates (Pantini, Borghi and Rigamonti, 2018).

Figure 3. Impact assessment for each input data: CEM III (blast furnace slag cement), water (framed with a continuous blue line), plasticizer, natural aggregate (sand and gravel), RAP (framed with an orange dotted line), electricity for concrete mixture, transport (as the total transport of all materials involved in concrete production) and the avoided natural aggregate (due to the use of RAP as recycled aggregate).

4 CONCLUSIONS

This study reports preliminary results in terms of mechanical and physical properties, as well as the environmental assessment by life cycle analysis (LCA) of concrete mixes prepared in a real industrial environment by partially replacing natural aggregates with Reclaimed Asphalt Pavement (RAP). In this study, a 3.5 m³ concrete mix with a replacement of 40% RAP has been evaluated. The main results can be drawn as follows:

- concrete with 40% RAP exhibits inferior mechanical properties in terms of compressive, tensile strength and elastic modulus for both 7 and 28 days compared to concrete with 100% natural aggregate (reference mix). These findings are mainly related to higher porosity of the mix with RAP incorporation as highlighted by the lower geometric density and MIP analysis results. In addition, incorporation of RAP as concrete aggregates also induces higher average pore diameters of one order of magnitude for both considered curing times.
- The incorporation of RAP (40%) induces a beneficial effect in terms of environmental impacts, as highlighted by LCA analysis. Especially for the most significant impact categories for concrete production, such as global warming potential, terrestrial ecotoxicity, human non-carcinogenic toxicity and fossil resource scarcity, a relevant reduction has been measured of an average value of 15%. Surely, increasing the RAP replacement a more significant reduction in the environmental impacts can be measured. However, higher RAP amount can strongly hinder the mechanical performances of resulting concrete. Thus, a complete characterization in terms of materials and environmental performance is a fundamental approach for sustainable building materials designing.

ACKNOWLEDGEMENTS

This study was carried out in the framework of RAPCON (“Sustainable concrete made with recycled asphalt pavement”) project (2020–2023), under the “Circular Economy for a sustainable future” call (2019) funded by Cariplo Foundation. The authors would like to acknowledge Eng. Luca Guardigli (CTI, Imola) and Mr. Paolo Carta (University of Bologna) for their precious help in preparing and testing concrete samples.

Life extension of existing steel reinforced structures by simple cathodic protection techniques for sustainable durability

G. Sergi

Vector Corrosion Technologies Ltd, West Midlands, UK

ABSTRACT: The most successful technique for controlling reinforcement corrosion of structural elements is Cathodic Protection (CP) which became well-established and acceptable over the last decades. Long-term maintenance of impressed current cathodic protection systems (ICCP), however, started to be seen as a burden to most structure owners and managers as it involves additional and continual costs. A requirement arose, therefore, for simpler CP systems to be made available which will involve less maintenance and monitoring requirements. As a first stage to simpler systems, galvanic cathodic protection anodes were developed in the 1990's, first, only to protect steel reinforcement immediately around patch repairs but subsequently to control reinforcement corrosion over wider areas where corrosion risk was found to be high. It was the combination of ICCP and galvanic anode systems, however, that set the benchmark for a simpler alternative long-term method for corrosion control of steel reinforcement. This paper attempts to follow the development of all galvanic CP systems utilised for atmospherically exposed steel reinforced structural elements and looks at recently developed simpler cost-effective systems and methodologies that would likely form the future of the CP industry and improve durability and sustainability of existing structures and buildings.

1 BACKGROUND

Concrete can be a very durable material. There are many examples of concrete structures that have remained serviceable for millennia such as the Pantheon in Rome. A greater risk for deterioration of concrete structures was created when steel reinforcement was introduced for improved tensile strength. Fresh and relatively new concrete normally contains an alkaline pore liquid phase which protects embedded steel from corrosion by allowing a highly dense passive oxide film to develop on its surface when oxygen is available. This form of protection can be lost, however, if the concrete undergoes either carbonation or chloride contamination in the vicinity of the steel. Such effects can lead to cracking and spalling of the cover concrete. There have been too many structures where corrosion was allowed to continue until they were no longer serviceable and led to their demolition and replacement.

Although modern standards (EN 1990) look for 100-year designs for monumental and historical structures, bridges and other civil engineering structures, it is still the case that deterioration occurs often within 20-30 years of construction. In most cases, the issue is corrosion of the steel reinforcement. This has been recognised by the Strategic Highway Research Programme in the USA (SHRP 2) who published a document which deals not only with the design of bridges for 100 or more years service life but, more appropriately, with the extension of the service life of existing bridges to beyond 100 years.

Cement production is now seen as a major issue with a massive carbon dioxide footprint. It is estimated that one tonne of cement produces 900 kg of CO₂ and globally cement production represents around one billion tonnes of CO₂ release annually. If manufacture of aggregate, steel reinforcement and transport of the products is taken into account, the carbon footprint rises to 1.5 billion tonnes of CO₂ per year. It makes perfect sense, therefore, to extend the surface life of structures to as long as realistically possible rather than demolish and reconstruct even if the structure requires downgrading or a change of use. As steel reinforcement corrosion is one of the most common deterioration processes of structures, developing and improving steel reinforcement protection techniques is of the utmost importance.

1.1 Cathodic protection

Cathodic protection has been established as the most successful process for controlling corrosion of the steel reinforcement. A major development in steel protection since the early 1990's has been the introduction and establishment of galvanic anodes. They were originally used to control the formation of incipient anodes, often described as the 'ring effect', around the periphery of patch repairs (Sergi & Page 1999), simply by attaching galvanic anodes to the exposed steel around the perimeter of patch repairs prior to the application of the repair material (Figure 1a). Subsequently, more and more applications of continuously improving galvanic anodes have been established (Sergi & Seneviratne, 2014) with anodes placed in a grid formation for more general corrosion control (Figure 1b) or along the exposed steel reinforcement where applicable (Figure 1c)

Figure 1. Alkali activated galvanic anodes, (a) as in inset, attached to steel reinforcement prior to the application of the repair material, (b) as in inset, inserted in a grid formation in drilled holes and (c) as 'rods' positioned along steel reinforcement in an expansion joint prior to the placing of the repair mortar.

That galvanic anodes control steel reinforcement adequately was demonstrated elegantly in large slabs in India (Krishnan et.al. 2019). These had dimensions of 1 m x 1 m x 0.25 m. Some had nine galvanic anodes attached to the steel members in a 3 x 3 grid configuration and some were cast with no anodes. All had 2% chloride by weight of cement additions in the mix water, a level that would normally cause significant corrosion of the steel reinforcement. After 10 years of exposure in the outdoor warm and humid conditions of Mumbai, the slabs containing the anodes remained intact while the slabs with no anodes had suffered from severe corrosion and cracking of the concrete cover (Figure 2).

Figure 2. Slab protected by galvanic anodes (left) and corroded slab without anode protection (right) showing extent of cracking of the concrete caused by steel corrosion after exposure to outdoor warm and humid conditions for over 10 years.

Figure 3. Reduction of mean current output of galvanic anodes embedded in structural elements of a bridge in the UK. Notice the variability caused by temperature.

2 LESSONS OBSERVED FROM LONG-TERM DATA

A major discovery with regard to galvanic anodes has been made from their long-term monitoring. Results from a 23-year field trial in the UK has indicated that the current output of alkali-activated galvanic anodes diminished approximately exponentially.

What is striking from Figure 3, is the different rates of exponential decay of the anode sets, described here as an Aging Factor (AF), in the three different structural elements. AF is the time it takes for the current output to be halved. The halving is repeated over the same period as would be expected in a half-life decay. Even though the anodes in the beam and in Column-1 are identical and were installed at the same time, the observed Aging Factor of each set is very different. Current output for the beam approximately halved over a 7-year period compared to a 4.8-year period for Column-1. As both structural elements are part of the same structure, concrete quality and steel density are expected to be comparable. The environment and concrete resistivity have been consistently similar over the whole exposure period. Only the spacing between adjacent anodes was different. In the beam the anodes were set at a spacing-on-centre of 600 mm whereas in Column-1 the spacing was 750 mm. The early current output of the anodes (Figure 3) was clearly affected by the anode spacing. In the beam the first mean maximum current output of individual anodes was of the order of 300 μA but in Column-1 this was in excess of 500 μA . This high current in Column-1 at the beginning was induced by the greater steel surface area that each anode in the set was required to protect. Consequently, the current output diminished more rapidly in Column-1.

In Column-2 of the same bridge but installed 10 years later, anodes of higher surface area, which were capable of delivering higher currents, were set out at only 300 mm centres so were not pushed to deliver current at the high rates of the earlier anodes resulting in a much-improved Aging Factor of 12.8 years. The reason why there is a diminishing performance when the anodes were forced to deliver a very high current early on is because the corrosion products, initially soluble zincate ions, are less likely to migrate away from the zinc/mortar interface before precipitating as solid zinc oxide hence blocking the pore system around the interface and reducing the volume of current paths.

By studying long term results from over a dozen monitored sites of alkali-activated anodes, the values determined for the Aging Factor were found to vary between 5 and 14 years. This compares very favourably with halide activated anodes (chloride, bromide) which achieve an Aging Factor of less than 3.8 years (Sergi & Seneviratne, 2021, Whitmore & Sergi, 2021).

In a strong alkali-activating medium, as is the case with the anode encasing mortar used for the above-mentioned anodes, zinc, following its dissolution, exists as soluble zincate ions which are able to migrate within the pore structure of the encasing mortar. When supersaturation of zincate gradually occurs, it precipitates out as zinc oxide (Sergi & Seneviratne, 2021, Sergi et. al., 2021). The fast early production of zincate ions in the case of Column-1 would have restricted their migration further into the encasing mortar pores as supersaturation occurred so zinc oxide would have formed close to the zinc/mortar interface reducing the immediate porosity around the zinc metal and slowing down further dissolution of the metal. The lower early current of the anodes in the beam and, particularly of the larger anodes in Column-2, ensured a gentler zinc dissolution, which permitted the zinc corrosion products to migrate further into the mortar pore structure allowing a more open path for electrolytic current flow (Sergi & Seneviratne, 2021).

The importance of the Aging Factor in the design of galvanic CP systems is considerable as the current density at a future time can be accurately estimated in order to design for long-term protection. Figure 4 demonstrates this elegantly. An alkali-activated anode set is, in this case, required to achieve a specific current density of 0.4 mA/m^2 at 20 years. For an Aging Factor of 11.5 years, the anode layout would need to be designed to deliver an early current density of around 2 mA/m^2 . Furthermore, the design will maintain a current density above 0.2 mA/m^2 even beyond 30 years. A typical halide anode set would require an initial current density of around 800 mA/m^2 in order to achieve the required 0.4 mA/m^2 at 20 years, clearly an improbability.

The current density was also found to vary with concrete temperature. Analysis of data sets of current output of galvanic anodes in relation to the concrete temperature had shown that the level of current output is related to the reciprocal of the absolute temperature according to the Arrhenius equation (Equation 1) as depicted in Figure 5.

$$k = Ae^{-\frac{Ea}{RT}} \quad (1)$$

Where, k = Rate constant, A = Frequency factor, Ea = Activation energy, R = Universal gas constant, T = Absolute temperature (K)

Figure 4. Anode current density vs time for two types of anode with different Aging Factors such that both anodes provide a current density of 0.4 mA/m² at 20 years.

Figure 5. Relationship between the reciprocal of the concrete temperature in K and the logarithm of current output of the anode.

A form of the equation (Emran, 2016) relates the corrosion rate, i.e. the current output from the zinc, to the reciprocal of temperature (Equation 2).

$$\text{Log}i_{corr} = \log A - \left(\frac{\Delta E_a}{2.303RT} \right) \quad (2)$$

Where, i_{corr} = Corrosion current of zinc metal, ΔE_a = Apparent activation energy of the corrosion process.

The relationship shown represents a doubling of current density every 10-15°C increase in temperature over ambient conditions. The same variation of current output with temperature was seen in all monitored galvanic CP installations (see, for example, Figure 3). This knowledge allows a better calculation of the required current density for particular climatic conditions, for example, a higher current output will be expected in tropical conditions compared to cooler climates.

3 THE NEED FOR SIMPLER ICCP SYSTEMS

There is no doubt that ICCP of steel reinforced concrete has, over the last decades, become a well-established technique for controlling reinforcement corrosion of structural elements. The expectation of long-life protection has, however, been somewhat reduced as some anode systems fail, monitoring equipment become antiquated, and lack of adequate maintenance makes the systems inoperable with the average service life of any CP system falling to 15 years (Polder et. al., 2014). Inevitable additional costs are involved in maintaining and prolonging correct operation of the system. It appears that there is a requirement by structure managers and owners for simpler CP systems which will involve less maintenance and monitoring requirements.

ISO EN 12696:2022 has clear performance criteria that need to be continuously satisfied to ensure that the system is working. A much-used criterion is that a depolarisation potential of 100 mV should be achieved when the system is temporarily turned off for a period of 24 hours. The standard also defines that a successful CP system either passivates the steel or reduces the corrosion rate of the steel reinforcement which implies, correctly, that achieving 100 mV of polarisation does not necessarily mean that corrosion has been arrested short-term. Nonetheless, it has been shown in several cases that if a CP system is running for an extended period, e.g. 5 years, and is then turned off, corrosion of the steel does not reinitiate over a significant time period (Christodoulou et. al., 2010). This phenomenon is believed to be caused by some secondary effects, primarily, the increase in alkalinity and reduction in chloride concentration at the steel/concrete interface (Sergi & Seneviratne, 2014), which in effect reduces the $[\text{Cl}^-]/[\text{OH}^-]$ ratio considerably below the critical ratio for initiation or maintenance of corrosion. It has also been suggested that realisation of the acidified pits occurs which allows steel repassivation within them (Glass & Davison, 2010).

3.1 A two-stage corrosion control system

It was soon realised that a system that can arrest steel corrosion relatively early and can then switch to cathodic prevention mode over the longer term is realistically possible. It was important, however, to identify the desired current density and overall charge delivery to the

steel reinforcement for successful corrosion arrest to occur before the current density is reduced to the lower cathodic prevention current density levels (0.4-2 mA/m²) which have been shown to be easily achieved by galvanic anodes (Sergi, 2011).

To develop a viable Stage-1 procedure in which corrosion arrest of corroding steel can be achieved, a series of experiments were conducted, the results of which are published elsewhere (Rathod et. al., 2018). What was discovered was very interesting. At two constant current levels, 30 mA/m² and 50 mA/m², the corrosion of pre-corroded steel plates in mortars containing increasing doses of chloride by weight of cement as NaCl, was arrested after a length of time under polarisation. The required charge (current in amps multiplied by time in seconds) delivered to the steel until passivation of the steel was achieved increased with the level of chloride but was lower at the higher current density of 50 mA/m², as summarised in Table 1. Passivity of the steel was assumed when the 24-hour depolarised potential had reached -150mV vs Ag/AgCl, 0.5M KCl as indicated in EN 12696:2022.

Table 1. Cathodic Charge required to passivate steel at the chloride levels and current densities shown.

Current Density (mA/m ²)	30		50	
% Cl in Mortar	2	3	2	4
Cathodic Charge (kC/m ²)	120	190	74	108

Work in Italy (Pedferri, 1996) and USA, (Presuel-Moreno et. al., 2005) had demonstrated that passivity of the steel can be maintained in a corrosive environment for considerable periods, by a process they termed Cathodic Prevention, by applying a current density of 0.4-2 mA/m². Even constant exposure to highly corrosive environments could not initiate corrosion at a current density of 1 mA/m². Once corrosion is arrested, it would appear reasonable to suggest that a second stage of a process, based on Cathodic Prevention, is likely to protect the steel from further corrosion. Thus, a CP system based on a Two-Stage process appears to be a viable corrosion mitigation method.

This understanding formed part of a process that has enabled the recent development of a simple to install and operate Two-Stage Corrosion Mitigation system (Arnesen et. al., 2018, Whitmore et. al. 2019) as illustrated in Figure 6. A trial was set up on a column of a bridge in Leicester, UK, where six anodes were set up at an approximate spacing of 500 mm on-centre around a repaired area where corrosion and spalling was caused by chlorides up to a concentration of about 2% by weight of cement (Sergi et. al., 2022). The ICCP element of the anodes had passed a current to the steel reinforcement over a range of 20-35 mA/m² of steel density over a period of several months ensuring a total of around 200 kC/m² of charge was delivered to the steel reinforcement. Once the battery-operated Stage-1 was completed, current was subsequently delivered from the galvanic anode at a level of 0.9-1.5 mA/m², sufficient for preventing corrosion long-term.

Figure 6. Two-Stage anode system and schematic of its operation and installation of the anodes in pre-drilled holes at a spacing of 500 mm around the affected area.

The potential of the steel within the repaired area was monitored at two positions using embeddable silver/silver chloride electrodes, 0.5 M KCl, and confirmed that the early high charge delivery over the first 120 days was sufficient to passivate the steel. The subsequent cathodic prevention current maintained passivity of the steel with 24-hour depolarised potentials remaining higher than -150 mV (vs Silver/silver chloride) as depicted in Figure 7. Depolarisation potentials during Stage-1 of high current delivery was of the order of 150-200 mV. Subsequently, during Stage-2, depolarisation was of the order of 50-70 mV (Whitmore et. al., 2023).

A second structure in Wales was also repaired using the Two-Stage technique (Whitmore et. al., 2023). Two piers and a crossbeam of a bridge had suffered from corrosion from chlorides in excess of 2% by weight of cement with cracking and spalling. Chains of up to 20 anodes were installed in several zones. The anodes were spaced out at 500 mm on centre in a grid configuration, designed to deliver a minimum of 300 kC/m² of charge during Stage-1. This was achieved over a period within 100 days (Figure 8). The current density was 30-80 mA/m². As in the Leicester column above, the high current density resulted in depolarised potentials during Stage-1 of the order of 180-230 mV, well above 100 mV suggested by the standards for cathodic protection. The high current density was required to achieve passivation of the steel which was achieved within Stage-1 with 24-hour depolarised potentials considerably higher than -150 mV vs silver/silver chloride, 0.5 M KCl.

Figure 7. Change of potential of steel reinforcement (vs silver/silver chloride) around the repaired zone 24-hours after depolarisation, including two sets of potentials following depolarisation over a two-week period within the first year.

Figure 8. Cumulative charge delivered to the steel in one zone indicating a sharp delivery of over 300 kC/m² over a period about 100 days.

3.2 Surface applied anodes

Galvanic anodes encased in an activating mortar need to be embedded in the concrete to at least the depth of the steel reinforcement so that the moisture level, when high enough to maintain corrosion of the steel reinforcement, is also sufficient to maintain current delivery from the galvanic anode. Because of this fact, attempts to position anodes on the surface of the concrete, instead of the normal practice of embedding the anodes beyond the cover depth, were generally unsuccessful. This was owing to their inability to maintain sufficient current owing to drying which resulted in moisture content around the anode much lower than at the depth of the steel. To overcome this problem and to allow the moisture level around the anode to be maintained to the level experienced by the steel reinforcement, long galvanic anodes were designed and were covered on the outermost end by an impermeable surface, wide enough to ensure that the distance of the centrally positioned anode rod from either edge of the impermeable surface is at least equal to the depth of cover of the reinforcement.

A schematic of the anode and a field trial installation on a cross beam of a bridge in the USA are shown in Figure 9. The steel reinforcement had suffered from corrosion caused by chlorides seeping through a joint above. The current output of the anodes delivered to the steel beneath was 3-20 mA/m², equivalent to an ICCP installation and was dependant primarily on the ambient temperature (Figure 10). As described in Section-2 the current output is governed by the Arrhenius relationship (Equation 1) so is expected to be lower over the winter months. The level of depolarisation on Day-60 was just short of 100 mV at 24 hours but was still rising up to 48 hours when the anodes were reconnected to the steel, reaching around 140 mV suggesting a high level of protection of the steel reinforcement.

3.3 The future of cathodic protection

Judging by advancements in the last 5-10 years, it is inevitable that further developments will occur in the field of cathodic protection of steel reinforcement. It is likely that reliable and greatly simplified cathodic prevention systems will become more of a norm in new construction where corrosion prevention would be considered more desirable and cost-effective than eventual corrosion mitigation and

Figure 9. Schematic of the new surface anode design and installed anodes on a cross beam in a field trial in USA.

Figure 10. Current density by area of steel over a period of around 140 days showing variation with mean ambient temperature.

repair or even replacement of the structure. Considerably less power would be required to drive cathodic prevention systems as the current density does not need to exceed 1-2 mA/m² but more importantly, disruptions and added expenses for subsequent repair can be eliminated. Such low levels of current density can be easily achieved by well-designed galvanic anode systems. Furthermore, intelligent monitoring systems may be set up to predict when steel reinforcement corrosion initiation risk increases and activate an already installed cathodic prevention system. A move in that direction will be driven by the requirement for more environmentally acceptable procedures for structure management. Such a need will make the replacement of existing structures, buildings and infrastructure in general, environmentally very costly, so maintenance of existing structures and their conversion to new use is likely to become standard practice. For steel reinforced structural elements, extensive repairs to reinstate corroded areas would have to be reduced and cathodic protection would be a prime candidate for maintaining the structure to a safe condition with minimal repairs. For the same environmental reasons, low emission power generation will start to proliferate and self-powered localised CP systems, i.e. driven by solar and wind energy or rechargeable components, will likely become the norm.

The concept of cathodic protection would likely also evolve as a two-stage process similar to what was described in Section 3.1. Allowing a higher than what is currently considered to be a normal long-term cathodic current density of less than 10 mA/m² will inevitably arrest corrosion owing to the rapid build-up of alkali ions and the depletion of the aggressive chloride ions after which cathodic prevention would again be viable. As an example of power use, the long-term charge required to achieve 30-year protection with an ICCP system at a mean current density of, for example, 6 mA/m² to maintain a minimum of 100 mV depolarisation as required by standards, is estimated to be of the order of 5,500 kC/m² of steel area. An equivalent 2-stage CP system where an early current density of 25 mA/m² for 2 months is applied to arrest corrosion and a long-term current density of 1 mA/m² up to 30 years to maintain steel passivity would use just 1,000 kC/m², achieving a substantial saving in power consumption.

The continual development of galvanic anodes would likely increase the Aging Factor to well beyond 20 years by a combination of better design of the metallic sacrificial element and of the encasing activating mortar. This would allow a much longer service life of galvanic anodes at designable current densities for specific environmental conditions and particularly, ambient temperature.

4 CONCLUSIONS

The Carbon Footprint of cement manufacture in combination with steel and aggregate production is very large so demolition of structures and their replacement is non-sustainable. Better initial design with in-build cathodic protection or prevention capabilities should be the norm for new construction. Maintenance of aging structures with sustainable cathodic protection techniques should always be preferred as an environmentally friendly alternative to replacement of the structures.

Cathodic Protection or Prevention methodologies have been improving over the years and new developments, clear understanding of anode behaviour and improved performance of galvanic anodes have given rise to better long-term steel reinforcement protection. For example,

an Aging Factor, describing the diminishing exponential current output of galvanic anodes and the Arrhenius relationship of current to temperature are critical predetermined parameters that must be used to aid in the design of the galvanic system.

A 2-Stage cathodic protection method involving early high current delivery by an ICCP component to arrest corrosion followed by prevention using a second galvanic anode has been successfully developed and tested and offers great promise for sustainable long-term cathodic protection systems.

The development of functioning surface applied galvanic anodes allows flexibility and ease of use whilst providing substantial protection equivalent to ICCP systems.

Corrosion of rebars in concrete: Comparison of preventative measures

F. Bolzoni, A. Brenna, S. Beretta, M. Ormellese, M.V. Diamanti & M.P. Pedferri

Dipartimento di Chimica, Materiali e Ingegneria Chimica “Giulio Natta”, Politecnico di Milano, Milan, Italy

ABSTRACT: Prevention of rebar corrosion is achieved in the design and construction phases, by means of suitable mix design, casting and curing, and adequate cover depth; this approach has been introduced in international standards (EN 206) and design codes (Eurocode 2). Preventative measures (cathodic protection, stainless steel or galvanised rebars, corrosion inhibitors, concrete coatings) can be used in very aggressive environments, especially in presence of chlorides, or when increased service life is required. In this work, a performance-based approach, based on Monte Carlo simulation, has been used to evaluate the service life (initiation time of corrosion) in chloride containing environments.

1 INTRODUCTION

In concrete pore solution, due to the high alkalinity (pH>13 in general), carbon steel reinforcements are protected from corrosion by a passive film. Corrosion initiation can occur due to: 1) carbonation of concrete that reduces its pH and 2) presence of chlorides in concentration superior to a critical threshold (CEB 1982; Bertolini et al. 2013; Pedferri 2018). In this article, we do not consider hydrogen embrittlement of high-strength reinforcements and stray current corrosion; in particular, the latter is not frequent in concrete.

Corrosion prevention must be addressed during design and construction, with proper concrete composition, sufficient cover thickness, and proper placement and curing of concrete. Additional corrosion protection methods may be useful in aggressive environments, especially in presence of chlorides, or when a high service life is required (Bertolini et al. 2013; Pedferri 2018).

In this work, performance based approach is used. Analytical solution of 2nd Fick's law of diffusion is used to evaluate corrosion initiation time (limit state) and its probabilistic distribution is calculated by Monte Carlo method. Some of the results were presented in (Bolzoni et al 2022d).

2 PREVENTION OF CORROSION IN CONCRETE

2.1 *Durability and service life*

The evolution of the corrosion phenomenon is interpreted by Tuutti's model, introduced in the '80s, which considers two periods: corrosion initiation and propagation (Bertolini et al. 2013).

In case of chloride induced corrosion, corrosion initiation occurs when at the rebar surface chloride concentration reaches a critical threshold. Moreover, chloride transport into concrete occurs mainly by non-stationary diffusion, that follows 2nd Fick's law. Under specific boundary and initial conditions, 2nd Fick's law has an analytical solution (Equation 1) first applied to chloride diffusion in concrete in 1972 by Collepardi and co-authors (Collepardi 2002):

$$C_x = C_s \cdot \left(1 - \operatorname{erf} \frac{x}{2\sqrt{D_{app}t}}\right) \quad (1)$$

Where erf is the error function, t is time, C_s and C_x are chloride concentration at the surface (constant over time) and at distance x from the surface, respectively, D_{app} is the apparent chloride diffusion coefficient, constant in space (homogeneous concrete) and time. The approach is valid considering a semi-infinite domain. An additional assumption for the Equation 1 is that the initial concentration of chlorides in concrete is zero. The assumptions underlying equation, i.e. constancy of C_s and D_{app} and the absence of other transport mechanisms are not always verified in practice (Bertolini et al. 2013). Despite this, experience has shown that experimentally measured profiles can be interpolated with good approximation with Equation (1).

The first protection against corrosion is represented by a sufficient thickness of cover and low porosity concrete (Colleparidi 2002, Bertolini et al. 2013). These concepts have been implemented, since the 1990s, in European standards, with limits on concrete composition (water/cement ratio), minimum concrete cover thickness and structures execution (curing) depending on the environment (EN 206, EN 1992-1-1). Compliance with these regulations would eliminate the vast majority of corrosion cases for usual service lives of 50 to 75 years, and even longer in the case of carbonation-induced corrosion.

There are some situations, characterized by high environmental aggressiveness, or when the required service life is longer than usual, in which preventative methods can be useful. In these situations, it would also be necessary to use a performance-based approach, to properly evaluate the influence of these methods on service life. deterministic or probabilistic. Deterministic methods are limited because they provide only an “average” value without information on the distribution. Therefore, in the last 20 years there has been a tendency towards the use of probabilistic methods. One example is FIB Model Code for Service Life design (FIB 2006): the service life of structures affected by reinforcement corrosion is approached by using Tuutti model, and the corrosion initiation time in case of chlorides-induced corrosion is calculated with a modified version of the Equation 1.

2.2 Preventative methods

Before dealing with preventative methods, it is fundamental to recall the effect of different types of concrete. In particular, since we focus on corrosion due to chlorides, the reduction of the diffusion of chlorides resulting from the use of a pozzolanic and blast furnace cement, if concrete is properly cured, has been known for long time (Bertolini et al. 2013; Colleparidi 2002).

Preventative methods can be effective on both corrosion initiation and propagation time, although the effect on the initiation time is generally the most important (Bertolini et al. 2013). Only techniques for which there is established experience are considered in the paper: cathodic protection, corrosion resistant reinforcements, corrosion inhibitors and concrete coatings. The effect of preventative methods on critical chloride content and chloride diffusion coefficient will be only briefly recalled in chapter 3. More details about their performances can be found in (Bertolini et al. 2013; Nurnberger 1994; Elsener 2001; Bolzoni et al. 2022a, b) and in literature cited herein. Cathodic prevention, if properly designed and monitored, is able to ensure a service life of at least 50 years without extraordinary maintenance even in presence of chloride content above the threshold (Pedefferri 1996; Bertolini et al 2013, Polder & Peelen 2019).

3 METHODS - ASSESSMENT OF SERVICE LIFE

3.1 Concrete and rebar properties

Environmental exposure was chosen in agreement with EN 206 standard: marine atmospheric (XS1) and splash zone/areas (XS3). Concrete with w/c ratio 0.45, according to EN 206 was selected. Three types of cement are considered: CEM I (Portland), CEM IV (pozzolanic, in particular with fly ash) and CEM III (blast furnace slag) according to the European standard EN 197.

Cover thickness (Table 1). The normal distribution was chosen according to the FIB Model Code with mean values for each exposure class equal to the minimum reported in the Euro-code (EN 1992-1-1) (Table 1); the standard deviation was 10 mm (Lollini et al 2015).

Surface concentration of chlorides (Table 1): the distribution (lognormal), mean values and standard deviation were chosen according to the literature in the case of exposure class XS3 (Lollini et al. 2015). For class XS1 the mean value and standard deviation were reduced by 50%, having not found indications in the literature. In presence of the coating applied on concrete cast with CEM I, surface concentration was reduced by 40% (Brenna et al. 2020).

Chloride diffusion coefficient (Table 2): values referred to long-term exposures were considered (Bertolini et al. 2013). In presence of concrete coating, when CEM I is used, a value reduced by 30% was considered (Brenna et al. 2020). The distribution is lognormal (FIB 2006).

Critical chloride concentration (Table 3). Values were chosen for carbon steel in accordance with the Model Code (FIB 2006). Preventative methods are: corrosion inhibitors, concrete coatings, use of stainless steel type 1.4307 (containing 18% Cr and 8%Ni, similar to the well-known AISI 304L). The critical chloride content for preventative methods was based on literature (Bertolini et al. 2013; Lollini et al. 2015; Ormellese et al. 2008; Bolzoni et al. 2022c) in absence of specific indication in (FIB 2006).

Table 1. Surface chloride content (Cs, % vs cement mass) and cover (d, mm).

	Distribution	Marine (XS1)		Tidal splash (XS3)	
		Mean	St. dev.	Mean	St. dev.
Cs no coating	Lognormal	2.5%	1%	5%	2%
Cs with coating	Lognormal	1.5%	0.6%	3%	1.2%
d (mm)	Normal	35	10	45	10

Table 2. Chloride diffusion coefficient (D_{app}).

D_{app} ($10^{-12} \text{ m}^2 \text{ s}^{-1}$)	Distribution	Mean	St. dev	Mean*	St. dev*
w/c 0.45 CEM I	Lognormal	1	0.2	2	0.4
w/c 0.45 CEM I + coating	Lognormal	0.7	0.14		
w/c 0.45 CEM IV	Lognormal	0.5	0.1		
w/c 0.45 CEM III	Lognormal	0.2	0.04	0.25	0.05

* values used only for the comparison with FIB 2006

Table 3. Critical chloride content (C_{cr}).

C_{cr} vs cement mass	Distribution	Mean	St. dev.
Carbon steel	Beta	0.6%	0.15%
Stainless steel 1.4307	Beta	5%	1.25%
Carbon steel + inhibitor	Beta	1.2%	0.3%
Carbon steel + inhibitor (“high dosage”)	Beta	1.8%	0.45%

3.2 Service life evaluation

In the case of chloride-induced corrosion, there is agreement among most researchers to consider the service limit state corresponding to corrosion initiation; in fact, localized corrosion propagation can lead to unacceptable cross section reduction in a short time (Bertolini et al. 2013). Corrosion initiation (t_i) occurs when at cover thickness ($x = d$), the chloride content C_{x,t_i} is equal to the critical value C_{cr} ; time for corrosion initiation can be evaluated inverting Equation (1), see Equation 2, in which erf^{-1} is the inverse of the error function and the other parameters have been already defined:

$$t_i = \frac{1}{D_{app}} \left\{ \frac{d}{2 \left[\text{erf}^{-1} \left(1 - \frac{C_{cr}}{C_s} \right) \right]} \right\}^2 \quad (2)$$

In the deterministic method, average values of the input variables, chloride surface concentration (C_s), concrete cover (d), apparent chloride diffusion coefficient D_{app} , critical chloride concentration (C_{cr}) are used (Tables 1, 2 and 3). In the probabilistic method, corrosion initiation time is evaluated by means of 4 independent extractions of random numbers and the following procedure is used:

- a random number ranging from 0 to 1 is extracted;
- this number is entered in the Y axis of the relevant cumulative probability curve (Figure 1);
- the value of the variable is determined on the X axis of the same graph.

Figure 1. Cumulative probability for apparent chloride diffusion coefficient D_{app} (left), critical chloride concentration C_{cr} (right).

Once all values have been evaluated for one simulation, the value of corrosion initiation time is calculated by means of Equation 2 and this value is stored. The simulation is repeated 1000 times according to previous experience (Cheldi et al. 1997) and the distribution of corrosion initiation time is plotted. The simulation was performed by using a datasheet (Excel©) with a modified macro used in a previous work (Cheldi et al. 1997).

4 RESULTS AND DISCUSSION

4.1 Deterministic evaluation of service life

Under severe exposure conditions (XS3), the use of carbon steel reinforcements in concrete with water/cement ratio 0.45 cast with CEM I is not a reliable option: service life is about 13 years with concrete cover 45 mm (Figure 2). In practice, the prescriptive approach based on EN 206 and Eurocode is not conservative. Service life 50 years is not reached even with 80 mm cover.

The use of different cement types, CEM IV or CEM III, can help to exceed 50 years service life (Figure 2) by the proper concrete cover.

In marine atmospheric exposure (XS1), the situation is less severe but considering the suggestions of EN 206 (cover 35 mm) and Eurocode the performance of carbon steel is not satisfactory: service life results at least 50 years only by selecting a concrete cover higher than 65 mm.

A sensitivity analysis relative to the critical chloride concentration was performed (Figure 3). In an aggressive environment (XS3) with 45 mm cover, there is a significant increase in the corrosion initiation time if the critical chloride content is at least 2.5% vs. cement mass. These values can be exceeded only by using stainless steel reinforcements. Less performing solutions can be used only in combination with low porosity concrete, cast with CEM III.

4.2 Probabilistic evaluation of service life

Results obtained using the probabilistic approach are represented in Figures 4 and 5. They should be considered as an indication of a trend. In real cases, the behavior of reinforcement, concrete, and/or the environment may vary depending on design and execution.

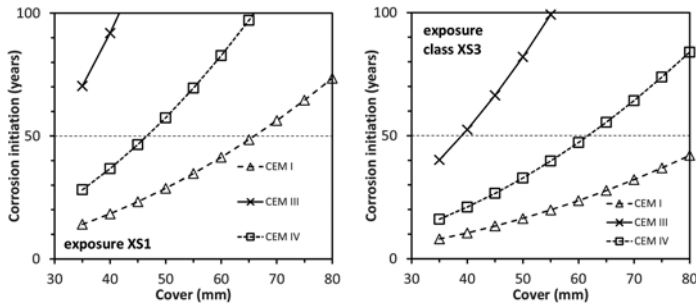

Figure 2. Time for corrosion initiation (service life) evaluated with deterministic method for carbon steel reinforcements (C_{cr} 0.6% by cement mass), with concrete w/c 0.45 and different type of cements in exposure class XS1 (left) and XS3 (right).

Figure 3. Time for corrosion initiation (service life) evaluated with deterministic method: sensitivity analysis on critical chloride threshold. Concrete w/c 0.45 and different type of cements in exposure class XS1 with cover 35 mm (left) and XS3 with cover 45 mm (right).

In the two graphs, a horizontal dashed line was drawn at a value equal to 10% of the probability of failure (Pf), defined as the probability of reaching the limit state (corrosion initiation). The value is considered a minimum target (FIB 2006). A vertical line is drawn at 50 years, the expected service life for common buildings according to Eurocode 2, while 100 years corresponds to a minimum service life for important structures.

In conditions of high aggressiveness, exposure class XS3 (Figure 4), it is clear that a concrete with w/c ratio 0.45 (as suggested by EN 206) and cast with CEM I and concrete cover 45 mm (Eurocode) is not a reliable solution, for. Considering a service life of 50 years, the probability of corrosion initiation is 90% or higher. In this severe exposure conditions, the technical solution that can guarantee at least 50 years service life with a probability of corrosion initiation equal to 10% are:

- Stainless steel rebar, independently on the concrete cover or cement type.
- Corrosion inhibitor, only if they are combined with low porosity concrete as the concrete cast with CEM III (blast furnace slag cement); the reliability of this technical solution depends on the maintenance of corrosion inhibitor concentration for long time, i.e. absence of leaching (for example in correspondence with cracks).

In less severe exposure (XS1), the surface concentration of chlorides is lower with respect to class XS3, as well as the minimum cover thickness recommended by the Eurocode (35 mm). These two factors have an opposed influence on the corrosion initiation. The overall results are more favorable in the less severe environment but the trends identified in the more severe exposure class are confirmed.

4.3 Comparison with FIB Model code for service life design

The results have been compared with those obtained by the FIB Model code for service life design (FIB 2016), reported in (Lollini et al. 2015). The same input data were used for critical chloride content, concrete cover and surface chloride content (Tables 1 to 3).

Figure 4. Cumulative distribution of the service life: exposure class XS3, mean cover 45 mm, concrete w/c ratio 0.45, cement type EN 197 CEM I (left) CEM III (right).

Figure 5. Cumulative distribution of the service life: exposure class XS1, mean cover 35 mm, concrete w/c ratio 0.45, cement type EN 197 CEM I (left) CEM III (right).

The situation is different for chloride diffusion coefficient: FIB model code suggest to evaluate the apparent chloride diffusion coefficient D_{app} with this formula:

$$D_{app} = k_c \cdot DRCM \cdot k_t \cdot \left(\frac{t_0}{t}\right)^a \quad (3)$$

where DRCM is an experimental value measured with accelerated testing (DRCM) at time t_0 (generally 28 days) or estimated according the annex B in (FIB 2006), k_c is related to the temperature, k_t a transfer parameter and a is the aging exponent, mean value 0.3 for CEM I and 0.45 for CEM III. The ratio between the values of D_{app} , calculated after 1 year and 100 years is around 8 for CEM III, and 5 approximately for CEM I.

The results of the two approaches are in agreement, especially in the case of concrete manufactured with CEM I (Figure 6). Significant differences can be observed in the case of concrete with CEM III, and this can be related to the higher change of the chloride diffusion coefficient through the exposure time considered in the FIB model code.

These results confirm that in service life models, i.e. the FIB model code, some factors require further research work, as already stated in (Lollini et al. 2011; Lollini et al. 2015). In particular more information is needed on traditional and new materials, regarding chloride transport and chloride threshold levels for different types of rebars or preventative methods: these last currently are not included in the FIB Model Code (FIB 2006).

4.4 Life cycle considerations

Life-cycle cost (LCC) analysis has not been explored in this article, but some considerations can be made by comparison with the literature.

Figure 6. Cumulative distribution of the service life: exposure class XS3, mean cover 45 mm, concrete cast with w/c ratio 0.45, cement type EN 197 CEM I (left) or CEM III (right). Open marks: data evaluated by FIB Model Code for service life design (Lollini et al 2015), filled marks: present work.

A preliminary life-cycle cost assessment was performed for a bridge slab exposed to aggressive environments due to chloride-containing de-icing salts in the work (Polder et al. 2016).

Different corrosion prevention solutions were compared by deterministic Life Cycle Cost, and it was shown that the use of stainless steel reduces the life cycle cost, similarly to water repellent coatings; the cost of cathodic prevention is slightly higher, while the cost of conventional repair, a solution still often used today, is significantly higher. Indirect costs (traffic disruption, etc.) were not considered in the cited article (Polder et al. 2016); if they were considered, stainless steels and cathodic prevention would become more cost effective.

Corrosion inhibitors, concrete coatings and galvanized reinforcements are less expensive and less effective in delaying corrosion, and they can reduce maintenance and rehabilitation costs vs the solution without any preventative measure. This achievement is conditioned by the durability of the preventative method, related to the stability of the coating in time (without disbonding for example) and the maintenance of the inhibitor concentration in concrete, i.e. absence of leaching.

The environmental impact of the different solutions has not been analyzed in the paper, but it can be argued that extending the service life can reduce the overall impact of the structure on the environment and the withdrawal of resources from it (Matthews 2020; Coppola et al. 2018). This is even more important for more durable solutions like stainless steels or cathodic prevention.

5 CONCLUSIONS

Performance based approaches have been applied to evaluate preventative methods against rebar corrosion due to chlorides. Considering the limitations of the analysis, some trend can be identified.

In concrete cast with Portland cement (CEM I) with w/c 0.45 and concrete cover (mean value) 45 mm, as suggested by EN 206 and Eurocode, only stainless steel rebars and cathodic prevention can guarantee more than 50-year service life in severe conditions, as in splash/tidal zone of marine structures (XS3). The use of corrosion inhibitors and coatings delay corrosion initiation, but the 50-year service life could be reached only if they are combined with low porosity concrete, i.e. manufactured with CEM III. These solutions can reduce maintenance and rehabilitation costs vs the absence of preventative measures, provide that their durability is guaranteed.

To improve the reliability of the prediction by means of service life models, is necessary to collect more data, mainly concerning critical chloride concentration for different preventative methods, not indicated in the FIB Model Code, and chloride transport with different concrete type.

Role of concrete and reinforcement characteristics to increase the service life of structures

M.C. Alonso

Institute of Construction Science Eduardo Torroja (IETcc-CSIC), Madrid, Spain

ABSTRACT: The advantages of reducing the transport of aggressive agents through the concrete cover, either through the use of cements with lower carbon footprint, incorporating supplementary cementitious materials (SCM) or using high performance concrete (HPC) to increase its density, are proven technologies to extend the service-life of concrete structures.

Another challenge is to delay the initiation of corrosion by using systems capable of increasing the corrosion resistance of reinforcement. The incorporation of additives in the concrete matrix with corrosion-inhibiting properties to improve the interaction between reinforcement and concrete at the interface. Inhibitors encapsulation is a promising technology that follows a controlled release of the inhibition part and at the same time is effective in capturing chloride. On the other hand, there is the use of new types of reinforcement, such as stainless steel, which significantly increase the critical chloride content to prevent the initiation of corrosion during the service-life.

1 INTRODUCTION

The guarantee of a high durability of concrete structures and, consequently, a longer service-life are increasingly demanding requirements in the increasingly challenging environmental conditions as a result of climate change.

The cost associated with repair work in Europe is estimated to be equivalent to half of the annual construction budget spent on the renovation and remediation of the existing structures to extend their service-life, Cailleux & Pollet (2009). Furthermore, although European Standards consider that any concrete structure must have a service-life of at least 50 years, contractors are generally liable for damages only up to 10 years, Silva et al (2015).

Reinforcement corrosion is the main cause of degradation and loss of service-life of concrete structures. The carbonation of the concrete cover and the presence of chlorides are the two main aggressive agents responsible for deterioration of concrete structures that operate in extreme environmental conditions. The ever increasing demand in the construction industry to build structures with long service-life necessarily leads to evaluating the incorporation of new technologies and methods of protection against corrosion in current engineering projects. The particular focus is to achieve the goal of the sustainability of construction and at the same time allow to reduce the maintenance in operation of the structures and the related costs.

2 SERVICE LIFE PREDICTION FOR CORROSION OF REINFORCEMENTS

The thermodynamic model proposed by Tuutti (1982) is the most accepted framework for the prediction of corrosion of reinforcements and after 40 years its basic concept is maintained. Tuutti's model considers two successive periods for the corrosion process of reinforcement in concrete identified as initiation (t_i) and propagation (t_p) periods

The end of the service-life of a reinforced concrete structure is usually associated with the durability limit state of corrosion initiation, preventing the propagation of corrosion, Browne

(1982), Funahashi (1990), Maage et al (1995). For this reason, special attention has been devoted to the quantification of the initiation period, differentiating two stages, one associated to the assessment of the transport of the aggressive agent and another focused on the determination of the critical concentration of the aggressive agent that accumulates on the rebar and causes the initiation of corrosion. These two stages in the initiation period are differentiated in the Figure 1-left, also reflecting the variability associated to the parameters involved in their determination.

Most of the research advances with this model have been dedicated to the quantification of the two stages that intervene in the initiation period ($t_i = t_{\text{transp}} + t_{\text{dep}}$), the transport of the aggressive, (t_{transp}) and the depassivation of the rebar (t_{dep}).

Figure 1. Left) Modified Tuutti's diagram differentiating two stages during the initiation period (t_i): 1) transport of aggressive agents (t_{transp}) and 2) rebar depassivation (t_{dep}). Right) effect of D_{app} decrease on the prediction of % of Cl accumulation at the rebar level in a Conventional Concrete (CC) and time to onset of corrosion at Cl threshold (dash line).

In the case of chloride-contaminated environments, t_i focuses primarily on determining the two critical parameters involved, the Cl diffusion coefficient (D_{app}) and the corrosion resistance of the reinforcement until a critical level of Cl accumulates on the rebar surface that causes the initiation of corrosion, the chloride threshold (C_{crit}).

The entry of chloride into reinforced concrete structures is complex since it depends on random parameters that are related to transport and characteristics of the concrete, resulting in high variability values. These variations raise the need for statistical approaches to assess the risk of corrosion initiation due to chloride ingress, Kiese et al (2020).

Song et al (2008) analyzed data reported in the literature on the evolution of diffusion coefficient (D_{app}) and surface content of chloride, C_s , of concrete structures and specimens exposed to marine environments. Several factors were found to influence the chloride transport in terms of D_{app} and C_s , such as concrete mix characteristics (water/binder ratio, binder type or air void content), curing methods, the external environment and proximity to seawater. The type of cement has a significant effect on the variability of D_{app} for similar concrete characteristics.

Kiese et al (2020) used sensitivity analysis to identify the influence of input parameters on the critical time period before the onset of corrosion predicted by the Cl diffusion model. The results showed that the corrosion initiation time was more sensitive to the effective diffusion coefficient of chloride, D_{eff} , a parameter more controllable by the stakeholders than C_s , which is an uncontrollable parameter that depends on surrounding conditions.

Furthermore, the micro and macro structural features at the steel/concrete interface are generally recognized as the most important factors influencing the chloride induced corrosion and threshold values, Angst et al (2017 & 2019). Regarding the critical chloride that can induced corrosion onset, in the reviews of the literature by Ann& Song (2007), Alonso & Sanchez (2008) and Angst et al (2009) a high variability was found. This large scatter in the literature data is associated with different experimental conditions, different definitions and methods and with the numerous factors that affect the critical chloride content suggested by Angst et al (2009).

Stochastic models have been used for the prediction of critical chloride concentration for the depassivation of reinforcements to statistically analyse the variability of the chloride

threshold. Izquierdo et al (2004) applied a normal distribution to the chloride threshold values obtained by the potentiostatic method using different types of cement; the 95% probability of depassivation of the reinforcement gave values from 0.62% to 0.77% for total chlorides; with a minimum value for the 5% depassivation risk of 0.32%.

Alonso & Sanchez (2008), based on a large collection of chloride threshold values, performed a statistical analysis of the variability. The frequency distribution of chloride threshold data are around 1% for total chloride.

To predict the service-life of concrete structures exposed to chloride environments it is necessary to know parameters such as, D_{app} , C_s and chloride threshold (C_{crit}), according to the Equation 1, considered in the Model Code (2006):

$$C_{crit} = C(x = a, t) = C_0 + (C_{s,\Delta x} - C_0) \cdot \left[1 - \operatorname{erf} \frac{a \cdot \Delta x}{2 \cdot \sqrt{D_{app,C} \cdot t}} \right] \quad (1)$$

Where

- C_{crit} : critical chloride content for rebar corrosion initiation [wt.-%c]
- $C(X,t)$: content of chlorides in the concrete at a depth x (structure surface $x = 0$ m) and a time t [wt.-%c]
- C_0 : initial chloride content of the concrete [wt.-%c]
- $C_s, \Delta x$: Chloride content at a depth Δx and a certain point of time t [wt.-%c]
- x : depth with a corresponding content of chlorides $C(X,t)$ [mm]
- a : concrete cover [mm]
- Δx : depth of the convection zone (concrete layer, up to which the process of chloride penetration differs from Fick's 2nd law of diffusion) [mm]
- D_{app}, C : apparent coefficient of chloride diffusion through concrete [mm^2/year]
- t : time [years]
- erf: error function

Figure 1-right shows the result of the prediction of accumulation of Cl at the level of the reinforcement with a conventional concrete (CC) using equation 1. The time to reach the chloride threshold for the onset of corrosion (end of service-life) is marked with a dashed line. The D_{app} used in the calculation were obtained from experiments performed in Luna et al (2018). The D_{app} was determined by Cl diffusion tests in concrete samples fabricated with OPC (CEM I type) using 380kg/m^3 and $w/c=0.6$. As chloride threshold (C_{crit}) the value of 0.6% of total Cl by mass of binder (bmb) was used. Figure 1-right shows that the time to reach the Cl threshold is less than 10 year. The effect of reducing chloride diffusion, D_{app} , increases the time to reach the Cl threshold for corrosion initiation but remain below 10 years.

The increase in the thickness of concrete cover depending on the aggressiveness of the environment, as prescribed in some standards, EN1992-1-1(2004), as a way of delaying the arrival of the aggressive agent at the rebar level, has a structural limit in design and increases costs.

The growing demand in the construction industry to build structures with long service-life, necessarily of at least 50 years, leads to evaluating the incorporation of corrosion protection methods in current engineering projects. Two tendencies are followed to extend the service-life of concrete structures, the action on the concrete matrix or on the reinforcement. That is, affecting the transport process of aggressive agents by modifying the concrete cover or improving the resistance to corrosion by changing the chemical characteristics of the reinforcement.

3 INTERVENTION ON THE CHARACTERISTICS OF THE CONCRETE COVER TO EXTEND THE SERVICE-LIFE OF STRUCTURES

A specific action to extend the transport period is to retard the penetration of the aggressive agent by manufacturing high density and less permeable concrete matrices, such as using high performance concrete (HPC) or ultra-high performance fibre reinforced concrete (UHPC). Also by using binders with a smaller footprint, that incorporate SCM capable of increasing

the binding of chloride ions, thus delaying the transport of chloride. These forms for corrosion prevention through concrete cover actions is being contemplated in standards based on the exposure class of the structure and the relationship with aspects of durability of reinforcement, ENV 206-100 (2022).

The type of cement, in terms of the incorporation of mineral additions has been revealed as one of the most influential factors in the resistance of concrete to the penetration of chlorides, Paiva et al (2016), Luna et al (2018). SCM lead to a denser microstructure and decrease the pore size distribution to more refined net-pore as found by Luna et al (2018) in concrete with 35% of Blast Furnace Slag (BFS) compared with Ordinary Portland Cement (OPC), using the same $w/b = 0.6$.

A clear decrease of the non-steady state diffusion coefficient, D_{app} , have been measured with BFS compared with OPC concrete in Luna et al (2018), plotted in Figure 2-left. The positive effect of BFS in reducing the chloride transport is attributed to reduced porosity and the Cl binding capacity, Leng et al (2000), Moon et al (2006), Song et al (2006), Luna et al (2018). Furthermore, the pore structure can be reduced by increasing the binder content and reducing the w/b ratio, Alonso at al (2021). Porosity reduction has a clear effect on chloride transport, as can be appreciated in Figure 2-right for $D_{app mig}$ and different concrete porosities. Porosities less than 6% leads to reduction in $D_{app mig}$ from 10^{-11} , for a CC, to $10^{-13} \text{ m}^2 \cdot \text{s}^{-1}$, with HPC and UHPFRC.

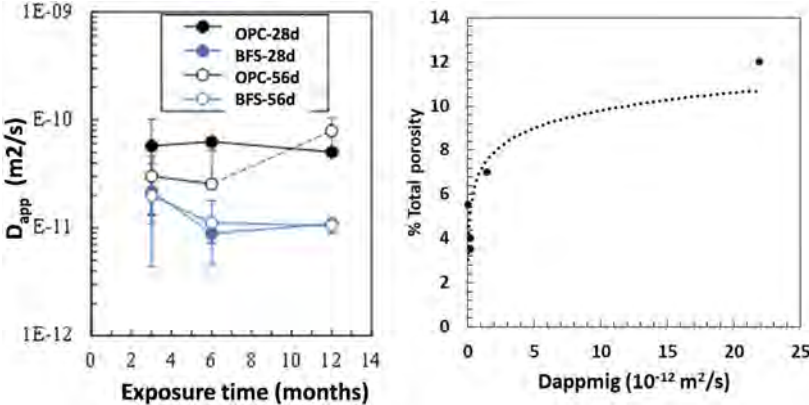

Figure 2. Left, Effect in Cl diffusion, D_{app} , for concretes with OPC and BFS (Luna Et al 2018). Right, Concrete total porosity vs $D_{app mig}$.

The chemical composition of the binder affects the pH of the pore solution and its microstructure, which would be important when considering the interaction of steel and concrete for the development of the passive layer. Those types of binders that contain pozzolanic properties, such as fly ash and silica fume, lower the pH of the pore solution and the tolerable amount of chlorides can be affected. Large amounts of pozzolan additions (above 30%) have been found to reduce the threshold value of chloride from 0.5 to 0.3%, Reddy et al (2002). In recent studies by Alonso et al (2021) Cl threshold values were found to vary from 0.5 to 0.35 % total chloride in HPC and 0.1 to 0.2 in UHPFRC.

The importance of the characteristics of the concrete cover in the service-life of the structures is significant, since it affects both the transport of the aggressive agent and the process of depassivation for the rebar corrosion initiation. The evaluation of both stages and their incorporation into the models will allow to more rigorous predictions of service-life of concrete structures and the benefits derived from considering the characteristics of the cover.

The positive effect of a CC with BFS in the prediction of time for chloride accumulation at the rebar level from Equation 1 has been plotted in Figure 3-left using in the calculation the experimental data of D_{app} obtained in Luna et al (2018) and chloride threshold. Reducing CC chloride transport by BFS can extend the service life of a concrete structure above 50 years. In addition, the use of HPC and UHPFRC also have significant beneficial effect in the span of

Figure 3. Left, Prediction of Chloride accumulation at rebar level with BFS concrete. Right, Influence of high density concretes: HPC and UHPFRC.

service-life due to the important reduction of the porosity and the drastic effect on the chloride transport given in Figure 2-right, which allow a significant delay in accumulation of chlorides at the rebar level, shown in Figure 3-right. The dashed lines indicate the chloride thresholds determined for corrosion initiation.

4 INTERVENTION ON THE REINFORCEMENT CHARACTERISTICS TO EXTEND THE SERVICE-LIFE OF CONCRETE STRUCTURES

Another challenge to take into account in order to increase the service-life of the concrete structures is based on the use of protection measures for reinforcements that increase the time to corrosion onset. Systems that modify the form of the interaction of the reinforcement with the concrete and at the same time improve the corrosion resistance in presence of the aggressive agents.

Protection methods incorporated into the concrete matrix, as the case of corrosion inhibitors additives. The most recent advances in this protection method are the encapsulation of corrosion inhibitors that modify the interaction at the steel/concrete interface through a controlled release of the inhibition part to improve the passive layer resistance; but at the same time, affecting the cover of the concrete by being efficient with the capture of chloride.

The role of corrosion inhibitors is to modify the surface passive layer of the steel bar to hinder the corrosion process. Calcium nitrite has been used extensively in concrete and is very affective in mitigating chloride-induced corrosion of reinforcement, reducing the corrosion rate and increasing the time to corrosion initiation, Ann et al (2006), Berke & Hicks (2004). The chloride threshold for this protection method has been reported primarily as the $[\text{NO}_2^-]/[\text{Cl}^-]$ mole ratio when calcium nitrite has been used, because it indicates the amount of corrosion inhibitor required to inhibit chloride-induced corrosion. For concrete, the inhibitive efficiency of nitrite is often considered to be in the range 0.5-1, Gonzalez et al (1998).

Corrosion inhibitor encapsulation is gaining increasing interest as a new promising technology for incorporating corrosion inhibitors in concrete. Layered double hydroxides (LDH) have a layered structure; three layers are the most common. The ion exchange capability of LDH is the most important property with respect its application in concrete. Mg-Al hydrotalcites have a large surface area, high anion exchange capacity, such as chloride ions, and if charged with an anion that has inhibitory ability they can prevent corrosion of reinforcement, Tedim et al (2012). In the case of LDH loaded with an inhibitory anion, the inhibitory response mechanism is based on ion exchange between free chloride ions and the inhibitory anion intercalated in the hydrotalcite matrix and simultaneous release of the inhibitor. The corrosion inhibition efficiency associated with the LDH released inhibitor has been demonstrated in mortar. Cao et al (2017) found a longer corrosion onset and decreased Cl transport when adding MgAlNO_2 and NO_3^- , more efficient with the first. The basic mechanism for corrosion inhibition and long-term delay of corrosion onset in LDH-Inh is attributed to simultaneous superposition actions, the decrease of Cl in the pore solution due to LDH anion exchange, the increase of pH due to the release of LDH hydroxides and the contribution of the released LDH inhibitor modifying the passive layer.

The positive effect of encapsulated inhibitors can be seen in Figure 4, from recent studies carried out by the author in concrete with and without of LDH inhibitor added in 1% by mass of binder. A positive effect on Cl transport and corrosion inhibition of reinforcement has been found. Chloride diffusion tests in Figure 4-left showed that the D_{app} can be decreased with the addition of LDH. But the most relevant effect found with LDH addition is the delay of the onset of corrosion of the bars due to the inhibition of the corrosion process, as shown in Figure 4-right. For this study reinforced concrete samples were immersed in 3% NaCl solution and the rebar corrosion was monitored for more than three years. A clear delay of more than three times in the onset of corrosion have been observed, values of $i_{corr} < 0.1 \mu A/cm^2$ indicative of a passive state of the rebar. In Figure 4-right after 400 days in REF samples corrosion has started, while after 1400 days of exposure the concretes with LDH do not showed sign of corrosion initiation.

Figure 4. Left, Chloride diffusion tests in REF vs. LDH concretes. Right, Retardation of corrosion initiation of reinforcement as i_{corr} ($\mu A/cm^2$) vs immersion time in NaCl solution.

Regarding the reinforcement, two types of actions are considered, on the one hand, the protection of conventional reinforcement with some type of coating that acts as a protective barrier of the bare steel, as well as an organic type through the application of epoxy coating. In addition, hot-dip galvanizing, highlighting this last technique over the other due to the metallic bond created between the galvanized coating and the bare steel. On the other hand, the replacement of conventional reinforcing steel by new type of reinforcements, such as stainless steel, which significantly increases the chloride threshold.

Stainless steel reinforcements (SSR) have been used for decades and have demonstrated their ability to prevent reinforcement corrosion damage for a long time in aggressive environments, both in laboratory and in field exposure, Castro et al (2002). Therefore, the use of stainless steel reinforcements is now considered a very reliable method to ensure the long-term durability of reinforced concrete structures when exposed to extremely aggressive environments.

Most of the research with SSR has concentrated on evaluating the increase of corrosion resistance in chloride environments. The high corrosion resistance of stainless steel in alkaline media is mainly attributed to the high resistance passive film that forms on its surface, being determined by the composition of the stainless steel alloy type, Abreu et al (2004). Austenitic SS and duplex SS show the highest resistance to chloride induced pitting corrosion, Garcia-Alonso et al (2007), Alonso et al (2019).

Figure 5 shows the chloride threshold values obtained with different duplex SSR in concrete, Alonso et al (2019). Values between 3 to 13% Cl (bmb) in OPC and BFS are shown in Figure 5-left. The variations depends on the quality of the SS, such as the Mo content, and the type of cement. Lower Cl threshold values were found for the concrete with high BFS. The high Cl thresholds with SS reinforcement allow the prediction of large extension of service-life. Long times are predicted to reach the accumulation of the Cl threshold at the level of the reinforcement, as represented in Figure 5-right, even with concretes that have high chloride transport, such as those in Figure 2-right considered in this calculation.

5 CONCLUSIONS

To face the challenge of sustainability through the extension of the service-life of concrete structures, it is necessary to act in the development of new products and technologies, guaranteeing the performance in operating conditions, as well as to facilitating the incorporation of the advances in the building codes.

Take advantages of materials and products that reduce the transport of the aggressive agents by modifying the concrete cover, using binders with smaller footprint incorporating SCM or with high-density concretes, such as HPC or UHPFRC. Both are technologies that have shown great influence on the extension of service-life of concrete structures.

Facilitate the use of reinforcement protection measures that increase the time to initiation of reinforcement corrosion. Protection methods such as new encapsulated corrosion inhibitor technology or the use of stainless steel reinforcement have been shown to increase the chloride threshold and contribute to extend the service-life. Technologies, such as SSR, for protection of reinforcement are well supported with extensive laboratory and field applications, but are not yet considered in the building codes.

Durability performance indicators for service life analysis and quality control

F. Moro

Hagerbach Test Gallery, Flums, Switzerland

R.J. Torrent

Materials Advanced Services, Buenos Aires, Argentina

ABSTRACT: Durability Performance Indicators (DPIs), measurable in relatively short time, are proposed to assess the durability performance of concretes under risk of chloride-induced corrosion. The suitability of these DPIs is validated against results of a comprehensive experimental investigation, conducted on 18 concrete mixes of two w/b ratios (0.40 and 0.65) and binder contents (280 and 380 kg/m³), made with nine different Portland clinker-based binders including two OPCs, Silica Fume, Fly-Ash, Blast-Furnace Slag and Limestone Filler. The mixes were evaluated for compressive strength and also by several DPIs: Coefficient of Chloride Migration (EN 12390-18), Rapid Chloride Permeability (ASTM C1202), Coefficient of air-permeability kT (Swiss Standard SIA 262/1 and Argentine IRAM 1892) and Electrical Resistivity (AASHTO T358 and UNE 83988-2). The validity of the proposed DPIs and their potential usefulness for Service Life design and quality control is discussed. The unsuitability of w/b ratio and compressive strength as durability indicators is confirmed.

1 INTRODUCTION

1.1 *Service life prediction in chloride-rich environments*

The prediction of service life (SL) of reinforced concrete structures exposed to a chloride-rich environment is a challenging endeavor. The main cause of deterioration is the degradation of the embedded steel due to the strong localized pitting corrosion of the metal by an electrochemical process, despite the passivating high pH environment of the concrete.

In the case of structures directly in contact with sea or salty water, the complexity of the chlorides accumulation into concrete involves several mechanisms governing the transport of matter through concrete (Hunkeler, 2000, Torrent et al, 2022). The complexity of the problem is aggravated by the fact that concrete transport properties, strongly associated to the pore structure and ionic composition of the pore solution of the material, evolve during the exposure time and are affected by chemical influences, like the chemical binding of chlorides.

In general, SL prediction models focus on the initiation/incubation phase, trying to predict the time at which the chloride concentration at the level of the steel reaches the critical level that will trigger the corrosion process.

Although there are more complex models, e.g. (Conciatori et al, 2008), the most spread ones (Duracrete, 2000; Life-365, 2019) introduce a simplification by considering that the penetration of chlorides follows a purely, non-steady diffusion process, based on the 2nd Fick's law of diffusion. The associated differential equation finds an explicit solution (Eq. 1) in the case of constant D (coefficient of chloride-diffusion through concrete) and constant C_s (concentration of chlorides at the concrete surface).

$$C(x, t) = C_0 + (C_s - C_0) \cdot \left[1 - \operatorname{erf}\left(\frac{x}{\sqrt{4 \cdot D \cdot t}}\right) \right] \quad (1)$$

where C is the concentration of chlorides at depth x and time t and C_0 is the initial concentration of chlorides (contributed by the concrete constituents).

Often, a mathematical manipulation is introduced to account for the strong decay of D with time, of the form:

$$D(t) = D_0 \left(\frac{t_0}{t} \right)^n \text{ for } t \leq t_d \quad (2)$$

where $D(t)$ is the coefficient of chloride diffusion averaged over a period of time t and D_0 is the coefficient of chloride diffusion measured at time t_0 (typically 28 days). Exponent n is a material property, called aging factor, which is a critical parameter in SL prediction (Gulikers, 2006; Torrent, 2018).

As a consequence, Eq. 1 becomes:

$$C(x, t) = C_0 + (C_s - C_0) \cdot \left\{ 1 - \operatorname{erf} \left[\frac{x}{\sqrt{4 \cdot D_0 \cdot (t_0/t)^n \cdot t}} \right] \right\} \quad (3)$$

The corrosion initiation time t_i is reached when:

$$C(d, t_i) = C_{cr} \quad (4)$$

where d is the cover thickness of the steel and C_{cr} is the (also elusive) critical concentration of chlorides capable of initiating the corrosion process.

1.2 Codes' classical approach to deal with chloride-induced corrosion

Reference is made to the two most influential codes worldwide: ACI 318 and European Standards EN 206 and EN 1992-1-1 (Eurocode 2), where the resistance to chloride-induced corrosion is based on specifying a minimum cover thickness d_{min} and a minimum concrete quality in terms of a maximum water/cement ratio w/c_{max} and a minimum concrete strength $f'c_{min}$.

Table 1 presents a comparison of the requirements specified by ACI for concrete structures exposed to chlorides (C2 exposure class) and those of EN for concretes under the most insidious chloride exposure classes XD3 (parts of bridges exposed to spray containing chlorides) and XS3 (parts of marine structures in the tidal, splash and spray zones). The cover thickness from EN 1992-1-1 corresponds to 50 years SL; for 100 years SL, the value has to be increased by 10 mm, which is not correct (Torrent, 2018).

Table 1. Codes' requirements for non-prestressed, cast on site concrete structures.

Requirement	Code/Exposure Class	
	ACI 318/C2	EN/XD3 & XS3
w/c_{max} (-)	0.40	0.45
$f'c_{max}$ (MPa) at 28 d. (cylinder)	35	35
d_{min} (mm)	54 or 40 (walls & slabs)	45
Expected SL (years)	not defined	50

The way SCM, added to the concrete mix, are considered as "cement" is different for both codes

There are two problems associated with w/c ratio as quality indicator: firstly, that for the same w/c ratio, the performance of the concrete depends on the quality of the constituents, chiefly the cement characteristics. Secondly, that so far it is not possible to accurately control the w/c ratio during production nor to measure it reliably on delivery for compliance purposes (Torrent, 2018). Therefore, specifying a characteristic that cannot be controlled is futile and may lead to unfair competition and fraudulent practices.

ACI 318 Section R19.3.2 explains that compressive strength is introduced as an indirect (surrogate) test to cope with the impossibility of accurately checking the w/c ratio by standard tests.

2 DURABILITY PERFORMANCE INDICATORS

The following definition of Durability Performance Indicator (DPI) has been proposed by one of the Authors (Torrent, 2022): *Characteristic of the concrete structure (e.g. cover thickness) or materials' property that is essential to or bear a significant role in the service life of a structure under its specific exposure conditions. A Durability Indicator should:*

- *be meaningful, i.e., as closely connected as possible to the relevant physical, chemical and/or electrochemical deterioration mechanisms that govern the performance of the structure*
- *be measurable, preferably in a reasonably short time (say one week), through well-defined, standardized methods of test or analysis*
- *allow conformity assessment with specified requirements based on tests conducted at suitable, well defined, sampling points (production plant, delivery point, placement point, in situ, in service)*
- *preferably be directly or indirectly (e.g., via robust correlations) included as parameters of existing performance prediction models*

2.1 Coefficient of chloride-diffusion as DPI

In the case of chloride-induced corrosion, as discussed in 1.1, the most relevant DPI of a given concrete would be its coefficient of chloride diffusion D_0 . There are standard test methods to measure it (ASTM C 1556 and EN 12390-11, both quite similar) which consist in immersing a concrete sample with an unsealed face in contact with a high NaCl concentration solution for a time that ranges between 35 and 91 days and in measuring the resulting chloride profile by analytical methods. The best fit of Eq. 1 to the obtained chlorides' profile $C(x)$ yields the value of D_0 . The problem is that the test is costly and time-consuming, therefore inadequate as practical DPI.

2.2 Chloride-migration as DPI

To overcome those limitations, good use has been made of Nernst-Planck Equation (Eq. 5), that describes the flow of ions in a fluid where an electric field is superimposed.

$$-J = D \left(\frac{\partial C}{\partial x} + C \frac{z.F}{R.T} \frac{\partial E}{\partial x} \right) \quad (5)$$

where:

J = flux of ions or molecules ($\text{g}/\text{m}^2/\text{s}$). The minus indicates that the flux is opposite to the gradients

z = electric charge of the ion (-)

C = ion concentration in the fluid (g/m^3)

F = Faraday constant = $96,485 \text{ J.V}^{-1}.\text{mol}^{-1}$

R = universal gas constant = $8.3144598 \text{ J.mol}^{-1}.\text{K}^{-1}$

T = absolute temperature (K)

$\partial C/\partial x$ = gradient of ion concentration (g/m^4)

$\partial E/\partial x$ = gradient of electric potential across the element (V/m)

The first term within the parenthesis in Eq. 5 corresponds to the component of the flow of ions driven by the concentration gradient (diffusion) and the second term by the electric potential gradient. This second component is known as migration. Notice that, according to Eq. 5, both diffusion and migration are, in theory, governed by the same property of concrete D . This opens the possibility of measuring D_0 much faster, by applying a convenient electrical field.

Two test methods have been standardized, based on forcing the penetration of chlorides into a concrete sample by applying an electrical field. Both consists in placing a fully saturated concrete disc in contact with two different solutions, one of them containing NaCl and forcing the penetration of Cl^- ions by applying an electrical field – during a certain period - through electrodes immersed in the solutions. The outcome of the ASTM C1202 test is directly the amount of electrical charge Q (Coulombs) passed after 6 hours under 60 V. In the EN 12390-18 test, after subjecting it during up to 168 h to 10-30 V, the specimen is removed, split and the penetration

depth of chlorides is measured colorimetrically on the split surface. This allows to yield, as test result, the coefficient of migration M , expressed in m^2/s , same units as for D_0 .

Relations have been established for both Q (Olek et al, 2002) and M (Li, 2016; Ren et al, 2021) with D_0 , of the form:

$$D_0(Q) = 0.4 + 0.002 \cdot Q \quad \text{with } D_0(Q) \text{ in } 10^{-12} m^2/s \text{ and } Q \text{ in Coulomb} \quad (6)$$

$$D_0(M) = M/2 \quad (7)$$

Migration tests are much faster than Diffusion tests but the duration is still considerable and the number of samples that can be tested simultaneously is limited by the amount of cells available.

2.3 Surface electrical resistivity as DPI

This test method consists in placing, on the tested concrete surface, a linear arrangement of four electrodes, the tips of which are moistened to ensure electrical contact. A current of intensity I is applied between the two external electrodes and the resulting potential U , established between the two internal electrodes, is measured. The surface electrical resistivity ρ is calculated as:

$$\rho = 2 \cdot \pi \cdot a \cdot G \cdot \frac{U}{I} \quad (8)$$

where

ρ = surface electrical resistivity ($\Omega \cdot m$)

I = intensity of applied current (A)

U = measured potential (V)

a = separation of the electrodes (m)

G = geometric factor (-); $G=1$ for application on a semi-infinite surface; (see Table 3)

The method has been standardized in the USA (AASHTO T358) and in Spain (UNE 83988-2) for use in the laboratory. The electrodes are applied on the surface of a fully saturated concrete specimen, yielding a result in a couple of minutes.

Its potential for site application is limited by the sensitivity of ρ to: degree of saturation, temperature, vicinity of steel bars, etc. To the authors' knowledge, there is no standard for site application of this test.

A relation between D_0 and the saturated surface electrical resistivity ρ has been proposed in (Torres-Acosta et al, 2019), of the form:

$$D_0(\rho) = 400/\rho^{0.908} \quad \text{with } D_0(\rho) \text{ in } 10^{-12} m^2/s \text{ and } \rho \text{ in } \Omega \cdot m \quad (9)$$

2.4 Coefficient of air-permeability as DPI

This test method measures, non-destructively, the coefficient of air-permeability kT of concrete by the double-chamber vacuum cell technique, and is standardized in Switzerland (SIA 262/1) and Japan (NDIS 3436-2) for site testing and in Argentina (IRAM 1892) for both lab and site testing. A relation has been established between D_0 and kT of the form (Torrent et al, 2022):

$$D_0(kT) = 10 \cdot \sqrt[3]{kT} \quad \text{with } D_0(kT) \text{ in } 10^{-12} m^2/s \text{ and } kT \text{ in } 10^{-16} m^2 \quad (10)$$

The vacuum cell is applied on the plane surfaces of 150 mm cubes or cylinders, or directly on structural elements *in situ*, which have to be relatively dry, yielding a result in up to 6 minutes.

3 EXPERIMENTAL VALIDATION OF DPIS

The validity of the proposed DPIS, briefly described in 2.1 to 2.4 was investigated on a series of concrete mixes, as described below. The Coefficient of Diffusion $D_0(M)$, obtained from the coefficient of migration M (Eq. 7) is taken as reference, given the closer relation between D and M , expressed by Eq. 5, also supported by experimental evidence (Vivas et al, 2007).

3.1 Concrete mixes

A total of 18 concrete mixes, nine with water/binder ratio $w/b=0.40$ and 380 kg/m^3 of binder and nine with $w/b=0.65$ and 280 kg/m^3 of binder, were prepared (Moro & Torrent, 2016).

3.2 Binder types

Each pair of mixes ($w/b = 0.40$ and 0.65) was prepared with a different industrial binder, covering a wide range of compositions, as described in Table 2.

Table 2. Binders used in the concrete mixes.

Code	Composition
OPCA	OPC (Clinker A)
MS8	92% OPCA + 8% Silica Fume
S22	Portland-slag Cement (22% GBFS, Clinker A)
S43	Portland-slag Cement (43% GBFS, Clinker A)
S69	Portland-slag Cement (69% GBFS, Clinker A)
OPCB	OPC (Clinker B)
L22	Portland-limestone cement (22% L. Filler, Clinker B)
FA25	Portland-fly ash cement (25% Fly Ash, Clinker B)
FA33	Portland-fly ash cement (33% Fly Ash, Clinker B)

3.3 Properties measured and test procedures

Table 3 presents a summary of the relevant properties measured on the 18 concrete mixes, the test methods applied and the specimen type and preconditioning employed. All specimens were cured under water (20°C) for 28 days prior to testing.

Table 3. Properties measured and test procedures.

Property	Test Method	Specimens and Preconditioning
Chloride Migration Q	ASTM C1202	$\text{Ø}100 \times 50$ mm discs, drilled and saw-cut from
Chloride Migration M	SIA 262/1-B (EN 12390-18)	150 mm cubes, water saturated
Surface Electrical Resistivity ρ	AASHTO T358; UNE83988-2	120x120x360mm saturated prism; electrodes spacing = 38 mm; $G = 0.8$ (Haldor Topsøe, 1968)
Air-Permeability kT	SIA 262/1-E – IRAM 1892	$\text{Ø}150 \times 50$ mm discs cut off cast $\text{Ø} 150 \times 300$ cylinders. Prior to testing, 6 d. oven-drying at 50°C .
Compressive strength f_c	EN 12390-3	150 mm cubes*

* Converted into 150×300 mm cylinder strength as described in (Moro & Torrent, 2016)

3.4 Test results

Table 4 summarizes the results obtained for the 18 mixes tested. Regarding the DPIs, instead of the test results, already the estimates of D_0 obtained from them (Eqs. 6, 7, 9 and 10) are reported.

Taking as reference the estimate $D_0(M)$, the standard error ξ_e of the other estimates is reported in the last row of Table 4.

3.5 Analysis of the results

Figure 1 shows the results of $D_0(M)$ for the 9 binders investigated, differentiating the concretes with w/b ratios of 0.40 and 0.65. As reference, the classification after [Tang, 1996] is shown: P (Poor), N (Normal), G (Good) and VG (Very Good).

Figure 1 shows that, for the same low $w/b = 0.40$, a large variety of performances are achieved with the different binders. Very Good chloride-resistance is achieved for binders containing 8% silica fume and 69% of GBFS. The two OPCs show a Good chloride-resistance, same as the

cements with 22 and 43% GBFS and 25% and 33% of fly ash, whilst the limestone-filler cement achieves just a Normal chloride-resistance. It can be seen also that a Good chloride-resistance can be achieved, at $w/b = 0.65$, with the binders containing 8% Silica Fume and 43 and 69% of GBFS.

Table 4. Compressive strength and estimated values of D_0 (Eqs. 6, 7, 9, 10).

Concrete mix		D_0 (10^{-12} m ² /s) estimated from				Mean strength*
w/b	Binder	Q	M	ρ	kT	f_{cm} (MPa)
0.40	OPCA	4.3	2.1	5.3	3.1	57.4
	MS8	1.2	0.6	1.3	1.3	66.5
	S22	2.8	1.5	3.9	2.7	65.2
	S43	2.5	0.5	2.6	2	51.5
	S69	1.2	0.2	1.3	1.4	48.5
	OPCB	6.2	3.6	6.9	2.9	65.1
	L22	6.4	5.4	7.7	4.9	32.7
	FA25	3.6	3.2	5.1	2.4	45.7
	FA33	1.9	2	2.8	2.2	49.4
0.65	OPCA	10.5	7.0	10.1	7.9	24.5
	MS8	2.9	2.0	3.2	2.6	30.2
	S22	6.9	4.7	8.5	4.9	25.5
	S43	3.4	2.0	4.1	3.5	23.3
	S69	1.7	0.3	1.7	3.4	19.7
	OPCB	11.2	9.3	12.5	9.2	31.8
	L22	14.4	14.1	12.4	8.5	15.2
	FA25	9.1	11.1	8.5	6.0	15.8
	FA33	3.5	5.9	4.6	3.6	17.0
\bar{s}_e (10^{-12} m ² /s)		1.8	—	2.3	2.2	*cylinder

Figure 1. Effect of binder type and w/b ratio on $D_0(M)$.

The results of Figure 1 confirm the unsuitability of the w/c or w/b ratio to specify resistance of concrete to chlorides, since the performance depends strongly on the binder type used. On one extreme, a concrete with $w/b = 0.40$ may not display enough chloride resistance for certain applications, whilst on the other, the required performance could be achieved with higher w/b ratios (and less binder content), with the consequent extra cost and reduced sustainability.

Figure 2 shows the results of $D_0(M)$ for the 18 mixes investigated, plotted as function of the mean cylinder compressive strength, measured at 28 days, with the same classification as for Figure 1.

It can be seen that all the mixes complying with the minimum requirement of 35 MPa (Table 1) of specified strength (say, 40 MPa of mean strength) present $D_0(M)$ values within the Good and Very Good chloride-resistant classes. Therefore, from the durability point of view, these limits look adequate. There are three mixes having strengths below the minimum requirements that, yet, show a Good performance, corresponding to the mixes ($w/b = 0.65$) made with 8% Silica Fume and 43

and 69% of GBFS. These three performing mixes, with just 280 kg/m³ of binder, are more sustainable and, yet, would be rejected due to lack of compliance with the specified $f'_{c_{min}}$.

Figure 2. Relation between $D_0(M)$ and mean compressive strength f'_{cm} of the 18 mixes tested.

Figure 3 compares the estimates of D_0 , obtained from the measured values of Q , ρ and kT , applying Eqs. 6, 9 and 10, respectively, with the adopted reference values of $D_0(M)$, obtained from the measured values of M , through Eq. 7.

Figure 3. Relation between $D_0(M)$ and D_0 values estimated from Q , ρ and kT test results of 18 mixes.

Figure 3 shows a visible trend that higher values of D_0 , estimated from the measured values of Q , ρ and kT , generally correspond to higher values of $D_0(M)$. This suggests that all the DPIs are, in principle, suitable to detect concretes of higher or lower chloride diffusivities.

In what concerns accuracy, quite accurate estimates of $D_0(M)$ are obtained, with a tendency to overestimate it, especially for low values, i.e., on the safe side. This is visible in Figure 3, but also from the low standard error of estimates \hat{s}_e shown in Table 4.

4 CONCLUSIONS

The investigation reported in this paper produced results that yield the following conclusions:

- The unsuitability of the w/c or w/b ratio as mix parameter to judge the resistance to chlorides of a concrete mix has been confirmed, because its true performance is strongly affected by the binder used. In addition, no standard method exists to measure it accurately. It should be substituted or complemented in Codes by suitable DPIs
- The minimum compressive strength specified in ACI and EN Codes seems adequate to ensure that chloride-resistant concretes are used. Yet, mixes not complying with the $f'_{c_{min}} = 35$ MPa may still be suitable, the rejection of which affects cost and sustainability of concrete structures

- w/c or w/b and $f^c_{c_{min}}$ cannot be associated with SL models and, therefore, the requirements cannot be tuned to SLs beyond the one expected by the Codes (typically 50 years)
- The evaluated DPIs, namely Chloride Migration (M and Q), Electrical Resistivity (ρ) and Air-Permeability (kT), show a good potential to assess the chloride-resistance of concrete mixes
- The more direct estimate of the Coefficient of Chloride-Diffusion D_0 is provided by the EN 12390-18 test for Coefficient of Chloride Migration (M)
- The problem with that test is its duration and the need to use special cells to conduct it, features shared with the ASTM C1202 “RCPT” (Q), which limits the testing capacity of a laboratory
- Both the Electrical Resistivity (ρ) and Air-Permeability (kT) tests present the advantage of being non-destructive, applied directly on specimens and lasting few minutes
- For lab applications, Electrical Resistivity (ρ) has the advantage of being measured on the same saturated specimens used for strength, whilst Air-Permeability (kT) requires a pre-drying
- Air-Permeability (kT) can be measured by standard procedures directly on site, thus providing a more realistic picture of the true quality of the end-product than cast specimens
- All DPIs provide an estimate of the Coefficient of Chloride-Diffusion D_0 , which is a key input for Service Life analysis. The accuracy of the estimates, based on M , Q , ρ and kT test results is quite consistent. Taken into consideration the strong effect of exponent n (Equations 2 and 3) on the SL prediction, the accuracy of the estimates of D_0 seems adequate
- The requirements of concrete mixes in terms of D_0 can be fine-tuned to the expected service life t_s , cover thickness d and aggressivity of the exposure C_s (Equation 3). This D_0 limiting values can be converted into limiting values of M , Q , ρ and kT through Equations 6, 7, 9 and 10, properties on which the routine quality control can be exercised

Measuring heavy traffic using alternative systems in an urban environment

M.L. Soudijn & S. van Rossum

Engineering office - City of Amsterdam, Amsterdam, The Netherlands

A. de Boer

Engineering office - City of Amsterdam, Amsterdam, The Netherlands

Ane de Boer Consultancy, Arnhem, The Netherlands

ABSTRACT: By recombining available traffic load data with local traffic measurements we aim to determine a more accurate traffic load model. The model we obtain should help verify more precisely which bridges and quay walls can still withstand current traffic loading and which need strengthening or replacing. The current assessment on structural safety of existing structures uses the national standards for traffic loads based on WIM-ROAD highway traffic measurements. WIM-ROAD is sub-optimal for urban environments because bumpy roads and traffic behaviour, e.g. proximity to traffic lights, can negatively impact measurement accuracy. Therefore, we investigate alternatives to get accurate and reliable measurements. We discuss combinations of sound-radar, advanced counting traffic hoses, ANPR cameras coupled to national vehicle databases and our own WIM-ROAD measurements within a semi-urban environment. We show the accuracy and reliability of these different measurement systems and the potential in coupling their measurements.

1 INTRODUCTION

The city of Amsterdam faces a large infrastructural challenge. About 830 historic bridges and 200 km of quay walls, loaded by motorized traffic, were built two or even three centuries ago on wooden pile foundations. An estimate is that a substantial number of these structures is in a poor state of repair due to a combination of (too much) heavy traffic and overdue maintenance. The challenge Amsterdam faces is huge because simply replacing or strengthening all the structures in need of maintenance at once is not an option. Apart from the enormous cost and time needed, the city would become uninhabitable by such an enterprise. Additionally, the exact numbers of which structures need replacing or strengthening are unknown, which is why investigations are underway to determine their current state: the (material) strength of the structures, the allowable traffic load and the actual current traffic loads. Here not only the traditional models are used but these are supplemented with experimental research. Overall it is essential to find a way that can help the city of Amsterdam improve planning this enormous challenge.

Simply checking current structures according to the current - relatively conservative - standards is insufficient, as it is expected that many structures will be rejected, possibly on unjust grounds. Particularly, with the introduction of the Dutch National Annex to the Eurocode (Steenbergen et al. 2012, NEN-EN 2019) in 2012 the traffic load models gave rise to a large increase compared to the Dutch traffic load models that were previously in use, especially for urban environments, such as Amsterdam. Taking into account these increased traffic loads combined with the situation in Amsterdam would undoubtedly lead to a mass rejection of bridges. However, the National Annex also leaves room for using the actual traffic loads to determine a local traffic load model. This requires accurate and reliable measurements of the local traffic loads. In this paper the traffic load measurements are described that were performed for the City of Amsterdam with the goal of

setting up a local traffic load model. Even though high accuracy Weigh-in-Motion (WIM) measurements were performed in a semi-urban environment, including Automatic Number (or License) Plate Recognition (ANPR) cameras and a sound-radar system (Soudijn et al. 2021, Soudijn et al. 2022), additional measurements are required to relate these WIM measurements to the inner city areas for which the aim is to set up our load model(s).

Using WIM systems in the inner city area is not preferable because bumpy roads and proximity to crossings lead to decreased measurement accuracy, due to erratic vehicle behaviour, rendering such measurements useless. The question remains however, how one can achieve accurate load measurements in an inner city environment. The approach to this challenge is trying to map the expected weights throughout the inner city of Amsterdam. The aim is to use a “resampling” method which uses both the urban WIM measurements as well as alternative measurement methods such as advanced counting pneumatic tubes, sound-radar detectors and ANPR cameras, whichever provides the most useful and accurate information. Both sound-radar (Ch. 2.2) as well as ANPR cameras (Ch. 2.3) were used at our WIM location (Ch. 2), and alternatively the advanced pneumatic tubes can detect similar vehicle classes as WIM. The goal is to investigate the method that will work best to relate the types of vehicles to particular WIM traffic load measurements and thus build up a traffic load spectrum through the “resampling” method. Furthermore, the municipality of Amsterdam decided in 2020 to enhance existing vehicle limitations to inner city areas. The precise limits are 10 m for the vehicle length and 75 kN for the vehicle mass. Permanent permits can be given to transport vehicles up to 300 kN or a longer vehicle length. These constraints give an alternative or additional way to correlate our measurements.

2 MEASUREMENT METHODS FOR HEAVY TRAFFIC

Various measurement systems were used at the WIM location in the western harbour district of Amsterdam at the location “Westpoortweg”. Both a WIM-ROAD and WIM-BRIDGE system were installed (based on COST 323 2002 & OIML 2006) at the pilot location in the western harbour district of Amsterdam as shown in Figure 1a. The WIM-ROAD system, which is the main system used in this paper (Ch. 2.1), consists of 8 lineas-quartz sensors (Kistler) per lane, as shown in Figure 1b, to achieve a high measurement accuracy. The WIM-BRIDGE measurements are still under evaluation, however, a sound-radar system was part of this setup from which measurements are used in this paper (Ch. 2.2). As part of the setup (Figure 1a) 4 ANPR cameras and 2 line-scan cameras were installed. The ANPR cameras were placed to detect both front and back license plates in order to include details of semi-trolley trucks from the Dutch Vehicle Authority (RDW) database. The line-scan cameras were used to detect lifted axle’s and special vehicles as shown in Figure 1c. A more detailed description of the WIM setup used in this research and its preliminary results are described in more detail in Soudijn, van Rossum & de Boer (2021 & 2022).

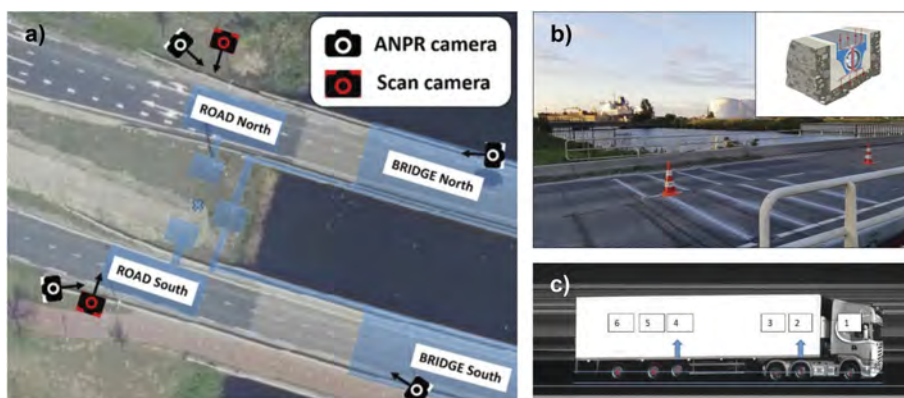

Figure 1. a) Location Westpoortweg: WIM systems and camera setup as indicated. b) WIM-ROAD North system: 8 Lineas-quartz sensors (inset) per lane. Induction loop detectors detect each vehicle. c) A vehicle ‘side-scan’ image where two lifted axles are visible.

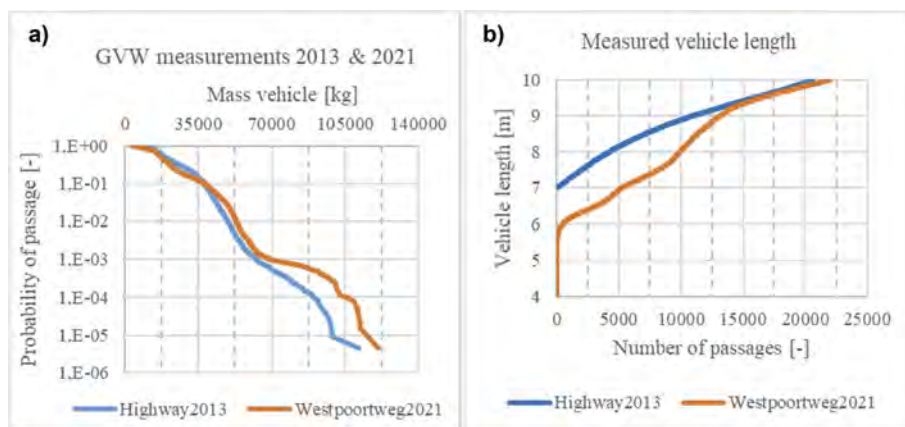

Figure 2. a) Heavy traffic measurements: GVW > 3.5 kN. b) Vehicle length versus occurrence numbers. For both figures a comparison is made between the 2013 highway and 2021 Westpoortweg measurements.

2.1 Relevant measurement results from the WIM-ROAD system at Westpoortweg

An overview of the heavy traffic vehicle passages from our own Westpoortweg WIM-ROAD system (one month, 95,000 passages) and of the relevant Dutch highway system in 2013 (Eurocode evaluation, one month, 220,000 passages) (Steenbergen et al, 2018) are shown in Figure 2a.

Figure 2a shows the Gross Vehicle Weight (GVW) occurrence with some more passages in the lower GVW region at the Westpoortweg than in the highway measurements. But at the Westpoortweg there are more heavier passages above the 60,000 kg vehicle mass than on the highway. The Westpoortweg lies within an industrial area of Amsterdam and forms a regional connection between the city and west side of the province, so both observations are realistic.

The highway 2013 measurements show only vehicles with a minimum length of 7 m, however this lower limit is too high when considering inner city areas. The Westpoortweg measurements show a minimum vehicle length of around 4 m. This is a more realistic lower limit in case of the inner city heavy traffic, where the narrow streets and tight corners constrain vehicle lengths. Figure 2b shows the relation between the length of the vehicles versus the occurrence numbers.

During the measurement period at the Westpoortweg the City of Amsterdam introduced enhanced restrictions on the maximum vehicle length and GVW for the inner-city area. The maximum length is now 10 m and the existing maximum GVW of 75 kN is enforced more seriously through camera surveillance. Permanent permits are given to vehicles with a GVW vehicle up to 300 kN with inner-city destinations. Single day permits with a prescribed route are given to transport firms who carry unmovable loads that go above a GVW of 300 kN or require a vehicle length of more than 10 m.

These limits and the registration of these permits can provide insight on the expected traffic loads in the inner city of Amsterdam. Figure 3a shows what a 10 m cap on length would mean for the amount of vehicles to consider for the inner city. As a first order approximation a GVW up to 300 kN can be assumed, however, an overload of 30% should be included as a safety margin. As an initial indication, Figure 3b shows the effect on the probability of passages derived from 5 months of Westpoortweg data using these GVW and length constraints. Comparing the overall measurements and the derived restriction measurements both curves show a very continuous probability of passages. An almost log linear function is seen from a mass of 3500 kg up to 45,000 kg for the 10 m length restriction and up to 35,000 kg for both restrictions.

In addition to the GVW measurements it is important to evaluate the single axle loads and the tandem/tridem axle configuration loads as well, especially for the more localized loads and when considering short span bridge structures. Figure 4a shows the probability of single axle load passages based on the 5 months of vehicle data including the inner-city restrictions as mentioned.

Near the probability of 10^{-5} in Figure 4a, a difference in axle weight of 25 kN is shown. Both curves show high maximum values regarding the legal axle load limit of 115 kN. Still

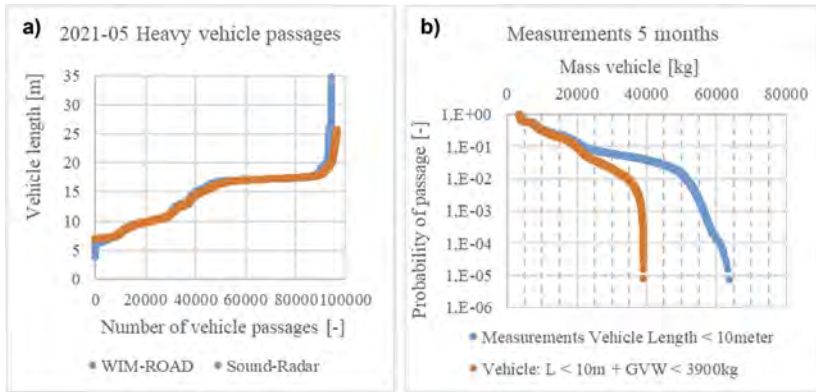

Figure 3. a) Vehicle length as function of heavy vehicle passages, results from WIM-ROAD and sound-radar system compared. b) GVW measurements with inner city restrictions to the vehicle length and GVW.

there is no asymptotic limit in the measurements and thus extrapolation to a maximum axle load limit is not possible from only 5 months of data. A whole year (2021) of measurements are available, but not properly checked yet for erroneous measurements at this time. The maximum measured axle load, however, is 230 kN, which is far below the 300 kN given by the Load Model 1 Eurocode or the 400 kN of Load Model 2 Eurocode. This is not a guarantee, but a good indication that a lower load limit can be found.

Finally, in Figure 4b we show the WIM-ROAD measurements in terms of the probability of passages of the tandem and tridem axle configurations. Only 4 quad axle configurations were measured in total, which is insufficient for a figure. These quads belong to vehicles with 6 or more axles and the restricted measurement set has a negligible number of 3 vehicles with 6 axles.

Both curves in Figure 4b show an asymptotic behaviour which means that an estimate tandem or tridem load limit can be made based on this data. Including the extra uncertainty factor of 10^{-4} in the Eurocode, the tandem axle load limit comes down to an estimate of 330 kN at a probability level of 10^{-8} . The tridem axle load limit could, by extrapolation, go to 375 kN at a probability level of 10^{-7} . This estimate for the tandem load limit is far below the standard Eurocode limit of 600 kN for the tandem axle configuration and also far below the Dutch reduced limit for regional areas, which is 480 kN. Thus far, the conclusion that can be drawn

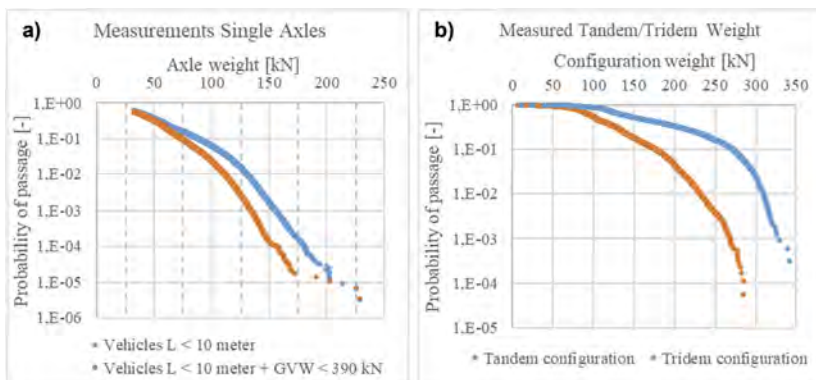

Figure 4. a) Probability of single axle load vehicles including the inner city restrictions. b) Probability of passages of tandem and tridem axle configurations for the inner city.

from our WIM measurement data for vehicles and axles is that the inner city load model, given the restrictions on vehicle length of 10 meter and GVW of 390 kN, could potentially be reduced substantially compared to the current Eurocode.

2.2 Sound-radar measurements

At the Westpoortweg pilot location, as part of the WIM-BRIDGE setup, a sound-radar system was installed to detect vehicle passages. The output of this sound-radar system is: a timestamp per vehicle, vehicle length, vehicle category, speed, number of axles, noise of the vehicle, lane number and the distance between the system and the passing vehicle. In Figure 3a we compare the number of heavy vehicles passages between the WIM-ROAD and the sound-radar systems.

There are some differences in the lower and higher region of the vehicle lengths, but compared to the expected inner city traffic flow, there is only a difference in the lower region of the vehicle length. For most passages up to the 10 m vehicle length restriction for the inner city a sufficient agreement is found when comparing the sound-radar with the WIM-ROAD data.

2.3 Camera measurements

The ANPR camera measurements of the front and backside of the vehicles make it possible to match the license plates of the vehicles with the Vehicle database of the Dutch Vehicle Authority (RDW). That means that additional information about the vehicle parameters can be included in the measurements. First these parameters can be used to check if the measured data of the passing vehicle is correct, which allows to ‘clean’ the WIM measurements. The possible overload of the passing vehicles can also be derived and estimates for the expected overload in the inner city can be made. The scan camera shows a photo of the side of the passing vehicle. With this photo it can be checked if a vehicle has one or more of its axles lifted (as shown in Figure 1c). This aspect is also a part of the information of the Dutch Vehicle database, so an additional check can be made. At this moment, work is still in progress on accurate automatic coupling of the camera data to the WIM measurement data (Ch. 3.2).

2.4 Vehicle distributions

The above measurement systems all have a means of detecting the number of axles for each vehicle. In Table 1 the different distributions from each of the systems are shown, by count and by percentage, for the Westpoortweg measurements during the same month (May 2021).

The camera system which, in this case, uses only the front license plate, detects relatively more 3-axle vehicles than the other systems. While the other systems detect more vehicles with > 3 axles. This is done to get an idea of what the camera system in the inner city – which has only front view cameras – would detect (Ch. 4.2). The reason can probably be found in a large quantity of 3-axle vehicles being part of a truck-trailer combination at the location, where the trailer is only detected by the back-camera (which is not coupled for this particular comparison).

Table 1. Vehicle distribution by axle for vehicles ≤ 10 m and > 10 m respectively.

Vehicle type	Vehicle length ≤ 10 m						Vehicle length > 10 m					
	Radar		WIM-ROAD		Camera		Radar		WIM-ROAD		Camera	
	[#]	[%]	[#]	[%]	[#]	[%]	[#]	[%]	[#]	[%]	[#]	[%]
2-axles	372522	80.4	467911	84.8	405560	94.2	13270	2.9	8342	1.5	4423	1.0
3-axles	4310	0.9	4093	0.7	12336	2.9	6009	1.3	5398	1.0	2171	0.5
4-axles	2914	0.6	4180	0.8	3123	0.7	25318	5.5	25905	4.7	425	0.1
5-axles	1447	0.3	1455	0.3	1785	0.4	30746	6.6	29654	5.4	792	0.2
6-axles	610	0.1	113	0.0	NA	0.0	4312	0.9	3723	0.7	3	0.0
> 6-axles	688	0.2	35	0.0	NA	0.0	1113	0.2	908	0.2	2	0.0
Total	382491	82.6	477787	86.6	422804	98.2	80768	17.4	73930	13.4	7816	1.8

For the inner city it is expected that the trailer data will be less relevant and thus the camera system may still be sufficient to get a good estimate of the vehicle distribution by axle count. The aim is to verify this assumption through traffic tube measurements.

3 MEASUREMENT ACCURACY & RELIABILITY

3.1 Comparison WIM-ROAD, sound-radar & cameras

The rough WIM-ROAD database can be ‘cleaned’ by checking and matching the measurements against the other 2 systems. This initially shows that there are a limited number of vehicles from outside the Netherlands. By using the optimal WIM-ROAD setup with 8 lineas-quartz sensors per lane (Ch. 2) a small amount of outliers in the heavy traffic vehicles can be seen. Table 1 shows the overall vehicle passages including the personal cars. The ratio between sound-radar, WIM-ROAD and the camera overall passages is 463:552:501. The results of the camera system shows about 90% coverage of the WIM-ROAD system and the sound-radar is at about 80% coverage. Several reasons can be found for these differences. The first one is that the cameras have a relatively high miss-rate as the trigger is ‘recognition’ of a license plate. Also, one camera covers two lanes, which can cause shielding (another vehicle is in front of the license plate). Additionally not every vehicle is well documented in the Dutch Vehicle database, losing some of the vehicle information. The heavy traffic vehicles show on average 100,000 passages every month for both directions, which is comparable with the periodic counting of vehicles (including type), also performed by the municipality of Amsterdam. Nevertheless, both installed systems show an 80-90% coverage compared to the WIM-ROAD system, which is acceptable for checking of vehicle passage types and numbers. Because of the importance of the camera systems in the inner city, this is discussed in the next section.

3.2 Coupling camera and WIM-ROAD measurements

To verify measurements and get a more accurate measure of overloading the goal was to couple the WIM-ROAD measurements to the camera data. As part of the camera data, vehicle characteristics were collected from the “RijksDienst voor het Wegverkeer” (RDW; the Dutch Vehicle Authority). The WIM-ROAD and camera datasets were matched by traffic lane and nearest time, with a correction for the mean difference in time between a vehicle passing the WIM-ROAD sensors and a vehicle being detected by the cameras.

Sometimes a picture was coupled to more than one WIM-ROAD measurement and vice versa. In those cases conditions were added by which the most relevant match should be made: the measured gross vehicle weight should be less than twice the allowed maximum weight; and the measured gross weight should be more than half the empty weight of the vehicle. Lastly, the duplicates are deleted, by first ruling out the duplicates that could not meet both conditions; and then ruling out the ones that had a bigger time difference.

Table 2. Detailed example of the coupling result.

WIM-ROAD	Camera/RDW	WIM-ROAD		RDW database		
StartTimeStr	StartTimeStr	Length [m]	Gross weight [kg]	Length [m]	Empty weight [kg]	Allowed weight [kg]
	13:12:28.602			3.84	953	1530
13:12:32.631		4.27	1220			
	13:12:37.880			9.70	13565	29000
13:12:41.998	13:12:41.880	9.59	19410	0	1110	1655
	13:12:43.160			3.56	840	1290
13:12:46.039		4.28	1330			
13:12:47.256		3.95	930			

Figure 5a shows the difference between the WIM-ROAD time and the camera time after the initial correction over the period of one week (delta_T). It is seen that the systems go out of sync during the day and at certain points, as indicated by the red lines, they get corrected, which happens at apparently random moments.

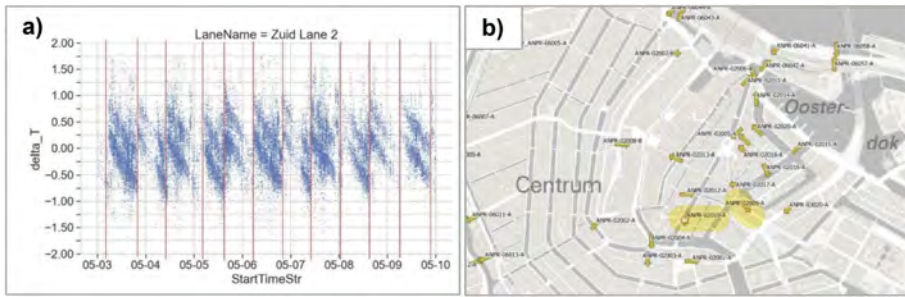

Figure 5. a) Timedrift between camera and WIM-ROAD data; the vertical axis shows the difference between the WIM-ROAD time and the camera time after the initial correction as described in the text. b) Selected cameras (yellow oval marking) for the zones of interest within the inner city of Amsterdam.

To check whether the coupling was done correctly the coupling is verified by looking for data with a big relative difference between the allowed weight as registered in the RDW database and the measured weight by our WIM-ROAD system. An example of a non-matched vehicle that should have been matched is shown in grey in Table 2. But the other vehicles shown are also wrong matches.

It can be seen that at this point in the dataset, the ΔT is about 4 s, which is significantly bigger than we found in Figure 5a. However, most of the time, by looking at samples of the data, the matching seems to be done correctly. It was not possible to accurately get numbers on how often and when the ΔT gets too big. A solution is yet to be found.

In conclusion it is recommended that for future measurements when data needs to be coupled; it needs to be coupled by a trigger cable between the WIM-ROAD and camera measurements. We cannot rely on their passing times being always in sync. Using the same process in the inner city it should be much easier to couple the measurements by the lower number of passages.

4 SETUP MEASUREMENTS CITY CENTER

4.1 General

Little to no reliable measurements are known within the inner city regions and it is often too expensive to set up a WIM measurement system like above for a small scope of bridges and quay walls; while also technically challenging due to the number of traffic lights and side roads in the inner city. A solution that we are currently exploring is to count and classify vehicles in the inner city with cameras, sound-radar or advanced pneumatic tubes.

4.2 Cameras – traffic research results inner city

Amsterdam is already full of ANPR-cameras that are used for enforcing restrictions on environmentally unfriendly vehicles in the inner city, which could help in this research. The cameras were selected based on their location and highlighted in Figure 5b. These cameras are most relevant for the next set of bridges and quay walls to be verified for their structural reliability.

In Table 3 the distribution of vehicles is shown by their number of axles as registered by the RDW and related to only the front license plate. They are divided in 2 categories: vehicles > 10 m and vehicles ≤ 10 m. This is done because the drivers need a permit to drive vehicles longer than 10 m in the inner city. Disadvantage of the camera method is that currently there are barely any back ANPR-cameras. So when a vehicle is pulling a heavy trailer, the unique license plate of the trailer will not show up in the data.

Table 3 shows no vehicles with over 4 axles. Which can be caused by the low total number of vehicles, but also by the restriction of the zone for vehicles over 30,000 kg which requires a more specific permit for a single route.

Table 3. Vehicle distribution by axle count and their allowed weight as counted during a month by 2 ANPR-cameras for vehicles smaller than or equal to 10 m in length (and greater than 10 m in length).

Axle count	Vehicle Count	Percentage of occurrences [%]	Mean of the maximum allowed weights [kg]	Standard deviation of the maximum allowed weights [kg]
2	643 (10)	56.1 (0.9)	14,769 (18,218)	4175 (1678)
3	451 (4)	39.3 (0.4)	25,032 (28,447)	2473 (415)
4	30 (9)	2.6 (0.8)	36,905 (37,278)	940 (2718)

As stated earlier, it is not known whether certain vehicles pulled heavy trailers while driving through the inner city. Though it might be assumable that those are exceptions, in which case we would like to verify this by other means of measurements or back-side cameras.

5 CONCLUSIONS

1. The WIM-ROAD measurement database gathered at the Westpoortweg location is a valuable and useful resource which is a good starting point for a ‘resampling’ approach to determine an adjusted traffic load model for the inner city of Amsterdam.
2. The various measurement methods that were introduced and partly researched (cameras, advanced pneumatic tubes, etc.) to determine the vehicle ‘spectrum’ for the inner city, each have their merits and their challenges. However, by using one or more of these systems together with WIM measurements, a usable traffic load model should be achievable.
3. Our expectation is that an early stage of this model should be presentable during the IALCCE conference in Milan 2023.
4. The next steps are to verify this model in cooperation with the Dutch recommendation organisation TNO-research and get acceptance of the model by the Dutch authorities.

ACKNOWLEDGEMENTS

The authors wish to express their gratitude and appreciation to the Programme Bridges and Quay Walls of the Engineering Office of the City of Amsterdam for support of the pilot project “Traffic load measurements”. Thanks also goes to all members of the team for their contributions.

ABSTRACT: An increasing number of researchers are working on Structural Health Monitoring (SHM) applications. However, the high price of traditional commercial accelerometers is known to be one of the significant drawbacks of SHM methods. On the one hand, to apply SHM applications to structures with a lower budget dedicated for their health and safety assessments, development of low-cost sensors can be an answer. On the other hand, low-cost sensors are known to have lower accuracy and resolution compared with those of traditional commercial accelerometers. For the first time in the literature, this paper represents a methodology for improving the resolution and accuracy of low-cost, low-resolution accelerometers. To do so, this paper proposes averaging the outputs of several aligned synchronized low-cost accelerometers.

The validity of the proposed methodology has been examined through a series of laboratory experiments. These experiments tested accelerometers made from one, two, three, four and five combined MPU9250 chipsets on a shaking table. Moreover, two commercial accelerometers (393A03 and 356B18) were used to validate the accuracy of the developed solutions.

1 INTRODUCTION

Structural Health Monitoring (SHM) systems are composed of sensors that measure the structural response (such as accelerations, rotations, strains, or deflections) over time. This information can be used to estimate changes in the structural performance of infrastructures (Gómez, Casas, & Villalba, 2020). The time variation of some environmental factors (such as temperature or humidity) that could produce crack opening (Komarizadehasl & Khanmohammadi, 2021), rotations, settlements, corrosion and other pathologies is so slow that they can be considered quasi-static or static (Baraccani et al., 2017)(Turmo, Lozano-Galant, Mirambell, & Xu, 2015). However, some events (such as the wave response due to earthquake ground motion, traffic-induced vibrations, or ambient activities) need to be accounted for for the dynamic nature of the structural response they induce. To observe and control them, dynamic SHM Systems are required (Chae, Yoo, Kim, & Cho, 2012). The modal parameters needed for SHM application are acquired mainly by accelerometers (Feng & Feng, 2015). MEMS (micro electro mechanical system) accelerometers are silicon-based micromachined devices that traditionally incorporate an accelerometer sensor and a signal conditioning

circuitry (Khandpur, 2020)(Komarizadehasl, Lozano, Lozano-Galant, Ramos, & Turmo, 2022). The low-cost MEMS accelerometers have found their way to various industrial applications due to their significant ongoing technology developments (Behnam Mobaraki et al., 2022). Some of these accelerometers offer low-cost alternatives compared with traditional applications (Looney, 2014)(J. A. Lozano-Galant & Turmo, 2014). Information on various MEMS accelerometers from various structural health monitoring applications is summarized in Table 1. This Table has been ordered by the price of the accelerometers.

Table 1. Summary of the characteristics of the accelerometers commonly used in the literature.

N ^{o1}	Name ²	Price (€) ³	Spectral noise (μg/√Hz) ⁴	Operation Temperature (C°) ⁵	Structural Type ⁶
1	3713B112G (PCB Piezotronics, 2012)	2070.0	22.90	[-54, +121]	Wind Turbine (Botz, Oberlaender, Raith, & Grosse, 2016)
2	3711B1110G (PCB Piezotronics, 2015)	870.0	107.90	[-54, +121]	Railroad Bridges (A. Ozdagli, Liu, & Moreu, 2019)
3	ADXL335 (Analog Devices, n.d.)	10.7	300.00	[-40, +85]	Bridges (Grimmelsman & Zolghadri, 2020)
4	LIS344ALH (ST, 2008)	12.0	50.00	[-40, +85]	Steel beam (Girolami, Zonzini, De Marchi, Brunelli, & Benini, 2018)
5	MPU9250 (Aguero, Ozdagli, & Moreu, 2019)	5.8	300.00	[-40, +85]	Steel Pile and Column (Chatterjee et al., 2017)
6	MPU6050 (InvenSense, n.d.)	5.4	400.00	[-40, +85]	Building Model (Varanis, Silva, & Mereles, 2018)

The analysis of Table 1 shows that low-cost sensors generally have higher noise density. This high noise density results in a lower resolution in comparison with expensive MEMS accelerometers.

Arduino is an open-source electronics platform based on easy-to-use hardware and software. The Arduino Due is a microcontroller board based on the Atmel SAM3X8E ARM Cortex-M3 CPU. Unlike most Arduino boards, the Arduino Due board runs at 3.3V. The maximum voltage that the I/O pins can tolerate is 3.3V. Applying voltages higher than 3.3V to any I/O pin could damage the board (Blum, 2013) (Komarizadehasl, Komary, et al., 2022). In fact, many of the MEMS sensors can interact directly with an Arduino microcontroller (Man & Chang, 2016). Sensors 2 to 6 from Table 1 are low-cost MEMS accelerometers. They need an external power supply and could work with Arduino (B. Mobaraki, Komarizadehasl, Pascual, & Lozano-Galant, 2020). The low-cost sensors in the literature are primarily dedicated to projects with low frequencies and strong acceleration amplitude (A. I. Ozdagli, Liu, & Moreu, 2018)(Mobaraki*, Komarizadehasl, Pascual, & Galant, 2021) as they do not have enough resolution to read low amplitude acceleration.

The literature review shows no solutions for improving the resolution of low-cost accelerometers. To fill this gap, this work investigates the increasing number of aligned accelerometers located in the exact location for measuring the same vibration is beneficial. In fact, individual sensors' individual noise density can better be detected by a Fast Fourier Transformation (FFT)

1. Sensor number.

2. Sensor name.

3. Sensor price: the prices are obtained from retailers (VAT excluded).

4. Spectral Noise: the power spectral density of noise per unit of bandwidth (1 Hz).

5. Operational temperature: temperature range where the sensor works accurately.

6. Structural type: where the sensors are used.

when the average results of a few sensors are evaluated (Jose Antonio Lozano-Galant, Nogal, Turmo, & Castillo, 2015)(Farré-Checa, Komarizadehasl, Ma, Lozano-Galant, & Turmo, 2022).

To validate the performance of the proposed device on laboratory conditions, five accelerometers (MPU9250) were aligned and tested on a hydraulic jack. The jack induced a number of low-amplitude vibrations, and the increasing benefit of accelerometers for decreasing the noise density of the whole system was evaluated (Komary et al., 2023)(Atencio, Komarizadehasl, Lozano-Galant, & Aguilera, 2022).

This paper is organized as follows: In section 2, the proposed system for validating the proposed theory is introduced. Then, in section 3, the laboratory test is used to validate the proposed methodology, and the obtained results are detailed. Finally, the main conclusions are drawn in Section 4.

2 ACQUISITION SYSTEM

In this section, the used equipment for making a vibration acquisition system is illustrated.

Five MPU9250 accelerometers were attached to an Arduino by a multiplexer. It is essential to report that although the sensors are not synchronized, the lag is known.

When the code is executed, the Arduino opens the library and uses the information to get the acceleration from the first sensor, and after the second one, and so on. The lag between each sensor-print is about 2.2 milliseconds. As the lag is known, the average of the measurement (information given by the proposed accelerometer) can also be located in time.

In a nutshell, the proposed accelerometer is working with the average value of the sensors. Therefore, this lag would not interfere with the needed information or the process as the FFT application, which is the heart of this system, and only requires amplitudes and frequency sampling. Frequency sampling is the number of acquired outputs in one second.

3 LABORATORY TESTS

This section compares the sensitivity, ND, and resolution of a single MPU9250 accelerometer. This section studies the performed experiments on the proposed accelerometer in laboratory conditions.

For validating the beneficial effect of using several sensors, an experiment on a hydraulic jack was performed. This jack (INSTRON 8803 (INSTRON, 2017)) is located at the Structural Laboratory Lluís Agulló of Technical University of Catalonia (Spain).

A sinus signal has been programmed with a dynamic jack, and the accelerometer has saved the vibrations. This jack can vibrate its lower jaw as was programmed. The hydraulic jack's instructions were to make a wave with a fixed frequency of 0.5 hertz (one complete wave in two seconds). The jack's movement was to go up to 0.1 millimeters up and -0.1 millimeters down from its null axis to make a sinus wave. With a two-time elementary differential, the acceleration equation could be calculated.

$$y = d * \sin(\omega * t + \varphi) \quad (1)$$

$$\omega = 2 * \pi * f \quad (2)$$

In the above equations, y is the displacement in time t , d is the maximum allowed movement of the jack in each cycle, ω is the angular frequency, and f is the set frequency, which equals 5Hz, and φ is the phase constant. On Eq.3, acceleration has been calculated from Eq.1. This was done by getting the second-order derivative of Eq.1. By putting all the data in Eq.3, the Input Acceleration (IA) was calculated as $0.1006 \text{ g} * 10^{-3} \text{ m/s}^2$.

$$a = (d^2 * y) / (dt^2) = \ddot{y} = -d * \omega^2 * \sin(\omega * t + \varphi) \quad (3)$$

4 EFFECT OF THE NUMBER OF SENSORS

In this section, the beneficial effects of adding an increasing number of averaged sensors are studied.

In Figure 1, estimated errors obtained for a different number of sensors in are compared. The Max and the Min in each graph represent the enveloped error for all the possible sensor selections from the five available accelerometers (the proposed accelerometer represents the proposed kit with five sensors). The results of the increasing number of sensors are presented in Figures 1, 1.a (one sensor), 1.b (two sensors), 1.c (three sensors), 1.d (four sensors). In all these figures, the horizontal axis presents the frequency of the experiment, and the vertical one illustrates the MA error in percentage. The MA for 0.5 Hz is not presented in Figure 1.a and b because the system resolution for acquiring low acceleration amplitudes was insufficient.

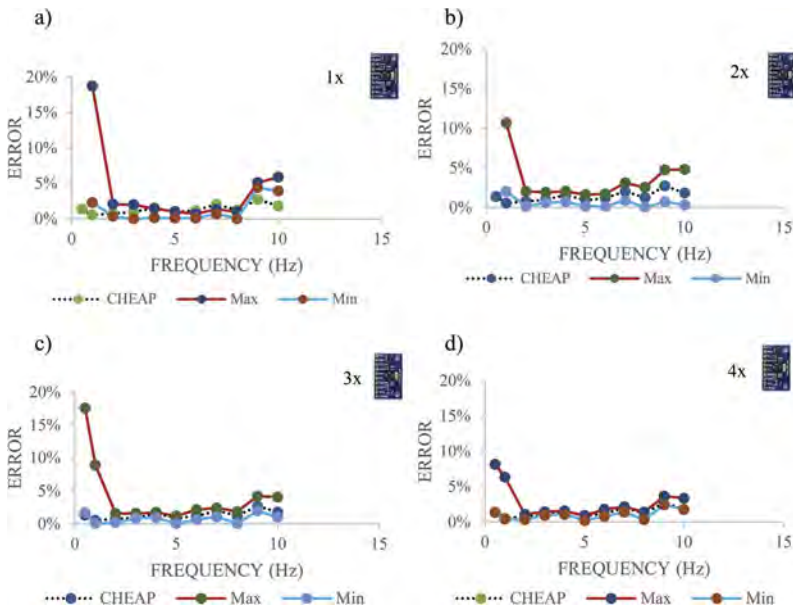

Figure 1. Estimated measured amplitude acceleration (MA) error for different number of sensors: one sensor (a), two sensors (b), three sensors (c), four sensors (d).

The analysis of Figure 1 shows that, as expected, the error depends to a greater extent on the number of sensors and the analyzed frequency. The experienced error for one, two, three, four and five (the proposed accelerometer) were at the worst-case scenario, 18.67%, 20.12%, 17.58%, 8.17%, and 1.55%, respectively. Therefore, it can be concluded that lower errors are obtained when the number of accelerometers is increased, especially on the tests with lower acceleration amplitude (less than 0.4 milli-g). Results in Figure 1 also show that the part of the experiment that had the lowest frequency (0.5 Hz) could be considered the most important one for the following reasons. Firstly, the highest experienced error appears there. Secondly, the lowest acceleration amplitude (0.1022 milli-g) is in this part of the experiment. In a nutshell, locating this low-level acceleration amplitude (MA) from the FFT evaluation was an opportunity to compare the resolution and accuracy of the proposed accelerometer with a different number of sensors.

For a single MPU9250 accelerometer, the resolution for this part of the experiment was not enough. The resolution of the kit with a single accelerometer appeared to be at least 0.19 Milli-g. The amplitude of the needed signal was less than this resolution. As a result, finding and reporting this signal from the FFT output was not possible. The resolution for the kit of sensors with two MPU9250 accelerometers was not entirely clear either. This resolution was

at least 0.13 milli-g, which is still 0.03 milli-g higher than the value of the captured signal. The resolution for the kit of sensors with three MPU9250 was about 0.10 milli-g. As a result, finding the amplitude of this part of the experiment was still impossible. The analysis of the same experiment with four MPU9250 accelerometers shows that the resolution of the system is slightly less than 0.08 Milli-g. This resolution made locating the needed signal from the FFT output diagram possible. This test reports the MA of the signal as 0.10384 Milli-g, which has a 3.22% error from the IA. On the other hand, the analysis of the kit of sensors with five MPU9250 (the proposed accelerometer) provides a resolution of around 0.06 Milli-g. In addition, it was deduced that the proposed accelerometer had an error of 1.55% from the IA.

5 CONCLUSION

In order to determine maintenance applications, minimize the reparation costs, and guarantee the safety of the structures, Structural Health Monitoring (SHM) systems are required. For applying the SHM application to structures with a lower budget for assessing their health state, this paper presents a novel method for enhancing the accuracy of low-cost accelerometers.

Adding an increasing number of averaged sensors is investigated to have beneficial effects on the resolution and accuracy. For example, it was seen on an experiment with a frequency of 0.5 Hz that a kit of sensors with four MPU 9250 had a resolution of about 0.08 Milli-g while with five accelerometers (the proposed accelerometer), the resolution became around 0.06 Milli-g.

In conclusion, the proposed methodology can solve the low resolution and high noise density of low-cost accelerometers. However, further research for implementing this idea on bridges and structures is needed.

Preventive SHM for asset management: A case study on the Mont-Blanc tunnel

F.B. Cartiaux & B. Prudhomme
OSMOS Group SA, Paris, France

ABSTRACT: The Mont-Blanc Tunnel is an infrastructure of strategic importance for Europe, linking France and Italy under the highest summit of the Alps. The tunnel was opened in 1965 and is a 11.6 km long single tube structure with 8.6m diameter. The road inside the tunnel is carried by a reinforced concrete slab, which is supported by two concrete linear walls, separating three service ducts. In the general scheme of preventive maintenance for this asset, this concrete slab is undergoing replacement works to build it new after nearly 60 years of operation. Before and during these works, planned over a few years, an exhaustive Structural Health Monitoring (SHM) system based on strain measurements on the lower face of the slab has been in operation. This paper describes the SHM strategy implemented since 2016 and its results for the asset manager. A first phase was achieved from 2016 to 2018 before the beginning of the slab works with 56 wireless optical strand sensors on a 555m long zone. Then, from 2019 to 2022, the SHM system was removed from the initial zone undergoing replacement works, and extended to next zones before and after, with a total of 117 sensors on 1200m along the tunnel. Starting from 2022, the wireless system has been replaced by a fully integrated wired solution, allowing the gathering of more volume of relevant data and an instantaneous dataflow while the works are going on. Long-term evolutions reflecting the effect of ageing, as well as short records at 100 Hz sampling rate for assessing the effect of the traffic loads on the concrete slab, are combined to give a synthetic stability index of each monitored location on the slab and check the health of the structure in real time throughout the duration of the works.

1 INTRODUCTION

Tunnels are transportation assets of great importance as they often stand as the shortest convenient way to cross significant obstacles, like wide sea channels, dense urban areas, and high mountains. They are sensitive to various phenomena induced by the soil conditions and the traffic throughout their life cycle, which deserve attention to be able to anticipate any anomaly before it becomes critical. Thus, they are usually monitored by their operator, at least with traditional means like regular visual inspection and periodic convergence assessment.

However, continuous monitoring of tunnels with a dedicated set of sensors and the associated means for data collection, transmission, management, and analysis are not widely spread. Experiments of continuous monitoring for durations over a few months have been documented on tunnels under current exploitation, for example with wireless tiltmeters in China (Zhang, 2017), and with strain measurements in Belgium (Maes, 2021). Specific tunnel installations like the one of the CERN near Geneva, very sensitive to soil movements, are monitored continuously as well (Cunningham, 2023).

This paper documents a recent and long-lasting SHM operation with continuous strain measurements, on the concrete slab of the Mont-Blanc tunnel under the Alps between France

and Italy. It focuses on the sensor and data management technologies and on the use of the SHM data for preventive asset management.

2 DESCRIPTION OF THE ASSET AND CONTEXT OF THE SHM IMPLEMENTATION

2.1 *The Mont-Blanc tunnel and its concrete slab*

Opened in 1965, the Mont-Blanc tunnel is a 11.6 km long single tube road tunnel with two lanes for traffic in opposite directions. The concrete tube has a diameter of 8.6 m and its cross-section is divided into four ducts. The main duct is located over a horizontal concrete slab which carries the road. Under the concrete slab, three service ducts are separated by two linear walls. One of them called “AV” is used for exhausting stale air and is not usually walkable. The two other ducts called “AF3” and “AF4” are used as service ducts.

The tunnel is divided into longitudinal portions called “fiches”, each one around 30 m long. This division allows an easy naming for specific zones along the tunnel to facilitate maintenance operations. Figure 1 shows a schematic view of the ducts and displays two “fiches” (nb 206 and 207), with the location of some of the long-basis strain sensors used for the SHM operation.

Figure 1. Schematic view of a portion of the tunnel, with two “fiches” and nine sensors.

2.2 *Motivation for the implementation of a SHM system*

The concrete slab which carries the road suffers from the usual effects of ageing for a concrete structure with almost sixty years of operation under a significant heavy traffic. Frequent visual inspections are carried out by the GEIE Tunnel du Mont Blanc, in charge of the asset, to check any default affecting the concrete, especially on the lower face of the slab. Because of some evidence of rebar corrosion and risk of spalling coverage concrete, and in prevention for potential harder damages due to the age of the structure in the future, the concrete slab is now undergoing reconstruction works, starting at a central portion of the tunnel and expanding towards the two ends.

Before, and during these reconstruction works, the remaining portions of the structure located in the vicinity of the works zone deserve a specific attention. The visual inspections enable a regular exhaustive report of damages, but in the period between two inspections, no information is available. Thus, it was decided to complement the monitoring of the concrete slab with sensors continuously measuring the strain in the slab, to get a quantified assessment of the evolutions of the structure, and eventually to be able to configure automatic real-time alerts in case of a critical situation.

3 STRUCTURAL HEALTH MONITORING OPERATION

3.1 *Optical strand technology*

The sensors chosen for the SHM operation on the concrete slab of the Mont-Blanc tunnel are fiber-optic based strain sensors called Optical Strands. They use the principle of the light intensity modulation through micro-bending of the fiber optic. In the case of Optical Strands, the micro-bending is generated by braiding three fibers together inside a coating duct.

The Optical Strands were chosen because of their robustness, sensitivity, and longevity. This type of strain sensor has indeed been used already for various applications linked to the SHM of civil works, including continuous assessment of both static and dynamic behavior over long durations (Cartiaux, 2019, 2021b) and Weigh-In-Motion on road bridges (Cartiaux, 2023).

The Optical Strands are available as wireless or wired sensors, and both options have been used in the case of the Mont-Blanc tunnel. The wireless option (Figure 2) offers an easier installation and does not require power supply but has a limited capacity for the data storage between data retrievals. The wired option requires cable pulling and power supply, but offers real-time transfer of the data on the internet, and both synchronicity and exhaustivity for the recording of dynamic effects on several sensors.

Figure 2. One wireless Optical Strand set under the concrete slab of the Mont-Blanc tunnel.

3.2 *Phases of the SHM of the Mont-Blanc tunnel*

The SHM of the concrete slab of the Mont-Blanc tunnel first started in November 2015 and went through successive different phases, distinguished by the number and type of sensors used (i.e. wireless or wired solutions) and by their location along the tunnel:

Table 1. Phases of the SHM of the Mont-Blanc tunnel.

Phase	Start	End	Type of sensors	Number of sensors	Length of SHM zone
Preliminary	11/2015	05/2016	Wireless	20*	420 m*
Before works	11/2016	03/2018	Wireless	56	555 m
Works Phase 1	02/2019	07/2022	Wireless	117	1200 m
Works Phase 2	08/2022	08/2026	Wired	74	720 m

* Rolling zones of 60 m with half of the 20 sensors moved every month

The average ratio is one sensor for 10 m length along the tunnel, which allows a dense sampling of the monitoring locations. The first phase in 2015 and 2016, called preliminary, is an exception to this rule: a stock of 20 sensors was used on rolling zones of 60 m, each zone being monitored for two months, and 10 sensors moved from one zone to the next one every month, to finally cover a 420 m long zone. This preliminary phase allowed to define priorities before the switch to permanent monitoring on well-chosen locations.

From November 2016 to March 2018, 56 wireless sensors monitored a 555 m long zone on which the first phase of works was scheduled. Then, from February 2019 to July 2022, while this first zone was totally rebuilt, 117 wireless sensors were set on next zones before and after, covering a total length of 1200 m. Finally, part of this second zone is currently undergoing replacement works while 74 sensors remain, after a switch to the wired solution.

3.3 Data flow and processing

The strain measurements are performed continuously with one point every hour for the wireless option, and one point every ten minutes for the wired option (customizable up to one point every second). In addition, dynamic records with a high sampling rate of 50 points every second (up to 100 points every second for the wired option) are automatically triggered in the case of rapid variations of the strain, including in the case of heavy vehicles driving on the slab.

The data flow has been organized through different means depending on the monitoring phases, as follows:

Preliminary phase (2015 to 2016): each month, half of the 20 wireless sensors are moved from one zone to the next one. At this occasion, the data of all sensors is retrieved manually through a radio modem connected to the operator's laptop on site.

Before works (2016 to 2018): six gateways are installed along the tunnel. These are industrial computers, connected to the tunnel's optical fiber network, and including a radio modem for the wireless communication with each wireless sensor in their vicinity. Every month, the data is retrieved remotely from the OSMOS office (or elsewhere) through the internet, by establishing a secured connection to the gateways.

During works phase 1 (2019 to 2022): to keep the monitoring data flow independent from the tunnel network again, the data retrieval is performed on site by an operator, every month.

During works phase 2 (2022, planned until 2026): the switch to the wired system allows a real-time transfer of the data on the internet, through a dedicated additional fiber optic network that has been installed on purpose along the tunnel.

Once the measurement data is retrieved (for the wireless option) or automatically sent every minute (for the wired option), it is received and organized on a remote cloud in a MongoDB database, from which the raw data is available for release on a dedicated web interface or through API routes. Every day, a dedicated algorithm gathers all available data to compute a synthetic stability index which is released on the same web interface.

4 MAIN RESULTS OF THE SHM

4.1 Stability index and anomaly detection

The first aim of the SHM operation is to keep an updated overview of the stability of the concrete slab, for every monitored location. This is achieved by the automatic release of a stability index, as one unique value for each location, which summarizes the general evolution of the strain in the concrete for each sensor (Figure 3). This index is computed every day on the cloud (if updated data is available), instantly released on the web interface as a color code for each location, from green to red, and summarized in monthly formal reports (Cartiaux, 2021a).

Figure 3. Synthetic release of stability indices on a sample of monitored locations.

The stability index processing gathers all available static data, i.e., one measurement every hour for the wireless option and one every ten minutes for the wired option. In parallel, it also gathers temperature measurements taken at the same sampling period by the monitoring system at different locations along the tunnel.

Even if the temperature variations are usually smooth inside the tunnel, a correction of the effects of the temperature is performed on the strain data. These effects are automatically learned by the algorithm through an analysis of the correlation between strain and temperature on limited periods of time (learning periods). The law linking strain and temperature identified by this analysis is then applied to the whole set of temperature data, to estimate the part of strain variations due to the temperature effects. Then, the raw strain data is corrected from this effect to obtain residual strain evolution without the incidence of temperature.

Once the strain data is corrected from temperature effects, its variations are analyzed to assess the stability of the concrete slab under quasi-permanent effects only. With no damages appearing, these variations are supposed to remain near to zero, and the stability index keeps a low value and remains in the “green zone”.

When damages occur in the concrete on the monitored locations, the loss of material induces a loss of rigidity, and additional tension under quasi-permanent loads. This evolution is pointed out with increasing values of the stability index, first corresponding to the opening of crack patterns (average tension strain around 0.5 mm/m for example) and eventually to concrete spalling (more than 2 mm/m, which is the “red zone”).

The automatic update of the index every day allows, first, an always updated overview of the evolution of strain in the concrete slab (corrected from potential temperature effects), and secondly, an early warning about potential damages, to schedule reparation works before they become critical.

4.2 Assessment of the effects of the traffic on the concrete slab

In addition to the synthetic stability index which summarizes long-term evolutions of the strain in the concrete slab, the monitoring system also detects rapid variations of the strain and releases them as dynamic records with a high sampling rate of up to 100 points every second.

Usually, this feature allows to detect and assess the effect of the heaviest vehicles driving on the road carried by the concrete slab. The sensitivity of the strain measurement is sufficient to get a very clear record of the local bending of the slab under the effect of each axle load (Figure 4). The customizable detection thresholds are set to optimize the volume of useful data, with not more than a few dozens of vehicles recorded each day, what is however enough to perform a statistical analysis on the amplitude of the strain due to the traffic, and to monitor potential changes of rigidity with this additional parameter.

Figure 4. Example of recorded passage of one truck by sensors on different locations.

4.3 Monitoring during works on the slab

While the concrete slab is undergoing replacement works, the monitoring system remains in operation on zones next to the location of the works. This enables to include the potential effect of the works on the remaining – or newly built in the case of works phase 2 – parts of the concrete slab as part of the stability assessment.

For example, the works require to use vehicles that are uncommon compared to the usual traffic loads in the tunnel, and the effect of these exceptional loads are assessed to check the amplitude of strain and the return to the initial state of the slab after their passage (Figure 5). The pattern of the strain measurements shows that these vehicles are driving very slow compared to usual traffic, and the induced strain is approximately the double of the strain due to common vehicles. However, the order of magnitude remains acceptable (up to 0.03 mm/m) and the slab always reaches its initial state back, showing that these passages do not have any consequence in terms of new damages.

Figure 5. One unusual vehicle recorded by an optical strand.

In addition, an automatic notification feature is activated for the works phase 2, which releases instantaneous messages by SMS and e-mail in the case of exceedance of some thresholds on the measured values, following two different modalities:

- Static threshold if the raw static measurement value becomes out of an acceptable range,
- Dynamic threshold if the range (maximum minus minimum) of the strain over four seconds exceeds a threshold value.

In both static and dynamic cases, the threshold values are learnt from the past data and customized for each sensor, to alert in case of an abnormal situation only.

5 CONCLUSION

Strategic tunnels supporting an intense heavy traffic deserve monitoring solutions which go beyond the usual visual inspections, in the frame of an optimized preventive maintenance. The Mont-Blanc tunnel is an interesting case study, which shows the applicability of SHM through continuous strain measurements at a wide scale in an operational context, including heavy maintenance works operations on the concrete structure of the slab supporting the road.

Measurements remotely available in real-time on a web interface, and daily updated synthetic stability indices for each monitored location along the tunnel, allow an efficient overview of the evolution of the concrete slab and help to intervene at the right place and at the right time in the case of a new damage. Moreover, the continuity of the measurements enables to anticipate further evolutions before they induce visible consequences like concrete spalling. In addition, threshold-triggered records at a high sampling rate of 100 Hz are used for the

assessment of the response of the structure to the traffic loads, including specific exceptional vehicles used for the works.

The SHM operation, which started in 2015 before the first reconstruction works of the concrete slab, is still going on and planned until 2026, to perform a continuous check of the stability of the structure during the works and to automatically notify in the case of abnormal evolutions.

ACKNOWLEDGEMENTS

The authors wish to thank the GEIE Tunnel du Mont-Blanc for its support in the release of this publication.

Characteristics of ultrasonics guided waves in timbers under moisture and temperature

R. Yassine & S. Mustapha

Laboratory of Smart Structures and Structural Integrity (SSSI), Department of Mechanical Engineering, American University of Beirut, Beirut, Lebanon

ABSTRACT: The application of ultrasonic guided waves (GWs) in evaluating the structural integrity of timber utility poles has shown high potential in detecting and assessing various types of defects. Yet, the effects of temperature and moisture content (MC) on the propagation of GWs are not well-understood and the uncertainty that may influence the results is not well-investigated. This study aims to scrutinize the effect of MCs (0% to 24%) and temperatures (-20° till 100°C) on the propagation characteristics of bulk wave, longitudinal and circumferential GWs in-cylinder timbers excited at 10-20kHz. The results showed that at 0% MC the velocity change is insignificant due to absence of water. As MC increases below the Fiber Saturation Point (FSP), the difference in mode velocities is 20% at -20°C, 50% at 100°C, and 40% upon varying the timber's temperatures. Above FSP, the difference was less than 2% at fixed temperatures and 58% under temperatures variations.

1 INTRODUCTION

1.1 Overview

Timber has long been used in various applications such as utility poles, as it is attributed to ease in production and adaptability in customized fabrications. The use of timbers as embedded utility poles for supporting overhead power electrical and communication lines, expose them to critical external factors affecting its mechanical characteristics (Bandara et al., 2021). At high moistures, the timbers become a favorable region for fungus and termite attacks yielding to complete material degradation with no exterior visible signs (Bandara et al., 2021). Accordingly, yearly inspections are employed on utility poles, which in some cases is unnecessary since the timbers might be healthy and serviceable (Bandara et al., 2021). Therefore, maintenance times should be scheduled based on continuous monitoring of timber poles and data assessment to ensure their safety, reduce maintenance cost, and prolong its lifetime by early damage detection.

Condition assessment of timber poles includes destructive, semi-destructive, and non-destructive techniques (NDT) (Rose, 2014). Destructive and semi-destructive testing apply a load and drilling on the structure, respectively, and assess its material properties based on its response. Sound poles will have higher resistance to load and drilling, and it decreases with material degradation. However, these techniques yield to permanent damage effect and provide discontinuous information about the structural health. From that ground NDT comes as a sufficient technique for structural health assessment based on its response to an input excited along the structure as waves or vibrations with no permanent effect (Rose, 2014). As stress waves propagate within the timber, any change in the applied loading, boundary conditions, material properties, are observed and detected as a change in the wave characteristics (Bandara et al., 2021). These methods are used frequently as they provide crucial information about the health of the structure and the effect of the surrounding environment while using simple and economical tools (Bandara et al., 2021).

Much research effort over the years employed stress waves on in-service utility poles to determine its embedment length, identify damages for health assessment, and investigate the effect of surrounding environment on the GWs in timbers. Subhani et al. (Subhani et al., 2013) used sonic stress waves to investigate the effect of timber's mechanical behavior (transversely isotropic vs. isotropic) on detecting its boundary conditions. Isotropic material assignment of timbers was not able to detect any change in the GW due to the surrounding soil, whereas transversely isotropic the GW velocity was greatly shifted. El Najjar and Mustapha (El Najjar and Mustapha, 2020), investigated the timber's embedded length and the presence of defects using GW reflections numerically and validated experimentally. The GWs are actuated using Macro Fiber Composites (MFC) (Smart Material Corp., 2017) transducers, where they studied MFC usage on rough curved surfaces as timbers. The authors aimed to improve the propagation of longitudinal modes by designing a ring of MFC actuators, which enhances the GW sensitivity to damage.

1.2 *Effect of moisture content and temperature on the propagating modes*

Timber's material can significantly degrade due to the surrounding temperature and MC which influence the propagation of the ultrasonic wave. The literature shows a decrease in the wave velocity as MC increases in all timber's orientations but at different rates (Bandara et al., 2021). Full saturation of water in the wood cells occurs at Fiber Saturation Point (FSP), where the timber's material changes negligibly, and consequently the GWs velocity remain constant. The FSP for Pine wood is 20% (Sakai et al., 1990). A work by Oliveira et al. (Oliveira et al., 2005) emitted GWs along the longitudinal and transverse timber's directions under MC variations from 6% to 60%. The longitudinal wave velocity of the BW dropped by 11.4% as MC varied, while the transverse wave velocity reduced by 7.6%. Acoustic waves were also used in the literature for assessing the effect of MC from 10 to 170% on propagating waves in the timber (Moreno Chan et al., 2011). The stress waves were emitted and received using a microphone. The work observed a rapid linear decrease in the BW velocity as MC varied below FSP at temperatures from -71° C to 59° C. Above FSP and at freezing temperatures, the BW velocity increased slightly and then decreased similarly to the other temperatures. At high MCs, the effect of high temperatures was larger than the velocity reduction at low temperatures from -71° C to -3° C.

This work evaluates the propagation of ultrasonic GWs (bulk, flexural and longitudinal) in Western White Pine timber pole actuated at various frequencies upon varying its temperature and MC. The work is studied numerically for a tapered timber pole model with transversely isotropic properties in COMSOL Multiphysics (Multiphysics, 1998). The ultrasonic waves are actuated and sensed using composite transducers (MFCs), which are mounted on curved the timber. The work scrutinizes the GW modes based on the dispersion curves obtained from DISPERSE (Pavlakovic and Lowe, 2003) as MC changes from 0% (dry condition) to values larger than the FSP, and temperature ranges from -20° C to 100° C excited at 10, 12.5, and 20 kHz.

2 METHODOLOGY

2.1 *Guided waves in solid circular structures*

The propagation of ultrasonics in cylindrical structures were studied and modeled extensively in the literature, whereby the longitudinal and flexural guided waves were strongly affected by the structure's health and hence can play as an important health indicator. The family of propagating modes are Torsional modes $T(n, m)$, Longitudinal modes $L(n, m)$ and Flexural modes $F(n, m)$ (Rose, 2014). Propagating modes are denoted by (n, m) , where the circumferential order (n) determines the symmetry of the solutions in the azimuthal direction and m is the branch number (Seco and Jiménez, 2012). Longitudinal and Torsional modes are axisymmetric with n denoted by zero $L(0, m)$, whereby non-axisymmetric flexural modes have $n > 0$ denoted by $F(1, m)$. The bulk longitudinal wave (BW) is constant at all exciting frequencies where m is denoted by 0, while the guided flexural and longitudinal modes depend on the exciting frequency. The first propagating modes are called Fundamental branches $L(0, 1)$ and $F(1, 1)$. The relation between the frequency and the group wave velocity is developed using the wavenumber of propagating GWs, which generates the dispersion curves for the longitudinal, and first-order

flexural modes (Rose, 2014). In this study, the dispersion curves for 22 cm diameter timber pole are generated using the DISPERSE software for transversely isotropic material properties (Table 1) (Green et al., 1999, Pavlakovic and Lowe, 2003).

Table 1. Material properties of the transversely isotropic white western Pine used in this study.

Material Property	Modulus of Elasticity			Shear Modulus of Elasticity			Poisson's ratio			Density
	E_L	E_R	E_T	G_{LR}	G_{LT}	G_{RT}	ν_{LR}	ν_{LT}	ν_{RT}	d
	GPa	GPa	GPa	GPa	GPa	GPa				kg/m^3
Value	11.11	0.866	0.866	0.577	0.577	0.0533	0.329	0.344	0.41	380

2.2 Numerical work

2.2.1 Material properties and characterization of timber poles

Timber is anisotropic, heterogeneously layered, and is mostly affected by the temperature and MC. Relevant studies in the literature states that an increase in timber's temperature yields to a decrease in the stiffness modulus ((Dinwoodie, 2000, Olsson and Salmén, 1997)). The range of MC in timbers that most influence its material properties are dry, below FSP, and after FSP conditions. Timbers under 0% MC have witnessed very low stiffness variation (6%) upon varying its temperature, and the variation increases to 40% at 20% MC (Dinwoodie, 2000). As more water is introduced to the timber, its material properties will vary until reaching full saturation, known as FSP = 20% (Sakai et al., 1990). Saturated timbers at elevated temperatures (>50° C) have observed the most loss in its properties (Olsson and Salmén, 1997). The stiffness is related to the temperature and MC through statistical analysis and empirical formulas derived from data collected under various temperature and moisture conditions. The stiffness-T-MC model that is applied in this work to find the mechanical properties of the timber numerical model under the three studied ranges of MC is shown in Equations (1) and (2) (Subhani et al., 2013). The tangential and radial E values are computed based on orthotropic relations with the longitudinal stiffness (Table 1) (Green et al., 1999).

$$E_a = E_0 (0.475 - 0.0038T) \quad (1)$$

$$(E_L - E_g)(E_L - E_0 + 5(E_0 - E_g)MC) = E_g^2 / 1000 \quad (2)$$

Where E_0 : stiffness at 0% MC, E_a : stiffness at instant T, and E_L is at a given temperature and MC.

2.2.2 Finite element analysis model

Finite element analysis (FEA) using COMSOL Multiphysics is employed in evaluating the effect of temperature and MC on the ultrasonic wave propagation (Multiphysics, 1998). Solid Mechanics and Electrostatics physics are used to model the piezoelectric devices. The actuation and sensing of GW by the piezoelectric transducer (PZT) is modeled using the Electrostatics physics module, and the particle displacement due to wave propagation is modeled using Solid Mechanics physics module. The numerical model is simulated on an Intel® Xeon® 2.10 GHz virtual machine with 64 GB RAM and 300 GB disc space. The FEA model is a 2 m tapered timber pole (Figure 1). The material is transversely isotropic (check Table 1) assigned using Equation (2) and the orthotropic relations for longitudinal, radial, and tangential stiffness as a function of temperature and MC (Green et al., 1999). The study covers timber's temperature of -20, 0, 20, and 100° C, and MC of 0, 12, 20 and 24%. The GWs are generated using MFCs as PZT placed 1 m apart. MFCs have the malleable ability to couple well on curved structures. The FEA model of the MFCs is modeled as a solid isotropic PZT of type PZT-5A despite its composite nature. The timber pole is singly actuated with the MFC emitting a 5-cycle Hanning window sine wave at 10, 12.5, and 20 kHz, and the MFC sensor is grounded with zero voltage sensing axial propagations. The exciting frequency should be set

in objective of tuning the propagating modes, and according to the dispersion curves high mode dispersion was seen at low frequencies. Hence, a frequency range of 10 to 20 kHz is considered where both longitudinal and flexural modes show relative stability. The GWs along the timber will be characterized based on their time of flight (ToF) from the actuator to the sensor. The model is discretized using a mesh size of 6 to 10 elements per wavelength (Marburg, 2002) resulting with 311408 as the total number of elements. This study explores the combination of the various factors including temperature, MC, and excitation frequency on the wave propagation characteristics.

Figure 1. Numerical model of the timber pole, a top view sketch of traction free timber pole and close view of the generated mesh showing the curved MFCs acting as an actuator and as a sensor.

3 RESULTS AND DISCUSSION

The temperature and MC conditions affect the timber's material properties which varies the propagating GW characteristics. This effect is studied numerically, and the results are discussed in this section. Finite element analysis (FEA) tool is used to model the GWs propagation in the timber pole and its varying surrounding conditions, which is COMSOL Multiphysics. The timber pole is modeled as tapered with traction free boundary conditions, considering no embedment since it has minimal effect on the direct wave propagation characteristics unlike its effect on the wave reflections (El Najjar and Mustapha, 2020). The effect of temperature and humidity on the GW characteristics propagating in the timber pole is studied at the following exciting frequencies: 10, 12.5, and 20 kHz. The data collected from the sensor was assessed and modes are identified by the group velocities obtained from the dispersion curves generated by DISPERSE (Pavlakovic and Lowe, 2003).

3.1 Effect of moisture content

The effect of timber's MC varying from 0% to 24% on the ultrasonic GW at 0° C excited at 12.5 kHz is displayed in Figure 2. The increase in MC yielded to modes arriving at longer times, and it was observed at all temperatures but displayed for 0° C only. The BW is the first arriving mode with a group velocity of 5000 m/s (El Najjar and Mustapha, 2020), after which the sensor receives the first order flexural mode F(1, 1) and the longitudinal mode L(0, 1) with 1498 m/s and 1226 m/s, respectively. As MC increases to 24%, the BW velocity is reduced by 27%, and F(1, 1) and L(0, 1) by 18%. The F(1, 1) and L(0, 1) modes propagated at similar speeds, and hence were difficult to be distinguished. The F(1,2) and L(0, 2) modes showed less dispersion upon varying the timber's temperature and MC. The F(1, 2) mode arrives in a distinctive wave packet with a speed of 1932 m/s at 0% MC and decreased till 1360 m/s at 24% MC. The L(0, 2) observed a 26% reduction in the velocity arriving with 1039 m/s at 0% MC and dropped to 769 m/s at 24% MC. The reduction in the wave velocities for F(1, 2) was higher with 29.6%. The increase in MC affected the second branch modes more than the first branches. Identifying the F(1, 3) was intricate and the mode peak observation and tracing was ambiguous with 36% difference in the wave velocity as MC varied. The received wave signals at FSP and beyond (MC \geq 20%) have the same shape and hence their characteristics are preserved as MC increases beyond FSP (Figure 2). The difference in the wave velocities beyond FSP at fixed temperatures is less than 2%.

3.2 Effect of temperature

The effect of varying timber's temperature from -20°C to 100°C on the ultrasonic GW at 0% MC excited at 12.5 kHz is displayed in Figure 3. At 0% MC, the observations from the results show that the GW signal has preserved its velocity and amplitude. This observation draws a conclusion that at complete absence of water (MC=0%) under varying temperatures the variation in the material stiffness is negligible since all wave velocities are maintained. Figure 4 validates this assumption upon plotting the variation of the material's stiffness at different temperatures and MCs. In Figure 4(a), the stiffness variation at varying MCs with respect to temperature variations is plotted, and Figure 4(b) presents the percentage difference of difference in stiffness along the temperature range as per the following relation $E_{\text{variation}} = E_{\text{at } -20^{\circ}\text{C}} - E_{\text{at } 100^{\circ}\text{C}}$. At 0% MC from -20°C to 100°C , the stiffness varied insignificantly with 0.07% difference with a value of 16 GPa (Figure 4(a)), while the literature computed a 6% stiffness difference within the temperature range of -20°C and 60°C (Dinwoodie, 2000). The stiffness slope varied in an increasing manner as MC increases with increasing temperature, which has led to a 40% velocity difference at MCs below FSP (MC=12%) and has increased to 58% at MCs above FSP (MC \geq 20%). The difference in stiffness modulus at fixed temperatures shows large difference as MC increases which led to large velocity variations, with 20% at -20°C , 50% at 100°C . Figure 4(b) shows that the percentage of stiffness difference between -20°C and 100°C increases from 0% at low MCs to 82.6% at higher MCs, however, a 40% reduction in stiffness is recorded in the literature at temperatures from -20°C till 60°C (Dinwoodie, 2000). At high MC values (\geq 20%), the material's stiffness plots are the same showing the highest variation (Figure 4(a)), by which the percentage difference became constant with 82.7% from -20°C to 100°C (Figure 4(b)) which explains the constant wave velocities (Dinwoodie, 2000, Sakai et al., 1990, Seco and Jiménez, 2012). The negligible difference in stiffness at high MCs in Figure 4(b) validates the observation that the material will not experience any further change beyond FSP due to full saturation (20% for Pine) (Sakai et al., 1990). Figures 5 and 6 present the wave propagation at 0°C under varying MC conditions excited by 10 kHz, and 20 kHz. At 10 kHz exciting frequency (Figure 5), and under dry conditions ($T=0^{\circ}\text{C}$ and MC=0%), the labeled modes propagate in indistinct wave packets. Mode peaks are packed closely, while only the trace of the second branch modes is apparent. As the exciting frequency is increased to 20 kHz (Figure 6), at 24% MC all modes are

Figure 2. Raw signals of GW propagating at $T=0^{\circ}\text{C}$ with varying MCs: 0%, 12%, 20% and 24%, excited at $f=12.5\text{ kHz}$. The dotted lines show the shift to the right as MC increases.

distinctive and clearly traced upon changing the MC. However, at 12.5 kHz, the wave packets are less dispersive and maintained the shape of the 5-peak packet input signal. This was also seen in a work by El Najjar and Mustapha on a similar setup which was validated experimentally (El Najjar and Mustapha, 2020). MFCs have proved to be effective in acting as a transducer for stress GWs in timber poles due to their malleable ability to couple on curved surfaces. This work can distinctively identify and trace the BW and the second branch flexural and longitudinal modes as MC increases from 0% to 24% at constant temperatures.

Figure 3. Raw signals of GW propagating at various temperatures, a MC=0 % and excited at $f=12.5$ kHz. The tracing of wave packets shows no shift in time as temperature varies in dry wood.

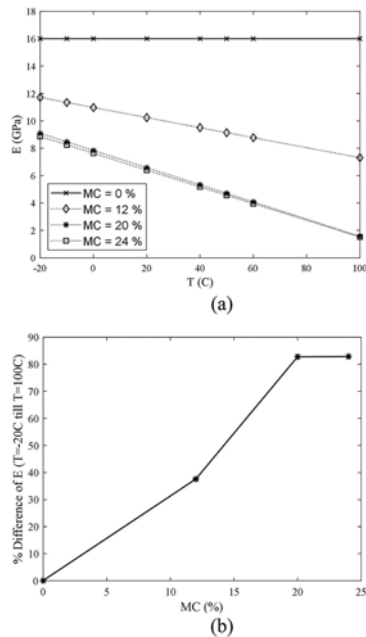

Figure 4. (a) Variation of modulus upon varying MC and temperatures, and (b) percentage difference of stiffness variation with respect to MCs between $T=-20^{\circ}$ C and $T=100^{\circ}$ C.

Figure 5. Raw signals of GW propagating at $T=0$ °C with varying MCs excited at $f=10$ kHz. The tracing of wave packets shows a shift to the right as MC increases.

Figure 6. Raw signals of GW propagating at $T=0$ °C with varying MCs excited at $f=20$ kHz. The tracing of wave packets shows a shift to the right as MC increases.

4 CONCLUSIONS

Timber poles should be continuously monitored to ensure safe and proper performance. Ultrasonic guided waves (GWs) have proven that it can indicate the health of the structure as it is sensitive to various types of defects, material degradation, and surrounding temperature and moisture content (MC) conditions. This work studies the behavior of

ultrasonic GWs in transversely isotropic timber pole using COMSOL Multiphysics under varying temperature and MC. Microfiber Composite (MFC) transducers are coupled to the curved timber pole to actuate and sense the GWs to achieve proper propagation. The GWs velocities decrease due to the reduction of timber's stiffness as temperature and MC increase, and the drop is compatible with the literature. Temperature's effect on the GWs characteristics is insignificant at low MCs and prominent at high MCs, consequently affecting the GWs characteristics. At 0% MC, the timber's stiffness changes insignificantly as temperature varies, and hence the wave maintains its characteristics. The reduction in GW velocities is larger upon increasing MC below the Fiber Saturation Point (FSP). The full saturation in timber cells abstain any further variations in the stiffness, hence, the GW velocities decrease negligibly above FSP at constant temperatures. The modes that are able to characterize the timber's material and be visually distinguished and identified are the BW, F(1,2) and L(0,2).

Asset management – Towards adaptive resilient infrastructures

Shaikha AlSanad & Jafarali Parol

Kuwait Institute for Scientific Research, Kuwait City, Kuwait

ABSTRACT: In middle eastern countries, investment in infrastructure is at an all-time high. This also means that a large number of decisions are being made now that will affect the patterns of development for future generations. It is worth noting that infrastructure can also create harmful social and environmental impacts, increase vulnerability to natural disasters and leave an unsustainable burden of debt. Interestingly, these investments in the infrastructures are intended to increase economic prosperity and employment. It is possible to achieve the necessary economic, social, and environmental results within the framework of sustainable development goals by the creation and use of sustainable infrastructure. Disruptions in infrastructure services in the event of blackouts, road closures, water services, etc make us realize the importance of these assets in our day-to-day living. Therefore, we should manage infrastructure in the best possible way to ensure that they are resilient or can withstand extreme events, continue to provide service, and are affordable to users. Although a new discipline, IAM is evolving and attracting the attention of many agencies that own infrastructure. Due to the high cost of infrastructure in terms of money and time to build, governments and organizations managing infrastructure would want to maximize its value by extending the life of their assets.

1 INTRODUCTION

Infrastructure is one of the key components of the United Nations Sustainable Development Goals (SDG). Careful planning, designing, implementing, and operating of the infrastructures are necessary to create a sustainable infrastructure, and to achieve target economic, social, and environmental goals within the framework of the sustainable development goals. Infrastructure systems provide essential services such as energy, water, waste management, transport, and telecommunications. The infrastructures are sustainable if they ensure economic, social, environmental, and institutional sustainability throughout the entire life cycle. Infrastructures form the backbone of every society. Infrastructure projects are projects that have high public benefits with a large cost that ranges from one hundred million to several billions of Dollars, mostly planned or administered by a government to bring an important outcome such as economic development and social needs in accordance to a State's development program (Eberts, 2014; Buhr, 2003). They are distinctive by strategic importance, dynamic complexity, adaptability and extensive impacts as they play an important role in the contribution to economic and social growths, however, such characteristics make them vulnerable to crisis (Flyvbjerg, 2014). For instance, Infrastructure projects require a huge amount of capital and other resources, such as technology, equipment, and labor. The decision-making criteria at the initiation stage is critical during infrastructure planning to ensure an efficient allocation of resources and risk mitigation. Infrastructure projects include a wide range of service projects like public utilities projects such as power plants, gas projects, water projects, sanitation and sewage, cable systems; or it could public works projects such as roads, airports, urban transport, ports, oil and gas fields development, museums, concert halls, convention centers and city parks (Wang *et al*, 2020).

According to Choguill (1996) infrastructure is an essential element if urban sustainability is to be achieved. They suggested programs that involve progressive improvement of such infrastructure in a more efficient way and cost-effective manner. The objectives of this study were (1) a literature review of all kinds of existing infrastructure, (2) developing a model for the progressive improvement of the infrastructure in a sustainable manner, (3) demonstrating the sustainability of the model in terms of cost, maintenance, and level of technology, and (4) suggesting management structures to attain the sustainability of such infrastructure. It is emphasized that government, non-government organizations, and local communities must work together to design a system to build, operate, and maintain from the ground-up toward sustainable infrastructure. A white paper reported published by Randall Elberts, (2014) focusing on transportation infrastructure and its contribution to the economy was a 3-year effort to review methods used to estimate the value of transportation infrastructure. Part of this review is to provide what statistical information should be generated at the national level to the decision-makers. This review also includes alternative strategies for using statistical data, relative strengths and weaknesses of methods used, and potential benefits of improved methods and data.

Qureshi (2016) examined the environmental effects on the sustainability of infrastructure have been thoroughly studied. It is mentioned that public policy plays an important role in the development of a country's economy once infrastructure investment is initiated. To boost infrastructure sustainability and resiliency, some specific public policies required more detailed, prioritized, and sequenced to be tailored to country-specific needs. The public policies for sustainable infrastructure should be publicized in overall projects and country investment and growth strategies.

It is observed that systematic, holistic, and sustainable asset management in developing countries is not adequately established despite the huge financial issues in funding infrastructure projects (Tafazzoli, 2017). This is mainly because of the lack of cost-effective management and long-term strategies for operating, maintaining, and upgrading of infrastructure projects. It was suggested that the essence of changes over the conventional methods for managing the development of the infrastructure. This can be achieved by providing a data collection system and up-to-date tools to analyze those data. Such an approach will make informed infrastructure investment decisions easily accessible to the private sector/partners.

The importance of designing and planning the construction has been evaluated by establishing a well-defined predictive sustainability assessment method called multi-criteria decision analysis (Ek et al, 2019). This method is supposed to increase the positives and decrease the negatives of sustainability impacts in infrastructure projects. It was recommended to use this method in the procurement stage of the infrastructure project. However, it was suggested for more future sustainability assessments due to limited information, and should comply with some international standards mentioned in this study.

2 ASSET MANAGEMENT OF INFRASTRUCTURES

Buildings and bridges are the two important civil infrastructures. These infrastructures are key elements of a city's development and social fabric. In Particular, bridges are critical to the operation of any city's road networks. Therefore, proper maintenance of bridge infrastructures is essential in order to ensure safety and minimize associated risks and more accurate short and long-term financial planning. Structural health monitoring technology is an important tool that allows city planners to collect data from the bridge infrastructures and to ensure safety and performance.

It is important to note that the resilience of infrastructures is the primary parameter of asset management. The data should be collected from all the bridges in the city in order to prepare an effective asset management plan. Individual bridges are seen as parts of wider networks and bridge risk and criticality assessment emphasize bridge failure or underperformance risk in the network context. It is therefore necessary to integrate the SHM system into the city's asset management plan. SHM has an important too in bridge asset management. An SHM system implemented in Kuwait as a pilot project is depicted in Figure 1.

Figure 1. SHM system implemented in a concrete Highway bridge in Kuwait.

In the bridge SHM system implemented in Kuwait, we have used accelerometers, strain-measuring optical strands, inclinometers, and temperature sensors. The data collected from the sensors are used to obtain an evolution score showing the behavior of the bridge structure, at every important location (based on data measuring location). The structural stability is then represented using the scale in Figure 2.

Figure 2. Stability Index used in the bridge SHM system in Kuwait.

The indicator can be used for planning maintenance, repair, retrofiting, etc. Therefore, this is an important indicator of the ecomanagement. If the SHM system is installed at several bridge networks, such a stability index can be prepared for each bridge and the city planners can use the indicators for the asset management plan. A sample of measured data from the bridge SHM system that is an important input for asset management is shown in Figure 3.

Figure 3. Measured strain from a typical optical strand (2 years of data).

We have implemented weigh-in-motion so that the weight of the truck can be estimated and connected to the bridge response. The entire life cycle events can be connected in a single window (Figure 4), which is quite handy for asset management. The resilience of the bridge infrastructure significantly improves if a proper asset management plan is in place based on the actual measured data.

Figure 4. Single window access to life cycle event.

Our experience is that SHM data is quite vital for major and regular maintenance, life estimation, etc, and, in general, asset management of infrastructures. Such a system also improves infrastructure resilience.

3 SUMMARY AND CONCLUSION

Although modern-day infrastructure is designed to ensure that large and complex structures perform safely in harsh environments under various loading conditions, deterioration and damage can occur during their operational life. Consequently, the protection, maintenance, and repair of infrastructure assets are crucial. Achieving optimal asset management is challenging, as the life-cycle costs of these activities must be minimized while ensuring that infrastructure performance and reliability related to the asset's condition, serviceability, safety, and capacity are adequately addressed. SHM is a technology that, if used strategically, can help to address these challenges. Currently, SHM technologies are used to assess structural performance, detect damage and continuously monitor the condition of a structure. These technologies have enabled data collection to support comprehensive asset management analysis and evaluation processes. However, SHM has not been explicitly designed to provide actionable information to assist asset management decision-making. With many infrastructure assets nearing their end of life, mainly those nearing their end of design service life, the management process focuses on the later stages of the asset's (infrastructure) life to prolong its usefulness through maintenance, rehabilitation, and replacement. We have briefly shared our experience in asset management of bridge infrastructures in Kuwait and how it can enhance infrastructure resilience.

ABSTRACT: Protective coating is considered to be one of the most economical and effective methods to protect steel from corrosion, as it can establish a physical barrier between the steel and the corrosive environment. In this study, silicate dioxide particle modified enamel (SDPME) coating is proposed for improved corrosion resistance and enhanced bond strength of steel bars in concrete structures. Plain steel bars with a diameter of 12 mm were used. Enamel slurry was made by mixing enamel frits with tap water, and silicate dioxide particle with an average size of 0.50 mm was added. The silicate dioxide particle is 10 wt.% of the enamel frits. The steel bars were dipped into the enamel slurry for 2 minutes and moved out, and then placed in a furnace at 800°C for 5 minutes, and finally cooled down to room temperature to produce SDPME-coated steel bars. The corrosion resistance of the SDPME-coated steel bar was tested by immersing in saturated calcium hydroxide solution containing 3.5 wt.% NaCl with open circuit potential, linear polarization resistance and electrochemical impedance spectroscopy. The bond strength was determined by using pull-out tests of SDPME-coated steel bar when embedded in concrete specimens. For comparison, both the corrosion resistance and bond strength of uncoated and pure enamel coated steel bars were also tested. Electrochemical corrosion results show that the corrosion resistance of SDPME-coated steel bar is ~300 times higher than that of the uncoated one. Pull-out tests demonstrate that the bond strength of SDPME-coated steel bar is 3.63 times greater than that of the uncoated steel bar. Therefore, SDPME coating increases both the corrosion resistance and the bond strength of steel bar.

1 INTRODUCTION

Concrete is a porous construction material, and the aggressive chemicals in the environment such as chloride can penetrate through the concrete cover to reach the surface of steel rebar and results in steel rebar corrosion (Angst, 2018). Corrosion of steel rebar causes cross-sectional area loss, concrete cover cracking, bond degradation, and consequently a reduction in the carrying capacity of both structural members and system (Li & Yang, 2011; Zhao et al, 2022; Tang et al, 2022). Application of rebar coatings is considered to be one of the most effective and economical methods to protect steel rebar from corrosion attack. The most widely used steel rebar coating is fusion bonded epoxy (FBE) coating, however, a major side effect of applying the FBE coating is the considerable reduction in the bond strength between steel bars and the surrounding concrete (Choi et al, 1991). Besides, under-film corrosion is prone to occur due to weak adherence of FBE coating with substrate steel (Tang et al, 2016).

Enamel coating, which is made by firing powdered glass on the surface of metal at temperature between 750 and 850 °C, is widely used in industry container or household application

(Jones, 1995). The enamel coating has many advantages, such as chemical inertia, corrosion resistance, flexible properties, and therefore has been used as a coating material for steel rebar (Tang et al, 2012a, 2012b, 2013; Yan et al, 2012). Previous studies show that enamel coating improves the corrosion resistance of steel rebar and enhances the chemical adherence with the steel substrate, and therefore prevents under-film corrosion (Tang et al, 2012a). As the enamel coating has a shining and smooth surface, silicate calcium has been added in the enamel frit during the firing process to manufacture chemically reactive enamel coating, which can chemically bond with the surrounding concrete. This chemically reactive enamel coating increases the bond strength with concrete (Yan et al, 2012). However, the corrosion resistance decreases due to presence of connected channels in the coating (Tang et al, 2012b, 2013). Therefore, it is necessary to modify the enamel coating for increase in both corrosion resistance and bond strength.

In this study, a silicate dioxide particle modified enamel (SDPME) coating, which is made by adding silicate dioxide particle in the pure enamel coating, is proposed for improved corrosion resistance and enhanced bond strength of steel bars in concrete structures. The corrosion performance is characterized by immersing in saturated calcium hydroxide solution containing 3.5 wt.% NaCl with electrochemical techniques including open circuit potential, linear polarization resistance and electrochemical impedance spectroscopy. The bond strength with concrete is determined through pull-out tests.

2 EXPERIMENTAL DETAILS

2.1 Specimen preparation

Table 1 shows the chemical composition of pure enamel (PE) coating. Plain steel bars with a diameter of 12 mm were used. Enamel slurry was made by mixing enamel frits with tap water, and silicate dioxide particle with an average size of 0.50 mm was added. The silicate dioxide particle is 10 wt.% of the enamel frits. The steel bars were dipped into the enamel slurry for 2 minutes and moved out, and then placed in a furnace at 800°C for 5 minutes, and finally cooled down to room temperature to produce silicate dioxide particle modified enamel (SDPME) coated steel bars. The yield strength and ultimate strength of the uncoated steel bars were 531.60 MPa and 613.01 MPa, respectively.

Table 1. Chemical composition of enamel coating.

Composition	Content(%)
SiO ₂	37.8
Al ₂ O ₃	15.8
B ₂ O ₃	14.6
KCO ₃	6.7
Li ₂ CO ₃	5.4
MnO ₂	5.2
NaNO ₃	4.8
CaF	3.6
TiO ₂	2.7
NaCO ₃	1.7
NiO	1.2
CoO	0.5

Figure 1 shows the dimensions of the steel bar specimens for electrochemical corrosion tests. The SDPME-coated steel bars were cut into a piece of 60 mm long, and one end was soldered with a copper wire for electrochemical corrosion tests. To limit the coated surface exposed to the test solution, the two ends of the steel bar were encased in PVC pipes filled with epoxy resin. Therefore, the length of steel bar is 40 mm and the surface area is approximately 15.08 cm² as

shown in Figure 1. For comparison, both pure enamel (PE) coated and uncoated steel bar specimens are also prepared and tested.

Figure 1. Steel rebar specimen for electrochemical corrosion test (unit: mm).

Figure 2 shows the concrete block specimen design for pull-out tests. The side length of the concrete block specimens is 120 mm. A 60 mm bonded length was used to achieve a relatively uniform bond stress distribution. Polyvinyl Chloride (PVC) pipes were used to create the unbonded regions in the specimens to prevent cone-type failure of the concrete at the loaded end.

Figure 2. Detail of pull-out test specimen (unit: mm).

The mix proportion of concrete is presented in Table 2. Three 150×150×150 mm concrete cubes were prepared and the average compressive strength at 28 days was 43.05 MPa.

Table 2. Mixture proportion of concrete.

Target concrete grade	w/c	Mix proportions (kg/m ³)				Mean compressive strength (MPa)
		Cement	Water	Sand	Coarse aggregate	
C30	0.47	350	165	719	1173	43.05

2.2 Electrochemical corrosion test

The steel rebar specimen including uncoated, PE-coated and SDPME-coated was first immersed in saturated calcium hydroxide solution for one week and then 3.5 wt.% NaCl powder was added. Electrochemical corrosion tests including open circuit potential (OCP), linear polarization resistance (LPR) and electrochemical impedance spectroscopy (EIS) were performed after three days of the addition of NaCl powder. The three-electrode system was used as shown in Figure 3: the steel bar worked as the working electrode, a platinum sheet with 20 mm ×20 mm×0.2 mm served as the counter electrode, and saturated calomel electrode (SCE) was the reference electrode. All of them are connected with Gamry reference 600 plus for data acquisition. LPR was conducted from -15 mV to +15 mV around the OCP with a scan rate of 0.167 mV/s. EIS was performed by applying a sinusoidal potential 10 mV around the OCP from 100 kHz to 5 mHz with a rate of 5 points per decade.

Figure 3. Electrochemical corrosion test setup.

2.3 Pull-out test

Figure 4 shows the pull-out test setup. A material testing machine with a capacity of 100 kN was used through displacement control. The loading rate used was 0.06 mm/s. Each specimen was installed with two Linear Variable Differential Transformers (LVDTs) at the end of the loaded and the free end of the concrete block specimen, respectively. The test terminated when the recorded free end displacement reached 20 mm. Test data were collected by IMC dynamic measurement system.

Figure 4. Pull-out test setup.

3 RESULTS AND DISCUSSION

3.1 Bond strength

Assuming a uniform distribution of bond stresses along the bonded length of the bar, then the average bond stress (τ) was calculated as follows:

$$\tau = \frac{P}{\pi dl} \quad (1)$$

where P is the pullout force, d is the nominal diameter of the rebar, and l is the bonded length.

Figure 5 compares the maximum bond stress (bond strength) of uncoated, pure enamel (PE) coated, and SDPME-coated steel bar. It can be observed that the bond strength of uncoated plain steel bar is 3.2 MPa, and the bond strength of enamel coated steel bar increases up to 4.29 MPa. The bond strength of SDPME-coated steel bar is 11.62 MPa, which is 3.63 and 2.17 times greater than the uncoated and PE-coated steel bar, respectively. The significant increase in the bond strength for SDPME-coated steel bar is attributed to the increase of the surface roughness of enamel coating after addition of silicate dioxide particles.

Figure 5. Comparison of bond strength.

3.2 Corrosion resistance

Figure 6a shows that comparison of open circuit potential (OCP) of uncoated, PE- and SDPME-coated steel bars immersed in saturated calcium hydroxide solution with 3.5 wt.% NaCl. The OCP of uncoated steel bar is -651 mV/SCE, which is more negative than those of PE- and SDPME-coated steel bars. The OCP of SDPME-coated steel bar is -547 mV/SCE, which is greater than the OCP of PE-coated steel bars (i.e., -574 mV/SCE). The corrosion current density obtained from the linear polarization resistance is shown in Figure 6b. The uncoated steel bar has a corrosion current density of $0.17 \mu\text{A}/\text{cm}^2$, which is lower than the typical active corrosion rate of steel bar (Tang et al, 2012b). This is because the majority of the steel bar is covered with a passive film and only small pitting corrosion occurred, and the corrosion current density is average by the entire surface area of the steel bar. The corrosion current density of PE- and SDPME-coated steel bar is $0.84 \text{ nA}/\text{cm}^2$ and $0.39 \text{ nA}/\text{cm}^2$, respectively, which is almost 1000 times lower than the uncoated steel bar. Therefore, SDPME-coating significantly increases the corrosion resistance of steel bar.

Figure 6. Comparison of (a) OCP, and (b) corrosion current density.

Figure 7 shows the impedance spectrum of uncoated, PE- and SDPME-coated steel bar immersed in saturated calcium hydroxide solution containing 3.5 wt.% NaCl solution in the format of both Nyquist and Bode plots. The impedance was fitted by using electrical circuit as shown in Figure 8: model (a) is used for uncoated steel bar and model (b) was used for PE- and SDPME-coated steel bar. In these models, R_s is the solution resistance, R_c is the coating

resistance, CPE_c represents the nonideal capacitive behavior of coating, R_{ct} is the charge transfer resistance, and CPE_{dl} represents the non-ideal capacitance behavior of the double layer at the interface where corrosion occurs between the solution and the steel bar.

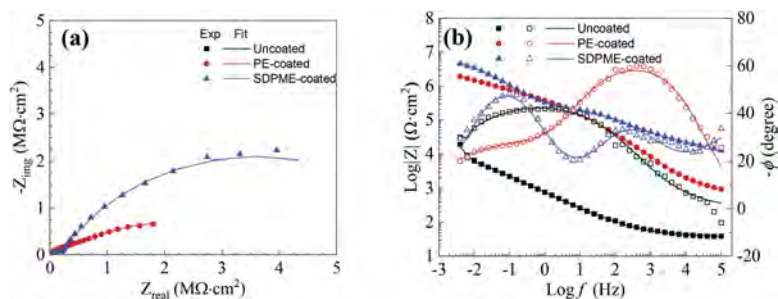

Figure 7. EIS in the format of (a) Nyquist, and (b) Bode plots.

Figure 8. Equivalent electrical circuit for (a) uncoated, and (b) PE- and SDPME-coated steel bar.

Figure 9 shows the charge transfer resistance of uncoated, PE- and SDPME-coated steel bars extracted from the impedance spectrum in saturated calcium hydroxide solution containing 3.5 wt.% NaCl. The charge transfer resistance of uncoated steel bar is $22.15 \text{ k}\Omega\text{cm}^2$. The charge transfer resistance of PE- and SDPME-coated steel bar is $4.15 \text{ M}\Omega\text{cm}^2$ and $6.79 \text{ M}\Omega\text{cm}^2$, respectively. The charge transfer resistance of SDPME-coated steel bar is ~ 300 times greater than that of the uncoated steel bar. Therefore, the SDPME coating dramatically enhances the corrosion resistance of steel bar.

Figure 9. Comparison of charge transfer resistance.

4 CONCLUSIONS

The bond strength and corrosion resistance of silicate dioxide particle modified enamel (SDPME) coated steel bar are experimentally investigated in this study. Pull-out was conducted to determine the bond strength. Linear polarization resistance and electrochemical impedance spectroscopy were used to quantify the corrosion resistance of SDPME-coated steel bar in saturated calcium hydroxide solution containing 3.5 wt.% NaCl. For comparison,

uncoated and pure enamel coated steel bar specimens are also prepared and tested. Based on the results and discussion, the following conclusions can be drawn:

- (1) Both pure enamel and silicate dioxide particle modified enamel improve the bond strength of steel bar with concrete. The bond strength of PE and SDPME-coated steel bar is 1.34 and 3.63 times greater than that of the uncoated steel bar.
- (2) The corrosion current density of PE- and SDPME-coated steel bars is 0.84 nA/cm² and 0.39 nA/cm², respectively, which is almost 1000 times lower than the uncoated steel bar.
- (3) The charge transfer resistance of SDPME-coated steel bar is 6.79 MΩcm², which is ~300 times greater than that of the uncoated steel bar.

Non-destructive investigation of corrosion in reinforced concrete structures and modelling the structural degradation

S.T. Yang, F. Zhang & Z. Yin
University of Strathclyde, Glasgow, UK

X. Xi
University of Science and Technology Beijing, Beijing, China

ABSTRACT: Corrosion-induced concrete cracking is a significant durability problem for reinforced concrete structures. Conventional method of examining corrosion progression is upon crushing the corroded samples which led to inaccurate or in some cases misleading estimation. This has hindered the development of rational corrosion models as reliable experimental data are rather limited. In this research, the chloride-induced corrosion progression of the steel bar in concrete was investigated by X-ray Computed Tomography (i.e., XCT). 3D XCT images were obtained and processed to characterize the different material phases. It has been found that pitting corrosion is prone to appear around the voids close to the steel bar, mainly due to the pre-existing supply of oxygen and moisture. In addition, a distinct transverse crack has been identified which is caused by non-uniform corrosion along the reinforcing steel bar. A non-uniform corrosion model was then parameterized based on the XCT results. It can be concluded that the combination of the use of wetting and drying cyclic corrosive environment and the XCT scanning can provide a new method to the non-destructive investigation of corrosion process, rust distribution and corrosion-induced concrete cracking in the reinforced concrete structures.

1 INTRODUCTION

Corrosion of the reinforcement in concrete structures is arguably the most significant durability problem, affecting the serviceability and safety of civil engineering structures and infrastructures. Corrosion can cause cracking of concrete and de-bonding between the reinforcement and concrete, which may destroy the integrity of concrete cover, reduce the reliability of concrete and lead to premature failure of the structures and infrastructures. Under the climate change, the aging infrastructure will face exacerbated deterioration which warrants new research in understanding the corrosion in civil engineering.

Over the last few decades, considerable researches have been conducted in understanding the corrosion mechanism (Česen et al. 2013; Angst and Elsener 2017), predicting the structural effect (Bazant 1979; Yang et al. 2018), preventing the corrosion initiation and propagation (Melchers and Li, 2009), etc. In particular, a variety of experiments have been carried out in understanding the corrosion phenomena of the reinforcement and the corrosion-induced concrete cracking (González et al. 1995; Andrade et al. 1993; Mullard and Stewart 2011). To understand the corrosion development of the reinforced concrete structures, the traditional method is to employ destructive means, i.e., cutting the samples to physically expose the cross section and then analysing the corrosion progression between the steel bar and the concrete. It was usually followed by crush of the samples for weighing the mass of the corroded steel to calculate of corrosion degree. This approach has been widely used to help understand the rust properties and distributions, the corrosion effect on the steel-concrete interface and the

corrosion products expansion behaviour coupled with digital optical microscope, scanning electron microscope (SEM) and energy-dispersive X-ray spectroscopy (EDS). However, the microstructures of the reinforced concrete samples are very likely to be affected or interfered by the cutting, grinding and polishing processes. Moreover, the technician skills, processing procedure and measuring method are likely to affect the results.

Using non-destructive imaging method, e.g., XCT, has become a promising approach to investigate the corrosion behaviour of the reinforced concrete structures. The distinct advantage of XCT test on corrosion of reinforced concrete is the corrosion development, e.g., initiation, propagation and rust distribution, can be imaged without any physical cut or smash. Beck (2007) perhaps first applied the XCT method to investigate the corrosion process of the reinforcing steel in a mortar cylinder with a height of 90 mm and a diameter of 40 mm. Michel et al. (2011) employed XCT to study the corrosion products and the formation and propagation of cracks in a reinforced mortar prism sample with a resolution of 75 μm . Šavija et al. (2014) investigated the corrosion induced cover cracking in a mortar cylindrical specimen with a diameter of 34.1 mm by XCT scanning with a resolution of 16 μm . Dong et al. (2017) observed the development of steel corrosion, corrosion products formation, as well as the subsequent initiation and propagation of corrosion-induced cracks by XCT. Itty et al. (2014) compared the difference in morphology of corrosion deterioration in the case of carbon steel or stainless steel reinforcement in mortar cylinders.

This paper attempts to investigate the corrosion progression of the reinforced concrete structure by XCT test, under the accelerated wetting and drying cyclic corrosion. High resolution XCT images are obtained and then processed by in-house scripts, to reliably characterize the different material phases, consisting of, steel bar, mortar, corrosion products and voids/cracks. The corrosion products expansion behaviors are analysed and discussed; the corrosion degree and the maximum and average radial losses of steel bar along the longitudinal direction are then evaluated. Further, the corrosion progression data obtained from analyzing the XCT results are used to parameterize a non-uniform corrosion model. This non-uniform corrosion model can then be applied to modelling the corrosion-induced concrete cracking problems with confirmed accuracy.

2 NONDESTRUCTIVE XCT ASSESSMENT

2.1 *Image processing and segmentation*

Figure 1 shows the reconstructed images of the specimen exposed to the corrosive environment for 112 days. The XCT attenuation value is quantified on a grey value scale with 65,536 levels (i.e., 16-bit image), which provide higher quality presentation than 256 levels (8-bit image). In the meantime, the 16-bit image data is much larger than an 8-bit image. Since steel, corrosion products, mortar and voids or cracks have different densities, the attenuation of X-ray will produce different grey values, in a wide range, as illustrated in Figure 1.

Depending on the densities of the materials, the XCT pictures show different grey value for each of the material phases; the denser material shows the brighter in the XCT image and has the higher grey value. In this study, we used trial and error approach coupled with manual check-up to identify the phases at some suspicious points. Once the thresholds are determined, they are then used for segmentation of the raw images. By using the segmentation thresholds, the 3D images of the corroded reinforced mortar sample can be separated and recognized in terms of the mortar, steel bar, corrosion products and voids/cracks. Figure 2 shows the 3D images of (a) mortar, (b) steel bar after corrosion, (c) distribution of corrosion products and (d) distribution of voids and cracks around the corner. In Figure 2(a), clearly, there are 2 longitudinal cracks presenting; most interestingly, a transverse crack close to the bottom of the sample also appears. The transverse crack takes place where the most corrosion products are accumulated along the longitudinal direction. This changes our usual understanding that corrosion induced concrete cracking is normally longitudinal cracking, whilst transverse cracks can also be induced by reinforcement corrosion. Moreover, it has been found that the transverse crack initials from the concrete surface and propagates towards the steel bar. From Figure 2(b) it can

be seen the corrosion of the steel bar is non-uniform along both the longitudinal and the circumferential directions. Figure 2(c) shows the accumulation of corrosion products along the reinforcing bar; it should be noted that the thickness of the cylindrical wall significantly varies, though it cannot be clearly observed from this figure and especially the current viewing angle. Figure 2 (d) illustrates the pore voids and cracks due to corrosion expansion.

Figure 1. Geometrically processed images.

Figure 2. Three-dimensional views of (a) mortar, (b) corroded steel, (c) corrosion products and (d) cracks and voids.

To better analyze the spatial distribution of corrosion, the 3D structure of the corroded sample is cut vertically (i.e., cross section) and longitudinally at a number of locations. Figure 3 shows three typical cross section images around the steel bar at different locations. Some useful

observations have been obtained, i.e., (i) pitting corrosion was initiated around voids (Figure 3 (a)), (ii) corrosion products penetrated or flowed into the cracks (Figure 3(b)) and (iii) corrosion rust layer was separated (Figure 3(c)). Given abundant supply of oxygen and water which were pre-existed in the voids, corrosion was more prone to occur at the location of the steel bar in contact with large voids. Moreover, the corrosion products had penetrated into the cracks and/or voids during the accumulation process of the rust. Figure 3(c) presents the image for a slice taken from the 3D structure where there was minor corrosion compared with other locations in the same sample at the same time. In this slice, corrosion rust layer separation is observed. Such a separation phenomenon of rust is caused by the stronger expansion in adjacent places.

Figure 3. Typical cross section images around the steel bar.

2.2 Quantification of the corrosion loss

By measuring the residual area of the steel bar after corrosion, corrosion degree of the steel bar at any given location can be calculated as follows:

$$\eta = \frac{W_0 - W_r}{W_0} \times 100\% \quad (1)$$

where W_0 is the original mass of the steel for any given cross section and W_r is the residual mass of the steel for the same cross section of the reinforcing bar.

Figure 4. Corrosion degree of the steel bar along the longitudinal direction.

Figure 4 illustrates the corrosion degree along the longitudinal direction of the steel bar, calculated from 933 slices cut from the 3D CT reconstructed structure. 15mm length structure was chosen for analysis. Clearly, the corrosion degree of the steel bar varies along the reinforcement.

The maximum corrosion degree is 7.5% while the minimum corrosion degree is only about 1%. It should be noted that, because the diameter of the steel bar is only 2.94 mm and thus W_0 is quite small, the corrosion degree to concrete cracking should become very high.

The residual cross section of the steel bar significantly influences the failure probability of corroded RC members. The maximum and average radial losses of steel bar for any cross sections can reflect the non-uniform or pitting corrosion nature along the longitudinal direction. The maximum radial loss can be obtained as follows:

$$R_{ml} = \max_{\theta \in [0, 2\pi]} \{1 - R_{re}(\theta)\} \quad (2)$$

where R_{ml} is maximum radial loss of the steel bar; R_{re} is residual radius of the steel bar; θ is the polar angle within the cross section of the steel bar which varies from 0° to 360° by the increment of 1° .

In addition, the average radial loss can be calculated as follows:

$$R_{av} = \frac{\sum_{\theta=0}^{2\pi} (1 - R_{re}(\theta))}{2\pi} \quad (3)$$

Figure 5 illustrates that the maximum and average radial loss along the reinforcement. The maximum radial loss considerably varies along the longitudinal direction. The maximum value of R_{ml} is 0.22 mm while the corresponding average radial loss is only 0.05mm which reflects severe non-uniformity. According to the definition, the average radial loss has a linear relationship with corrosion degree. Generally, the average radial loss and the maximum radial loss keep the same trend of change.

Figure 5. Maximum and average radial losses of the steel bar along the longitude direction.

2.3 Rust distribution

The processed binary images were used for rust thickness measurement. As shown in Figure 6, a polar coordinate system was built with its origin located in the centre of the steel bar. The rust thickness was calculated by measuring the distance between the first two points at the black and white boundaries along the radial line. This radial line was rotating against the origin for 360° to obtain the thickness for the whole circumference of the steel bar. The measurement approach was achieved by an in-house script written in Python. It should be noted that the corrosion products flowed into the surrounding cracks were not counted. This measurement approach can provide an effective and accurate way to analyze the rust distribution.

Figure 6. Radial thickness measurement of the rust along the circumference of the steel bar.

3 CT-INFORMED CORROSION MODEL

A non-uniform corrosion model has recently been developed by the authors based on von Mises distribution which is a continuous probability distribution on a circle (Xi et al. 2018). This model describes the non-uniform distribution of corrosion rust around the steel bar as a modified function of von Mises distribution. The model is simply composed of three parameters including the corrosion degree indicator λ , the non-uniform coefficient k and the location of the maximum thickness of the corrosion layer μ . In this paper, the non-uniform corrosion model is parameterised by the experimental data obtained from the novel X-CT analysis. The corrosion rust layer thickness around the reinforcing steel bar is formulated as follows:

$$T_{cl}(\theta) = \lambda \frac{e^{k \cos(\theta - \mu)}}{2\pi I_0(k)} \quad (4)$$

where λ is a corrosion degree indicator, μ is the location where the maximum thickness of corrosion layer appears, k is the non-uniform corrosion coefficient, $I_0(k)$ is the modified Bessel function of order 0.

After the regression analysis of the von Mises corrosion model fitted with the XCT data, we have fitted the corrosion model for all the cross sections along the longitudinal direction of the sample which has 933 slice cuts. Figure 7 shows the fitted parameters k and λ along the longitudinal direction. The maximum value of k is about 10.6 and the minimum value of k is about 2.0 and k significantly varies along the reinforcing steel bar. k in a range of 3-4.5 accounts for 64% of the total cut cross sections. The number of cross sections with k larger

Figure 7. Parameter fitting for von Mises non-uniform corrosion model.

than 5 is very small. This finding suggests that the non-uniform corrosion coefficient k might fall within a small realistic range, affected by chloride content, geometry of the RC structures, corrosion degree and surface crack of concrete. More experimental study would be necessary to clarify the effects of different underlying parameters on k and ideally to formulate an analytical function for k . The experimental results and the parameterised von Mises corrosion model can be applied to civil engineering practice in predicting the corrosion induced concrete cracking problems.

4 CONCLUSIONS

In this paper, the corrosion of corner-located steel bar in mortar was non-destructively examined through XCT scanning. 3D images were obtained and segmented in terms of concrete, steel bar, corrosion products and voids or cracks. It has been found that pitting corrosion is prone to appear around voids close to steel bar because the pre-existing supply of oxygen and moisture. Moreover, corrosion has been found varying considerably along both the longitudinal direction of the sample and the cross sections. Also, the ratio of maximum to average radial loss of the steel bar differs from about 4 to 13 along the reinforcing bar. The rust distribution in the cross sections obtained has been used to parameterise the von Mises corrosion model. The non-uniform coefficient which represents the non-uniformity of the rust distribution has been found tending to fall in the range of 3 – 4.5. The experimentally validated non-uniform corrosion model can be applied to corrosion induced concrete cracking problems with good accuracy.

Guangdong Provincial Key Laboratory of Durability for Marine Civil Engineering, College of Civil and Transportation Engineering, Shenzhen University, Shenzhen, China

ABSTRACT: Limestone powder has been used to replace part of Portland cement because of environmental and economic benefits. The durability of the cement-based materials is important to consider the performance of concrete structures under a long-term service life. Under a marine environmental condition, the chloride-induced corrosion is the main mechanism for the degradation of reinforced concrete structures. In this study, the effects of limestone addition on the pore structure, chloride binding capacity and apparent chloride diffusivity of Portland cement paste were investigated. The porosity and pore size distribution were obtained by mercury intrusion porosimetry, focused ion beam/scanning electron microscopy and X-ray computed tomography. The chloride binding isotherms and the binding kinetics of cement paste with different limestone addition were studied. The apparent chloride diffusivity was obtained by a ponding test. The MIP results showed that the addition of limestone powder led to a coarser pore structure, especially when more limestone powder was added or coarser limestone powder was used. Limestone powder accelerated the rate of chloride ion binding at first and then the binding rate slowed down as the absorption time increased. The bound chloride amount was larger as the particle size of limestone powder was smaller. The result also showed that cement paste containing 5% replacement of limestone powder had positive effect in resisting chloride ion penetration before 14 d of diffusion. For a longer diffusion time, the apparent chloride diffusivity of cement paste was greater with greater limestone powder content or larger limestone powder size.

1 INTRODUCTION

In order to reduce the emission of carbon dioxide and the consumption of natural resources, fly ash, slag, silica fume and other supplementary cementitious materials are used to partially replace cement with commonly 20% replacement (Scrivener et al., 2018). However, the supply of these industrial by-products is relatively limited with non-uniform regional distribution. Therefore, it is necessary to find supplementary cementitious materials that can partially replace cement without significantly affecting the performance and are also rich in resources. Limestone powder is an industrial by-product produced when crushing limestone to produce manufactured sand in quarries. It is not only inexpensive and stable in composition, but also can partially replace cement as a supplementary cementitious material, effectively reducing carbon emissions in the cement production process. So far, many studies have been carried out on the mechanism of limestone powder in cement-based materials, including filling effect, nucleation effect, chemical effect and dilution effect (Aqel and Panesar, 2016). The research results showed that when the content of limestone powder is less than 5% - 10%, the diffusivity of chloride ions in cement-based materials will be reduced to some extent. However, with the increase of limestone powder content, due to the dilution effect, the chloride diffusivity of cement-based materials increases (Meddah et al., 2014).

Chloride ions in seawater transport into the concrete through its pore structure. Therefore, the pore structure characteristic of concrete is a direct factor affecting the chloride transport. The transport properties of chloride ions in cement-based materials are highly dependent on the pore network. At present, many methods have been used to characterize the pores of cement-based materials. The indirect method detects the response of the measured material under external stimulus and converts it to the pore structure parameters by a proper model. The direct method images the material microstructure directly and characterizes the three-dimensional pore network in the material intuitively. X-ray computed tomography (XCT) is a non-destructive imaging method. However, the resolution of conventional CT scanning system generally stays at the micron level, so that most of the nano-scale pores in cement-based materials cannot be observed. XCT is more suitable for characterizing the large pores and cracks of cement-based materials at the micron level. Compared with XCT, focused ion beam/scanning electron microscopy (FIB/SEM) can obtain images at nanometer scales. Song et al. (2018) used FIB/SEM to characterize the three-dimensional pore structure of high performance concrete, and the pore size range studied was between 10 and 600 nm. The permeability of cement-based materials was predicted by combining the FIB/SEM results with the Katz-Thompson model. However, the dimension of the observed volume in FIB/SEM is only tens of microns, which leads to insufficient representativeness of the volume. Jiang et al. (2022) used XCT and FIB/SEM to characterize the three-dimensional pore structure of cement paste, indicating that these two methods have significant advantages in measuring characteristic pore parameters such as pore connectivity and tortuosity. In addition, the hydraulic tortuosity values measured by the two methods are similar and close to the calculated values of Archie's law tortuosity.

This paper investigates the effect of limestone powder on chloride transport and pore structures in cement-based materials. Three pore characterization methods, i.e., mercury intrusion porosimetry (MIP), FIB/SEM and XCT, were used to obtain the pore characteristic parameters of cement paste containing limestone powder with different fineness and addition. The chloride binding isotherms and binding kinetics of cement paste were tested. The effect of limestone powder on the chloride ion diffusion performance of cement paste was studied under different fineness and addition of limestone powder.

2 MATERIALS AND METHODS

2.1 Materials and specimen preparation

Portland cement, natural limestone powder with different fineness and deionized water are used for cement paste. The chemical composition of the cement and limestone powder is determined by X-ray fluorescence analysis (XRF), and the results are shown in Table 1. The median particle sizes of cement, fine limestone (FL) and coarse limestone (CL) are 13.68, 1.71 and 19.97 μm , respectively. The mix proportion of each cement paste group is shown in Table 2. The water-binder ratios of all groups are 0.45. The cement pastes with 5%, 10%, 15% and 20% replacement of fine limestone are designated as 5FL, 10FL, 15FL and 20FL, respectively, and those with 10% and 20% replacement of coarse limestone are designated as 10CL and 20CL, respectively. After mixing the binder with deionized water, the cement paste was cast into $40 \times 40 \times 160$ mm and $100 \times 100 \times 100$ mm molds and they were vibrated for 60 seconds. The molds were demoulded after 24 hours and cured at 20 °C and relative humidity (RH) of 95% for 28 days.

Table 1. Chemical composition of cement and limestone powder (% in weight).

	CaO	SiO ₂	Al ₂ O ₃	SO ₃	Fe ₂ O ₃	MgO	Other	LOI
Cement	64.46	20.37	5.04	2.93	2.69	1.02	0.67	2.37
Limestone	55.45	0.35	0.18	-	0.10	0.27	0.12	43.50

2.2 Pore structure characterization

2.2.1 Mercury Intrusion Porosimetry (MIP)

Small cylinders with a diameter of 3 mm and a height of 5 mm were cored at the center part of the cured $40 \times 40 \times 160$ mm specimens. The cored samples were soaked in isopropanol solution for 7 days to stop hydration, and then they were vacuum dried at 40°C until the equilibrium mass was reached. The samples' pore structures were measured by mercury porosimeter (Auto Pore IV 9500 produced by Micromeritics). The samples were subjected to step-by-step increasing pressures with the maximum pressure at 3.0×10^4 psia. The relation between the pore size and the implied pressure is obtained by Washburn's equation (Washburn and E., 1921):

$$d = -\frac{4\gamma\cos\theta}{P} \quad (1)$$

where d is the pore diameter, P is the implied pressure, γ is the surface tension of the mercury and θ is the contact angle between mercury and pore walls.

Table 2. Mix proportion of each cement paste group (kg/m^3).

Groups	Water	Cement	Fine limestone	Coarse limestone
PC	586	1302	—	—
5FL	586	1237	65	—
10FL	586	1172	130	—
10CL	586	1172	—	130
15FL	586	1107	195	—
20FL	586	1042	260	—
20CL	586	1042	—	260

2.2.2 Focused Ion Beam/Scanning Electron Microscopy (FIB/SEM)

Thin slices with dimensions of $5 \times 5 \times 5$ mm were cut from the cured cement paste specimens. After being soaked in isopropanol solution to stop hydration, the samples were impregnated with a low-viscosity epoxy in a vacuum chamber. The sample surfaces were mechanical ground and then polished by argon ion beam. The polished samples were dried at 40°C before the test. The instrument crossbeam 540 (produced by Carl Zeiss, Germany) was used to observe the microstructure of the cement paste. The imaging process was conducted as follows:

- (1) The polished samples were sprayed by a layer of gold and then was fixed on the sample stage. After the sample chamber was vacuumed, the sample surface was observed in a scanning electron mode, and the target area of about $11 \times 10 \mu\text{m}$ which was away from the anhydrous cement particles and microcracks was selected.
- (2) The sample stage was rotated by 54° so that the sample surface was perpendicular to the electron beam. A positioning mark was made near the selected target area for image alignment correction. Platinuma was then plated on the surface of the target area to reduce damage to the area during ion beam etching.
- (3) The areas surrounding the target area were etched by the ion beam and the imaging surface was finely cut by a small beam of ion. The ion beam cut every 10 nm, and the electron beam was used to image the freshly cut surface. The working voltage of gallium ion beam is 30 kV and the working current is 700 Pa. The working voltage of the electron beam is 1.5 kV and the working current is 500 pA. The FIB/SEM system can automatically perform subsequent repeated cutting and imaging to obtain 1048 two-dimensional sequence images with a resolution of 5 nm/voxel.

2.2.3 X-ray Computed Tomography (XCT)

Cylinder samples with a diameter of 2 mm and a height of 2 mm were cored for the XCT test. A high-resolution X-ray CT instrument SkyScan2211 (Brook, produced in Germany) was used. A voltage of 80 kV and a current of 280 μA were used. The samples were scanned using

4032 × 2688 pixel CCD detector. The distance between radiation source and sample was 9.7 mm, and the distance between radiation source and detector is 146.8 mm. The three-dimensional internal structure of the cement paste was reconstructed with a resolution of 0.60 μm/voxel.

2.3 Chloride binding test

Crushed cement paste samples of sizes between 0.25 to 2 mm were collected for the dynamic chloride binding tests. The crushed samples were vacuum-dried at 25 °C for 2 days, and then they were dried at a 11% RH until mass balance in a desiccator with saturated LiCl solution for 7 days. After drying, 20 g sample was collected and soaked in 60 g 6% NaCl solution. At a given soaked time from 1 h to 28 d, 2 mL supernatant of the standing solution was taken and then the potentiometric titrator was used for titration by 0.1 mol/L AgNO₃.

The crushed samples were also collected for the chloride binding isotherms. The dried sample was soaked in 60 g of sodium chloride solution with different concentrations from 0.0125 to 1.829 mol/L. Tang and Nilsson (1993) pointed out that the chloride binding for the crushed cement paste samples reached equilibrium at about 10 d. To ensure sufficient binding, we tested the bound chloride content at 14 d as the equilibrium binding. The bound chloride content at equilibrium is obtained by:

$$c_b = M_{Cl} \times V \times \frac{c_0 - c}{w_d} \quad (2)$$

where c_b is the bound chloride content at equilibrium (mg/g), c_0 is the initial concentration of NaCl solution (mol/L), c is the free chloride ion concentration in solution (mol/L), V is volume of NaCl solution (mL), M_{Cl} is the molar mass of chloride (g/mol), and w_d is the mass of the dry sample which is calculated by

$$w_d = w_{11}(1 - \xi_{11}) \quad (3)$$

where w_{11} is the sample at 11% RH (g) and ξ_{11} is the evaporable water content at 11% RH.

2.4 Chloride diffusion test

For the chloride diffusion tests, 100 × 100 × 100 mm cement paste cubes were used. The first 5 mm layer of the specimen was removed and the freshly cut surface was used as exposure surface. The specimen was vacuum-saturated by saturated calcium hydroxide solution and then the specimen surfaces were sealed by epoxy resin except the exposure surface. The sealed specimens were immersed in 6% NaCl solution in a container. The container was shaken and the solution was replaced regularly to keep the solution concentration unchanged. After the immersion for 7, 14, 28, and 60 days, cement paste powder was obtained by layered grinding from the exposure surface to the inner part of the specimen. The total chloride content in each layer was measured through potentiometric titration by 0.02 mol/L AgNO₃ solution.

3 RESULTS AND DISCUSSION

3.1 Pore structure parameters

The porosity and pore size distribution (PSD) of different specimen groups measured by MIP are shown in Figure 1. The results show that the total porosity increases with the increase of limestone powder content. Under the same limestone replacement, the porosity of cement paste with coarse limestone is greater than that with fine limestone. The addition of limestone powder reduces the amount of small capillary pores (10 – 50 nm), and increases the amount of medium (50 - 100 nm) and large (0.1 - 10 μm) capillary pores. The proportion of large capillary pores in the cement paste is greater with more limestone powder addition. The critical pore size is closely related to the permeability and ion diffusivity of the material (Halamickova et al., 1995). The PSD measured by MIP shows that the PSD gradually shifts to the large pores and the critical pore size gradually increases as the limestone powder content increases.

Even 5% replacement of limestone powder leads to coarser pore structure, and the pore coarsening becomes more obvious when limestone powder with larger replacement or larger particle size is used.

Based on the three-dimensional pore structure measured by FIB/SEM and XCT, the simulated MIP (SMIP) PSD was obtained by simulating the mercury intrusion process from the low-Z surface of the sample. The PSD results by SMIP are shown in Figure 2. The PSD of all groups obtained based on FIB/SEM is between 10 and 300 nm, while the PSD based on XCT is between 600 nm and 15 μm . The results of FIB/SEM show that the peak pore size of PSD includes 20, 40 and 80 nm. In Figure 2(b), the PSDs of different specimens based on the XCT show a single peak distribution. Due to the difference in resolution between FIB/SEM and XCT, the obtained PSD is different. The PSD for FIB/SEM is different from that by MIP, because the samples tested in MIP are millimeter-scale, which is more representative than FIB/SEM samples which are micrometer-scale. MIP samples contain multi-scale pore structures with pore diameters ranging from a few nanometers of gel pores to tens of microns of macropores, while FIB/SEM samples are mainly concentrated in capillary pores in hydrated matrix.

Figure 1. Pore structure parameters of cement paste measured by MIP.

Figure 2. Pore size distribution by simulating mercury intrusion based on FIB/SEM and XCT images.

3.2 Chloride binding behavior

3.2.1 Binding kinetics

Figure 3 shows the change of bound chloride amount in different cement paste groups as soaking time increases. At 24 h, the chloride binding reached more than 70% of the equilibrium amount. After that, the binding gradually slows down, and the binding equilibrium is basically reached at 14 d. The results are consistent with the results of Feng et al. (2018) on the binding kinetics of chloride ions in cement paste. The results in Figure 3 also show that the addition of limestone powder accelerates the chloride binding within 4 h, and the accelerating effect is more obvious as the addition increases. After 8 h, the dilution effect of limestone powder gradually reduced the binding rate of chloride ions.

For solid-liquid adsorption, Equation 5 for the pseudo-first-order kinetic (Boparai et al., 2011) and Equation 6 for the pseudo-second-order kinetic equation (Yu and Zhang, 2017) are

used to analyze the binding kinetics. In general, pseudo-first-order kinetics is related to physical adsorption (Page and Vennesland, 1983), and chemical adsorption (Boparai et al., 2011) is expressed by pseudo-second-order kinetics with more required energy.

$$\lg(q_e - q_t) = \lg q_e - \frac{K_1 t}{2.303} \quad (4)$$

$$\frac{t}{q_t} = \frac{1}{K_2 q_e^2} + \frac{t}{q_e} \quad (5)$$

where t is the binding time (h), q_t is the bound chloride content at time t (mg/g), q_e is equilibrium bound chloride content (mg/g), K_1 is quasi-first-order kinetic adsorption rate constant (1/h), and K_2 is quasi-second-order kinetic adsorption rate constant, (g/(mg·h)).

Figure 3. Bound chloride amount of cement paste at different absorption time.

Based on Equations 4 and 5, the fitting results are shown in Figure 4. the chloride ion binding in the cement paste conforms to the quasi-first-order kinetics within 12 h, and it conforms to the quasi-second-order kinetics after 24 h. The results indicate that the chloride binding is mainly controlled by physical action at first and then the chemical binding dominates. The addition of limestone powder accelerates the chloride binding and shortens the time to reach binding equilibrium.

Figure 4. Chloride binding kinetic model fitting.

3.2.2 Chloride binding isotherms

Figure 5 shows the chloride binding isotherms of cement paste containing limestone powder with different addition and fineness. The relationship between the amount of bound chloride ion c_b and the free chloride ion concentration c in the solution is nonlinear. The binding isotherms are fitted by Freundlich's equation (Tang et al., 1993).

$$c_b = K_F c (Cl^-)^{1/n} \quad (6)$$

where K_F (mL/mol) and $1/n$ are two parameters for the Freundlich's equation.

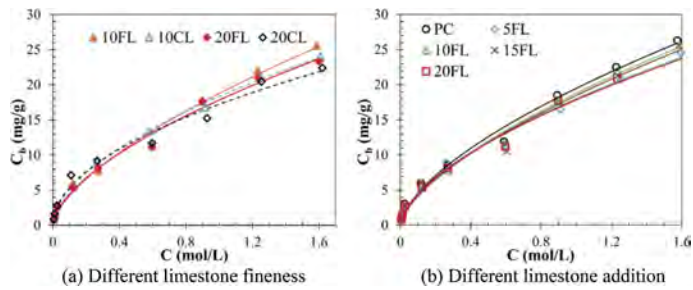

Figure 5. Chloride binding isotherms of cement paste.

The results in Figure 5 show that the bound chloride amount decreases with the increase of limestone powder content. Similarly, Ipavec et al.'s results (2013) showed that the replacement of 10% limestone powder would slightly reduce the chloride binding capacity of the cement paste. The results in Figure 5 also show that under the same limestone powder content, the amount of chloride ion adsorbed by the fine limestone group is greater than that of the coarse limestone group. This is because the smaller the particle size of limestone powder, the more obvious the filling effect and the nucleation effect. The formation and precipitation of hydration products (Bentz, 2006) is accelerated, thereby increasing the chloride binding through physical adsorption of C-S-H.

3.3 Apparent chloride diffusivity

Figure 6 shows a comparison of apparent chloride ion diffusivity for different specimen groups. The results show that the apparent diffusivity for PC and fine limestone groups decreases with the increase of soaking time, while the diffusivity of coarse limestone group increases from 7 to 14 d and then decreases gradually. When the soaking time is 7 d and 14 d, the diffusivity of 5FL group is slightly smaller than that of PC group, indicating that a small amount of limestone powder at the beginning of diffusion has a positive effect to resist chloride ion penetration. As the diffusion time increases, the diffusivity for 5FL is larger than that for PC because of the dilution effect. At 28 d and 60 d, the apparent chloride diffusivity in the 5FL, 10FL and 15FL groups are close to each other. For the convenience of comparison, the specimens were further divided into four groups: no limestone powder NL (PC group), a small amount of fine limestone powder SL (5FL, 10FL and 15FL groups), a large amount of fine limestone powder ML (20FL), and coarse limestone powder CL (10CL, 20CL). In general, the apparent chloride diffusivity of ML group is larger than that of NL and SL groups. Under the same limestone addition, the smaller the particle size of the limestone powder, the smaller the apparent chloride diffusivity of the cement paste.

Figure 6. Apparent chloride diffusivity of cement paste at different diffusion time.

4 CONCLUSIONS

In this paper, the pore structure of cement paste containing limestone powder was studied by different test methods. The effects of limestone powder content and fineness on chloride binding and chloride diffusivity of cement paste were investigated. Based on the test results, the following conclusions can be drawn:

- (1) The MIP results show that the addition of limestone powder makes the pore structure of the paste coarser, especially when more limestone powder is added or coarser limestone powder is used.
- (2) At the adsorption time of 4 h, limestone powder accelerates the rate of chloride ion binding. After that, due to the dilution effect, the binding rate of chloride ions slows down and the total adsorption capacity decreases. The bound chloride amount is larger as the particle size of limestone powder is smaller, because of the limestone powder's filling effect and nucleation effect.
- (3) Cement paste containing 5% replacement of limestone powder has positive effect in resisting chloride ion penetration before 14 d of diffusion. For a longer diffusion time, the apparent chloride diffusivity of cement paste is greater with greater limestone powder content or larger limestone powder size.

Simplified analytical method for moment-curvature response of corroded prestressed concrete beams

S. Ravasini, L. Franceschini & B. Belletti

Department of Engineering and Architecture, University of Parma, Parma, Italy

ABSTRACT: Nowadays, the corrosion phenomenon is recognized as one of the main causes of deterioration of reinforced and prestressed concrete (*PC*) structures. Several experimental and numerical investigations have been proposed in the literature for the flexural and shear response of reinforced concrete structures. However, the lack of simplified yet accurate analytical models have been outlined, especially concerning the residual mechanical response of corroded prestressed concrete members. To this aim, the present work focuses on the proposal of a simplified analytical model for the flexural resistance of prestressed concrete beams - subjected to chloride-induced corrosion - in terms of moment-curvature response. Firstly, the basic assumptions of the approach and the validation against un-corroded *PC* beams are described by adopting a novel stress-strain relationship for corroded strands previously proposed by the authors. Secondly, the effect of the corrosion level on the moment-curvature response of deteriorated *PC* beams is investigated. Finally, outcomes are provided concerning: (i) the expected flexural failure mode, (ii) the evaluation of useful parameters for the assessment of flexural and shear resistances - the latter referring to the current formulation provided in the Model Code 2010.

1 INTRODUCTION

The corrosion phenomenon is one of the most investigated topics in the engineering community since it affects the durability and residual capacity of existing structures. During the years, studies were conducted aimed to the assessment of prestressed concrete (*PC*) structures (Vereecken et al., 2021). Different authors investigated the performance of corroded pre-tensioned (Dai et al., 2020; Wang et al., 2018) and post-tensioned (Jeon & Shim, 2020; Zhang et al., 2017) beams. In addition, experimental pull-out tests on the bond-slip behaviour between prestressing strands and concrete (Wang et al., 2017b; Wang et al., 2017a) and prestress loss due to corrosion (Dai et al., 2020) were conducted. Belletti et al. (2020) and Vecchi et al. (2020) experimentally investigated the performance of naturally corroded pre-tensioned concrete beams without shear reinforcement. Thereafter, the same authors studied in detail the pit morphology of the prestressing strands relieved from the mentioned beams (Vecchi et al., 2021). Coronelli et al. (2022) recently investigated both pre- and post-tensioned beams subjected to natural corrosion. Despite the availability of studies on corrosion effects on prestressed concrete members, simple yet reliable analytical approaches are rare in the current literature.

In this context, a recent novel stress-strain relationship for corroded prestressing strands has been developed (Franceschini et al., 2022), which provided good agreement against experimental tensile tests on corroded strands. On this basis, this paper deals with the proposal of an analytical method for the flexural performance of pre-tensioned beams. Firstly, a piecewise moment-curvature response is proposed and validated. Secondly, the corrosion effect was applied on such response to investigate the capacity reduction in terms of both resistance and ductility. Finally, useful insights for the sectional assessment of flexural and shear resistance of *PC* members are provided.

2 THE MOMENT-CURVATURE RESPONSE

In the following, the simplified analytical approach of the moment-curvature response, $M-\chi$, for prestressed concrete sections is described.

2.1 Main assumptions and failure cases

The constitutive laws for concrete and un-corroded prestressing strands are shown in Figure 1(a) and (b), respectively. The strands' stress-strain is based on a recent publication by Franceschini et al. (2022), where the main points are highlighted as "a" ($\varepsilon_{pp,0}; f_{pp,0}$), "b" ($\varepsilon_{py,0}; f_{py,0}$) and "c" ($\varepsilon_{pu,0}; f_{pu,0}$). The stresses, $f_{pp,0}$ and $f_{py,0}$, are assumed equal to $0.7 \cdot f_{pu,0}$ and $0.882 \cdot f_{pu,0}$, respectively, while the strains, $\varepsilon_{pp,0}$ and $\varepsilon_{py,0}$, are assumed equal to $f_{pp,0}/E_p$ and 0.01, respectively.

Figure 1. (a) Stress-strain of concrete in compression and in tension, (b) stress-strain of un-corroded prestressing strands (Franceschini et al., 2022), and (c) piecewise moment-curvature response.

The assumed piecewise moment-curvature response is shown in Figure 1(c). The main events are related to the achievement of: (A') the negative curvature at prestress with eventually the moment due to self-weight, M_{sw} , (in the following, this contribution is neglected), (A) the cracking moment, (B) the point "a", (C) the point "b" of the strands' relation and (D) the first occurrence of concrete crushing or strands' fracture.

The basic assumptions are:

- The centre of gravity, G , is located at the mid-height of the cross section and the eccentricity of the strands, e , is $e = d_p - h/2$, where d_p is the effective depth of strands.
- The concrete tensile strength is used to evaluate the cracking moment. The tensile strength and the elastic modulus of concrete, f_{ct} and E_c , are calculated according to the Model Code 2010 (fib, 2013). The tension-stiffening is roughly considered by connecting the events A , B .
- A Euler-Bernoulli behaviour is assumed, where the strain compatibility condition between concrete in compression, ε_c , and strands in tension, ε_p , is expressed with the Equation (1):

$$\varepsilon_c = \frac{\Delta\varepsilon_p x}{(d_p - x)} \quad (1)$$

where x is the neutral axis depth, $\varepsilon_{p,0}$ is the prestressing strain of strands, calculated as the ratio $\varepsilon_{p,0} = \sigma_{p,0}/E_p$ and $\Delta\varepsilon_p = \varepsilon_p - \varepsilon_{p,0}$.

The limitations of the model are:

- It is limited to rectangular pre-tensioned cross sections.
- The ordinary rebars are neglected.

The geometrical features are shown in Figure 2 and the failure cases are:

- "1": the section is under-reinforced. The failure mode is associated to the achievement of the maximum strength of the strand, while concrete may behave elastically.
- "2": the section is balanced. The failure mode is attributed to concrete crushing, while strands are yielded (beyond the point "b" of the strands' stress-strain response).
- "3": the section is over-reinforced. The failure mode is due to concrete crushing, while strands are not yielded.

The failure case "3" will not be described since: (i) it is quite rare in practice and (ii) the corrosion effects on reinforcement leads to ductile-to-brittle failure (from failure case "2" to "1").

The mechanical reinforcement ratio, ω_p , is calculated with the Equation (2):

$$\omega_p = \frac{n_p A_{1p,0} f_{py,0}}{f_c b d_p} = \frac{A_{p,0} f_{py,0}}{f_c b d_p} \quad (2)$$

where $A_{1p,0}$ and n_p are the area of a single strand and the number of strands, respectively.

Figure 2. Failure cases for prestressed concrete beam sections.

The previous value must be compared with threshold limits depending on strain distribution of each failure case. The threshold limit between failure cases “1” and “2”, ω_{21} , is:

$$\omega_{21} = \frac{\lambda \varepsilon_{cu}}{(\varepsilon_{pu,0} - \varepsilon_{p,0} + \varepsilon_{cu})} \frac{f_{pu,0}}{f_{py,0}} \quad (3)$$

The threshold limit between failure cases “2” and “3”, ω_{23} , is:

$$\omega_{23} = \frac{\lambda \varepsilon_{cu}}{(\varepsilon_{py,0} - \varepsilon_{p,0} + \varepsilon_{cu})} \quad (4)$$

where λ is the “stress-block” parameter, assumed equal to 0.8. Finally, the expected failure case is identified as follows: (i) if $\omega_p \leq \omega_{21}$, the expected failure case is “1”, (ii) if $\omega_{21} < \omega_p < \omega_{23}$, the expected failure case is “2” and (iii) if $\omega_p \geq \omega_{23}$, the expected failure case is “3”.

2.2 Piecewise moment-curvature response for un-corroded members

The events of the sectional moment-curvature response are described herein. The events A' and A are related to linear elastic behaviour and the steps are the same for all the failure cases.

2.2.1 Events A' and A

The curvature at event A' is calculated by assuming a linear elastic calculation, Equation (5):

$$\chi_{A'} = \frac{M_{p,0}}{E_c I_i} = \frac{N_{p,0} e}{E_c I_i} = \frac{(-A_{p,0} \sigma_{p,0}) e}{E_c I_i} \quad (5)$$

Where $N_{p,0}$ is assumed as negative. The terms I_i are the second moment of inertia and A_i is the gross section area. The strands' strain is calculated with a linear elastic calculation. The mid-height strain of the section, $\varepsilon_{x,A'}$, is evaluated by considering the superimposition of effects:

$$\varepsilon_{x,A'} = \frac{N_{p,0}}{E_c A_i} \quad (6)$$

The event A corresponds to the achievement of the cracking moment (i.e., a stress equal to f_{ct} is reached at bottom of the beam section), M_A , and is calculated with the Equation (7):

$$M_A = \frac{2I_i}{h} \left[f_{ct} - \frac{N_{p,0}}{A_i} - \frac{M_{p,0} h}{I_i} \right] \quad (7)$$

The strain at strands' level is calculated with usual linear elastic calculation. In this case, the curvature is positive and is evaluated with the Equation (5) by substituting the numerator with M_A of the Equation (7). The mid-height strain is calculated with the Equation (6).

2.2.2 Event B

This event corresponds to the point “a” ($\varepsilon_{pp,0}; f_{pp,0}$) of the stress-strain relation of strands.

Regarding the failure case “1”, the concrete is assumed linear elastic, and the equilibrium is:

$$0.5bx_{1,B}\varepsilon_c E_c = A_{p,0}f_{pp,0} \quad (8)$$

By adopting the equilibrium and the compatibility in Equation (1) for ε_c , the neutral axis depth is:

$$x_{1,B} = \frac{A_{p,0}f_{pp,0} \left(-1 + \sqrt{1 + \frac{2bE_c\Delta\varepsilon_{pp,0}d_p}{A_{p,0}f_{pp,0}}} \right)}{bE_c\Delta\varepsilon_{pp,0}} \quad (9)$$

where $\Delta\varepsilon_{pp,0} = \varepsilon_{pp,0} - \varepsilon_{p,0}$. The moment and the curvature are evaluated with Equations (10) and (11):

$$M_{1,B} = A_{p,0}f_{pp,0} \left(d_p - \frac{x_{1,B}}{3} \right) \quad (10)$$

$$\chi_{1,B} = \varepsilon_c / x_{1,B} \quad (11)$$

If the concrete strain, ε_c , is greater than ε_{c0} , the first trial of the failure case “2” must be used.

Regarding the failure case “2”, as first trial, the neutral axis is calculated by using the equilibrium in Equation (12) by considering the concrete compressive strength, f_c , and the stress block formed:

$$x_{2,B} = \frac{A_{p,0}f_{pp,0}}{0.8bf_c} \quad (12)$$

If the corresponding concrete strain in compression, ε_c , is greater than ε_{c0} , the moment results:

$$M_{2,B} = A_{p,0}f_{pp,0}(d_p - 0.4x_{2,B}) \quad (13)$$

Otherwise, the concrete remains linear elastic and the neutral axis depth, $x_{2,B}$, and the moment, $M_{2,B}$, are evaluated as the previous case with the Equations (9) and (10) while the curvature, $\chi_{2,B}$, is calculated with the Equation (11). As stated by the Model Code 2010 (fib, 2013), for shear resistance verification, the longitudinal strain is calculated at half of the effective shear depth, z . This latter is assumed equal to $z = z_p = 0.9d_p$. Based on geometrical features, ε_x is calculated with the Equation (14). The same formulations can be applied to the events *C* and *D*.

$$\varepsilon_{x,2,B} = \chi_{2,B}(0.55d_p - x_{2,B}) \quad (14)$$

2.2.3 Event C

This event corresponds to the achievement of the point “b” ($\varepsilon_{py,0}; f_{py,0}$) of the stress-strain relation of strands. For both the failure cases “1” and “2”, the formulations and steps of the paragraph 2.2.2 are still valid.

2.2.4 Event D

Regarding the failure case “1”, the equilibrium is expressed with the Equation (12), where $f_{pp,0}$ is replaced by $f_{pu,0}$ and the check on concrete strain is done. The moment, the curvature, the concrete strain and the longitudinal strain are calculated by adopting the same steps of the paragraph 2.2.2.

Regarding the failure case “2”, the concrete crushing ($\varepsilon_{cu}; f_c$) is reached, and the equilibrium is expressed with the Equation (12) where $f_{pp,0}$ is substituted by $[f_{py,0} + E_p''(\varepsilon_p - \varepsilon_{p,0})]$. Thus, the neutral axis depth (with $f_{p,2,D}^* = [-f_{py,0} + E_p''(\varepsilon_{cu} + \Delta\varepsilon_{py,0})]$) and the moment are calculated as:

$$x_{2,D} = \frac{-A_{p,0}f_{p,2,D}^* + \sqrt{\left(A_{p,0}f_{p,2,D}^*\right)^2 + 3.2bf_cA_{p,0}E_p''\varepsilon_{cu}d_p}}{1.6bf_c} \quad (15)$$

$$M_{2,D} = A_{p,0}\left(f_{py,0} + E_p''(\varepsilon_p - \varepsilon_{p,0})\right)(d_p - 0.4x_{2,D}) \quad (16)$$

The longitudinal strain, $\varepsilon_{x,2,D}$, is calculated with the Equation (14) where the curvature, $\chi_{2,D}$, is:

$$\chi_{2,D} = \varepsilon_{cu}/x_{2,D} \quad (17)$$

The proposed approach is validated against some experimental tests (Billet, 1953) on moment-curvature of un-corroded beams. The analytical results in Figure 3 show good agreement with the tests, although a slight overestimation of the ultimate curvature is detected.

Figure 3. Comparisons between analytical and experimental moment-curvature responses.

2.3 Corrosion effects on the moment-curvature response

To the best authors' knowledge, experimental campaigns aimed to the moment-curvature response of corroded prestressed concrete members are not available. The experimental campaign by Belletti et al. (2020) and Vecchi et al. (2020) is taken as reference, where three- and four-points (“3p” and “4p”) tests on corroded pre-tensioned concrete beams without stirrups were carried out. The following corrosion levels were estimated on strands relieved from beams, based on probabilistic analyses of the maximum pit depth of the most corroded wire, $P_{max,sect}$: (i) $P_{max}=0.05$ mm; $P_{max}/r_{outer}=0.023$ (ii) $P_{max}=1.13$; $P_{max}/r_{outer}=0.531$, (iii) $P_{max}=1.75$; $P_{max,sect}/r_{outer}=0.822$, where r_{outer} is the radius of exterior wires. The ultimate stress and strain of un-corroded strands were 1901.75 MPa and 5.1%, while the concrete compressive strength was 45.4 MPa. By considering long-term effects, the prestressing stress, $\sigma_{p,0}$ was estimated equal to 1171 MPa. According to Franceschini et al. (2022), the corroded strand' stress-strain relation can be evaluated as:

- Calculate the ultimate corroded strain of the most corroded wire, $\varepsilon_{pu,cor}$ based on its maximum pit depth $P_{max,sect}$, which corresponds to the conventional failure of the strand.
- Calculate the average pit depth $P_{av,sect}$ of the remaining wires and the corroded areas of each wire $A_{w,cor}$ and finally the remaining strand's area, $A_{p,cor}$. The section loss is $\mu = A_{p,cor}/A_{p,0}$.
- Calculate the ultimate stress at failure, $f_{pu,cor}$, and the stress-strain relation is completed.

For details refer to Franceschini et al. (2022). The reduced concrete compressive strength was not considered herein since the reinforcement ratio of compressive bars was negligible. In addition, the concrete spalling may be considered for high corroded members (Franceschini et al., 2021).

Concerning the $M-\chi$ response, the failure case is evaluated by updating the equations from (2) to (4), by substituting the corroded properties of prestressing strands ($\varepsilon_{p0,cor}$; $\sigma_{p0,cor}$) and ($\varepsilon_{pu,cor}$; $f_{pu,cor}$). The reduction of the bond between strands and concrete, induced by corrosion, is $\sigma_{p0,cor} = R\sigma_{p0}$ (Dai et al., 2020). The coefficient R was estimated by Wang et al. (2017b) on tests on specimens failing by pull-out. In another work (Wang et al., 2017a), specimens failing by splitting failure mode were tested and, in this paper, a related reduction coefficient R is proposed.

Table 1. Features of some *PC* beams (Belletti et al., 2020; Vecchi et al., 2020) and corrosion data.

<i>PC</i> beam	L, a^* [mm], [mm]	$A_{p,0}$ [mm ²]	$b \times h$ [mm ²]	$P_{max,sec}/r_{outer}$ [-]	$A_{p,cor}$ [mm ²]	μ [%]	$R, \sigma_{p,0,cor}$ [-, MPa]
<i>PBN3P1</i> (3p)	5040, 2520	201	150x300	0.0	201	0.0	1, 1171
<i>PBN4P2</i> (4p)	5040, 1680	(2 ϕ 12.9)		0.0	201	0.0	1, 1171
<i>PB3P11</i> (3p)	4710, 2520			0.822	166	8.08	0.14, 167
<i>PB4P5</i> (4p)	4260, 1420			0.531	185	17.24	0.40, 470

* a is equal to $L/2$ and $L/3$ for 3p and 4p, respectively

The corrosion level was not constant along the beams and the failure was governed by the most corroded strand in the sections in proximity of the loads. In these zones, the corresponding corrosion levels were considered for the comparisons, reported in Table 1 with the features of some of the *PC* beams analysed and the corroded prestress level, $\sigma_{p,0,cor}$. The resulting stress-strain relations of corroded strands are shown in Figure 4(a). The coefficients R are shown in Figure 4(b) (note that $P_{max}/r_{outer}=0$ is the un-corroded case).

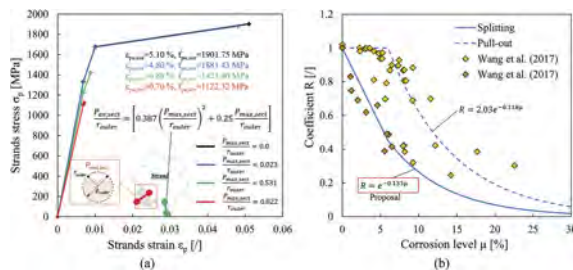

Figure 4. (a) Corroded stress-strain relations for strands, (b) coefficient R for bond reduction.

The formulations of the previous paragraph are still valid by using the corroded properties for the $M-\chi$ response of corroded *PC* members. It is worth mentioning that, the un-corroded strands area is adopted, since the corrosion effect is implicitly considered in the stress-strain relation by Franceschini et al. (2022). The moment-curvature responses are reported in Figure 5(a), where the reduction of both ultimate moment and curvature, as well as the cracking moment, is observed. Figure 5(b) shows both strands and concrete strains at failure, where it is evident the failure mode's transition from concrete crushing to steel fracture with increasing corrosion level.

Figure 5. (a) Corroded $M-\chi$ responses, (b) strands and concrete strains vs corrosion levels.

3 FLEXURAL VS SHEAR RESISTANCES

The flexural resistance of a three- and four-point *PC* beam is calculated with the Equation (18):

$$P_{Rd} = 2M_{Rd}/a \quad (18)$$

where M_{Rd} is the ultimate moment calculated in the previous section. The shear resistance is calculated with the *LoA II* of Model Code 2010 (fib, 2013), Equation (19):

$$V_{Rd} = k_v \frac{\sqrt{f_{ck}}}{\gamma_c} z b_w = \left[\frac{0.4}{1 + 1500 \varepsilon_x} \frac{1300}{1000 + k_{dg} z} \right] \frac{\sqrt{f_{ck}}}{\gamma_c} z b_w \quad (19)$$

where $\gamma_c=1$ and $k_{dg}=1$ is assumed, and the average concrete strength, f_{cm} , is used for the comparisons. The longitudinal strain is established with (i) the proposed analytical model, $\varepsilon_{x,an}$, and (ii) the formulation of the Model Code 2010, modified to account for corrosion Equation (20):

$$\varepsilon_{x,mod} = \frac{1}{2(z_p E_p A_{p,cor}/z)} \left[\frac{(M_{Ed0} + N_{p,cor} e)}{z} + V_{Ed0} + N_{p,cor} \frac{(z_p - e)}{z} \right] \quad (20)$$

where $N_{p,cor} = -A_{p,cor} \sigma_{p0,cor}$ is the prestress level of corroded strands. As suggested in *MC 2010* (fib, 2013), the shear verification is conducted at a distance equal to d_p from the loads (or, at a distance $(a - d_p)$ from the support), where M_{Ed0} and V_{Ed0} are the corresponding moment and shear demands, depending on the applied loads. In addition, $z=z_p=0.9d_p$ is assumed.

The comparisons between analytical and experimental results in terms of failure loads and failure modes (flexural, *I*, and flexural-shear, *II*) are shown herein. To consider the shifting of moment diagram and the shear demand, the proposed analytical strain is amplified by a factor $(1+\beta)$:

$$\varepsilon_{x,an}^{MV} = \varepsilon_{x,an} [1 + \beta] = \varepsilon_x \left[1 + \frac{V_{Ed0} z}{M_{Ed0} 2} (\cotg(\theta) + \cotg(\alpha)) \right] \quad (21)$$

Since in the reference work no stirrups were provided, $\theta=45^\circ$ and $\cotg(\alpha)=0$ is assumed. Figure 6(a) shows the longitudinal strain vs bending moment for the beams *PBN3P1* (black lines, $P_{max,sect}/r_{outer}=0$) and *PB3P11* (red lines, $P_{max,sect}/r_{outer}=0.822$). For un-corroded members, the positive strains are similar for both approaches till the event *C*, where the strands' yielding starts. The upper limit strain from *MC 2010* is also assumed. For corroded members, the proposed approach provides lower strain compared with the Equation (20). Figure 6(b) shows the shear demand and capacity by using the proposed analytical procedure. The shear capacity was calculated by adopting the longitudinal strain of Equation (21) and substituted in Equation (19). The flexural-shear failure occurs if the shear capacity intersects the shear demand, leading to the onset of a shear crack.

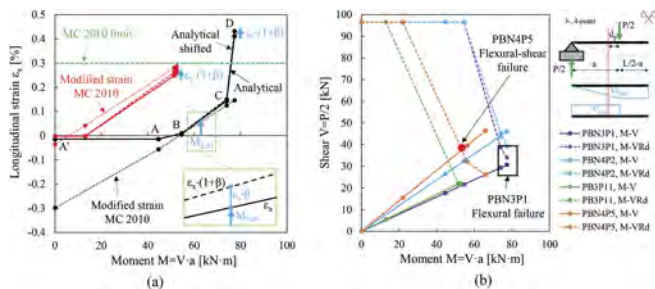

Figure 6. (a) Longitudinal strain, (b) demand vs capacity for the different *PC* beams.

Table 2 shows the obtained results, where the proposed model tends to provide better predictions for corroded *PC* members compared with the modified formulation of Model Code

Table 2. Summary of results in terms of failure loads and modes.

<i>PC</i> beam	M_{Rd} [kN·m]	$P_{fail,exp}$ [kN]	$P_{fail,mod}$ [kN]	β [%]	$P_{fail,an}$ [kN]	$P_{fail,exp}^I / P_{fail,mod}^I$ [I]	$P_{fail,exp}^{II} / P_{fail,an}^{II}$ [II]	Failure mode exp./an./mod.
<i>PBN3P1</i>	77.4	70.1	61.4	4.9	61.4	1.14	1.14	I/I/I
<i>PBN4P2</i>	77.4	98.5	89.2	7.8	89.2	1.12	1.10	II/II/II
<i>PB3P11</i>	52.4	62.0	42.8	5.3	44.0	1.45	1.41	I/II/II
<i>PB4P5</i>	65.9	90.2	70.0	9.6	75.1	1.28	1.20	II/II/II

2010. The coefficient β increases with loading configuration (from “3p” to “4p”) and seems also with the corrosion level. Failure modes are well captured except for the beam *PB3P11*.

4 CONCLUSIONS

In this paper, an analytical method for the sectional moment-curvature response of corroded pre-tensioned beams is proposed. The following conclusions can be drawn:

- The effects of corrosion are investigated through a simplified moment-curvature response, based on a novel stress-strain relationship of prestressing strands. The proposed method can predict the failure mode of the section and the loss of both resistance and ductility. Future improvements concern the role of ordinary rebars and the extension to post-tensioned beams.
- The proposed sectional approach was then used to predict the failure load of available experimental tests on *PC* beams, showing good yet conservative results in terms of failure load.
- Further experimental campaigns should be aimed to the evaluation of: (i) corrosion patterns and spatial variability of reinforcement pit depths, (ii) the bond-slip behaviour of full-scale beams, and its effects on the prestress level and on the capacity and ductility of such members.

Structural behavior of PC beams under simultaneous corrosion and sustained loads

F.F. Bico, M. Bartoli, F. Di Carlo, A. Meda, F. Molaioni & Z. Rinaldi

Department of Civil Engineering and Computer Science Engineering, University of Rome “Tor Vergata”, Rome, Italy

ABSTRACT: The paper presents an experimental study for the evaluation of the flexural response of prestressed concrete beams subjected to simultaneous sustained loads and corrosion. The tested beam features a 200 x 300 mm rectangular cross section, a total length of 3700 mm and a clear span of 2700 mm. In the performed four-point bending test, the beam was subjected to about 60% of the ultimate load of an identical undamaged reference beam, and to a simultaneous accelerated corrosion process of the strands. The flexural response of the tested element was monitored over a period of 70 days, up to failure, shown to be highly dependent on the localization of the corrosion phenomena affecting the strands, especially when coinciding with the maximum bending moment position. The obtained results confirm the importance of accounting for the combined effect of reinforcement corrosion and loading when assessing the structural performance of prestressed concrete beams.

1 INTRODUCTION

The assessment of degraded prestressed concrete (PC) existing structures is nowadays a topical problem. In this framework, corrosion of internal reinforcements represents one of the main causes of long-term deterioration. Potential consequences can be extremely serious, even more serious than those in reinforced concrete (RC) structures, as witnessed by recent cases worldwide, in which severe damages can lead to unexpected structural crisis. A crucial aspect for the structural safety consists in the combined effect of corrosion-induced sectional reductions and wires rupture failures. Despite the need to deepen the knowledge of the influence of corrosion on the behavior of PC elements, not many research documents are available in literature. Experimental tests have been performed on rectangular-shaped [Rinaldi et al. 2010] and T-shaped [Menoufy & soudki 2014] PC beams in four-point bending, varying the corrosion level. The results of cyclic loading tests on T-shaped corroded PC beams are discussed in [ElBatouny et al. 2015]. The fatigue behavior of pre-tensioned partially pre-stressed concrete beams with corroded prestressing wires or rebars is studied in [Zhang et al. 2016]. Post-tensioned concrete beams with corroded strands were tested in bending by [Zhang et al. 2017]. Studies regarding the possible relationship between the prestressed concrete cracking induced by strand corrosion and the corrosion itself can be found in [Dai et al. 2016, Dai et al. 2020]. Finally, experimental tests on PC beams [Mircea et al. 1994, Belletti et al. 2020] and actual bridge PC beams [Pape and Melchers 2011, Rogers et al. 2012, Rogers 2012] subjected to natural corrosion are also available.

Nevertheless, much of these works are based on laboratory procedure in which the artificial corrosion and loading processes are considered as two distinct and sequential phases. Actually, corrosion affects the steel reinforcement of a real structure simultaneously with the application of the sustained load. This results in an increase of the deterioration state of the structure since cracks due to the formation of the corrosion products are widened by the applied loads and vice versa. In this way, a greater diffusion of oxygen and water takes place, resulting in a more rapid corrosion process. Many studies on the coupled effect of sustained load and corrosion on the

long-term behavior of RC beams exists in literature (Yoon et al. 2000, Ballim et al. 2001, Ballim and Reid 2003, Malumbela et al. 2009a). A critical review of the studies carried out to investigate the effects of simultaneous load and steel corrosion on the rates of corrosion and the behavior of RC structures is performed in Malumbela et al. (2009b). Hariche et al. (2012) investigate the effect of reinforcement corrosion on the serviceability behavior of RC beams under load. Further studies regarding the influence of simultaneous loading and reinforcement corrosion on the structural performance of RC beams can be found in (Du et al. 2013, Zhu et al. 2013, Dong et al. 2017, Li et al. 2018, Zhang et al. 2018). On the contrary, with reference to PC elements, not many research documents are available in literature on the coupled effect of sustained load and corrosion on the long-term behavior. An experimental investigation based on a set of six PC beams simultaneously corroded and subjected to a sustained load is reported in Yang et al. (2020).

In the present paper, an experimental study for the evaluation of the flexural response of PC beams, subjected to the simultaneous effect of sustained loads and corrosion of the strands, is presented. Section 2 describes the experimental campaign, giving an insight on the geometry and material properties of the specimen and on the test set-up, realized ad-hoc to allow the simultaneous execution of the two processes of artificial corrosion and loading. The main outcomes in terms of cracking pattern and load-dependent and time-dependent deflections of the PC beam are shown in Section 4.

2 EXPERIMENTAL CAMPAIGN

A wide experimental survey for the evaluation of the flexural response of corroded RC (Di Carlo et al. 2022a) and PC beams has been planned and conducted at the Laboratory of the University of Rome “Tor Vergata”, within the framework of an Italian PRIN project. The research program is based on a set of twelve RC and twelve PC beams, that have been subjected to artificial corrosion processes and to four-point bending tests up to failure. One of the aims of the research consists in the comparison of the results obtained through different test methods. The first and most currently used method for the assessment of the effects of corrosion of the steel reinforcement on the behavior of a RC and/or PC element, is based on the execution of two distinct and sequential phases, consisting in the artificial corrosion process and bending test. Nevertheless, the above test method is clearly not able to faithfully represent the actual condition of the element within the real structure, in which these two phases cannot be considered as separate, since reinforcement corrosion naturally occurs together with the application of loads. For this reason, an alternative test method can be adopted, considering the artificial corrosion and loading as two simultaneous processes.

This paper, starting from the outcomes related to five PC beams tested within the same research project with the usual Laboratory procedure (Di Carlo et al. 2022b), presents a more realistic experimental test procedure of PC beam corroded under loading.

2.1 *Geometry and materials of the specimens*

The experimental campaign includes at the present the execution of six four-point bending tests, of which one performed on a beam kept uncorroded (PC-UC) for reference, four adopting the usual test method (PC-C1 to PC-C4) – the four specimens were subjected before testing to accelerated corrosion, with different corrosion levels of the prestressing reinforcement (Di Carlo et al. 2022b) – and one with simultaneous corrosion (PC-CL1), better described in the following. All beams feature a 200×300 mm rectangular cross section and a total length of 3700 mm. The longitudinal reinforcement is made of three $\frac{1}{2}$ -inch seven wires strands, two placed at the bottom of the section and one at the top, and four $\text{Ø}10$ mm ordinary rebars. $\text{Ø}8$ mm bars are adopted for the stirrups, with a spacing of 100 mm and 200 mm in the outer (1450 mm) and inner (800 mm) zones of the beams, respectively. The concrete cover is equal to 20 mm. Figure 1 shows the geometry and reinforcement details of the specimens.

Concrete with a mean compressive strength equal to 52.6 MPa – value measured on 100 mm side cubes - has been used, while the ordinary rebars are characterized by yielding and ultimate strengths equal to 510 MPa and 630 MPa, respectively. The initial wire prestressing stress is equal to 1300 MPa, corresponding to about 70% of the ultimate strength equal to 1860 MPa.

Figure 1. Geometry and reinforcement details of the PC beam.

For further details about the accelerated corrosion process and the set-up of the four-point bending test of the specimens tested with the usual Laboratory procedure see Di Carlo et al. 2022b. A full list of all the performed tests is reported in the following table, together with the correspondent nominal corrosion level, expressed as percentage mass loss and evaluated after the tests by cleaning (ASTM G1-90 2002) and weighing the strands extracted from each specimen. The experimental values of the maximum loads are also summarized.

Table 1. List of the performed tests nominal corrosion level and maximum load.

N	Beam	Mass loss %	Maximum Load [kN]
1	PC-UC	-	241
2	PC-C1	1.6	232
3	PC-C2	9.03	124.5
4	PC-C3	19.15	40.5
5	PC-C4	27.48	47.2

2.2 Test set-up

This section is devoted to the description of the test set-up of the PC-CL1 specimen, designed ad-hoc to allow the simultaneous execution of the two processes of artificial corrosion and loading. The testing procedure foresees in fact the application of two vertical 75 kN point-loads on a scheme of simply supported beam – corresponding to about 60% of the ultimate load of the uncorroded reference beam – and the implementation of a corrosion process of the two bottom longitudinal strands at the same time.

The artificial corrosion is provided with an accelerated process through electrolytic cells, by dipping the beam within a 3% saline solution, up to half of the height of the cross section. To this aim, a wooden box, coated with a waterproof membrane and two plastic sheets, has been realized, fully embedded with the loading system. Only the two lower longitudinal ½-inch strands are connected to the positive pole of the power supply (anode), while the cathodes are realized with two Ø10 diameter steel bars soaked in the saline solution. A current intensity equal to 0.65 A has been applied. Some images of the artificial corrosion set-up are shown in Figure 2.

Figure 2. Artificial corrosion set-up.

The vertical load is applied through two hydraulic 300 kN jacks, connected to a 700 bar hydraulic pump for the automatic pressure recovery, ensuring the maintenance of the pre-set load during all the test period, with a deviation lower than $\pm 5\%$. The contrast frame, made with

steel beams, is anchored to the laboratory strong floor by means of two pre-tensioned high strength rebars, running outside the wooden box. The two supports are realized with two rotating cylinders, resting on the bottom panel of the wooden box and connected with each other by means of two C-shaped steel profiles. Figure 3 shows some images of the overall test set-up.

Figure 3. Details of the experimental test set-up.

A scheme of the experimental test-set, with superimposed the type and location of all measuring instruments, is shown in Figure 4. The span of the PC beam during the test is equal to 2700 mm, while the shear length is 900 mm, corresponding to one third of the total span length. The vertical load is measured with a load transducer, while five potentiometer transducers have been used to measure the vertical displacements at the midspan (P1), under the two point-loads (P2 and P3) and at the support point (P4 and P5). Furthermore, five 2-axes MEMS clinometer (T1 to T5) are placed on the extrados of the beam to measure the tilting of the specimen throughout the entire test period (Figure 4).

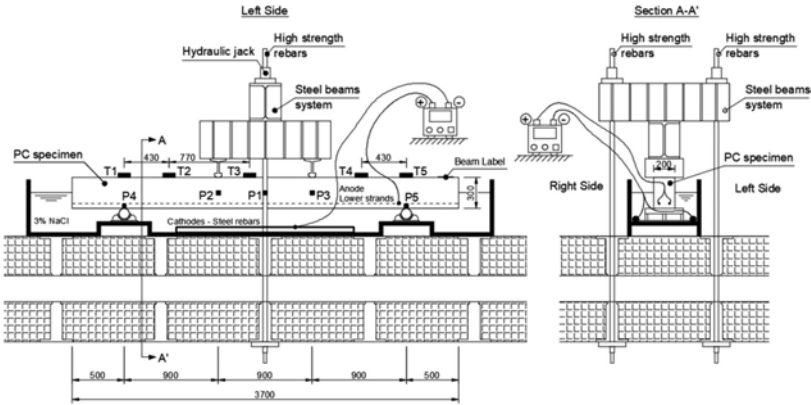

Figure 4. Scheme of the set-up with superimposed the measuring instruments.

3 EXPERIMENTAL RESULTS

This section presents the main experimental results in terms of cracking pattern, load-dependent and time-dependent deflections of the PC beams under simultaneous loading and corrosion of the two bottom longitudinal strands. Figure 5a shows the cracking pattern detected during the entire period of execution of the test, up to failure. The first cracks occurred in the central portion of the beam between the two point-loads. During the test, a wide spread of cracks developed towards the longitudinal middle axis of the beam and the two supports. A view of the beam failure condition is shown in Figure 5b. It is worth to highlight that the evaluation of a corrosion index based on the estimation of the percentage mass loss of the strands is not applicable in this specific test, since the corrosion of the reinforcement results to be highly concentrated in the middle section of the beam.

Figure 5. (a) Cracking pattern detected during the execution of the test. (b) Beam failure.

Figure 6 shows the trend of the beam deflection measured by the five potentiometers. The displacements measured at locations P1, P2 and P3 are corrected for the support settlement (even if almost negligible), measured by the potentiometers P4 and P5. In particular, Figure 6a refers to the entire test period, while Figure 6b shows a detail at the beginning of the test, up to 0.1 day, from which the initial loading history to reach the pre-set load of 150 kN can be observed. Superimposed in the same graphs with a dashed black line is the trend of the load during the test. It can be noted that the applied vertical load has been properly maintained during all the test period.

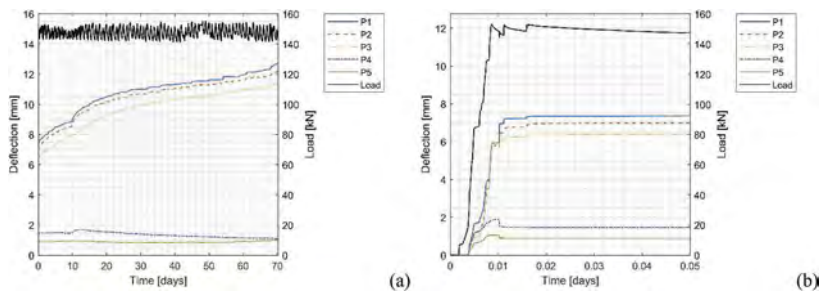

Figure 6. Trend of the beam deflections and load with time: (a) entire test period (b) detail at the beginning of the test.

The experimental results of the tested beam are summarized in Figure 7 in terms of Load-Deflection graph. In particular, Figure 7a refers to the entire test period, while Figure 7b shows a detail related to the end of the test. The failure, shown in Figure 5b, occurred in a brittle way, due to the breakage of the two bottom longitudinal strands in their middle section, corresponding to the section characterized by the maximum bending moment.

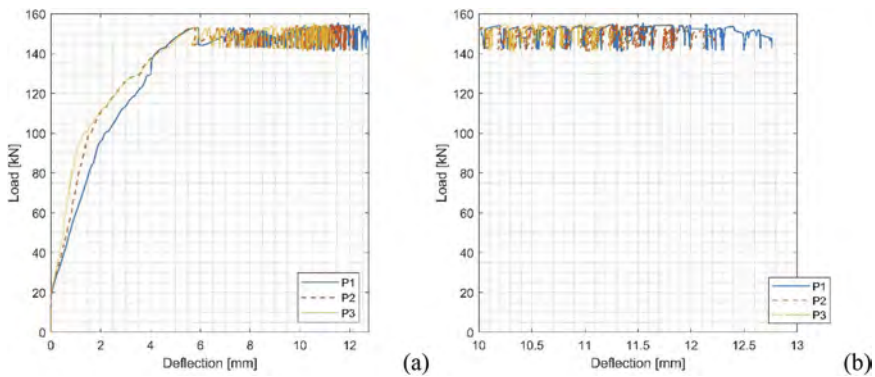

Figure 7. Load-deflection curves: (a) entire test period (b) detail at the end of the test.

For the sake of clarity, Figure 8 summarized the load and displacement measurements over the entire test period through the use of a three-dimensional graph.

Figure 8. Three-dimensional graph: trend of load and displacement over the entire test period.

Figure 9 shows the trend of the tilting of the beam measured by the five 2-axes MEMS clinometer. In particular, Figure 9a refers to the entire test period, while Figure 9b shows a detail at the beginning of the test, up to 0.1 day, from which the initial loading history to reach the pre-set load of 150 kN can be observed. Superimposed in the same graphs with a continuous black line is the trend of the load during the test.

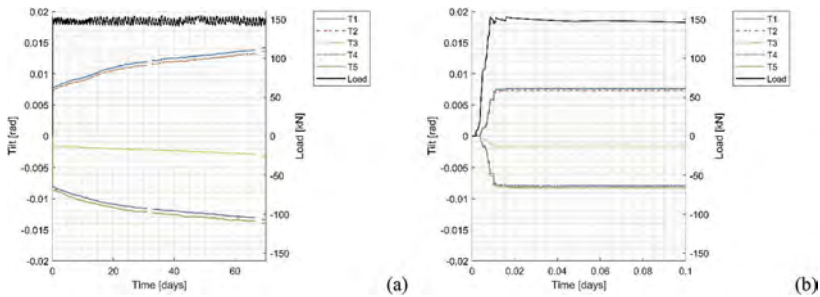

Figure 9. Trend of the beam tilting and load with time: (a) entire test period (b) detail at the beginning of the test.

Finally, a comparison of the displacement and tilting measurements of the tested beam is carried out in Figure 10. As it can be noted, the two different measurements are in good agreement over the entire test, showing their effectiveness in catching the structural response of the element.

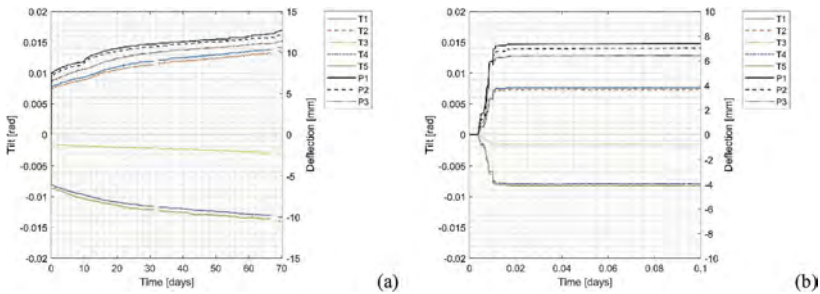

Figure 10. Comparison of the displacement and tilting measurements: (a) entire test period (b) detail at the beginning of the test.

4 CONCLUSIONS

The experimental campaign described in the paper provides an important reference to deepen the knowledge about the evolution of the corrosion process in PC elements. A more realistic test method has been adopted to investigate the flexural response of corroded PC beams, in order to overcome the limits of traditional laboratory procedures. Current test methods, considering the artificial corrosion and loading processes as two distinct and sequential phases, are not able to faithfully reproduce the actual behavior of the element within the real structure. Reinforcement corrosion phenomena occurring simultaneously with sustained loads, are in fact responsible for an increase of the deterioration state of a real element, due to the widening of corrosion-induced cracks because of applied loads and vice versa. Aiming to improve the understanding of the effect of corrosion of the steel reinforcement on the behavior of PC elements, the adoption of a test method considering the simultaneous action of sustained loads and corrosion is therefore fundamental. The described test method has been applied to a 3700 mm long PC beam, subjected to two vertical 75 kN point-loads on a scheme of simply supported beam and to a corrosion process of the two bottom longitudinal strands at the same time. As a result, the collapse of the PC beam occurred after 70 days in a brittle way, due to the failure of the two bottom longitudinal strands in their middle section, corresponding to the maximum bending moment section. It is worth to highlight that the evaluation of a corrosion index based on the estimation of an average percentage mass loss of the strands is not applicable in this specific test, since reinforcement corrosion results to be highly concentrated in the middle section of the beam. The flexural response is shown to be highly dependent on the morphology and localization of the corrosion phenomena affecting the strands, especially when coinciding with the maximum bending moment position. A good agreement between displacement and tilting measurements is found, highlighting the importance and usefulness of implementing a proper monitoring system, in order to constantly control the response of the structure. The obtained results confirm the importance of accounting for the combined effect of reinforcement corrosion and loading when assessing the structural performance of prestressed concrete beams.

ACKNOWLEDGEMENTS

The research presented in this paper is supported by the PRIN 2017 grant, from the Italian Ministry of University and Research, within the project “Life-long optimized structural assessment and proactive maintenance with pervasive sensing techniques”.

Random field analysis of corrosion of steel in the artificial marine atmosphere

Weiping P. Zhang, Xianglin L. Gu, Qianqian Q. Yu & Jinping Chen
Department of Structural Engineering, Tongji University, Shanghai, China

ABSTRACT: This paper presents a study on the surface morphology of corroded steel in the artificial marine atmosphere. Three groups of specimens in three different supported angles were obtained in the environmental cabinet. The 3D scanner was used to digitalize the corrosion surface. The geometry characteristics contributing to the random field model of the corrosion surface were studied statistically. Results show that the corrosion depth obeys the normal distribution as corrosion proceeds and the corrosion surface random field can be regarded as a weak stationary random field. The better fitting model for autocorrelation function is cosine exponential model and the distribution of parameter correlation length l_c is related to the supported angles.

1 INTRODUCTION

Corrosion is a widespread problem for steel structures during service. The reduction in material leads to a deterioration of the structural component, thus raising the probability of structural failure. Exposed to higher salinity and humidity, steel structures in the marine environment are more susceptible to corrosion, resulting in a more rapid rate of degradation than those in the normal environment. Since 1985 in Switzerland (Ortega & Bisgaard 2000), a certain number of collapses of steel swimming pools have been reported worldwide, in the Netherlands in 2001 (Heselmans & Vermeij 2013), in Perm, Russia in 2005 and China in recent years. Reports suggest that the cost of corrosion amounts to about 3% of the gross global domestic product, leading to an estimated worldwide direct cost exceeding \$1.8 trillion (Schmitt et al. 2009). From the point of view of structural safety and socio-economic benefits, scholars are increasingly focused on assessing the load capacity of corroded steel structures in the marine environment.

The geometry of the corroded component determines its mechanical properties, implying that the remaining load capacity of the component can be estimated by the corrosion degree approximately. Corrosion depth, the most common geometric representation of corrosion on steel, was statistically normal, log-normal or mixed-normal (Kim et al. 2013; Paik et al. 2004; Rivas et al. 2008; Tang et al. 2014) in distribution meanwhile the maximum corrosion depth shown to obey the extreme value distribution (Rivas et al. 2008). The ratio of width to depth of the visible corrosion pits was also adopted to represent the shape of corrosion geometry (Nakai et al. 2004). As the width-to-depth ratio is not enough to present a corrosion geometry. The relation between corrosion surface characteristic parameters and the corrosion degree was statistically studied in the surface geometry evolution (Qin et al. 2016). For the reason the corroded steel bars and steel plates tend to fail at the minimum cross-section under tensile load, the factor R (the ratio of the average cross-sectional area to the minimum one) was put forward to quantify the longitudinal non-uniformities of corrosion (Cairns et al. 2005; Zhang et al. 2014). Those statistical works allow us to predict the mechanical properties of components with different corrosion geometries. However, these predictions can be defective for the overall corrosion shape cannot be captured to obtain specific mechanical properties, leaving the prediction at the probabilistic analysis stage. In some assumed corrosion models, such as

randomly shaped corrosion pits set into steel plates, there is a lack of consideration in expressing the continuity of the corroded surface. Teixeira considered to represent distributions of the thickness of the corroded plate by random fields and demonstrated the importance of using random field models (Teixeira & Soares 2008), though the correlation length was chosen as 0.3m subjectively. A latent Gaussian random field was applied as a useful tool to characterize the corrosion depth on the external surface of buried steel oil and gas pipelines (Bao & Zhou 2021).

This study aims to analyze and simulate the surface morphology of corroded steel in the marine atmosphere. Three groups of specimens in three different supported angles were obtained in the environmental cabinet. The 3D scanner was used to digitalize the corrosion surface. The geometry characteristics contributing to the random field model of the corrosion surface were studied statistically. The main parameter correlation length l_c was estimated by cosine exponential model to represent the corrosion surface.

2 MATERIALS AND METHODS

2.1 Specimen and preparation

A survey by the China Steel Structure Association showed that the proportion of Q235 steel and Q345 steel in the production of steel stood at 31% and 62% respectively in 2010 (Li et al. 2013). The Q345 steel plates with a thickness of 6mm were used in the study. The size of the specimen is 950mm × 500mm × 6mm. To retain the uncorroded surface as a reference, layers of epoxy were wrapped around the four edges of the steel plates after recording the original mass m_0 . The specimens were to be placed in the environmental chamber at 0°, 45° and 90° angles. Figure 1a shows that wooden frames and spacers were used to support the specimens inside the environmental chamber to ensure that the steel plates are insulated from each other. The solution, pH, RH and fog rate in the environmental chamber conditions were 5±1% NaCl solution, 6.5~7.2, 95%~98% and 1~2mL/h·80cm² respectively (ASTM 2019). The parameters and numbering of the specimens are listed in Table 1. Three specimens at each of the three angles were taken out every four months. The corrosion products were removed from the surface of the specimens according to ISO standard (ISO 2009). Figure 1b shows an example of specimens before and after the removal of corrosion products. Then the mass of the specimen m_1 was measured to quantify the mass corrosion degree η_m . Each corrosion surface point cloud data were captured by a ZEISS COMET scanner as shown in Figure 1c. Geomagic Studio 12 was adopted to optimize point cloud data by removing data points exclusive from steel bars, processing filtering and removing noise to improve the signal-to-noise ratio.

Figure 1. a) Placement of specimens inside the environmental chamber b) Before and after removal of corrosion products c) 3D optical scanning of the specimen.

Table 1. The parameters and numbering of the specimens.

No.	Angle	Corrosion duration	η_m
H1	0°	4 months	0.0274
H2	0°	8 months	0.0543
S1	45°	4 months	0.0523
S2	45°	8 months	0.0574
V1	90°	4 months	0.1110
V1	90°	8 months	0.0897

After coordinate system alignment, the 3D coordinates of equally spaced points with 1mm were exported from PolyWorks.

In the paper, the suffixes '-1' and '-2' after the specimen number represent the two faces of the specimen.

2.2 Detrending of point cloud data

As steel plates inevitably warp during manufacture and transport, the surfaces are not ideal planes and the 3D data need to be de-trended before corrosion depth statistics. Taking the area covered by epoxy resin as a reference, the 3D coordinate data of the area were extracted first and fit the surface using the fifth-order polynomial. Based on the initially fitted surface equation, the corrosion depth of the corroded area on the surface was then adjusted. Although the goodness of fit was greater than 0.98, the fitted surfaces were not the true warped surfaces and part of the adjusted corrosion depth was less than zero, which means that the fitted surfaces needed further modification. With the fitted corrosion depth data, the points above the fitted surface in the z-direction were obtained and re-fitted by incorporating them into the sample points used in the previous fit, repeating this process to obtain the corrosion depth data after several cycles of the fitting under condition that the percentage of corrosion depth less than zero is less than 5%. By comparison with the measured mass corrosion rates, the set of cyclically adjusted data closest to the actual average corrosion depth was chosen as the sample to be analyzed. The flow chart for de-trending using S1-1 as an example is shown in Figure 2. The volume corrosion degree η_v was obtained from the adjusted corrosion depth and was also compared with the mass corrosion degree η_m obtained from weighing in Figure 2. It can be seen from the figure that the processing errors using this rule are relatively small and the adjusted corrosion depths obtained are truly representative of the mass corrosion degree.

Figure 2. The flow chart of de-trending of the point cloud and the the volume corrosion degree η_v obtained from the adjusted corrosion depth and the mass corrosion degree η_m obtained from weighing.

2.3 Analysis of the corrosion random field

In the paper, the corrosion on the steel surface was taken as a random field. Spatial data distributed on a regular grid was extracted from the cloud point. The sample set X contains point sets on 12 faces of 6 specimens. Each distribution was characterized by parameters mean μ and standard deviation σ . The covariance function (Hristopulos 2020), which was defined by the expectation of the product of the field values at two different points minus the product of the respective mean functions at the same points, is introduced to describe the correlation between two locations s_1 and s_2 in the field. The spatial correlation between two locations s_1 and s_2 with distance τ was characterized by autocorrelation function defined as:

$$\hat{\rho}(\tau) = \frac{\hat{C}(s_1, s_2)}{\hat{\sigma}^2} \quad (1)$$

Before performing parameter estimation of the corrosion random field autocorrelation function, a stationarity and statistical homogeneity analysis was carried out in later sections. A weakly stationary random field should meet two conditions: the mean is constant and the covariance function is a function of τ . In the paper, the correlation length was estimated in two ways: i) fitting the theoretical model to the sample autocorrelation function, ii) evaluating

the distance (Jaksa 1995) the sample autocorrelation function first intersects Bartlett's upper limit r_B given in Equation (2). The common used theoretical autocorrelation models and the corresponding correlation lengths l_c are listed in Table 2.

$$r_B = \pm \frac{1.96}{\sqrt{N}} \quad (2)$$

where N is the dataset size.

Table 2. Theoretical autocorrelation models and the correlation length.

Model	Markovian	Gaussian	Cosine exponential	Second-order autoregressive
ACF	$\rho(\tau) = e^{-\frac{ \tau }{a}}$	$\rho(\tau) = e^{-\left(\frac{ \tau }{a}\right)^2}$	$\rho(\tau) = e^{-\left(\frac{ \tau }{a}\right)^2} \cos\left(\frac{ \tau }{b}\right)$	$\rho(\tau) = \left[1 + \frac{ \tau }{a}\right] e^{-\left(\frac{ \tau }{a}\right)^2}$
l_c	$2a$	$\sqrt{\pi}a$	a	$4a$

3 RESULTS AND DISCUSSION

3.1 Distribution of the corrosion depth

The mean and standard deviation of the adjusted corrosion depth on the surfaces of each specimen is shown in Figure 3. The figure first shows that the standard deviation of the corrosion depth is approximately linear to the mean value. As corrosion develops, the inhomogeneity of the corrosion surface increases. Secondly, the corrosion rates were different for different exposure conditions at the same supported angle. The discrepancy between the two faces (solid dots and hollow dots) of the specimens taken out of the second batch in the figure is larger than that of the first batch (solid and hollow square dots). Finally, it can be seen that the corrosion rate and dispersion of the horizontally placed specimens are the smallest under the three angles, followed by the vertically placed slightly less than the obliquely placed.

The observed and adjusted corrosion depth distribution according to Section 2.2 for each specimen surface is given in Figure 4. The figure also gives the percentage of corrosion depth less than zero (shaded bars) before and after adjustment. Noticeably, the corrosion depth distribution on each surface follows a bell-shaped shape. The normal distribution was used to fit the corrosion depth, and the distribution parameters μ_N and σ_N of the fitted results are listed in each subplot. To ensure data accuracy, portions of the corrosion depth that are less than zero were included in subsequent analyses.

Figure 3. The mean and standard deviation of the adjusted corrosion depth of the specimens.

3.2 Stationarity and statistical homogeneity analysis

In this section, the statistical properties of the mean and correlation functions of the corrosion random field are analyzed based on the definition of stationary.

Figure 4. The distribution of corrosion depth of the specimens before and after de-trending.

3.2.1 Changes of the mean value function with position

To investigate the change in the mean value of the random field with position, the corrosion depth at each cross-section was counted individually and compared to the corrosion depth of the entire surface. The Kullback-Leibler divergence (Csiszár & Shields 2004) (Equation (3)) was employed to measure the similarity between the distributions of individual cross sections and the whole surface for analyzing the translation invariance of the mean corrosion depths of the cross sections.

$$D_{KL}(P \parallel Q) = \sum_{\delta \in \Delta} p(\delta) \log \frac{p(\delta)}{q(\delta)} \quad (3)$$

where $p(\delta)$ and $q(\delta)$ are respectively the statistical frequencies at corrosion depth δ for the whole surface and for a single cross-section.

The value of D_{KL} being equal to zero means that the two distributions are identical. It is an approximation in the calculation in relation to the statistical spacing division; the smaller the statistical spacing, the closer D_{KL} is to the true value. The lower bound of D_{KL} (Nishiyama 2019) (Equation (4)) is also used to assess the similarity between the distributions. Figure 5a gives the similarity between the corrosion depth distribution at cross-section $x = 300$ mm and the corrosion depth distribution over the whole surface with statistical spacing division of 0.05mm, using S1-1 as an example.

$$D_{KL}(P \parallel Q) \geq \frac{(A - 2V_P)}{D} \tanh^{-1} \frac{D}{A} + \frac{1}{2} \log \frac{V_P}{V_Q} \quad (4)$$

where $A = (E_Q - E_P)^2 + V_P + V_Q$, $D = \sqrt{A^2 - 4V_P V_Q}$,

E_P, E_Q and V_P, V_Q denote $E_P[f], E_Q[f]$ and $V_{arP}(f), V_{arQ}(f)$, respectively.

Figure 5b gives the empirical distribution function of D_{KL} for the 12 corroded surfaces of the six specimens and the lower bound of D_{KL} . It can be observed that the lower bound of D_{KL} for all surfaces except H2-1 and H2-2 is approximately within 0.2 at 70% guarantee and the mean value of the lower bound of D_{KL} for all surfaces is approximately 0.35 at 90% guarantee. This indicates that the mean values of the corroded surfaces are fairly translational invariant.

Figure 5. A) An example of determining D_{KL} and lower bound of D_{KL} b) The empirical distribution function of D_{KL} and the lower bound of D_{KL} .

3.2.2 Changes of the sample autocorrelation function in two directions

Examining the second condition for the weakly stationary random field: the covariance function is a function of τ . Since the autocorrelation function and the covariance function are related. The positional correlation and anisotropy of the random field are discussed through the statistical autocorrelation function. Taking H-1 as an example, the corrosion depth data at each cross-section was extracted along two vertical directions within a square domain (400mm×400mm) and

a rectangular domain (850mm×400mm) of the plate (Figure 6a) and the autocorrelation function was separately calculated at different sections (Figure 6b). The autocorrelation coefficients for the different sections in the other direction were counted according to the distance and autocorrelation coefficient interval of 5mm and 0.05 respectively (Figure 6c). The intensity of the coefficients on the whole surface (rectangular area with 850mm×400mm) is represented in the form of a planar heat map in Figure 7.

The intensity heat maps of the autocorrelation coefficients for the surfaces of the twelve specimens are shown in Figure 7. It can be observed that except for V1-1, the autocorrelation functions are all around a statistical average, concentrated around the dotted line of the mean in the figure, which means that the autocorrelation functions of the surfaces along that direction can be seen to vary to a small extent. It can be assumed that the corrosion surface is a weakly stationary random field. Regarding the method proposed by Jaksa (Jaksa 1995) for estimating the correlation length. The autocorrelation lengths obtained by Bartlett’s upper limit method for each section along both directions were counted separately on square domain. The two-sample K-S tests on the two direction sets of estimated autocorrelation length on square domain from specimen H1-2, S1-2 and H2-2 are not significantly different at the level of 0.05. It is difficult to completely confirm or deny the isotropic nature of the corrosion surfaces, but the results of the two-sample K-S test suggest that there shows less directional variability in the surface of specimens laid horizontally. More research is necessary on the directional variability of corrosion surfaces.

Figure 6. The calculation process of intensity heat maps of the autocorrelation function: a) obtain the corrosion depth at each cross section, b) autocorrelation function map, c) histogram of autocorrelation coefficients along longitude x.

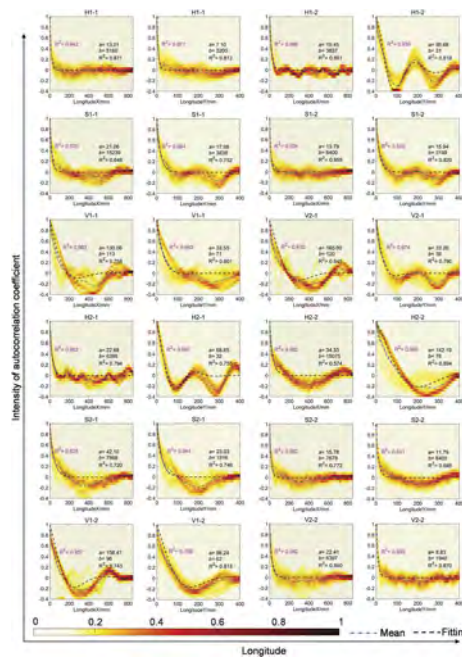

Figure 7. The intensity heat maps of the autocorrelation coefficients of the specimens in the rectangular sample domain (400mm×850mm) and the parameter fitted results of the mean of the coefficients (in black) as well as the R^2 of the function greater than Bartlett’s limit (in magenta).

3.2.3 Model fitting and parameter statistics

As the estimated correlation length l_c depends on the sampling domain length (Christodoulou et al. 2021; Fenton 1999), the main analysis adopted in this paper is the long-edge direction of the specimen surface. A preliminary estimate of the autocorrelation length in both directions is likewise carried out for the entire plate surface (400mm×850mm) according to the steps in Figure 6. In order to choose a suitable correlation function model, the goodness-of-fit of the four models fitting to the mean of sample autocorrelation function are plotted in Figure 8a. The cosine exponential model and the Markovian model in the graph show similar goodness of fit. Observation can be found in Figure 7 that the sample autocorrelation function decreases mainly in the shape of the cosine exponential. The cosine exponential model is used for the parameter fitting to preserve the information in the latter part of the sample autocorrelation function.

Figure 7 also shows the statistical results of the sample autocorrelation function for each specimen surface and the fitting of the cosine exponential model based on the mean value of the sample autocorrelation function. As Uzielli et al. recommended that only the theoretical autocorrelation model with the goodness of fit of the sample function before Bartlett's limit is greater than 0.9 is accepted (Uzielli et al. 2006), the R^2 of the function greater than Bartlett's limit is also shown in the figure in magenta. Apart from two samples less than 0.5 and five less than 0.9, all other seventeen R^2 for sample autocorrelation function before Bartlett's limit are greater than 0.9.

As the correlation length is related to the parameter a in cosine exponential, the statistical result of a in two directions is shown in Figure 8b and c. There is a certain similarity in the distribution of a in two directions. Pearson correlation coefficients of 0.065 and -1.397 indicate that there is no relationship between the corrosion degree and the correlation length along the x and y directions. In contrast, the mean and standard deviation of parameter a have linear relationships at different placement angles. Regression analysis suggests that the dispersion of autocorrelation lengths is greatest for horizontally placed specimens, followed by obliquely placed specimens and least for vertically placed specimens. This may be associated with the fact that the adhesion of the aerosol is influenced by gravity. On the surface of a vertically placed steel plate, the salt spray will condense into water droplets and then flow down in clumps due to gravity. On the contrary, on the surface of a horizontally placed steel plate, the salt spray adheres to the surface and merges with other tiny liquid droplets in the vicinity by tension, showing greater randomness. Comparing the results in two directions shows that the dispersion of the statistical parameters is lower in the shorter sample domain (y direction), which is caused by the fact that the sample domain is not large enough to cover five times (Christodoulou et al. 2021) of the length of the autocorrelation.

Figure 8. A) The goodness-of-fit of the four models fitting to the mean of sample autocorrelation function, b)-c) relationship of the standard deviation and of the parameter a of the specimens at different supported angles along longitude x and longitude y respectively.

4 CONCLUSION

- 1) The corrosion depth obeys the normal distribution as corrosion proceeds. There is a linear relationship between the mean and standard deviation of the corrosion depth. The corrosion rate and dispersion of the horizontally placed specimens are the smallest under the three angles, followed by the vertically placed slightly less than the obliquely placed.
- 2) The lower bound of D_{KL} for most specimen surfaces is approximately within 0.2 at 70% guarantee and the mean value of the lower bound of D_{KL} for all surfaces is approximately 0.35 at 90% guarantee. The mean values of the corroded surfaces are fairly translational invariant.

- 3) The autocorrelation functions are all around a statistical average, suggesting that the corrosion surface is a weakly stationary random field.
- 4) The better fitting model for autocorrelation function is cosine exponential model and the distribution of parameter correlation length l_c is related to the supported angles.

Installation, structural, and sustainability characteristics of direct fastening in textile reinforced concrete plates

P. Spyridis & J. Orłowsky

TU Dortmund University, Dortmund, Germany

K. Bergmeister

University of Natural Resources and Life Sciences, Vienna, Austria

ABSTRACT: Currently, the construction sector is experiencing a wider development of different sustainable concrete types, such as thin concrete plates with fibre reinforced polymer textiles in an effort to reduce the energy and material related carbon footprint of building materials and structures whilst enhancing durability of built assets. One of the aims of the structural engineering community at this stage is to confirm the applicability of such beneficial materials and techniques for existing needs in the building industry. Textile reinforced concrete (TRC) has seen radical development in the recent years as a high-performance laminar material for various applications such as lightweight shell structures, sacrificial load bearing formwork, strengthening and facade components. Fastenings on this type of material have scarcely been researched, although structural connections are an essential part for many components of structural and non-structural systems. Direct fastening by use of powder actuated nail-type fasteners is also an established connection method for non-structural applications in common concrete, since it brings along several benefits in terms of energy and material consumption, site safety, welfare and labour skills, time and costs in construction logistics, which reflect aspects environmental, social and economic sustainability. This paper presents first experimental results on direct fastenings to thin TRC plates, and discusses the practical applicability of this technique.

1 STATE-OF-ART AND SUSTAINABILITY ASPECTS

1.1 *Textile reinforced concrete*

Textile reinforced concrete (TRC) has seen radical development in the recent years as a high-performance laminar material for various applications such as lightweight, modular or 3D printed structures, sacrificial formwork, strengthening layers, noise barrier and facade components (Beckmann et al., 2021; Ivaniuk et al., 2023; Brameschuber et al., 2008; Thomoglou et al., 2020; Flansbjerg et al., 2018; Orłowsky et al., 2021; Orłowsky et al., 2023). A decisive advantage of this composite construction material, as described by Curbach and Jesse (2009), is the possibility to minimise the dimensions of structural components and thus their self-weight, compared to typical reinforced concrete elements. The carbon fibre-based textile reinforcement used instead of steel has a substantially smaller cross-section. It is not affected by corrosion and it poses a much higher durability than steel reinforcement. Consequently, a minimal concrete cover is required (both for bond and corrosion resistance purposes) and structural elements can be dimensioned with a thickness of even 10 mm. Such composite components can then lead to up to 86% reduction of material resources in relation to conventional concrete and much lower total CO₂-equivalent emissions than steel reinforced concrete over the entire life cycle of comparable building components (Orłowsky et al., 2021; Haist et al., 2022). On the example of a pedestrian bridge deck exclusively built with TRC, Kulas et al. (2012) predicts a reduction in terms of material related CO₂-equivalent glasshouse gas emissions in the order of 25% for reinforcement and 30% in terms of concrete, besides maintenance and transportation gains due to high durability and reduced component weights. Laiblová et al. (2019) perform a comparative investigation of TRC (with glass, carbon and basalt fibres) and steel reinforced facade

panels based on a series of environmental impact indices and lean to the conclusion that TRC scores overall better than steel reinforced concrete, although they highlight drawbacks of the fibre materials and particularly carbon in regards to abiotic and ozone depletion. Scope et al. (2020) perform a series of comparative analyses between steel reinforced concrete and carbon concrete for sandwich wall elements based on an innovative combination of environmental and social life cycle assessments, life cycle costing, as well as circularity opportunities and conclude that the latter have a superior performance in all aspects of sustainability.

1.2 *Direct fastenings*

The very special nature of the material requires the re-examination of conventional fastening systems or the development of new methods. One approach to improving sustainability can be to minimise the material volume and production complexity of fastening products and at the same time the energy resources of the fastening process itself. One such efficient methodology is the direct fastening of nails. Further positive characteristics of this fastening method are the very fast – virtually instant – installation and the overall reduced labour time, reduced noise/absence of dust and vibrations (compared to e.g. hammer drilling), and the independence from weather conditions, specially trained and qualified labour, and power supply on site, which reflect aspects environmental, social and economic sustainability as well as potentials for automatization.

On the other side, the highly dynamic installation characteristics may lead to a substantial variability of the load resistance as discussed by Patzak (1979) and demonstrated on the basis of probabilistic analyses by Mellios et al. (2022). Nails for use in concrete may have a diameter and embedment depth of up to approximately 5 and 40 mm respectively. The fact that concrete is quite inhomogeneous at this scale, and considering that the nail encounters a hard region during the setting procedure (typically a tough large aggregate or weak spots and microcracks in the cement matrix) can lead to a dislocation and distortion of the nail, to local spalling and then possibly to a significant reduction in the load-bearing capacity or even to a setting failure. Therefore, design of direct fastenings typically relies on redundancy approaches by use of multiple fixing locations with the possibility of load redistribution among the participating fasteners. Such are prescribed already in standards (CEN 2019) for other types of lightweight concrete fixings. Applications of setting bolts are accordingly non-structural – but often safety critical – systems such as pipe and electrical conduits, suspended ceilings, partition walls, architectural finishes, auxiliary temporary works elements (Hilti 2019). Further applications in load-bearing structures have been proposed in research, particularly for attachment of strengthening materials such as steel plates, shape memory alloys, or fibre reinforced polymers to allow a fast retrieval of load bearing and as such to enhance the resilience of damaged concrete structures – see (Shan et al. 2020), (Michels et al., 2018), (Lamanna et al, 2004).

1.3 *Previous investigations and scope of the study*

One of the first areas of application for TRC is facade construction. An officially approved system is specified with the following fastening requirements (DIBt 2019): Four internally threaded sleeves are cast into the back of the panel for later assembly using special screws. The special screws are fastened to the substructure using support profiles or agraffes. An alternative approved fastening method for the same type of panels is achieved by means of a shallow post-installed undercut anchor (DIBt, 2021a). The building system approval specifies, among other things, that the fastening is realised by use of four anchor points, and an M6 threaded connector must be inserted at a depth of at least one diameter in the panel to ensure the anticipated bearing conditions. Another possible system that is available in the market specially approved for fastening thin facade plate elements, including TRC panels is also a cast-in element integrated to the substructure with a mechanical connection system for a board typology of external walls (DIBt, 2021b).

Curbach and Speck (Curbach and Speck, 2008) carried out extensive experimental investigations on the use of dowels in glass-fibre-reinforced plates. Headed steel anchors were cast into the slab and tested with axial tension load. Based on these investigations, basic influences between the applied load and the concrete failure mechanism and resistance were established. It has been found that the flexural strength of the test specimen is strongly related to

the load-bearing capacity of the anchor. At the same time, the failure mode was found to be more brittle, due to a lower participation of the reinforcement. An increasing of reinforcement ratio in the specimen also led to an increase in load-bearing capacity of the anchor. It was also noted that, although additional layers of reinforcement do not have a positive effect on the load capacity, the failure is more ductile when several textile layers are used. As a reference for the study herein, tests with an anchor embedment depth of about 9 mm at a diameter of 20 mm in a 16 mm thick, single-layer reinforced slab, pull-out forces of around 2 kN could be achieved.

In addition to the previously mentioned examples of insertion installation, post-installation methods are also common in concrete construction in principle. For the application in TRC, investigations were carried out by Höpfner et al (Hoepfner et al, 2021) with undercut anchors and bonded anchors in embedment depths between 10 and 25 mm were tested. The resulting range of anchor tensile resistance was between 2.0 and 6.0 kN, with a strong dependence on the embedment depth.

TRC is characterised by a relatively fine concrete matrix (Beßling et al., 2022), while the tension bearing reinforcement is more uniformly distributed with the matrix. Hence, the use of direct fastenings in TRC is a promising solution also in terms of load bearing reliability, which forms the motivation of the study reported herein. The aim of the work is first of all to establish the practical feasibility of direct fastenings in TRC plates. The study presents the most promising results out of large exploratory testing campaign carried out at the Technical University of Dortmund (Langenbeck 2022; Langenbeck et al, 2023). These refer to TRC panels with a quadratic arrangement of uniform fibre quantities in both directions. Based on these results, an applicability spectrum but also the limits of the TRC and direct fastening system are disclosed for the first time in international scientific literature. The following presented experimental investigations and results are part of the cited study. In this article the most promising results will be presented in detail and discussed regarding sustainability. Thereupon the limits of practical application are to be explored.

2 EXPERIMENTAL CONFIGURATION

2.1 *Materials*

In the experimental campaign, two strength levels were used, namely 40 and 80 MPa in accordance with DIN EN 12390-2, i.e. measured on a cube with an edge length of 150 mm (DIN, 2019). As part of the mix development, prisms were produced and tested following DIN EN 196-1 with varying mixing process (DIN, 2016). The conversion of the cube compressive strength from a cube with an edge length of 40 mm to a cube with an edge length of 15 cm is carried out by means of the factor 0.86, based on previous experience at the TU Dortmund. The bending tensile strength is derived from 3-point bending tests of 40x40x160 mm prisms according to (DIN, 2016). The TRC plates were produced through a horizontal casting process with short vibration intervals and keeping the textile clamped at the edges of the formwork. Spacers were deliberately omitted in order to be able to safely exclude a possible influence on the nail setting, which led to a slight waviness in the finally cast reinforcement placement. A set of material tests prisms was produced and stored in the same process as the plates, and another one was produced following the above-mentioned standards. The latter specimens were subjected to immersed and climate chamber curing. The TRC plates and the similarly produced set of prisms were placed together in the non-conditioned indoor environment of the laboratory, covered with a canvas until stripping and then wrapped in a wet canvas and tarpaulin.

The specimens included styrene-butadiene impregnated carbon fibre textile reinforcement, commercially identified as HTC 21/21-40 (Hitexbau, 2022), placed in three parallel layers within a plate thickness of 40 mm at two different strength classes of nominal strength at 40 MPa and 80 MPa respectively. For the series with 40 MPa strength which showed the most promising results regarding reliability of the system, a second test set of the same parameter combination was retroactively conducted for confirmation. Also, a test series with a predrilled pilot hole was conducted as explained below. The used fastener was the Hilti X-U 27 P8, made of high-strength steel with 4 mm diameter and 27 mm shank length. Table 1 presents the constituents of the concrete mix and Figure 1 basic details of the specimen preparation and textile reinforcement. An overview of the test series is given in Table 2.

Figure 1. Specimen geometry and textile layout (top) and casting and testing configuration (bottom).

Table 1. Concrete mix compositions of the used specimens.

Ingredients/Properties	Class 40 MPa	Class 80 MPa
Cement	CEM I 32.5: 501.57 g	CEM I 42.5: 527.16 g
Water	275.84 g (w/c =0.55)	210.85 g (w/c =0.40)
Superplasticizer MasterGlenium ACE 460	0.80 g (0.16% wt.)	4.23 g (0.80% wt.)
Rhine sand 0-2 mm	1323.96 g	1391.55 g
Limestone powder Millsil W12	137.93 g	212.72 g

Table 2. Test series description.

Test series	Compressive strength Standard/Plain curing [MPa]	Flexural strength Standard/Plain curing [MPa]	No. of tests, remarks
A-40-21/21-3-0	39.8 / 38.1	8.0 / 5.1	N = 6
A-80-21/21-3-0	80.9 / 74.3	12.1 / 7.5	N = 6, high strength
A-40-21/21-3-0_WH	37.7 / 36.0	8.8 / 4.5	N = 6, repetition series
A-40-21/21-3-7	36.1 / 36.2	8.7 / 4.7	N = 6, predrilling

2.2 Setting and pull-out process

Observing the installation and pull-out test results, a comparison of the different substrate configuration is made in terms of safety and the most efficient combination of fastening parameters is determined with respect to TRC strength, as well as the implementation of a pilot pre-drilling hole. A comparative evaluation of the nail setting performance and the respective load bearing capacity of the nail is also carried out. The specimen and test set-up are shown in Figure 1.

Pre-drilling was of a 4 mm diameter and 7 mm depth and it was carried out for one of the test series by use of a rotating drill bit without percussion; otherwise the nail fasteners were directly set on the formwork-free side of the plate. Setting was performed with the Hilti DX 5-F8 powder-actuated setting tool at an approximate setting energy of 150-200 Joules depending on the concrete strength and pre-drilling (Hilti 2021). The specimen is placed on a 1 cm thick elastomer with a hardness of 65 +/- 5 at the Shore A scale. A 2 mm thick metal adapter with a 4 mm hole was designed and laser-cut to simulate a realistic fixture element and also to attach the load adapter.

The load capacity of the nails was tested in terms of axial tensile load. The load cell is placed centrally on the wooden frame construction which also acts as a resistance boundary for the load. When the plate is pressed under the wood girders due to the tensile load, an approximately symmetrical line support of the plate is created on two sides. The installation of the plate is always done in such a way that the plate is subjected to bending in a 90° direction. The metal adapter is connected to the cylinder's piston, with two through-pins which resist rotation. The tensile force is introduced into the nail connection by a displacement-controlled upward movement, at 0.02 mm per second. The applied load and the displacement of the nail head in relation to the concrete surface are measured hydraulically on the load cell and by use of LVDT's respectively.

3 RESULTS AND DISCUSSION

3.1 Nail setting performance

Once the nails were installed according to the procedure described above, the setting quality was recorded regarding cracking and spalling on both sides of the plates, so called the fastening side and the fixture-free side. The general setting quality respecting these two defect characteristics is evaluated by a visual classification in 4 categories (defect classes 0 - 3) as described in Table 3 and shown in Figure 2. Invisible spalling under the metal adapter is neglected. By spreading a water solution on the panel surfaces the maximum visible crack width was measured by means of a crack loupe magnifier with an accuracy of 0.02 mm. Additionally two different crack patterns characterized as follows were identified, namely (A) Crack paths perpendicular to the panel edges, with one significant large crack quasi-parallel to the panel edge, and (B) Radial cracks starting from the nail and running in different angles towards the edges of the panel, with crack width uniform distribution. Settings without any visual damage only occurred occasionally and only on the fastening side of the panel – this was, however, also the case for severe spalling. Besides this, the defect classes of the two panel sides did not necessarily correlate or coincide. This may indicate a plate thickness influence, but possibly also an interruption of the failure progress between the different concrete layers separated by the textile reinforcement. With regard to the herein presented testing series the following observations can be summarized:

- Defect class 1 in general dominates for all test series on the fastening side as well as on the fixture-free side in test series A-40-21/21-3-0 (40 MPa concrete).
- The most severe damage (defect class 3 on both panel sides) only occurs in series A-80-21/21-3-0 (80 MPa concrete).
- Crack pattern B occurs in 83% of the settings.
- The measured maximum crack width at setting ranges in between 0,02 mm and 0.12 mm. The average maximum crack width within one parameter combination is highest on both panel sides in series A-80-21/21-3-0 (80 MPa concrete). The lowest average crack width could be obtained on the fastening side by the application of an additional pre-drilling in series A-40-21/21-3-7 (also lowest strength concrete). The fixture-free side of the latter test set shows slightly higher defect classes and crack widths compared to the sets without pre-drilling.

Table 3. Defect class description.

Defect class	Fastening side of the panel	Fixture-free side of the panel
0	No damage	No damage
1	Cracking	Cracking
2	Cracking, spalling but firm fastening	Linear and circular cracking
3	As above but loose parts	As above but with surface spalling/flaking-off

3.2 Load resistance

A summary of the load resistance characteristics is given in Figure 3 and more details on the results can be found in (Langenbeck et al. 2023). As regards the maximum load, it is evident that the overall highest average and maximum loads of 5.43 kN are observed in A-80-21/21-3-0 plates. The absolute highest load capacity of a nail within this test series is 7.29 kN, and the standard deviation of the test series is 1.56 kN (variation coefficient CoV = 28.7 %). The smallest scatter of results was achieved when using the lower strength concrete without additional pre-drilling (A-40-21/21-3-0 and A-40-21/21-3-0-WH). The average pull-out load of the latter series was 4.92 kN with a standard deviation of 0.17 kN (CoV = 3.5 %). The repetition series A-40-21/21-3-0_WH reached a mean load of 4.37 kN and a standard deviation of 0.52 kN (CoV = 11.9 %). Summarizing the results of these two sets, an average load of 4.64 kN and a standard deviation of 0.47 kN (CoV = 10.1 %) is reached. The tests A-40-21/21-3-7 (with pre-drilling) did not exhibit an influence of the mean load or scatter significantly. Figure 4 presents all L-D curves of the test sets showing a significant variance. A rough distinction can be made between a linear load drop and a stepwise failure. This indicated a brittle failure which is more frequent in series

Figure 2. Damage images of classes 0 (left), 1 (centre-left), 2 (centre-right) and 3 (right) on both the fastening (top) and the fixture-free side (bottom).

Figure 3. Overview of the average values and standard deviations of the fastening load capacities.

Figure 4. Load-Displacement curves.

A-80-21/21-3-0, and a quasi-brittle failure, which slightly more pronounced in other series, respectively.

4 CONCLUDING REMARKS

This paper presents experimental investigations of nail fastenings in carbon textile reinforced concrete panels. Test parameters include the concrete strength (40 and 80 N/mm²), and the installation with or without pre-drilling of a pilot hole. The feasibility of this structural system is evaluated and confirmed for the first time in international literature. Focus is drawn on the load bearing capacity of the fastenings, the associated uncertainty, and the visual quality that can be achieved during installation. Some minor cracking in the panel could not be avoided completely. Furthermore, the pilot hole pre-drilling which is proven of benefit in previous concrete applications (both in research and practice) did not indicate significant benefits on load or damage characteristics in the presented tests. Although TRC is often used for visible concrete applications

(such as e.g. facades), the virtually unavoidable defects in the conducted tests can only render the application of the system for outdoor facade construction as rather debatable. The use of a 40 MPa concrete class is associated with significantly less spalling and crack width damage compared to 80 MPa concrete, while a noteworthy load bearing capacity remains, moreover with even minor scattering of results (i.e. high structural reliability). Therefore, the new system still seems to be promising regarding use cases with subordinate visual requirements or indoor applications.

As discussed above the combined materials and structural techniques of TRC and direct fixings may come with several advantages in terms of sustainable construction. Toward a sustainable solution the following principles should be particularly addressed when future practical applications are considered. This also leads to the potential of future research in the field.

- The tests carried out have certain limitations: the tests samples are relatively few to allow safe conclusions or design recommendations, while the size of the tested panels may still need to be increased to eliminate boundary effects and adequately assess the damage potential of the installation. This damage potential needs to also be investigated and optimised with respect to the supporting conditions of the plate. Additional evaluations need to be carried out in order to identify optimal configuration of the system in terms of concrete and its constituents, textile reinforcement, fastener and pre-drilling properties and dimensions. Local strengthening in fastening locations may also be considered, by local thickening and/or enhanced reinforcing elements such as short fibres or additional textile layers.
- The durability and service life of the fastenings should meet the ones of the TRC substrate to allow full exploitation of both components. Respective investigations need to be carried out among others in terms of load and crack cycling as well as concrete creep effects.
- The nail and textile reinforcement should be separable from each other but also other construction elements as for example the substructure or the plates. One advantage of the use of direct fastening is the small shape of the nails which saves valuable materials and eases removal and reuse or recycling at the end of the lifecycle. Besides, the use of exclusively mineral components for the TRC plates (e.g. cement based impregnation and mineral fibre textiles) may enhance the recycling potential of the system.
- Promising current applications of TRC that might benefit of the new system could be lightweight and shell structures, sacrificial formworks or TRC-retrofitting.

ACKNOWLEDGEMENTS

The textiles used in the experimental investigations were kindly provided by Hitexbau GmbH. The fastening tools and consumables were offered by Hilti Corporation. The laser cutting of the metal sheet adapters was delivered by the laboratory of the Institute of Forming Technology and Lightweight Components of the TU Dortmund. Ms A.D. Langenbeck has conducted a major part of the experimental research in the frame of her MSc studies at the TU Dortmund. M. Bessling and L. Walter of the TU Dortmund also assisted in the experimental research. The authors express their strong appreciation for this support and contributors.

ABSTRACT: Fastenings to concrete are implemented in a wide variety of statistically indeterminate structures such as suspended ceilings. In contrast to statistically determinant systems, failure of one fastener does not lead to direct collapse but to a redistribution of the load to adjacent fasteners. This concept can serve well in situations of high uncertainty and variance at the failure time, particularly with some level of tolerance for states of limited damage – an example is non-structural safety-critical suspended installations. Such systems can be subjected to sustained or dynamic loading. This can result in very brittle failures without any prior signs throughout the system's life-cycle, making the safety evaluation crucial. The present study focuses on the evaluation of safety in redundant fastening systems with fatigue and corrosion effects. A computational probabilistic model is used to evaluate the life-cycle performance of a redundant installation to showcase the feasibility of this approach. The virtual system consists of anchor groups and a fatigue-relevant load in each group is determined and distributed among the anchors. Degradation of the system is also implemented by randomly assigning corrosion damage to individual elements and by reducing annually the level of prestress in the anchors. Failure of a single anchor leads to redistribution and possible progressive collapse of the system. The year of failure is collected from multiple realizations and it is evaluated statistically. The resulting probable year of element and system failure for the entire system are calculated accounting for stochastic degradation processes, and it subsequently provides the basis for inspection and maintenance plans.

1 INTRODUCTION

Fastening to concrete is gaining a lot of ground in the last decades in everyday construction for various building, industrial and infrastructure applications such as attaching necessary equipment and other non-structural architectural details. These connections are typically realised through precast or post-installed steel anchor bolts. The installations are often statically indeterminate by use of multiple anchor points and with significant stiffness and strength of the fixture. In such systems failure of a single element does not necessarily lead to a collapse of the system but to a redistribution of the load to adjacent elements, a so-called alternative load path.

The static indeterminacy alone, however, cannot provide information about the system reserves in the event of a loss. It must be known where the reserves are present in the system and where damage cannot be tolerated due to a lack of alternative load paths. The excess of load-bearing elements combined with the ability of a system to transfer residual loads from failed

elements to alternative paths is expressed by the term “redundancy” (Frangopol & Curley 1987; Biondini et al. 2008; Spyridis & Strauss 2020). Apart from accidental actions, particular life-cycle risks can be considered in conjunction to damage to the load-bearing structure due to deterioration processes, which are governed by significant uncertainties and hidden defects. This renders the evaluation of their structural performance and safety a daunting task.

In this article, the research approach to provide a method for the structural evaluation of redundant fastening systems is presented. Emphasis is given to failure caused by deterioration factors, namely cyclic fatigue which can also be accelerated by corrosion. To showcase the benefits of a probability-based approach, a virtual case study of a redundant fastening system is investigated. The system is assumed to replicate a tunnel (or broadly speaking a linear infrastructure) catenary system. The installation of the catenary is formed by groups of anchors in two parallel lines. Each group consists of four anchors. In the case of a local failure i.e. anchor or group, the load can be redistributed among anchors of a group or adjacent groups respectively. To account for the inherent uncertainty of defects, material properties, and loading conditions, a probabilistic approach with random sampling is implemented yielding multiple failure scenarios. All calculations are integrated in an optimized object-oriented algorithm. The aim is to propose a more sophisticated design approach that accounts for both element and system properties, providing a safer and more economical result. These models can also be implemented to facilitate decision-making as regards the life-cycle management of an existing system as a performance-based design paradigm (Urban et al. 2012), (Strauss et al., 2016). A similar analysis but without account for accelerated degradation from corrosion effects is presented by Mellios et al. (2021).

2 FATIGUE AND CORROSION OF ANCHOR BOLTS IN CONCRETE

Designing a fastener against steel fatigue failure is based on the specific properties of the corresponding product derived from an experimental assessment carried out at the TU Dortmund. The current state of assessing anchors against fatigue cyclic loading in combination with or without quasi-static load is described by EOTA (2018). Fatigue cyclic loading can be caused by pulsating tension load or alternating shear load or combinations of both. The reasons that can cause the dynamic loading vary, but they are typically imposed by weather/climate phenomena, vehicle traffic, or machinery effects, and load actions are considered harmonic or periodic for simplicity. Assessment of a specific fastening product against fatigue relies on the product specific S-N design curve where the load amplitude is represented as a continuous function of the load cycles. As simplified assumption for the case study, one cycle stands for the static resistance of the fastener and fatigue limit resistance stands for an infinite number of cycles (see Figure 1). For a load range smaller than the fatigue limit range the anchor does not suffer any deterioration due to fatigue, which can e.g. rely on the design provisions of EN 1992-4 (CEN 2018). Experimental S-N curves for product specifications are derived for anchors without prestressing since this is an onerous case and it is known that prestressed anchors subjected to cyclic loading can gradually lose the torque at the nut, they become unfirm, and the fatigue effects are magnified.

Outside of pure dynamic loading, another deteriorating factor that can also threaten the fasteners structural performance is also present. In particular, corrosion, like fatigue, is also a time-dependent process, which acts on the steel surface leading to degradation in its mechanical properties and consequently effects the fatigue behaviour. This alteration in fatigue properties appears in two different forms on the S-N curve. In order to understand this, a distinction between corrosion fatigue and fatigue of pre-corroded steel (e.g. due to accelerated corrosion) is necessary. The latter case is relatively straightforward. Here, corrosion causes cross-sectional loss combined with surface irregularities like formation of notches, leading to decreased mechanical resistance and shorter fatigue life (see Figure 1 – left – green line) (Apostolopoulos & Michalopoulos 2007). In case of corrosion fatigue, the situation is different. Here, both electrochemical and mechanical attacks act simultaneously leading to mutual impacts on each other. Unlike artificially corroded steel, long-time corrosion impacts the steel surface more inhomogeneously causing a gradual decline in fatigue life over time (Zhang et al. 2012). Thus corrosion fatigue appears on the S-N curve as a decline in the fatigue limit which is anticipated to appear only in the absence of corrosion fatigue (see Figure 1 – left – red line) (Gehlen et al. 2016).

3 CASE STUDY OF ROBUSTNESS ASSESSMENT

3.1 Overview

For the analysis in this study, a simplified S-N curve was assigned to every anchor, formed by two points, i.e. the static resistance at $N=1$ and the fatigue limit resistance that stands for a stochastically assigned amount of cycles (Figure 1 – right). Initially, the same static resistance of 128 kN is assumed and deterministic assigned to all anchors. The assignment of the second point corresponds to a fully random value between 900,000 and 1,100,000 cycles. A further step was taken here to account for both the beneficial effect of the prestress in anchors and the negative effect of unfirm installation. The correct prestress level was assumed at $F_{pre}=60$ kN, and the fatigue limit of each anchor is set equal to this prestress load. Finally, the two points are connected linearly in logarithmic scale of the horizontal axis to form the fatigue resistance curve, described by a bilinear function (see green curve in Figure 1-right). To consider the installation inaccuracies, 5% of the anchors are considered insufficiently torqued. Additionally, a deterioration rate for the prestress load is assigned and gradually anchors lose their prestress with a time-dependent rate. Loose elements are then randomly assigned a new prestress load between 30 and 60 kN and their S-N curve is updated.

The deterioration due to corrosion is assigned to the individual anchors at a subsequent phase of the algorithm. After each anchor is stochastically assigned a unique S-N curve and installation defect status, corrosion effects are added. Initially a percentage of anchors afflicted by corrosion is predefined and randomly tagged to individual elements. The predefined percentages that were investigated range between 0 % and 100 % of the anchors. Furthermore, four deterioration levels are parametrically considered, i.e. 0 %, 20 %, 40 %, and 60 % resistance loss from the initial fatigue resistance, reflected by an inclination of the deteriorated S-N line (see red lines in Figure 1-right). Consequently, corroded anchors experience a reduction of the total number of load cycles that they can sustain as well as an elimination of their fatigue limit state, considering that the material cannot sustain a load infinitely, whilst being under progressive corrosion.

3.2 Geometrical characteristics

The multiple fastening system (catenary fixture) consists of anchor groups positioned in two parallel lines. Each group is formed by four individual anchors. Anchors within groups are considered to be connected by a rigid plate. Each line of anchor groups consists of 120 groups. In total, the system contains 960 individual anchors. All groups are considered to be connected with a rigid beam or truss system as sketched in Figure 2. Possible failure of the fixture elements outside the anchors is neglected. The exact geometrical dimensions and properties of the truss system and anchor connection plate were considered to be unnecessary for explicit simulation, but it was assumed that adequate tying of the fixture elements is achieved, allowing for the creation of alternative load paths. Therefore, instead of explicitly designing the truss system, failure scenarios are examined and corresponding predefined alternative load paths are assigned.

3.3 Load and progressive failure simulation

The system is considered to be loaded only under cyclic tension, with a harmonic pulsating load of a constant period. The frequency of the pulsating load was kept constant throughout the entire analysis, at ten thousand cycles per year (10,000 c/y). Each group of anchors is initially loaded with a deterministic load i.e. 240 kN, which is then stochastically distributed among the anchors of each group. The element load distribution is updated within a group in the event of failure of a single anchor (when the fatigue resistance of an anchor is exceeded) or in adjacent groups in the event of full group failure. At the initiation time of the calculation, the maximum possible load for a single anchor is 96 kN and the minimum is 24 kN, so no failure is considered. Based on the individual load and S-N curve of each anchor the estimated life expectancy is evaluated. The status of the anchors (algorithm loop) is evaluated on a yearly basis, namely after every 10000 load cycles. Degradation of the anchors due to loosening is based on a rate that increases yearly to represent the increment of the degradation rate seen in existing application (Equation 1) and respectively the new prestress load is assigned.

$$r = 1 - (1 - 0.002)^y \tag{1}$$

with: r the degradation rate and
 y the number of years in service.

If two anchors in a group fail then the entire group is considered to have failed. The load of the group is redistributed among adjacent groups. Through this interaction between the adjacent groups, alternative load paths can be achieved in a group failure event. To account for the system's material and geometric properties implicitly, predefined load paths were assigned based on deliberate assumptions of load transfer as depicted in Figure 2. Two main redistribution scenarios were identified subject to the boundaries of the system. The first (general) failure scenario is covering

Figure 1. Effect of corrosion on fatigue properties. Left: S-N curve of uncorroded steel (green line); S-N curve of corroded steel (red line); declination of fatigue limit due to corrosion fatigue (dotted lines). Right: Simplified assumed S-N Curve used in the analyses for different levels of corrosion.

Figure 2. Geometry of the investigated system, each rectangle represents a group and each circle an individual anchor.

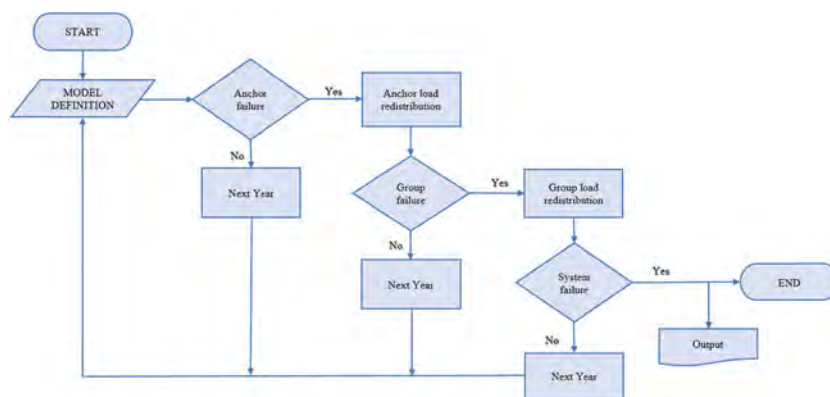

Figure 3. Graphical representation of the algorithm for the calculation of the system performance.

the internal groups of the system and the second one the two groups at each end of the system. The alternative load paths here are defined as percentages of the load of the failed group.

These percentages are corresponding to the distance that the load has to be transferred. The load is only redistributed to groups that are in the immediate circumference of the failed group. This corresponds to five groups in the case of the internal group failure and three groups in the case of edge failure. This discrepancy between these two cases, caused by the geometry of the system, results in a higher concentration of load in the case of end failure and it is more bound to lead to progressive failure. The total system failure is considered when two adjacent groups have failed. In this event, the concentration of the load on the remaining anchors leads to instantaneous failure under static load and it is considered to be the initiation of a progressive collapse. The year that this failure occurs and the total amount of failed anchors per year form the model output. For this example, it was decided to run 100,000 different combinations by use of random input property generators. The conceptual algorithm flow is shown graphically in Figure 3.

4 RESULTS AND DISCUSSION

Indicative results from the evaluation of structural performance with regard to redundancy are presented below. They can be separated into two categories, the ones describing the entire system performance and the ones regarding the individual anchors, both providing insights into the behaviour of the investigated type of redundant systems. The reference case is considered to be on the one hand side the case without corrosion effects, achieving an average service life of 100 years and on the other, the average situation with 20% of all anchors afflicted by corrosion, as listed in Table 1. In this Table, it can already be seen that the uncorroded situation achieves by far higher service life thresholds, more than double the one of extensive corrosion affecting all anchors in the system, i.e. nearly 100 years compared to 40 years or less for different confidence quantile levels. Moreover, the uncorroded case exhibits relatively narrow variation, which maintains also the quantile confidence levels at relatively high values (90 % to 93 % for typical quantile levels in engineering structures). On the contrary, comparing these design thresholds for corroded systems, it is made evident that a redundancy-based design service life converges to approximately 40-50 years even from just a 4 % of the anchors being affected by corrosion.

This is correspondingly evident in the representation of Figure 4, which depicts the development of individual anchor failure per year. In this case, it is seen that, for the same corrosion

Figure 4. Mean percentage and total number of failed anchors per year of operation, assuming a 20 % material corrosion rate and various extends of corrosion afflicted anchors.

Table 1. Model results for reference case of 20% of all anchors afflicted by corrosion.

Anchors afflicted by corrosion (%)	Mean failure time (years)	Standard deviation (years)	Coefficient of variation (-)	1% Quantile (years)	5% Quantile (years)
0%	101.5	5.3	0.05	90.0	93.0
1%	90.9	10.8	0.12	52.5	69.0
2%	84.4	11.9	0.14	50.0	61.5
4%	72.0	12.7	0.18	48.0	51.0
8%	54.4	7.4	0.14	44.5	46.0
16%	46.3	2.1	0.04	42.0	43.0
32%	43.1	1.4	0.03	40.0	40.0
100%	40.0	0.9	0.02	38.0	39.0

Figure 5. Failure year/life expectancy probability density functions for various parameters (extend of corrosion afflicted anchors and material corrosion rate).

rate at material level of 20 %, a 4 % of the anchors is expected to fail within the first 40 to 60 years of operation. Conversely, if the corrosion is restricted to 2 % of the anchors (e.g. if the corrosive agent is contained only in one small region of the system), the same anchor failure

rate is expected to occur only after the 90th year of operation, which approaches the system without corrosion effects. The analyses indicate also an abrupt increase of system failure after failure of a 5 % of the individual anchors regardless of the corrosion rate – this is discernible in the instabilities of the curves in the upper right area of the graph in Figure 4.

The life expectancy of the entire system is presented for various values of material corrosion rate under two different extents of corrosion afflicted anchors, namely 1 % and 4 %, as illustrated in Figure 5 on the basis of probability density functions. The left column (blue) represents the corrosion extend of 1 % in the total individual anchors, this being 4 % for the right (green) column. The first (grey) graphs are the same and they reflect the uncorroded situation. Here it is also made obvious that a relatively small extend of corroded anchors influences the catenary systems service life forecast only to a minor extend. The mean value is at 100 years and the minimum-to-maximum range is mostly at 90 to 110 years for the uncorroded case. This becomes 90 years at mean value and ranges at roughly 60 to 110 years, independently to the material corrosion susceptibility. However, already at a small increase of the corrosion extend to 4 %, the mean value drops to approximately 70 years and the minimum values are at 25 to 45 years, subject to the material corrosion resistance.

5 CONCLUSIONS

This study examines the feasibility to assess the redundancy and associate service life of fastening systems with multiple anchors using probability-based methods with integrated deterioration models. Degradation mechanisms due to fatigue and deficient prestressing in combination with corrosion are identified and investigated in conjunction with the beneficial effect of alternative load paths. The aim is to demonstrate a methodology that can realistically calculate the performance of redundancy in structural systems under multiple uncertainty agents. To this end, an object-oriented algorithm is coded with explicit definitions of both the alternative load paths and the degradation of the system during its life cycle. A virtual tunnel catenary – or broadly speaking linear infrastructure installation – is investigated. The results highlight the sensitivities of the system to the extent of corrosion along the structural system in terms of a ratio of anchors afflicted and the anchor material susceptibility to corrosion in terms of fatigue resistance degradation rate. It further calculates a service life expectancy in terms of probabilistic distribution, which enables risk-based decisions and planning with respect to life cycle management activities, such as inspection and maintenance exercises. With increasing computational power, and automated monitoring of degradation agents and processes, such an assessment approach can be implemented to design against various disruptive events and provide a life time performance profile for this and similar engineered systems.

ABSTRACT: The recent research developments regarding the utilization of time-to-failure testing as an assessment tool for the long-term behavior of bonded fasteners under sustained load raise the question of the link between the current assessment procedure (so called Findley extrapolation method) with the time-to-failure approach. The two methods are using data from tests loaded at different relative load levels. Nevertheless, both methods require sustained load tests which are analyzed with the objective of deriving the ultimate long term bond resistance. Although both methods use the same type of tests, they differ with respect to (i) the actual result of the tests (failure/no failure), (ii) the measured quantities during the tests, and (iii) the analysis. These essential differences make a direct comparison of the two approaches rather challenging. However, the link between the two methods and ultimately a comparison of the assessment that they provide is feasible when some assumptions that are supported by the literature are considered. This contribution presents a detailed comparison of the two assessment methods using the same datasets of experimental data of bonded anchors with two different adhesive mortars. The current contribution establishes a clear link between the two assessment methods. Additionally, it confirms the conservatism of the currently used approach. Finally, an optimized approach is proposed based on time-to-failure tests, which could serve as an optimized and yet still sufficiently conservative assessment method for the long-term behavior of bonded anchors under sustained loads.

1 INTRODUCTION

Fastening technology plays a key role in structural engineering. As a matter of fact, their role is the connection of different structural elements, assemblage of precast elements, and the attachment of non-loading bearing components. The previous can be done during construction, as well as during strengthening and retrofitting. The adhesive anchors are post-installed fastening systems which ensure the connection of the steel member with the concrete substrate in terms of bond through a layer of adhesive agent (Cook, Kunz, Fuchs, & Konz, 2006). In general, all fastening systems need to go through rigorous tests which assess their performance under the influence of various environmental conditions, loading direction, concrete class, and condition in order to obtain an approval for a lifetime of 50 years (ACI Committee 318, 2019;

EAD 330499-01-601, 2018). Additionally, the international standards require the performance assessment of bonded anchors under sustained load (EN 1992-4:2018, 2018).

The long-term performance of bonded fasteners is assessed on experimental data from sustained load tests in a confined configuration and the Findley approach for extrapolating the creep displacements. As a matter of fact, following this assessment method the anchors are installed in the concrete member and, after the required curing time has passed, are loaded to a target load, typically ~30-40% of the ultimate bond resistance, $\tau_{R,k}$. Then the load is kept constant for a certain period, usually 2.000 hours and the displacements at the top of the anchor are measured. After the target testing time has passed the anchors are unloaded and tested in a confined configuration to characterize the residual resistance. The measured displacements are analyzed and a power function (see Equation 1) is fitted on the last points of the measured displacements in course of time.

$$s = s_0 + \alpha t^n \quad (1)$$

with s the time dependent displacement, s_0 the initial displacement after the target load has been reached, t the time and α , n the power law parameters to be fitted.

Then the power function is extrapolated to a time of 50 years and the corresponding displacement is predicted. Finally, the latter displacement is compared with the displacement at loss of adhesion, $s_{adh\ loss}$ which is typically the displacement at the ultimate pull-out resistance obtained in a confined pull-out test (EAD 330499-01-601, 2018). In case the extrapolated displacement is below the critical displacement $s_{adh\ loss}$ then the anchor passes the test and the long-term characteristic resistance, $\tau_{Rk, L}$ as well as the sustained load factor ψ_{sus} as it is imposed by the EN 1992-4 are calculated (EN 1992-4:2018, 2018).

Despite its simplicity the Findley approach has also some limitations. Its main problem is that it fails to provide an expected failure time and thus an expected life-time for a given load level. The assessment furthermore needs to be repeated to assess the influence of elevated temperature on the long-term characteristic bond resistance. Additionally, it shows significant sensitivity on the initial displacement as well as on the selected data for fitting, the measurement frequency, and the testing time range (Stierschneider, Tamparopoulos, McBride, & Bergmeister, 2021). An alternative assessment approach, the stress vs. time-to-failure, has been proposed by Cook et al. (Cook & Davis, 2009) to overcome the aforementioned limitations. Following this approach, the anchors are tested again under sustained loads. However, the load levels are selected such that they result in failure within a reasonable time range, typically between few seconds and weeks/months. The failure times are recorded and plotted against the corresponding load level. Finally, a logarithmic function (see Eq. 2) is fitted on the data and its extrapolation reveals the long-term bond resistance of a bonded anchor system.

$$N_{sus}/N_u = \alpha \cdot \ln t_f + b \quad (2)$$

where N_{sus} the sustained load, N_u the ultimate bond resistance, t_f the failure time and α , b parameters to be fitted.

This approach has the advantage of fitting and extrapolating actual failure. Nevertheless, the selected logarithmic function has the problem of resulting in failure time even for zero or negative load level when it is extrapolated. Therefore, it has no physical interpretation, and it should be considered as a purely empirical regression model. Additionally, the logarithmic function is unnecessarily conservative since it fails to capture the transition to an asymptotic behaviour which is a typical characteristic of the stress vs. time-to-failure curve (Blochwitz, 2019). Recent research advances have proposed alternative assessment equations which overcome the problem of the physical interpretation. As it has been derived in (Boumakis, Nincevic, Vorel, & Wan-Wendner, 2019) the stress vs. time-to-failure can be considered as a combination of creep rate failure criterion (Monkman & Grant, 1956) and the widely used Prandtl creep model (Prandtl, 1928). This study reveals a reduction of the time-dependent behavior until a critical load level below which no more time-dependent failure is expected.

Furthermore, an empirical sigmoid function (see Eq. 3) derived from experimental and numerical studies of time-to-failure of concrete specimens has been adopted and successfully evaluated for the time-to-failure tests of bonded anchors (Ninčević, Boumakis, Meissl, & Wan-Wendner, 2020).

$$N_{sus}/N_u = (1 - L) + L \cdot [1/(1 + bt_f)]^n \quad (3)$$

where N_{sus} the sustained load, N_u the ultimate bond resistance, t_f the failure time, $0 \leq L \leq 1$, b , and n parameters to be fitted, with $(1-L)$ defining the load level for infinitive failure time. Eq. 3 results into an asymptotic behavior of the stress vs time-to-failure curve which is theoretically supported by the findings of (Boumakis, Nincevic, Vorel, & Wan-Wendner, 2019) while it has the advantage of controlling the asymptotic value of the load level, ensuring that always a conservative assessment has been obtained. However, a comparison of the long-term assessment with the Findley approach and the stress vs. time-to-failure method cannot be directly derived and therefore still misses.

This contribution formulates a failure criterion based on the Findley approach and compares the long-term assessment obtained by the two approaches on experimental data of bonded anchor systems with two different adhesive agents, an epoxy based adhesive mortar (P1) and a vinylester based adhesive mortar (P2). The experimental data have been obtained by the literature (Boumakis, Nincevic, Vorel, & Wan-Wendner, 2019; Ninčević, Boumakis, Meissl, & Wan-Wendner, 2020) and are based on tests with anchor rods with a nominal diameter of 16 mm and an embedment depth, $h_{ef} = 75$ mm.

2 DESCRIPTION OF THE ANALYSIS METHODS

2.1 Time-to-failure

The time-to-failure analysis is performed on the reported failure times vs. load. This manuscript uses a modified version of the Eq. 3 by having as dependent variable the load expressed in terms of bond strength τ_{sus} calculated by a uniform bond model. Thus, the assessment equation becomes

Figure 1. Failure time definition.

$$\tau_{sus} = (\tau_u - a) + a \cdot [\tau_u / (\tau_u + bt_f)]^n \quad (4)$$

with τ_u the ultimate bond resistance, $0 \leq a \leq \tau_u$ a parameter to be fitted with $\tau_\infty = \tau_u - a$ and b , and n parameters to be fitted. The conversion of the sigmoid function into the form of Eq. 4 allows directly collecting the long-term bond resistance at 50 years. Moreover, for the purpose of the analysis the asymptotic value can be fixed at 40% and 0% of the ultimate bond resistance by having $\alpha=60\% \tau_u$ and $\alpha = \tau_u$ respectively.

Note that for this method the failure times are defined as the time interval from the instant when the load is fully applied until the instant that the load drops instantaneously. Therefore, the failure time does not include the duration of the loading. In order to have a consistent criterion for all different cases the failure instant is defined when the instantaneous drop of the load is larger than 5% of the sustained load as it is illustrated in Figure 1.

2.2 Times based on the displacement criterion

The main obstacle for the realization of the comparison between the Findley and the time-to-failure (ttf) method is that the Findley approach does not provide any estimate of failure time (t_f) for a given sustained load (τ_{sus}). The present contribution overcomes this problem by defining failure times which are determined from the displacement criterion used in the Findley method. Therefore, a specimen is considered as failed when the total displacement $s(t)$ under sustained load exceeds the critical displacement at the loss of adhesion ($s_{adh loss}$), as it is calculated according to (EAD 330499-01-601, 2018). Then the failure time noted in this manuscript as “Findley failure time” is the time when the displacement at loss of adhesion has been reached. The Findley failure time is obtained either by actual data or in the case that the displacement has not reached the critical displacement $s_{adh loss}$ by following the fit and the extrapolation scheme that is imposed in the EAD (EAD 330499-01-601, 2018). The calculation of the Findley failure times is shown in Figure 2. Note that the failure times obtained by the displacement criterion are always shorter than the actual failure times if failure has occurred. That is expected since the failure displacement in the time-to-failure tests is always larger than the displacement at the ultimate capacity and it tends to follow the descending post-peak branch of the short-term load-displacement curve (Muciaccia, Consiglio, & Rosati, 2017; Boumakis, Di Luzio, Marcon, & Vorel, 2018).

Figure 2. Examples of Findley failure times calculation.

Following this approach all the sustained load data (also the failed ones) can be considered in the analysis. Then the data are analyzed in terms of stress vs time-to-failure and Eq. 4 is fitted on them.

3 ANALYSIS AND RESULTS

First the stress vs. time-to-failure model is fitted on the experimental data of both products. The failure times and the corresponding load levels are shown in Table 1 for the epoxy based

P1 and in Table 2 for the vinyl ester based P2, respectively. As it can be seen many of the specimens have already exceeded the critical displacement during the loading phase. Therefore, the corresponding Findley failure time is zero. However, and in order to be also used in the analysis a fictitious failure time of 10^{-10} hours is assigned to them.

Table 1. Failure times and Findley failure times for P1.

Load [MPa]	Failure time [h]	Findley time [h]
39.644	0.003	0
39.644	$8.24 \cdot 10^{-5}$	0
39.644	$8.42 \cdot 10^{-4}$	0
35.471	0.003	0
35.471	0.008	0
35.471	0.004	0
31.298	0.252	0.155
31.298	0.060	0
31.298	0.311	0
31.298	0.016	0
27.125	15.620	0
27.125	23.729	1.89
27.125	2568	0
25.036	1296	0.98
25.036	1296	0.003
25.036	4290	26
25.036	-	9.2
12.52	-	$2.54 \cdot 10^{25}$
12.52	-	$1.80 \cdot 10^5$
12.52	-	$4.77 \cdot 10^8$

Table 2. Failure times and Findley failure times for P2.

Load [MPa]	Failure time [h]	Findley time [h]
25.20	0.05	0
25.20	0.004	0
25.20	0.002	0
23.72	2.20	0
23.72	0.16	0
23.72	0.50	0
22.23	0.44	0
22.23	0.52	0.002
22.23	0.96	0.003
20.75	41.72	0
20.75	-	0.003
20.75	-	0.10
19.27	25.75	0.09

Then the different datasets are expressed in terms of stress vs. time-to-failure and Eq. 4 is fitted on them. Figure 3 and Figure 4 present the different stress vs. time-to-failure datapoints obtained as actual failure times (blue points) and by the displacement for the two different bonded anchor systems.

Nevertheless, this is expected since the failure displacement under sustained loads is usually larger than the displacement at loss of adhesion (Muciaccia, Consiglio, & Rosati, 2017). Therefore, this preliminary analysis indicates that a three domain stress vs. time-to-failure curve which can be approximated by a sigmoid function is not only suitable for results from time-to-failure tests but also for sustained load tests that exhibit no actual failure assuming as failure time the

Figure 3. Stress vs time-to-failure of P1 on failure times and on times obtained from the displacement criterion.

Figure 4. Stress vs time-to-failure of P2 on failure times and on times obtained from the displacement criterion.

time when the displacement at loss of adhesion is reached. Based on the analysis the long term bond resistance obtained by the extrapolation of the stress vs. times when the displacement criterion is exceeded (Findley) found to be 70% and 75% of the long term bond resistance obtained by the extrapolation on the time-to-failure data for P1 and P2, respectively.

Finally, when the 5% prediction bound of the stress vs. time-to-failure based on the actual failure times is calculated and compared to the assessment curve based on the displacement criterion, as it is shown for P2 in Figure 5, a relatively good agreement is observed. Thus, the time-to-failure method could serve as an alternative more physical and less conservative assessment method for the characteristic long term bond resistance for combined pull-out and concrete cone failure and the calculation of the ψ_{sus} as it is imposed in EAD 330499-01-0601 (EAD 330499-01-601, 2018) and in EN 1992-4:2018 (EN 1992-4:2018, 2018).

The current European assessment approach (EAD 330499-01-601, 2018) results to the calculation of the long-term characteristic bond resistance from the sustained load that passes the displacement criterion after extrapolation. As a matter of fact, the sustained load, N_{sus} that leads to displacement with an extrapolated value at 50 years lower than the critical displacement at loss of adhesion, $s_{50} < s_{adh loss}$ is converted to sustained load in terms of bond according to Eq. 5.

Figure 5. Comparison of the 5% prediction percentile of stress vs time-to-failure with the extrapolation based on the displacement criterion for P2.

$$\tau_s = \frac{N_{sus}}{\pi \cdot d \cdot h_{ef}} \cdot \min\left(1; \frac{a}{0.9}\right) \quad (5)$$

where α reduction factor based on the residual capacity of the sustained load specimens. Then the basic characteristic long-term bond resistance τ_{Rk}^0 is defined as $\tau_{Rk}^0 = \tau_{sus}$. Finally, the characteristic long-term bond resistance is calculated as $\tau_{Rk} = \tau_{Rk}^0 \cdot a_3 \cdot a_4 \cdot a_{setup} \cdot k_{sus} \cdot \min\beta_{CV}$, with α_3 , α_4 reduction factors for the effect of the maximum short temperature and of high alkalinity and sulphurous atmosphere, $a_{setup} = 0.75$ the reduction factor for uncracked concrete, $k_{sus} = 1.1.35$, and $\min\beta_{CV}$ the minimum of the β_{CV} factors related to the scatter represented by the coefficient of variation. Finally, the factor ψ_{sus} is calculated as $\psi_{sus} = \tau_{Rk} / \tau_{Rk,ucr} \cdot 1.15$ where $\tau_{Rk,ucr}$ the short-term characteristic bond resistance for combined pull-out and concrete cone failure.

Based on the results of the present comparison the long term sustained load for a service lifetime of 50 years can be directly obtained by the stress vs time-to-failure curve. The advantage would be that the long-term bond resistance is obtained by the fit on actual time dependent failure tests. A conservative assessment approach would be to consider the 5% prediction bound $\tau_{5\%}$ for the determination of the τ_{sus} . Then all the other steps of the calculation of the ψ_{sus} could stay the same. Therefore, based on that the calculation of the ψ_{sus} based on time-to-failure data could follow the scheme below:

- i. fit Eq. 4 on the time-to-failure data
- ii. calculate the 5% prediction bound $\tau_{5\%}$ and extrapolate
- iii. calculate the sustained load as $\tau_{sus} = \tau_{5\%} \cdot \min(1; a/0.9)$, where a reduction factor as it is determined in clause 2.2.2.6.2 of EAD 330499-01-0601 (EAD 330499-01-601, 2018).
- iv. take the characteristic bond resistance τ_{Rk}^0 as $\tau_{Rk}^0 = \tau_{sus}$.
- v. Apply the reduction factors of EAD 330499-01-0601 (EAD 330499-01-601, 2018) and calculate $\tau_{Rk} = \tau_{Rk}^0 \cdot a_3 \cdot a_4 \cdot a_{setup} \cdot k_{sus} \cdot \min\beta_{CV}$.
- vi. Calculate ψ_{sus} as $\psi_{sus} = \tau_{Rk} / \tau_{Rk,ucr} \cdot 1.15$ where $\tau_{Rk,ucr}$ the short-term characteristic bond resistance for combined pull-out and concrete cone failure.

4 CONCLUSIONS

This contribution explores the link of two different methods for the assessment of the long-term behaviour of bonded anchors under sustained loads. The comparison of the long-term bond resistance for an epoxy based and a vinylester based bonded anchor system calculated based on time-to-failure tests found to be 1.25-1.30 of the corresponding value based on the

displacement criterion (Findley approach). The analysis, even in a preliminary state, indicates that the stress vs. time-to-failure curve can be well described by a sigmoid function which imposes a critical sustained load below which no failure is expected under sustained load in course of time. Furthermore the 5% prediction bound of the stress vs. time-to-failure curve and its extrapolation shows no significant difference compared to the extrapolated curve obtained by the displacement criterion. Therefore, the stress vs. time-to-failure method using a sigmoid function could be used as an assessment method in the corresponding EAD without violating the necessary conservatism.

ABSTRACT: Fastening systems have become essential elements in civil engineering constructions as the field of application of modern fastening technique is expanding. In recent years, the construction industry saw a shift towards rehabilitation and modular construction to address the growing demand for faster construction on one side and the change in usage and sustainability on the other side. Consequently, efficient design and utilization require a thorough understanding of all involved materials and their changes throughout their lifetime. Considering the potential damage and consequences due to anchorage failure, it is obvious that such products must undergo rigorous approval tests. Practice has shown that for the same concrete class and anchor type load capacities can vary, especially when the results are compared between different laboratories in a worldwide scope. There are several different possible reasons that can cause such differences, and for some of these limited restrictions are given (e.g., only the minimum concrete age is specified). This contribution presents an experimental campaign investigating two potential influence factors on the concrete cone capacity: (i) age and curing, and (ii) the aggregate effect. The investigation comprises full material characterization for each aggregate and concrete, and structural pull-out tests on mechanical anchors performed at two ages. Finally, the experimentally obtained data is used to check the current design codes in an attempt to evaluate the predictive quality of the investigated models and their sensitivity with regard to the discussed influence factors.

1 INTRODUCTION

Over the last years, fastening systems became an essential component in the business that deals with the designing, planning, and construction. The rapid growth in construction engineering is ensured by relatively “user-friendly” products with a high ability to fulfil all demands in modern design and fast modular construction. Currently, various fastener types can be found on the market, usually grouped by the working principle (mechanical or bonded anchors), and by installation time (pre- or post-installed), see Eligehausen (2006). Fastener classifications, working principles, load scenarios, and failure mechanisms were in-depth discussed many times in the past. Therefore, all relevant references are provided in the manuscript, while deeper discussion would exceed the scope of this paper. In general, fasteners are mostly steel components made to mechanically join or affix two or more objects together (e.g., load-bearing structural members, installation of equipment). As such, these products must meet the two most important requirements: (i) high performance and safety requirements through the most rigorous testing and development methods, and (ii) to ensure innovative solutions supported by easy installation procedure and relatively simple design.

In many applications, fasteners are typically installed in a concrete base material, which became one of the most used structural materials. Concrete is a well-known cementitious material made of cement, aggregates, and water. As widely known, concrete properties improve over time. With the highest portion of space in concrete, aggregates are one of the most important mix design parameters. Their shape, size and surface roughness highly influence the fresh concrete workability, and the mechanical concrete properties (e.g., compressive, and tensile strength). Because concrete is used worldwide, it is obvious that the used cement and aggregate types can vary significantly, thus influencing the concretes' performance. Naturally, different local concrete properties in a structure will affect crack propagation and consequently failure mode. Following the current design guidelines, concrete is typically characterized in terms of 28-day compressive strength only (Eurocode 2 Part 1-1 (2009), fib Model Code for Concrete Structures (2010)). The same approach is also followed by fastening related approvals (e.g., EOTA (1997), EOTA (2002)) and design standard (EN 1992-4 (2018)). Here, the concrete compressive strength is the only material parameter used to describe the anchor load capacity, regardless of the curing condition, cement type, mix-design, and the failure mechanism.

In the last few decades, many different studies on fastening systems (see Ballarini (1986), Bazant (1985), Bazant (1989), Eligehausen (1985), Eligehausen (1989), Eligehausen (2006), Fuchs (1995), Krenchel (1985), Ottosen (1981), Ozbolt (1990), Stone (1983)) were performed to experimentally determine the load capacities for different fastener types, and to develop simple “user-friendly” predictive models. These contributions aimed to not only derive the predictive equations, based on the best fit of the experiments, but also to understand the anchor behavior, and the different failure mechanisms. In the present study, the focus was merely on only one failure mechanism, most known in the anchor community as concrete cone breakout, as shown in Figure 1. It is a typical failure mode for mechanical anchors under pure tensile loading, determined by the crack initiation at the anchor head as soon as the concrete tensile strength is exceeded and subsequent propagation.

Figure 1. Considered failure mechanism: concrete cone failure.

After several basic studies, Fuchs (1995) proposed an empirical model to calculate the load capacity for anchors under tensile loading. This method is known as the Concrete Cone Capacity Design (CCD) method. The mean concrete cone failure load of a single anchor loaded in tension is given by Equation 1 and is currently used in design to predict concrete cone capacity:

$$N_{u,c} = k \cdot \sqrt{f_c} \cdot h_{ef}^{1.5} \tag{1}$$

where k is calibrated factor; f_c = concrete compressive strength; h_{ef} = embedment depth.

Following this approach, the concrete cone capacity is a function of a dimensional $[N^{0.5}/mm^{0.5}]$ anchor dependent calibration factor k (in case of considered headed studs is proposed to be 15.5), the concrete cube compressive strength f_c [MPa] measured on a 200 mm side cube, and the anchor embedment depth h_{ef} [mm]. As introduced above, the predictive equation assumes that all possible differences in the concrete mix-design and the curing conditions are captured by the compressive strength, and such no additional effect on the anchor performance is expected. In other words, regardless of the cement type, water to cement ratio, aggregate to cement ratio, aggregate type, and curing condition, the concrete compressive strength is the only material

input required to predict the anchor load capacity in any point in time. Of course, simplified empirical models supported by limited numerical investigations cannot be experimentally validated for all possible scenarios, due to time and costs restrictions. However, they are an essential tool for design purposes and can, if necessary, be improved. In some cases, limited guidelines are provided and can contribute inconsistencies between different research groups attributing it to one effect rather than the other. For instance, current anchor related codes specify minimum requirements for the aggregate type, specifically it is suggested to use aggregates of medium hardness only. Furthermore, merely a minimum age of the tested concrete member is given, while no upper limit specified (only in the case of bond tests an upper limit of 18 months is given). However, situations may exist where different laboratories test anchors installed in concrete with different ages or different maturity depending on the history of environmental boundary conditions, and as a result, might obtain differences which are not attributed to the effect anticipated to study (e.g., aggregate type effect).

Based on the above-mentioned facts, the motivation of systematically carried out experimental investigations was to quantify (i) the influence of the concrete age, and (ii) the possible effect of different aggregate types on the concrete cone capacity. The experimentally obtained data is normalized to remove the known functional dependencies using the current predictive equation and to compare the results. Due to the paper limits, this contribution is limited to the most relevant information summarizing the work of two recent publications (Nincevic (2019) and Nincevic (2019)). In the original referenced manuscripts, more detailed discussions with corresponding details and figures are provided.

2 EXPERIMENTAL DESIGN

2.1 Overview

The present work attempts to determine how the used aggregate type and the concrete age affect the concrete cone capacity by normalizing the pull-out loads by the corresponding compressive strength. The experimental program comprises the characterization of both aggregates and concretes identifying the most practically relevant mechanical properties. The properties of the used coarse aggregates were determined by grid-indentation and standard abrasive Los Angeles Tests. Concretes were fully characterized by means of compressive strength, tensile strength, elastic modulus, and fracture properties. In parallel to the material tests, structural tests were performed on cast-in headed studs under tensile loading. Both concrete and structural tests were performed at two different ages: 28- and 70-days. In total 12 slabs were used for anchor tests, together with 70 cylinders, 90 cubes and 24 prisms.

2.2 Concrete mix design and selected aggregate types

Three different concrete mix designs were considered, with the aim to keep all mix-design parameters the same but varying the aggregate type. Therefore, all three concretes have the same cement type CEM II 42.5N and are following the sieve curve according to the ETAG guidelines (ETAG (2012)). Table 1 shows the exact values and differences among the used concretes. As can be seen, the water to cement (w/c), and the aggregate to cement (a/c) ratios were very similar. Even though the aim was to keep all parameters the same, it is important to note that basalt aggregates in case of the E3 batch could not be delivered with a maximum coarse aggregate size of 16 mm and in round shape. Therefore, broken aggregates with a maximum coarse aggregate size of 22 mm were used for concrete E3.

Table 1. Concrete mix design.

Concrete ID	Cement type	Aggregates		Max. size [mm]	w/c ratio [-]	a/c ratio [-]
		Type	Shape			
E1	CEM II 42.5N	Quartz	Round	16	0.63	6.93
E2	CEM II 42.5N	Limestone	Round	16	0.6	7.27
E3	CEM II 42.5N	Basalt	Broken	22	0.58	7.19

2.3 Material characterization tests

2.3.1 Aggregate characterization tests

The selected coarse aggregate types are grouped as quartz, limestone, and basalt type. These groups are based on a mineralogical analysis performed by the X-ray powder diffraction method (XRD). For each representative coarse aggregate type, mechanical properties such as modulus and hardness were obtained by nanoindentation tests (Doerner (1986), Fischer-Cripps (2002), Oliver (1992)). Additionally, standard abrasion tests, so-called Los Angeles (L.A.) tests, were carried out to identify the coefficient of abrasion (BS EN 1097-2:2010-03). Those properties are listed in Table 2. It can be seen that quartz aggregates are by far the softest among the three considered types. The expected trend is confirmed with the L.A. results, where the softest aggregate resulted in the highest coefficient of abrasion.

Table 2. Experimentally obtained aggregate mechanical properties.

Aggregate type	L.A. coefficient [-]	Hardness [GPa]	Modulus [GPa]
E1 - Quartz	26	0.5	11.4
E2 - Limestone	22.6	1.4	37.5
E3 - Basalt	15	2.3	45.6

2.3.2 Concrete characterization tests

The standard concrete characterization tests were carried out to identify the most important concrete mechanical properties. Since the current design approach considers the concrete compressive strength only, also in this contribution merely the compressive strength data is used to perform the analysis of the anchor load capacities. The extended analysis that includes all the other concrete properties (e.g., Young's modulus, tensile strength, fracture energy) and discusses correlations between aggregates/concretes/anchor load capacities are reported in Nincevic (2019).

Concrete related codes require the concrete specimens for the material characterization to be stored in "lime-saturated" water or in high humidity conditions (> 95%) prior to testing, ensuring that the constant water supply needed for the hydration process is guaranteed.

In contrast, anchor related codes require no specific storage conditions for concrete specimens and structural members. They may be stored inside or outside the laboratory exposed to the environmental relative humidity and temperature. It is only required to store specimens (both test members and concrete specimens) indoor for the first seven day, and after can be stored outdoor, ensuring they are protected from frost, rain, and direct sun deterioration (ETAG – Annex A (2012)). The concrete compressive strength used to predict the concrete cone capacity using Equation 1 needs to be obtained from concrete specimens undergoing the same temperature and humidity histories as the structural member.

In this study, one set of specimens was stored inside the laboratory at an ambient temperature of 23°C in "lime-saturated" water after being in the moulds for the first 24 h. Those specimens were following the concrete-related codes and are named "moist-in cured" specimens. The second set of specimens stored according to the anchor related codes. Those specimens are named "dry-cured" specimens. An additional set of specimens followed the moist curing conditions but were stored outside at variable ambient temperature. The results of the outside stored moist specimens are not further discussed in this contribution, see in Nincevic (2019) for further details and results.

Table 3 contains all experimentally obtained mechanical properties at two ages for the "moist-in cured" specimens (following the concrete-related codes). The cube compressive strength results were obtained from 150 mm side cube ($f_{c, cu}$) following EN 12390-3 guidelines. The results show that the concrete with the limestone and the basalt aggregate type resulted in a similar strength class, while the concrete with quartz aggregate has the lowest compressive strength. As expected, the results are following the same trend for the second age. Additional material properties are reported in Table 3, such as the compressive strength obtained from cylindrical specimens ($f_{c, cyl}$), the modulus (E), and the indirect tensile strength properties ($f_{t, sp}$). More details about the testing procedure, followed standards and specimen geometries are reported in Nincevic (2019).

Table 3. Experimentally obtained concrete mechanical properties for moist-in cured specimens.

Concrete ID	$f_{c, cu}$ [MPa]	$f_{c, cyl}$ [MPa]	$f_{t, spl}$ [MPa]	E [GPa]
E1-28d	34.3 ± 6.2%	32.3 ± 7.7%	3.0 ± 20.8%	30.6 ± 8.1%
E2-28d	40.3 ± 4.2%	33.9 ± 9.7%	4.1 ± 3.3%	31.4 ± 11.2%
E3-28d	42.1 ± 4.9%	36.3 ± 6.7%	3.4 ± 2.0%	31.8 ± 4.0%
E1-70d	38.7 ± 7.6%	36.5 ± 2.9%	3.4 ± 8.6%	31.2 ± 7.5%
E2-70d	45.6 ± 4.3%	44.8 ± 6.4%	4.4 ± 4.2%	42.2 ± 6.4%
E3-70d	46.7 ± 9.6%	39.4 ± 6.2%	3.5 ± 9.1%	34.4 ± 5.6%

2.4 Structural tests on cast-in headed stud anchors

Structural anchor tests were performed on cast-in headed studs loaded in tension with concrete cone failure. The anchors were made of M20 hex-bolt anchors with the head of 40 mm (2 x size of anchor rod diameter) with 12.9 steel grade design to avoid potential steel failure. Only one embedment depth of 100 mm was investigated (h_{ef} =100 mm). The tests were performed in displacement control mode under quasi-static loading on concrete slabs with dimensions of 250 x 100 x 30 cm. The anchors were spaced such that the splitting of the concrete member or influences by adjacent anchors are avoided. All tests were carried out in a so-called “unconfined configuration” using a circular steel ring with an inner diameter of 400 mm. The exact anchor design, slab layout and test setup, as well as the testing procedure are reported in Nincevic (2019). The experimentally obtained mean concrete cone capacities based on four tests each are listed in Table 4 together with the corresponding coefficient of variation (CoV). Additionally, the mean “dry-cured” cube compressive strengths based on 4 tests each following the anchor related code are shown.

Table 4. Experimentally obtained pull-out load capacities with corresponding cube strength with required curing conditions (“dry cured”).

Concrete ID	N_{exp} [kN]	$f_{c, cu}$ [MPa]
E1-28d	111.2 ± 8.3%	29.1 ± 5.0%
E2-28d	136.6 ± 9.6%	35.3 ± 3.4%
E3-28d	124.4 ± 1.2%	35.0 ± 6.3%
E1-70d	143.4 ± 4.9%	30.6 ± 5.5%
E2-70d	183.4 ± 7.0%	40.0 ± 6.7%
E3-70d	173.9 ± 5.6%	39.7 ± 8.0%

Considering the mean concrete cone capacity as a function of compressive strength, the expected trend is confirmed for E1 concrete which showed the lowest compressive strength and as well resulted in the lowest cone capacity, while the other two concretes have similar cube strengths and also cone capacities.

3 RESULTS AND DISCUSSION

In order to facilitate the comparison of different concrete batches, the results are presented in terms of normalized values. The most basic approach given by Equation 2 defines the ratio (α) between the experimentally obtained (N_{exp}) and the predicted pull-out load capacities (N_{uc}) according to Equation 1. That means that for all concretes and all ages the results are individually normalized using the cube compressive strength for the given concrete batch and age.

$$\alpha(t) = \frac{N_{exp}}{N_{u,c}} = \frac{N_{exp}(t)}{k \cdot \sqrt{f_c(t)} \cdot h_{ef}^{1.5}} \quad (2)$$

Ideally, the normalized values (α) should be equal to 1.0, or closely scattering around that value, indicating that the predictive equation based on the concrete compressive strength is

able to accurately predict the load capacity for any given age, regardless of the concrete aggregate type, and any other mix-design parameter.

3.1 Age effect

The main interest here is to answer the question whether there is an additional age effect on the concrete cone capacity that is not captured by the current predictive model formulated in terms of the compressive strength. In other words, if the concrete compressive strength is a sufficiently good material parameter to predict the concrete cone capacity at any point in time. As a first check, the experimentally observed evolution of concrete compressive strength obtained with moist-in cured specimens following the concrete-related codes is checked using the ageing law suggested by codes BS-EN-1992-1-1:2009. Evaluating the ageing law based on the experimentally obtained 28-day values, the 70-day predictions are in very good agreement with the experiments, underestimating the actual results by 4.5% for E1, 4.8% for E2, and 2.9% for concrete E3. A more detailed analysis is reported in Nincevic (2019). This confirms that all three tested concretes showed the expected strength evolution for the considered time window.

Figure 2 shows the normalized load capacities by the concrete compressive strength obtained on dry-cured specimens (as suggested by the anchor-related codes) for all tested concretes and both ages. The normalization is performed according to Equation 2, using the coefficient $k = 15.5 \text{ (N}^{0.5}/\text{mm}^{0.5}\text{)}$, as proposed by the codes for the given anchor type.

Figure 2. Normalized load capacities using Equation 2 and “dry cured” specimens.

As can be seen, the results indicate a significant offset from the target value at 28 days, indicating that the calibration factor k is approximately 40% higher than proposed for this specific anchor type and geometry. Additionally, it can be clearly seen that there is a significant difference between the normalized 28- and 70-day values. In study reported by Nincevic (2019) is shown that the same trend is observed for all three concretes regardless of the curing protocol of the concrete specimens used to obtain the concrete compressive strength.

These results might indicate that the small cubical specimens do not fully represent the material properties of a larger structural member in some cases. Additionally, it shows that the current predictive equation captures insufficiently well the ageing phenomenon, where the 70-day predictions are approximately 25% more conservative than the predictions at 28 days.

3.2 Aggregate effect

The presence of an aggregate effect on concrete cone capacity is evaluated based on the above introduced normalized values and the variability (CoV) among all the concretes. Figure 3 shows the normalized pull-out load capacities for all three concretes tested at an age of a) 28 and b) 70 days. The red markers represent the mean normalized values using the concrete compressive strength obtained from “dry-cured” cubes, while the blue markers represent the “moist-in cured” concrete specimens. As can be seen, the relative difference among the concretes/markers is relatively small compared to the standard scatter observed in this type of experiments (~10%).

The results clearly show that the current predictive model is able to predict the concrete cone capacity regardless of the considered coarse aggregates used in this study. In both cases,

using either “dry-cured” or “moist-in cured” compressive strength, the relative difference is still much lower than 10%. Therefore, from a practical point of view, no significant aggregate effect on concrete cone capacity can be assumed. The effect of coarse aggregate type is reflected in the concrete mechanical properties. Beyond that, no significant deviations in the relationship between concrete compressive strength and concrete cone capacity can be observed. A systematic analysis including other predictive energy-based models and correlations between material properties and load capacities are reported in Nincevic (2019).

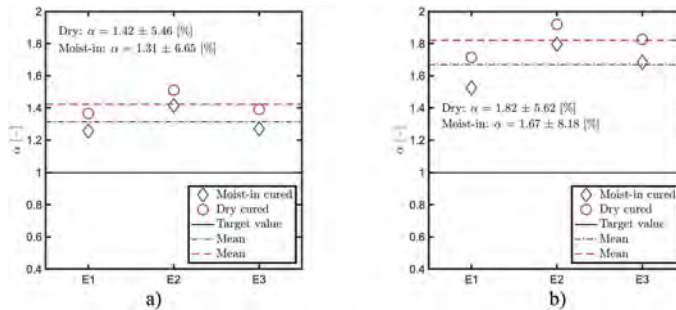

Figure 3. Normalized load capacities using Equation 2 with “dry” and “moist-in cured” specimens for a) 28 days, and b) 70 days results.

3.3 Age and aggregate effect on the cone shape and size

Finally, a photogrammetric analysis was performed to reconstruct 3D models of the concrete fracture surface (concrete cones) to analyse potential correlations between concrete age and aggregate effect on one side, and shape and size of concrete cones on the other side. The analysis showed neither a significant effect of the concrete age nor of the aggregate type on the mean cone profiles and sizes (more details and result reported in Nincevic (2019)). Additionally, all concrete cones were localized at the circular steel support with an inner diameter of 400 mm, corresponding to four times the embedment depth ($d=4 \cdot h_{ef}$). It must be noted here that the anchor-related code requires a circular support with an inner diameter of minimum three times the embedment depth ($d=3 \cdot h_{ef}$) to avoid influences of the boundary conditions on the peak load.

4 CONCLUSIONS

In the present contribution, a comprehensive and systematically carried out experimental investigation on cast-in mechanical anchors comprising three concretes tested at two different ages is presented with the aim to investigate the effect of age and aggregate type on the concrete cone capacity. In parallel to the structural anchor tests, the analysis involves full material characterization tests on concrete specimens following different curing protocols. Based on the presented results of the experimental investigations, the following conclusions are drawn.

1. Three investigated concretes tested at two ages showed the expected evolution of concrete compressive strength. The evolution of the material properties is in good agreement with the concrete-related codes suggested ageing law. The predictions at 70 days deviate only 2-5% from the experimentally observed values.
2. The concrete cone capacities predicted using the current predictive model based on the concrete compressive strength underestimates the experimental results. This indicates a very conservative choice of the calibration factor k used in the equation for the investigated hex bolt anchor type.
3. For the investigated concretes and anchor type, a clear age effect is revealed, where the 70-day concrete cone capacity predictions are approximately 25% more conservative than the predictions at 28 days.

4. The currently established predictive model captures and accounts for the effect of different coarse aggregate type. The results based on normalized pull-out load capacities showed an insignificant remaining aggregate effect, typically smaller than the experimental scatter of 5% - 10% in anchor pull-out tests.
5. A photogrammetric analysis was performed on the extracted concrete cones geometrical properties and showed no significant age and aggregate effect on the cone shape and size.

ACKNOWLEDGEMENTS

Marco Marcon and Lisa-Marie Czernuschka are gratefully acknowledged for their contribution performing the concrete characterization tests, and Stefan Meißl for his support in performing the anchor pull-out tests and the data post-processing. Gabriel Pfuner is acknowledged for his support performing the photogrammetric analysis and detailed documentation. The financial support by the Austrian Federal Ministry of Economy, Family and Youth and the National Foundation for Research, Technology and Development is gratefully acknowledged.

Impact of end-of-life stage in cradle-to-cradle LCA analysis of timber and timber-hybrid buildings

L. Corti & G. Muciaccia

Politecnico di Milano, Milan, Italy

ABSTRACT: Timber and hybrid timber buildings are very-well known for their properties of optimizing structural performances through a forward-looking combination of timber with other materials. These types of structures are also more sustainable from environmental perspective if compared to traditional RC buildings, especially considering the End-Of-Life stage (stage C) and Beyond System Boundary Stage (stage D) of Life Cycle Assessment (LCA) analysis where timber members contribute to the reduction of e.g., Global Warming Potential, given their very low – or even negative – values in terms of released kg CO₂ eq.

Two main issues have been identified by the authors concerning assessment of that topic, as first of all no standard methods are available for stage D impact evaluation; this problem is exacerbated by data shortage, given that this stage is currently not compulsory in the development of LCA analysis. In order to standardize this phase with the goal of spreading its importance, the authors investigated different case studies. Analysed previous studies are also needed for the second issue development, as a point of primary importance is the building structural scheme, with particular focus on fastening technology. Considering re-use, recovery or recycling potential of a building part or member, a key issue is the disassembling simplicity: this characteristic should be definitely taken into account in a cradle-to-cradle LCA analysis as this is the unique way to design the building in sustainable terms.

Reducing number of steps from building dismantling to the new building construction and minimizing amount of materials destined for disposal become measures of the building ability to reverse CO₂ emissions to zero or negative values with stages C and D detailed assessment.

1 INTRODUCTION

Nowadays global attention is focused on environmental impact of every product and process, with special careful on emissions of each phase of the life cycle, starting from the raw material extraction to the end-of-life, possibly including re-use, recovery or recycling procedures. This special care is needed as the current situation is the result of the last decades continuously increasing harmful emissions which are leading to irreversible damaging of the planet (Solomon, Plattner, & Knutti, 2009). The issue is complex as several problems can be identified, apart from already mentioned matter of emissions quantities; resources exploitation by the most developed countries is no more compatible with the Earth's capacity to regenerate these resources. This unbalance reflects in every aspect of human life, from the economical, to the social and health aspects (Lenton, et al., 2019) (Markkanen & Anger-Kraavi, 2019). In Figure 1 two indicators of the gravity of the situation are represented.

Climate change has been treated for years as a slow process which implications would have been far away in time: this assumption is proven to be wrong, just considering sudden temperature growth. This laxity has placed both changes observations and mitigation measures in a secondary position that lead to even more severe consequences that nowadays are visible to everyone. Another issue that draws the attention on the topic is the irreversibility of some processes, such surface's temperature increase that continues growing even though CO₂ emissions are reduced to zero, following a hysteretic path behaviour delayed in time (Soong-Ki, et al., 2022).

Figure 1. Carbon dioxide concentration in part per million (https://gml.noaa.gov/webdata/ccgg/trends/co2/co2_mm_mlo.txt) and Earth Overshoot Day starting from 1970 (<https://www.overshootday.org/newsroom/past-earth-overshoot-days/>). Year 2020 drop of the Earth Overshoot Day is caused by pandemic lockdown effects.

Considering that building and construction sector is responsible for almost 40% of the emissions (Jahan, et al., 2022) (taking into account both energy usage and processes related) and that the building stock is growing in order to accommodate increasing population especially in urban areas, a special effort is required. Considering annual reports delivered by the Global Alliance for Buildings and Construction (GABC) that started monitoring the sector under consideration from the COP21, some mild improvements have been noticed, as the increase of green building certifications (Global Status Report for Buildings and Construction: Towards a Zero-emission, Efficient and Resilient Buildings and Construction Sector, 2021) Considering on the other hand the building sector emissions, last two years data – in particular year 2020 – have recorded significant decrease, which is again a pandemic effect that hides the fact that building decarbonization is not on track.

This fact claims for new solutions and greater attention in terms of sustainability actions for new and existing buildings. Considering new buildings, the sustainability perspective is imperative and of primary importance; on the other hand, also existing buildings should be considered. These buildings will contribute to waste generation once reached their end-of-life, which treatment contribute to soil consumption, power usage and greenhouse gases emissions (Alsheyab, 2022), even though applying a waste management hierarchy significant mitigation of impacts is granted (Sasitharan, et al., 2012). Amount of waste generated by construction and demolition (C&D) contributes worldwide for about 25% of the total generated waste, even though discrepancies are recorded for different countries (Nunes & Mahler, 2020), which again establishes an alarming datum. Reuse, recycling and recovery must be always hierarchically considered to guarantee a sustainable management, as sketched in Figure 2.

Figure 2. Waste management sustainability, adapted from Sasitharan, et al., 2012.

In a holistic approach to guarantee sustainability, it turns crucial to monitor each phase of the building's life by Life Cycle Assessment (LCA) analysis. This is a worldwide-accepted method whose main outcomes are classified with a tree-model of impacts. Considering e.g.,

carbon dioxide (CO₂) emissions, the resulting effect is interpreted in terms of climate change which is part of the macro category of harmful effects on the ecosystem. In this way a methodological approach is available for evaluation and comparison of different technologies, even though some shortages are noticed; the main issues are linked with phases C (End-of-Life stage) and D (Benefits and Loads beyond the System Boundary) of LCA. First of all these stages are intrinsically affected by indelible uncertainties due to their non-immediate applications, as they are expected to be involved some decades later than building design phase. Moreover, given that stage D is nowadays not mandatory, low level of standardization and short amounts of data are available in literature (Delem & Wastiels, 2019).

Considering a sustainable building, an interesting solution lies in Timber-Concrete Composite (TCC) buildings, which optimize timber in an engineered perspective and reduce concrete volumes. In more general terms, engineered timber products like CLT, Glulam, LVL... are characterized by low values of carbon footprint thanks to a low-energy consumption production process (Khorsandnia, Valipour, Schänzlin, & Crews, 2016), reduced construction times compared to traditional RC buildings (Mirdad, Daneshvar, Joyce, & Chui, 2021), lower values of density-to-strength ratio and reduced thermal conductivity (Khorsandnia, Valipour, & Bradford, 2018); moreover the concept of disassembling simplicity is more readily enforceable with members made by timber-based products (Bertino, et al., 2021). In this way e.g., deconstructable connections facilitate dismantling and recycling processes, leading to lower waste amounts (Derikvand & Fink, 2021), which imply less material destined to landfilling, a reduction of dismantling times and preservation of natural resources (Hradil, et al., 2014). Almost all of the current studies on connectors accurately focus on their performances (Mirdad, Khan, & Chui, 2022), without explicitly considering the fact that they may hinder building deconstruction and saving of the greatest possible quantity of materials, so without carrying out environmental considerations.

The authors suggest an overview of today's practices concerning the End-Of-Life management of TCC buildings, with a focus on fastenings technology and their disassembling simplicity, range of expected scenarios (Quéheille, Ventura, & Saiyouri, 2022), convergence towards a cradle-to-cradle approach and waste minimization through reuse, recycling and recovery. Nowadays most widespread approaches are cradle-to-grave (from stage A to stage C of LCA) and no or limited alternative scenarios are generally considered (Allan & Phillips, 2021). Moreover, given the actual difficulty in finding literature where the issue of scenarios concerning End-Of-Life stage is assessed considering also disassembling simplicity, an innovative perspective towards a closed loop in terms of LCA is suggested.

The paper is organized as follows. Section 2 presents the method applied for literature selection. Results of such phase are presented in Section 3, identifying main strategies for stages C and D of LCA and detecting common disassembling procedures. Finally, Section 4 provides discussion of results and conclusions.

2 METHOD

The methodology adopted for this study consists of different steps sorted in this way:

- i. Identification of literature concerning End-Of-Life and Benefits and Loads beyond the System Boundary stages with focus on timber or timber-hybrid buildings. The reason of the emphasis on buildings with timber members lies in the fact that accurate scheduling of dismantling phase should be foreseen; otherwise, environmental advantages of using timber-based products is – at least partially – missed. This first step pursues the aim of creating a photograph of current considerations of such phases.
- ii. Analysis of widespread scenarios for End-Of-Life stage. The aim of this step is highlighting importance of accurate considerations taking into account uncertainties that naturally occur due to long terms and deficiency of real-cases data.
- iii. Detection of fastenings common technologies and analysis of disassembling procedures with identification of common patterns. Disassembling simplicity always guarantees the

most efficient solution in terms of sustainability; by observing Figure 2, it is clear that apart from comparisons of the solutions at the opposite ends, also consecutive approaches bring different levels of emissions. Comparing e.g., reuse and recycling, the second solution includes some manufacturing processes that generate Greenhouse Gases (GHG), while the first one does not need any working process.

- iv. Proposal of a flow chart in order to facilitate the transition from the current most widespread cradle-to-grave approach to the more forward-looking and sustainable cradle-to-cradle one, where the concepts defined in points ii. and iii. are assessed together.

The suggested method starts from a literature review in order to offer an innovative methodological approach, especially designed for timber-hybrid buildings.

3 RESULTS

Literature retrieved during the review is formerly subdivided in three categories, according to the topics addressed in the work. Considering the issues of End-of-Life scenarios and of disassembling simplicity, the following classes of papers are identified:

- a. Articles with focus on strategies for LCA's stages C and D and without consideration of connectors role in disassembling procedures. The following papers are identified: Quéheille, Ventura, & Saiyouri, 2022, Tam & Tam, 2006, Mirdad, Khan, & Chui, 2022, Jahan, Zhang, Bhuiyan, & Navaratnam, 2022, Nunes & Mahler, 2020, Younis & Doodoo, 2022, Lukić, Premrov, Passer, & Žegarac Leskovar, 2021, Bertino, et al., 2021, Hart & Pomponi, 2020, Niu, Rasi, Hughes, Halme, & Fink, 2021, Alsheyab, 2022, Condotta & Zatta, 2021, Hradil, et al., 2014, John & Buchanan, 2013. The most widespread scenarios are: 1) reuse of timber-based materials panels; 2) recycling of timber-based panels with production of microchips and production of new panels without usage of virgin resources; 3) energy recovery through incineration and reduction of natural gas use; 4) landfilling, which is substantially a non-development of stage D.
- b. Articles addressing the connectors role in disassembling procedures and not focusing on strategies for LCA's stages C and D. The following papers are identified: Derikvand & Fink, 2021, Khorsandnia, Valipour, & Bradford, 2018, Derikvand & Fink, 2020, Khorsandnia, Valipour, Schänzlin, & Crews, 2016. These studies present experimental and numerical results of different TCC connections, with comparisons between permanent and deconstructable solutions. In general terms, even though some quantitative predictable differences, failure modes are comparable according to some expedients as insertion of internal threads in the PVC plug (Derikvand & Fink, 2020) or different angles of connectors insertion and different timber joists thickness (Khorsandnia, Valipour, Schänzlin, & Crews, 2016).
- c. Articles dealing both with the connectors role in disassembling procedures and with strategies for LCA's stages C and D. The following papers are identified: Hafner, Ott, Bodemer, & Winter, 2014, Cristescu, et al., 2020, O'Grady, Minunno, Chong, & Morrison, 2021.

In class a. 14 papers are collected, while just 4 articles are included in b. class; on the other hand, 3 articles consider both topics of classes a. and b., populating class c. Considering aforementioned literature, Table 1 lists recurrent topics for classes a. and b., thus common best practices and widespread investigated issues are detected.

Considering subjects listed in Table 1, they clearly reflect the current approach that still struggles to reach a circular economy outline, as detected best-researched topics are strongly related to a two-track view; thereby a flow chart with an innovative methodological approach is suggested in. The role of this original perspective arises from the necessity to take into account together structural and environmental requirements, as nowadays – as confirmed by literature review outcomes – the trend is closer to a separated approach, with some serious practical and methodological shortcomings. The proposed tool is a methodological and theoretical support which recommends some best practices which mainly lead to structural and environmental advantages: disassembling simplicity significantly reduces dismantling times, with dropping of GWP gases emissions and greater reuse rates of e.g., timber-based products panels.

Table 1. Recurrent topics for two literature categories identified.

Strategies for LCA's stages C and D	Connectors role in disassembling procedures
<ul style="list-style-type: none"> • Development of different scenarios • Waste management: assessment accuracy as a function of the country's sensitivity to environmental issues • Overview of recycling technologies • Importance of comparative LCA • Rising importance of circular economy • Critical considerations of unavoidable uncertainties linked with broad temporal perspective 	<ul style="list-style-type: none"> • Comparative failure analysis of permanent and deconstructable shear connectors • Investigation of different alternatives with comparisons of waste at the End-of-Life stage of the building • Disassembling simplicity before and after load application • Identification of obstacles in disassembling procedures that hinder timber re-use

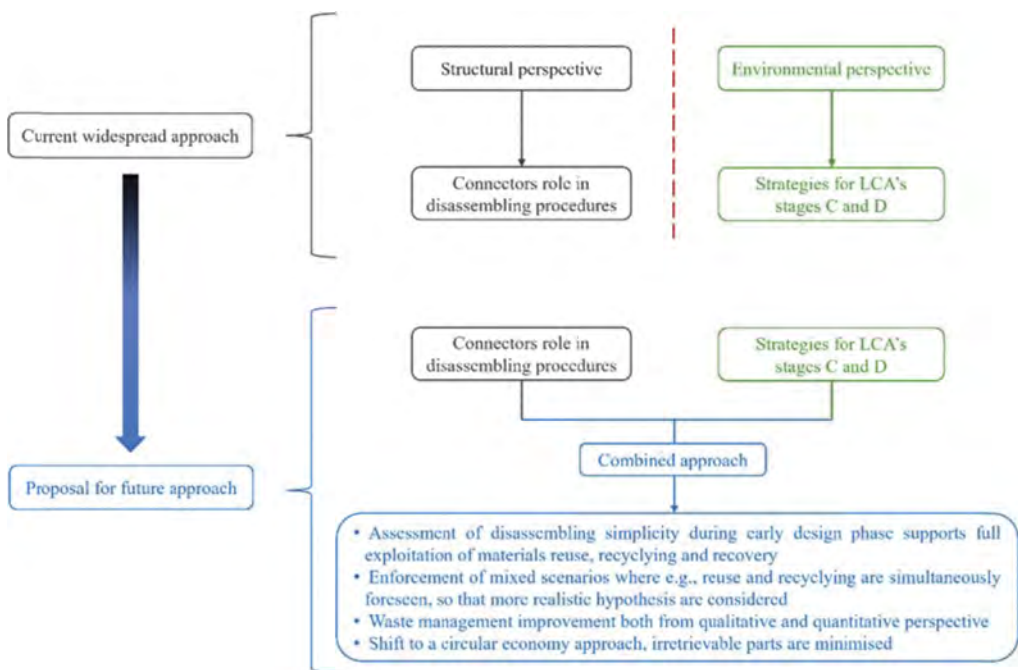

Figure 3. Flow chart with authors' original proposal concerning the combination of structural and environmental requirements.

One of the issues nowadays scarcely considered is the possibility to foresee different scenarios, as e.g., considering just a reuse hypothesis may be limiting, even if this is the most preferable from a sustainability perspective.

Unexpected events and damages experienced and encountered during the dismantling phase may hinder a “total reuse” scenario, so it is worth providing one or more alternative chances where damaged parts are not directly destined for landfilling, but recycling is scheduled, chips are produced, and virgin material is not used for panels manufacturing. This example represents how a combination of both structural and environmental points of view is extremely favourable, even though up-cycling is not always totally practicable. Moreover, this approach reduces wastes both from physical (materials) and organisational (times and costs) sides. An example of applicability of a mixed scenario is presented in Figure 4, where firstly reuse of suitable parts is carried out and recycling of portions probably damaged during dismantling is suggested.

Figure 4. Example of reuse and recycle of a timber beam from a TCC slab.

4 DISCUSSION AND CONCLUSIONS

The literature review acknowledged that environmental and structural fields still suffer of a communication problem; the fact that environmental issues linked to the building sector have been realised in recent years, while the structural side is obviously the core of this field, produced some gaps that still need to be filled.

This work first proposes as a preliminary methodological research which findings are mainly:

- i. Identification of research shortcomings, mainly detected in the missing relationship between structural and environmental requirements.
- ii. Dismantling procedures are generally not accounted for during building design phase, so at the End-of-Life many uncertainties that increase times and costs should be faced.
- iii. Planning of building End-of-Life is becoming widespread from a theoretical point of view, such that a plurality of scenarios is always more frequently suggested.

In addition to such methodological observations, the paper proposes an innovative outlook concerning simultaneous consideration of structural and environmental requirements. First of all, the novelty introduced by the flow chart presented in is the concomitant mention to connectors and their role in building dismantling, stages C and D of LCA, sustainable waste management and consequently reasonings towards a circular economy approach. An example of such approach is reported in Figure 4, where a TCC solution is conceived according to a reuse and recycle scenario.

Finally, the proposed approach paves the way to future developments, where considering buildings impact on climate change is everyday more urgent; it is expected that building environmental standards will become more stringent, so a close link between structural and environmental requirements is no longer deferrable; this cooperation is intended as an optimization on both sides, with an accurate design of connectors in order to guarantee the maximum rate of material to be reused in a cradle-to-cradle approach.

Shear strength assessment of FRP pre-tensioned concrete beams

A. Marí, E. Oller, J. Murcia-Delso, J.M. Bairán & N. Duarte

Universitat Politècnica de Catalunya, Barcelona, Spain

ABSTRACT: The low susceptibility to corrosion of fiber reinforced composite materials (FRP) has led to considering their use for prestressing reinforcement, as an alternative to steel. However, the effects of FRP fragility, low elastic modulus, and low bond with concrete, when compared to usual prestressing steel, must be accounted for in the design of structures. This paper presents a theoretical model for predicting the shear strength of FRP prestressed pre-tensioned concrete beams, extending a previously developed model (CCCM), to account for the properties of FRP as active reinforcement, and to capture reductions in shear strength caused by bond loss in the FRP tendons. The model has been validated by comparing the theoretical predictions with the results of shear tests available in the literature. Good accuracy has been obtained in predicting the shear capacity and also in identifying those cases where shear failure is associated to loss of anchorage bond.

1 INTRODUCTION

Fibre reinforced polymers might be a suitable alternative to conventional steel reinforcement to avoid corrosion of prestressing reinforcement, which is one of the main causes of deterioration of concrete structures. Although the use of FRP as passive reinforcement has been studied in depth during the last decades, the level of knowledge of FRP prestressed concrete structures is much lower, and there are few design guidelines or recommendations.

Up to date, few analytical models have been proposed to assess the ultimate shear strength of FRP prestressed beams. Kueres et al. (2020) and Küres (2019) extended a variable strut inclination model to determine the shear strength of non-prestressed FRP reinforced beams with shear reinforcement to consider the beneficial effects of prestressing on the shear strength. ACI440.4R-04 (ACI 2004), CSA S806-12 (CSA 2012) and JSCE (Astuhiko Machida 1997) consider that the ultimate strength is provided by the concrete, by the shear reinforcement and by the beneficial vertical component given by the prestressing force, with different provisions for each component.

The aim of this paper is to present an extension of the Compression Chord Capacity Model (CCCM) (Cladera et al. 2016), previously developed by the authors together with Cladera and Ribas from the University of Balearic Islands (UIB), to predict the shear strength of prestressed concrete beams with FRP tendons and FRP passive shear reinforcement. This model includes the effects of loss of anchorage of the FRP tendons. The performance of this model is assessed by comparing the theoretical predictions for the ultimate shear strength to the experimental ultimate values of 43 FRP pre-tensioned beams.

2 DESCRIPTION OF THE DEVELOPED SHEAR STRENGTH MODEL FOR CONCRETE MEMBERS PRESTRESSED WITH FRP TENDONS

2.1 *The Compression Chord Capacity Model for steel reinforced and prestressed concrete members*

It is generally accepted that the shear strength in a RC beam is provided by the contribution of the un-cracked concrete chord V_{cc} , the shear transferred along the cracks, V_{cw} , due to

aggregate interlock and the residual tensile forces transferred across the crack, the shear resisted directly by the transverse reinforcement, V_s , crossing the critical crack, and the shear resisted by the longitudinal reinforcement, V_l , so called dowel action. However, the relative contribution of each shear transfer action change along the loading process since, as the loading and the critical shear crack width increase, the shear transferred by aggregate interlock and the residual stresses crossing the crack tend to reduce as well as the dowel action. Then, shear stresses redistribute, increasing in the region of the uncracked compression chord; which becomes the most relevant shear transfer action until failure takes place under a biaxial stress state. To account for this experimental evidence, the Multi-action Shear Model (Mari et al. 2014) which included the four shear transfer actions, was simplified, into the Compression Chord Capacity Model (CCCM) (Cladera et al. 2016). In this model, the critical shear crack typically involves two branches, as shown in Figure 1. The opening of the first branch of the critical crack is assumed to be the result of a rotation around its tip. The compression zone above the tip prevents any meaningful contribution of shear slip along the crack interface, thus the contributions of aggregate interlock and dowel action are small, considered as constant values and incorporated into the contribution of the uncracked concrete chord.

Figure 1. Assumed shape of the critical shear crack; internal forces equilibrium.

The most relevant assumptions of the CCCM are:

- The shear stresses are concentrated in the uncracked compression chord, concrete tensile strength is neglected and the normal compressive concrete stresses distribution is linear.
- The critical shear crack starts at a section where at shear failure, the bending moment reaches the cracking moment of the section. The horizontal projection of the critical shear crack is $0.85d$, based on experimental observations.
- The weakest section subjected to a combined shear-bending failure is considered to be located at the tip of the first branch of the critical crack, where it reaches the flexural neutral axis
- Failure is assumed to take place when the pair of principal stresses reach the Kupfer's Biaxial Failure Envelope (Kupfer & Gerstle 1973).
- For usual values of $ald=MI(V \cdot d)$, the critical point inside the compression chord, is located at a vertical distance from the neutral axis $z=0.425c$, being c the neutral axis depth.

The key equation to obtain the contribution of the concrete chord V_c , is the following:

$$V_c = \int_0^c \tau(z)b(z)dz = K_\tau \zeta b c \sigma_1 \sqrt{1 - \frac{\sigma_x + \sigma_y}{\sigma_1} + \frac{\sigma_x \sigma_y}{\sigma_1^2}} \quad (1)$$

where $\tau(z)$ = shear stress at a point of the uncracked chord at a distance z of the neutral axis; c = neutral axis depth given by Eq (11b) of Table 1; b = rectangular section width; σ_1 = principal tensile stress; σ_x = normal longitudinal stress due to bending; σ_y = normal vertical stress; K_τ = integration constant of value 0.682, and ζ = size effect factor given by Eq. (10) of Table 1.

Relating the normal stresses with the internal forces, and setting the equilibrium conditions Eq. (1) can be expressed as a function of the internal forces and the components of the shear

transfer actions, see Figure 2. Once solved, Eq (1) provides a solution in which the contribution V_c is almost a linear function of c/d , including the effects of the confining stresses in the concrete generated by the stirrups.

Figure 2. Internal forces and stress resultants considered in the shaded free body equilibrium.

The CCCM shear model, initially derived for reinforced concrete members with rectangular cross section, was extended to T sections, in which a non-negligible contribution of the flanges to the shear strength exists. This and other effects produced by the differences in section shape were incorporated by using an effective shear flanges width $b_{v,eff}$, as detailed in Cladera et al. (2016).

The CCCM was also extended to incorporate the effects of longitudinal prestressing of a beam in the shear strength (Marí et al. 2015). The increment of the neutral axis depth due to the axial compressive force, the reduction of inclination angle of the cracks and the increment of the cracking moment and, therefore, of the position of the critical shear crack were accounted for. For inclined tendons, the vertical component of the prestressing force $V_p = P \cdot \sin \alpha$, is deducted from the shear force due to external actions.

For simplicity reasons, the effects of confinement of the concrete chord due to stirrups, initially included into V_c , were incorporated into V_s . These changes and extensions gave place to the following expressions for the concrete and steel reinforcement contributions to the shear strength in reinforced and prestressed concrete beams with rectangular T and I section, in which, for design purposes, the tensile strength was replaced by an equivalent term in terms of the concrete compressive strength:

$$V_{cu} = 0.3 \zeta \frac{c}{d} f_{cd}^{2/3} b_{v,eff} d \leq V_{cu,min} = 0.25 \left(\zeta K_c + \frac{20}{d_0} \right) f_{cd}^{2/3} b_w d \quad (2)$$

$$V_{su} = 1.4 \frac{A_{sw}}{s} f_{yw} (d_s - x) \sin \alpha (\cot \theta + \cot \alpha) \quad (3)$$

where $K_c = cd \geq 0.2$; $d_0 = d \geq 100$ mm; and $b_{v,eff}$ = shear effective web width, which accounts for the flanges contribution, given by Eqs. (12a) and (12b) of Table 1. The neutral axis depth in prestressed concrete sections c is approached by a linear interpolation between the state with zero prestressing ($c = c_0$) and the decompression state ($c = h$), given by Eq (11a) in Table 1.

2.2 Extension of CCCM for beams reinforced with FRP bars as prestressing and transverse reinforcement, without anchorage loss of prestressing reinforcement

Due to the elastic-brittle nature of FRP, the contribution of the shear reinforcement to the shear strength must be modified. As no yielding occurs in FRP reinforcement, the stirrups behave elastically until failure and their individual stress is not constant along the shear crack, but it depends on their deformation. Therefore, the vertical shear force provided by the

stirrups (V_f) can be estimated using an average value of their stress along the critical crack (Oller et al. 2015), resulting for vertical stirrups ($\alpha=90^\circ$):

$$V_f = 0.85 \frac{A_{fw}}{s} \sigma_{fw,m} d_s (1 + \Delta V_{cu}) = 0.85 \rho_{fw} \cdot E_f \cdot \varepsilon_{fw,m} \cdot d_s (1 + \Delta V_{cu}) \quad (4)$$

where A_{fw}/s = area of FRP stirrups per unit length of the beam; $\sigma_{fw,m}$ = mean stress of the stirrups at shear failure, $\varepsilon_{fw,m}$ = mean strain of the stirrups at shear failure; E_f = modulus of elasticity of the FRP bars; and ΔV_{cu} = effect of confinement due to stirrups given by Eq. (14) of Table 1.

The mean strain of the FRP stirrups at failure ($\varepsilon_{fw,m}$) is obtained assuming a linear variation of the stirrups strains along the crack length (Figure 3), as recommended by Oller et al. (2015). The stirrup that fails is assumed to develop a strain of $0.45 \varepsilon_{fw,u}$, where the 0.45 factor is derived from the strength limit of bent FRP bars proposed in JSCE (Astuhiko Machida 1997) assuming a bent radius of 3 bar diameters and $\varepsilon_{fw,u}$ is the ultimate strain of the FRP stirrup. This results in an average stirrup strain along the shear crack of $0.225 \varepsilon_{fw,u}$. As a result, the shear force resisted by the stirrups in a length equal to the horizontal projection of the crack until the neutral axis, $0.85 d_s$, is:

$$V_f = 0.85 \rho_{fw} 0.225 \varepsilon_{fw,u} d_s (1 + \Delta V_{cu}) \approx 0.191 \rho_{fw} E_f \varepsilon_{fw,u} d_s (1 + \Delta V_{cu}) \quad (5)$$

Table 1 summarizes the proposed formulation for predicting the shear strength of prestressed concrete beams with or without FRP stirrups, assuming that no anchorage failure takes place.

Table 1. Proposed shear strength formulation.

Strength parameter	Equation	Eq. #
Shear strength	$V_{Rd} = V_{cu} + V_f \leq V_{Rd,max}$	(6)
Shear strength limit (diagonal compression)	$V_{Rd,max} = \alpha_{cw} b_w z v_{fd} \frac{\cot\theta + \cot\alpha}{1 + \cot^2\theta}$	(7)
Concrete contribution	$V_{cu} = 0.3 \zeta \frac{c}{d} K_{ad} f_{cd}^{\frac{3}{2}} b_{v,eff} d$	(8a)
	$V_{cu} \not\leq V_{cu,min} = 0.25 \left(\zeta K_c + \frac{20}{d_0} \right) f_{cd}^{2/3} b_w$	(8b)
Shear reinforcement contribution	$V_{frp} = 0.191 \rho_{fw} E_f \varepsilon_{fw,u} d_s (1 + \Delta V_{cu})$	(9)
Size and slenderness effect	$\zeta = \frac{2}{\sqrt{1 + \frac{d_0}{200}}} \left(\frac{d}{a} \right)^{0.2} \not\leq 0.45$; $d_0 = d \geq 100 \text{ mm}$	(10)
Relative neutral axis depth	$\frac{c}{d} = \frac{c_0}{d} + \left(\frac{h-c_0}{d} \right) \left(\frac{d}{h} \right) \frac{\sigma_{cp}}{\sigma_{cp} + f_{cm}}$; $\sigma_{cp} = \frac{P}{A_c}$; $A_c = \text{Section Area}$	(11a)
	where $\frac{c_0}{d} = \alpha_e \rho_l \left(-1 + \sqrt{1 + \frac{2}{\alpha_e \rho_l}} \right)$; $\rho_l = \rho_s + \rho_p$	(11b)
Effective flange width	if $c \leq h_f \rightarrow b_{v,eff} = b_v = b_w + 2h_f \leq b$	(12a)
	if $c > h_f \rightarrow b_{v,eff} \approx b_w + (b_v - b_w) \left(\frac{h_f}{c} \right)^{3/2}$	(12b)
Crack inclination	$\cot\theta = \frac{0.85d_s}{d_s - c} \leq 2.5$	(13)
Stirrup confinement factor	$\Delta v_{cu} = 0.5 \zeta \frac{c}{d} \left(1 + \frac{b}{b_v} \right) \frac{b_{v,eff}}{b}$	(14)

2.3 Shear strength considering anchorage loss of FRP prestressing bars (shear-bond failure)

As evidenced by experimental tests, premature shear failures may occur due to slip of the prestressing tendons at the critical shear crack. This type of failure occurs when the available bonded length between the critical shear crack and the free end of the beam (l_{av} in Figure 4a) is smaller than the anchorage length (l_{req}) required to develop the tensile force of the prestressing reinforcement at the cracked section. The shear-bond failure mode can be considered by computing l_{av} and l_{req} based on the position of the critical shear crack.

The available bonded length is equal to the sum of the beam offset (e) and the distance between the centre of the support and the critical crack (s_{cr}):

$$l_{av} = e + s_{cr} = e + \frac{M_{cr}}{V_u} \quad (15)$$

Figure 3. Idealized tensile stress distribution for stirrups crossing the critical shear crack.

Figure 4. Available bonded length and forces acting in critical section.

The required anchorage length can be computed based on equilibrium of the tensile force and bond forces acting on the FRP reinforcement:

$$l_{req} = \frac{F_p}{u \cdot \tau_{max}} \quad (16)$$

where F_p = tensile force of prestressing reinforcement at the critical crack; τ_{max} = average bond strength along the anchorage length; and u = total perimeter of prestressing reinforcement. The value of F_p is obtained by studying moment equilibrium at the critical crack. Based on the moment equilibrium at point O of the free body diagram shown in Figure 4b:

$$F_p = \frac{M_{cr} + V_c \cdot \beta \cdot d + 0.5V_t \cdot \beta \cdot d}{z} = \frac{M_{cr} + V_c \cdot 0.85 \cdot d + 0.5V_t \cdot 0.425 \cdot d}{z} \quad (17)$$

Assuming no bond failure will occur, the shear strength and critical section can be initially estimated using the equations in Table 1. The available bonded length and required anchorage length are then calculated using Eqs. (15) and (16), respectively, given the position of the critical section. If $l_{av} \geq l_{req}$, the prestressing reinforcement is capable of developing the tension force at the shear crack (no bond loss) and the development of the full shear strength is confirmed. If $l_{av} < l_{req}$, a bond failure will occur prior to reaching the required tension force at this critical section, which implies that a reduced prestressing force (P_{red}) is acting at the instant of failure. The reduction of the prestressing force results in a smaller shear strength and a shorter distance to the critical section (s_{cr}). Bond failure has to occur for the value of P_{red} that satisfies $l_{av} = l_{req}$. The shear strength for bond loss ($V_{Rd,B}$) is obtained using the equations in Table 1 for $P = P_{red}$. The values of P_{red} and $V_{Rd,B}$ are obtained by iteration since both l_{av} and l_{req} depend nonlinearly on P .

3 VERIFICATION OF THE PROPOSED MODELS

A database of shear tests on FRP prestressed concrete beams reported in the literature has been compiled in order to assess the accuracy of the proposed model. The database includes 43 tests on FRP pre-tensioned beams, with and without FRP shear reinforcement. The tests correspond to studies conducted by Grace et al. (2015), Kueres et al. (2020), Nabipay & Svecova (2014), Park & Naaman (1999), Preinstorfer et al. (2021), and Whitehead & Ibell (2005). Table 2 provides the list of beam tests included in the database and their key geometrical and reinforcement characteristics. As shown, the beams present a variety of types of FRP as prestressing and shear reinforcement (aramid, glass, carbon, parafil), shear span ratios (a/d ranging from 1.5 to 6), prestressing stress levels (σ_{cp}/f_c ranging from about 2% to 20%) and amounts of transverse reinforcement (ρ_{fv} ranging from 0 to 1.5%).

The shear strength of the beams the database has been estimated using the model presented in Section 2. The shear-bond failure mode has been considered only for the nine beam tests by Kueres et al. (2020), since this was the only study providing bond strength data for the FRP bars and in which shear-bond failures were actually observed in beam tests. In addition to the shear failure modes associated to the proposed model, potential shear failures in flexurally uncracked regions have been considered following the equations of Eurocode 2 (European Committee for Standardization 1992).

Table 2 presents the results of the analytical predictions, including the predicted shear strength (V_{pred}) and failure mode, as well as the experimental-to-analytical strength ratios (V_{exp}/V_{pred}). Figure 5 compares the experimental and analytical strengths, and presents statistics of the V_{exp}/V_{pred} ratios. The average value of V_{exp}/V_{pred} is 1.08 and its coefficient of variation (C.V.) is 23%. Hence, the proposed model provides an overall good match with the experimental results. The level of accuracy of the model is similar to that obtained with the original CCCM formulation for steel reinforced and prestressed concrete presented in Cladera et al. (2016), which provided an average of 1.17 and a C.V. of 19%.

Regarding the shear-bond failure mode, specimens LV-1-1, LV-1-2, LV-2-1, LV-2-2 and LV-4 of Kueres et al. (2020) exhibited this type of failure during testing. This type of failure was correctly predicted for the first four specimens with an average value of the strength ratio of 1.03, as depicted from Table 2. The bond failure observed in the fifth specimen (LV-4) was correctly identified analytically, but the strength prediction is very close to the experimental value.

Figure 5. Experimental vs. predicted shear strengths.

4 CONCLUSIONS

A mechanically-based theoretical model to predict the shear strength of prestressed concrete beams with FRP reinforcement has been proposed. The model is an extension of the Compression Chord Capacity Model (CCCM) formulation, which has been modified to account for the brittle nature of FRP transverse reinforcement and potential bond loss of prestressing reinforcement. The accuracy of the model has been verified using a database of 43 shear tests from the literature. The analytical strength estimations are in good agreement with experimental data,

* Predicted failure modes: failure of compression chord (CC), shear-bond (B), diagonal compression (DC), and shear failure in uncracked regions (U).

** Test specimens exhibiting shear-bond failures

providing an average experimental-to-predicted strength ratio of 1.08 and a coefficient of variation of 23%. The model has been also shown to identify shear-bond failures in four of the five cases in which this type of failure was reported experimentally. With the appropriate safety factors, the proposed shear strength formulation can be, therefore, employed to efficiently design and assess for shear resistance FRP-prestressed concrete elements.

ACKNOWLEDGEMENTS

Life-cycle cost of CFRP and steel prestressed concrete elements

J.M. Bairán, J. Murcia-Delso, N. Duarte, E. Oller & A. Mari

*Department of Civil and Environmental Engineering, Universitat Politècnica de Catalunya
(UPC - BarcelonaTech), Barcelona, Spain*

ABSTRACT: Carbon steel reinforcement is vulnerable to corrosion, degrading the structure with time, and has large economic implications for aging infrastructures. CFRP is an alternative in reinforced and prestressed concrete, not prone to corrosion. However, its cost is considerably larger than steel, and its mechanical properties enforce different design criteria. Therefore, it is not evident when CFRP is a convenient solution. In this paper, benefits of CFRP reinforcement are investigated in LCC context. An archetype prestressed-concrete bridge is designed with the two types of reinforcement. Two environment scenarios are analyzed, representative of current and increased chloride concentration in coastal regions. The costs investigated include routine inspections, major repairs and users' affectation. Although requiring less maintenance cost, the design with CFRP has a higher LCC than the steel-reinforced alternative, in the current chloride scenario close to the coast. However, in scenarios of larger chloride exposure, the CFRP solution may be more competitive.

1 INTRODUCTION

Carbon steel reinforced concrete elements may suffer corrosion when located in aggressive environments. As the share of built infrastructures in most countries ages, the economic and social implications of corroded structures have become evident. It has been estimated that worldwide cost of corrosion is in the range of 2.5 trillion dollars per year. According to Pacheco et al (2018), the national budget for maintenance and rehabilitation in many countries has begun to exceed that for new constructions.

In order to mitigate this durability problem, crack limitations, minimum concrete class and cover are required, which frequently may control the design of some elements. Nevertheless, durability requirements have evolved in the last decades, so many existing structures do not comply current standards. Moreover, corrosion has also been observed in some relatively recently built structures.

An alternative approach consists of replacing traditional carbon steel reinforcement with non-corrosive reinforcement, such as stainless-steel reinforcement or fiber reinforced polymers (FRP) reinforcements, either as non-prestressed or prestressed reinforcements. Nevertheless, the mechanical behavior of FRP reinforcement differs greatly from traditional one, being the most relevant characteristics the lower stiffness and brittle failure mode, when compared with carbon-based steel. Therefore, different design strategies are needed. Moreover, the current cost of these alternative reinforcements significantly exceeds that of carbon steel, which has prevented a more extended use of them.

FRP prestressing tendons are typically produced with one of four basic fibers: aramid, carbon, basalt, and glass. Among them, the carbon FRP (CFRP) shows higher strength and elastic modulus than the rest, which suggests possible advantages in terms of stiffness and stress increment at failure.

In order to provide detailed insight of the actual benefits of using CFRP as alternative prestressing reinforcement, an analysis comprising the life cycle cost (LCC) of the structure is carried out in this study. The analysis will take into consideration the cost and durability dimensions of the problem. An archetype prestressed concrete bridge located in a coastal environment will be considered as case study.

Two alternative design solutions will be developed and compared, one with conventional carbon steel and another using CFRP as active and passive reinforcement tendons. Different

corrosion-related requirements will be adjusted to each case, in order to seize the advantages of each reinforcement material. In particular, concrete cover, and allowable crack width will be adjusted as appropriate, while designed for a nominal service life of 100 years. The life-cycle cost of the structure will be computed, considering initial costs and typical maintenance operations during the nominal life. A comparative analysis will be carried out in terms of the LCC in two different environmental scenarios.

2 ARCHETYPE STRUCTURE

A 20 m span bridge deck, consisting of prestressed concrete girders is taken as an archetype structure for this study. This type of bridge is one of the most extended solutions in most countries; hence, it is considered as representative for a big number of situations. Figure 1 shows the cross-section of the deck, showing the general dimensions and the number of girders and general data of the concrete girder. The girder will be prestressed with pre-tensioned strands. It is assumed that the complete bridge has 3 identical simply supported spans of 20 m, with identical deck configuration.

Figure 1. Bridge deck cross-section and concrete girder cross-section general data.

The structure is considered to be located in a coastal environment, at less than 5 km from the Mediterranean coast of Spain. The permanent loads acting on the structure are its self-weight, additional dead load of 3 kN/m^2 , accounting for pavement, rails, and sidewalks. The variable loads considered in the design are a load of 4 kN/m^2 , distributed in the worst position, and a moving vehicle load of 600 kN.

Two alternative designs were carried out; namely, one using carbon steel (CS) tendons and another with CFRP tendons. Passive reinforcements are also made of CS and CFRP, respectively. The minimum cover for the CS prestressed structure was selected as 35 mm, based on Spanish specifications (EHE-08) for this type of environment. This cover must be guaranteed in construction; hence, a bigger specified cover of 40 mm is used, which includes the construction tolerance. The latter is used for the design of the reinforcement, was 40 mm. In addition, the prestressing is designed to guarantee no-decompression under the frequent load combination.

As CFRP tendons are not affected by corrosion, cover and maximum crack width are not controlled by durability requirements. However, concrete cover affects the bond performance of the strands. Therefore, a concrete cover of 10 mm was considered in design, according to the Eurocode 2 draft of version of 2022 (CEN, 2022). The maximum crack width considered in design was 0.4 mm under frequent load combination, defined for aesthetic reasons. Table 1 summarizes the material properties considered in both designs.

FRP reinforcement exhibits linear elastic stress-strain behavior up to failure, with smaller elastic modulus than steel. Limited element ductility of the element can be achieved only through the concrete response, when failure is controlled by concrete crushing rather than reinforcement tension, i.e. over-reinforced design. The smaller elastic modulus is potentially beneficial for reduction of prestress losses, moreover typical relaxation loss of pretension force is also smaller. Particularly, in the case of CFRP, relaxation may be less than 50% of that of steel tendons, ACI 440 (2011), Oller et al (2022), Rossini (2019).

Although FRP is not affected by corrosion degradation, different phenomena degrade its mechanical capacity in the long-term. On one hand, creep-rupture is the tensile fracture of the

Table 1. Material properties considered in design.

Parameter	Steel	CFRP
Strand area (mm ²)	140	140
Wedge penetration (mm)	5	5
Characteristic strength: f_{pk} (MPa)	1860	2137
Elastic Modulus: E (GPa)	190	126

material subjected to sustained high stresses. Typical residual strength at long-term ranges between 30% and 80% of the short-term strength, with smaller values for glass fibers, intermediate values for aramid fibers, and larger sustained resistance in the case of carbon fibers (CFRP). This phenomenon limits the maximum permanent load of the FRP which, in turn, will require lower pretension ratios of the material strength compared with steel. The larger resistance to sustained loads of the CFRP suggests it as more adequate for prestressing applications.

On the other hand, strength is also degraded under temperature produced by solar radiation and aging. In general, guidelines and codes provide reduction factors for the strength and allowable sustained load to consider in design, e.g. ACI-440 (2011), Model Code 2010 (fib, 2013), Eurocode 2 (CEN, 2022). However, it should be noticed that some differences still exist between them when implementing the strength reduction factors and the design safety factors. In this study, the design of the CFRP bridge was carried out following the informative annexes of the latest available draft Eurocode 2 (CEN, 2022).

Two alternative designs were carried out considering steel and CFRP reinforcements, considering ultimate limit state (ULS) of normal and tangential forces. The service limit states (SLS) were considered, including different crack limitations for steel and CFRP reinforcement alternatives, as described above. In both cases, the provided longitudinal reinforcement was controlled by ULS conditions rather than SLS.

Table 2. Comparison of designs with alternative reinforcements.

	Steel	CFRP
Number of strands	18	29
Passive long. reinforcement	4Ø2	-
Transversal reinforcement	1Ø10 stirrups/140 mm	1Ø15 stirrups/300 mm
Cost per girder	5,000 €	13,000 €
Normalized cost to reference girder	1	2.6

Table 2 summarizes the main differences of the two designs, as well as the estimated cost per girder. It is noticed that the CFRP alternative exceeds the cost of the steel girder by a factor of 2.6. This result is consistent with similar costs analyzed in other studies, such as Balafas and Burgoyne (2003). In the following, all costs will be presented normalized to the cost of the steel reinforced alternative.

3 LIFE CYCLE COST

Life cycle cost (LCC) considers the costs related to the construction (CC), inspections (CI), maintenance repairs (CM), and failure cost (CD) during the design life span of the structure, as described in Equation (1). CC is considered to occur at initiation of the service life, which is taken as reference. The remaining costs occur at different time instants during the analyzed time. Therefore, they are adjusted the present value (PV), by multiplying the cost expended in time t by the factor $PV(t)$ defined in Equation (2). It is considered that the decommission cost at the end of life is the same for the two alternative designs. Hence, it has not been included in Equation (1), as the goal of the analysis is comparing the economical differences between them.

$$LCC(t) = CC + CI + CM + CD \quad (1)$$

$$PV(t) = (1 + s)^{-t} \quad (2)$$

In Equation (2), s is the discount rate of money and t is the time, in years, where the cost takes place. The discount rate accounts for the opportunity cost and inflation rate. The choice of the discount rate s depends on the expected economical conditions, capital risk of the facility owner or investor. In previously LCC analyzes conducted on medium length bridge structures s has ranged between 3% in Grace et al (2012), while Hasan et al (2019) used a discount rate of 2%. In this study, the discount rate is taken as the average of these values, $s=2.5\%$.

Inspection costs (CI) accounts for routine inspections to assess the condition of the structure. The associated costs include the displacement of inspection engineers, minor operations. The cost of each inspection is estimated as $0.005CC$, similarly to the adopted value in Grace et al (2012). The previous costs are associated to direct agency expenditure. However, maintenance operations generate additional costs to the users of the infrastructure due to the affectation of the service, which have not always been estimated in previous studies. The present study will consider the cost of the infrastructure users (UC) during maintenance, inspections and repair works.

The users' cost is estimated using the equations proposed in Ehlen (1999). This cost consists of three contributions; namely, the increment of drivers' delay (DD) cost (Equation 3), vehicle operation (VO) cost (Equation 4), and accident increment (AI) cost (Equation 5) during the affectation of the road.

$$DD = \left(\frac{L}{S_a} - \frac{L}{S_n} \right) \times ADT \times N \times w \quad (3)$$

$$VO = \left(\frac{L}{S_a} - \frac{L}{S_n} \right) \times ADT \times N \times r \quad (4)$$

$$AI = L \times ADT \times (A_a - A_n) \times c_a \quad (5)$$

Table 3. Parameters for estimating users costs during inspections and major repairs.

Parameter	Symbol	Units	Inspection	Major repair
Length affected road	L	km	2	5
Average daily traffic	ADT	cars/day	30000	30000
Duration of works	N	days	1	90
Normal speed	S_n	km/h	120	120
Speed during works	S_a	km/h	80	40
Normal accident rate	A_n	1/(veh*km)	1.50E-06	1.50E-06
Accident rate during works	A_a	1/(veh*km)	2.00E-06	2.00E-06
Drivers hourly time value	w	€/h	10	10
Vehicle hourly time cost	r	€/h	8	8
Cost per accident	c_a	€	100000	100000
User cost	UC	€	7500	4725000
Normalized user cost per girder*	UC	CC	0.042	26.25

*considering 18 girders in the bridge

In Equation (3) through (5), L is the road length affected by maintenance works. S_n and S_a are the traffic speed at normal situation and affected by the works, respectively. ADT is the average traffic rate, in vehicles per day. N is the number of days during the affection. A_n and A_a are accidents rate of the road in normal situation and during the affectations, in terms of accidents per number of vehicles in the road and km. w is the drivers' hourly value, r is the vehicle hourly cost, c_a is the cost per accident. The values considered for estimating UC are summarized in Table 3, for routine inspections and major repairs.

The total inspection cost is computed as indicated in Equation (6), where c_i is the cost of a routine individual inspection (0.005CC) in time t_i , and UC is the user cost. Routine inspections are planned at a frequency of 5 years.

Maintenance cost (CM) are computed according to Equation (7), based on the formula used in Hasan et al (2019), where the users' cost has been added. In Equation (7), t_m is the time when a major repair is made, associated to chloride induced corrosion deterioration detected during routine inspections. This repair may consist on the activities associated with the removal of cover, reinforcement protection, and restitution of concrete cover, or the substitution of a heavily deteriorated girder, as well as the auxiliary means needed for the works. The relative cost of a unit major repair (c_r) is estimated as 5CC. UC is the users' cost during a major repair, as shown in Table 3. $P_{sf}(t_m)$ is the probability of the durability limit state failure in time t_m .

The cost of ultimate limit state failure is computed according to Equation (8). The term c_d in Equation (8) includes the cost of bridge replacement, casualties and injuries cost, functional disruption, and environmental, social, cultural and historical cost. It is assumed that $c_d=10CC$, like in Hasan et al (2019). $P_{uf}(t)$ is the probability of failure of the ultimate limit state in time t . Differently from the inspection and maintenance costs, which are expended only during inspections and maintenance, the probable CD cost during each year is computed in the LCC.

$$C_I(t) = \sum_{t_i} PV(t_i)(c_i + UC) \quad (6)$$

$$C_M(t) = \sum_{t_m} PV(t_m)(c_r + UC)P_{sf}(t_m) \quad (7)$$

$$C_D(t) = \sum_t PV(t) c_d P_{uf}(t) \quad (8)$$

4 ANALYSIS SCENARIOS

As described in the previous section, LCC includes the initial construction costs and the maintenance costs associated to regular inspections, planned every 5 years, and major repairs. Major repairs are considered to be triggered by damage already detected during the regular inspections, e.g. steel depassivation, surface cracks, etc. In order to determine the time when a major repair will be carried out, degradation of the nominal reliability to durability limit state (DLS) is simulated.

As depicted in Figure 2, the nominal reliability is considered to be constant until the critical chloride concentration reaches the reinforcement layer. For prestressed steel reinforcement, the critical chloride concentration is taken as 0.3% of the weight of cement, based on EHE-08 (2008). This occurs in the initiation time (t_i), which can be computed from Equation (9), where K_{cl} is the chloride penetration coefficient of the concrete, and d is the reinforcement cover. After this moment, the steel process starts at a corrosion velocity (v_{cor}) that depends on the environmental conditions and chloride concentration. To estimate the rate of DLS reliability, it is considered that the initial reliability is the nominal code annual value (3.0) and decays to a minimum (1.0) when the corrosion produces a pit of 0.01 mm. The ULS reliability is assumed to decay at the same average rate.

$$t_i = \left(\frac{d}{K_{cl}} \right)^2 \quad (9)$$

Figure 2. Degradation of annual reliability to DLS and threshold triggering major repairs.

In the years in which regular inspections are made, the DLS reliability is compared with a threshold value and, if detected to be lower than the threshold, a major repair is computed that year. It is assumed that, after each major repair, the durability reliability is completely reestablished, and the process starts again. Notice that, with this maintenance strategy, it is possible that the threshold is crossed in between inspections, but will not be detected until the next inspection. The amount of damage and, consequently, probability of ULS failure increase between inspections.

In the described maintenance protocol, major repairs and probabilities of failure depend on the concentration of chloride in the environment that causes corrosion. In this study, two different scenarios are investigated, summarized in Table 4. Scenario 1 corresponds to the surface chloride concentration of 0.14% of the weight of concrete, as considered for this design exposure class in EHE-08 (2008). This value is of similar to the one reported in Val and Stewart (2003) for atmospheric chlorides at 1 km from the coast. This scenario is considered representative of the current environments. Nevertheless, chloride concentration in air may increase in the future, due to increase of sea level and wind speeds produced by climate change. Therefore, a second scenario is also investigated with a more severe surface chloride concentration of 0.25%. Table 4 also summarized the corrosion velocity considered for each scenario, and the corrosion initiation and propagation times.

Table 4. Chloride exposure scenarios.

Scenario	Cs (% concrete)	v_{cor} ($\mu\text{m}/\text{year}$)	t_i (years)	t_p (years)
1	0.14	20	15	8.5
2	0.25	25	7.7	6.8

Based on the previous scenarios, the DLS reliability degradation are plotted in Figures 3a and 3b, for scenarios 1 and 2, respectively. As CFRP is not affected by chloride corrosion, a minor degradation rate is considered for this reinforcement, as shown in Figure 3c, which is the same for both scenarios. The figure also shows the threshold crossing events for all cases, which trigger a major repair event. Notice the first threshold crossing in scenario 2 occurs 5 years earlier than in scenario 1. Similarly, 4 threshold crossings take place in scenario 1, compared to 6 in scenario 2. No threshold crossing occurs in the CFRP design alternative.

Figure 3. Degradation of nominal DLS annual reliability and threshold triggering major repair. a) Design with steel tendons in scenario 1, b) Design with steel tendons in scenario 2, c) Design with CFRP tendons.

Figure 4 shows the maintenance calendar for each designed structure. The routine inspections, scheduled at a frequency of 5 years, are applied to all three alternatives during the whole service life. Major repairs only take place in designs with steel tendons, as described above.

5 RESULTS

Figure 5 compares the LCC of the steel and CFRP alternative designs under scenario 1 (Figures 5a and 5c) and scenario 2 (Figures 5b and 5d). Curves in the upper row (Figures 5a and 5b) include the users' costs (UC), while this cost was excluded in the bottom row (Figures 5c and 5d) for comparison purpose. All costs are normalized to the CC of the steel tendons alternative.

Although CFRP has an initial cost of 2.6CC, its LCC shows a moderate increment in time, as no major repair was considered. The maximum LCC of CFRP after 100 years is estimated

Figure 4. Maintenance calendar showing inspections, and major repairs. a) Design with steel tendons in scenario 1, b) Design with steel tendons in scenario 2, c) Design with CFRP tendons.

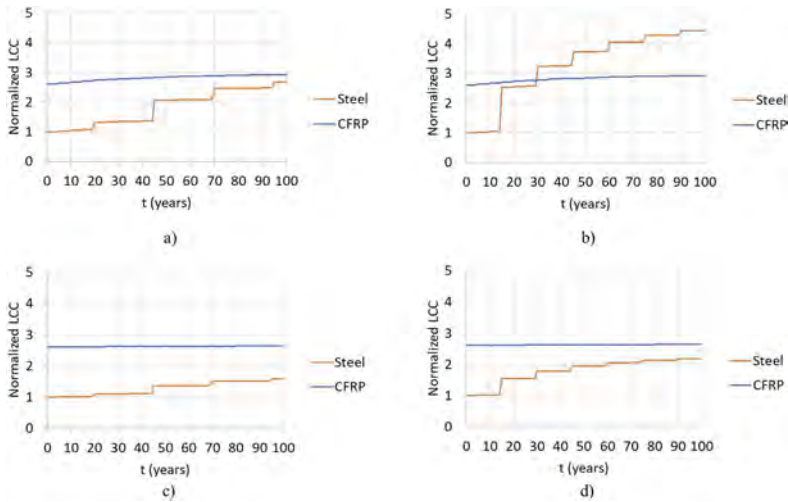

Figure 5. Compared LCC for designs with steel and CFRP tendons. a) scenario 1 including UC, b) scenario 2 including UC, c) scenario 1 without UC, d) scenario 2 without UC.

Table 5. LCC and payback time for each scenario.

Scenario	Users cost	LCC steel (CC)	LCC CFRP (CC)	Payback time(years)
1	included	2.68	2.93	>100
2	included	4.44	2.93	29
1	not included	1.58	2.64	>100
2	not included	2.18	2.64	>100

as 2.93 CC. On the other hand, LCC of steel tendons alternative steel increases up to 2.68 in scenario 1, and 4.44 in scenario 2, when the UC are accounted for. Comparing the top and bottom rows, it is evidenced that the UC contributes with 40% to 50% of the total LCC.

Table 5 compares the computed LCC for the different designs, in the two scenarios. The table also shows the payback time of CFRP alternative, considered as the time needed to recover the initially larger investment of the CFRP reinforcement. Notice, that in the scenario 1, the LCC of the steel alternative does not exceed that of CFRP in scenario 1 during the analyzed time. Therefore, the payback time is reported as larger than 100 years. As the payback time is larger than the period of interest, it is concluded that the steel alternative should be preferred in this scenario.

On the other hand, scenario 2 represents a more aggressive environment, which triggers more major repair works. Even more relevant is the earlier need for major repairs in scenario 2, which implies a larger PV of these works. Therefore, the payback time in scenario 2 occurs on year 29. Conversely, if UC are not accounted for, no payback time is found within the period of analysis.

6 CONCLUSIONS

The LCC of a medium-span prestressed concrete bridge girder was analyzed in a coastal environment. Two alternative designs were investigated, one with carbon steel tendons and passive reinforcement, representative of the majority of current applications. The second alternative used CFRP tendons and transverse reinforcement. In addition to the construction cost, the life cycle costs of inspections, major repairs, users cost, and ultimate failure were valued. The maintenance strategy consisted of routine inspections, expected in the maintenance plan, throughout the life span. Major repair was considered triggered by a degradation threshold. Two environmental scenarios were simulated, representative of surface chloride concentration in current codes (scenario 1), and a potential increment due to climate change (scenario 2). After this analysis, the following main conclusions can be drawn.

The current cost of CFRP reinforcement makes its initial construction cost in the order of 2.6 times the construction cost of the girder with steel tendons. Due to this initial cost, a payback time is not reached in the scenario 1 during the design service life of 100 years. Scenario 2, with the higher chloride surface concentration, showed a payback time within of 29 years, when the cost of the affectation to the users is valued. Although this value lies within the service life of the structure, it might be large from a financial point of view of road managers. An improved design of the concrete steel structure could show a better performance in the LCC, at the expense of a moderate increment of the CC.

The cost of the affectation to the users during maintenance operations has relevant share of the total LCC, particularly, during the major repairs. Neglecting these costs will underestimate the real cost of the maintenance. In this case, no payback time is found in neither of the 2 scenarios analyzed.

Numerical analysis of short-term performance of CFRP new composite anchorage

S.Y. Sun

Department of Bridge Engineering, College of Highways, Chang'an University, Xi'an, China

ABSTRACT: The transverse and interlaminar shear strength of carbon fiber reinforced composites (CFRP) is smaller than its tensile strength, and the traditional clip-type anchorages used to anchor steel cables will exert a large occlusal force on the tendons. As a result, the CFRP tendon fails prematurely and cannot fully exert its high axial strength. The composite anchorage avoids the large stress concentration generated by the mechanical clamping anchorage at the anchorage port, and also avoids the bond-slip damage that is prone to occur in the bond-type anchorage, so that the high-strength characteristics of CFRP tendons can be fully utilized. A finite element model of a new type of composite anchorage was constructed, the failure mode of the anchorage, the ultimate load of the tendons, and the slip deformation were explored, and the stress-strain curve and the load-slip curve were obtained. The length of the steel sleeve, the inclination angle of the clip, Influence of parameters such as preload on the pull-out test results of the composite anchorage. The finite element results show that the anchoring efficiency increases with the increase of the bond length, and the anchoring efficiency increases with the increase of the inclination angle of the clip. Increasing the pre-tightening force helps to enhance the anchoring efficiency.

1 INTRODUCTION

Cable-stayed Bridges are used in rivers because of their beautiful appearance, convenient construction and strong crossing ability. The increase of the span of cable-stayed Bridges leads to the increase of the requirements on the length and diameter of cable-stayed Bridges. Because the cable-stayed cables in the state of high stress will receive fatigue vibration and electrochemical corrosion, the service life of cable-stayed Bridges will be limited and the wide application of cable-stayed Bridges will be affected.

Carbon Fiber Reinforced Polymer has the advantages of high strength, high elastic modulus, corrosion resistance and fatigue resistance. (Wang, 2005) Replacing steel cables in cable-stayed bridges can greatly reduce the maintenance cost during the design reference period, and because its specific strength is higher than that of high-strength steel, it can greatly improve the bearing efficiency and span capacity of cable-stayed bridge, which is conducive to the full use of cable-stayed bridges.

Although CFRP has high axial tensile strength, the strength and modulus perpendicular to the fiber direction are much lower than that of the fiber direction. The traditional clip anchorage used to anchor steel cables will produce a large bite force, resulting in the shear failure of tendons at the anchorage port cannot give full play to its advantages. Therefore, a safe and reliable anchorage system is the key to determine whether CFRP reinforcement can be used in cable-stayed bridges. If we want to apply CFRP tendons to bridge engineering better, we need to develop small size, simple anchoring technology, safe and reliable anchorage.

2 DEVELOPMENT OF ANCHORAGE AT THE PRESENT STAGE

According to different anchoring principles, CFRP anchorage can be divided into three types: mechanical clamping anchorage, bonding anchorage and mechanical clamping-bonding composite anchorage.

Mechanical clamping anchorage mainly relies on the friction force and bite force between the clip or cone plug and CFRP tendons to achieve anchoring. Since the transverse shear strength of CFRP tendons is low, the tendons are easy to be sheared at the stress concentration of the anchorage port. Measures should be taken to protect the tendons from being sheared.

Nanni, Sayed And Mahmoud et al. improved the traditional clip anchorages from the aspects of improving the friction between the clips and CFRP tendons and reducing the shear force of the clips on CFRP tendons. However, their reliability is generally not ideal. The surface form of CFRP tendons is required to be high and the versatility is not strong. (Nanni 1996, Sayed-Ahmed 1998, Taha 1998, Taha 2003)

Campbell et al. designed a wedge clip-type anchorage, used finite element method to simulate the stress distribution of tendons in the anchoring area, and tested the static load performance of the anchorage through tests. (Campbell, 2000)

Bonding anchorages mainly transmits the shear force through the bonding force and friction force on the interface, which can prevent excessive stress concentration. The anchorage reliability is high, and the fatigue performance is better than that of mechanical clamping anchorage, but the anchorage length is long.

Meier et al. designed a CFRP anchorage with variable stiffness bonding medium to make the shear stress distribution on the contact surface of bonding medium more uniform than that of single stiffness bonding medium. (Meier, 1996)

Mei Kuihua et al. respectively conducted a static performance test study on the bonding type anchorage system with 6, 11 and 16 CFRP tendons, and applied it to the first domestic CFRP cable-stayed bridge. (Mei, 2005)

Zhang and Fang et al. designed 9 and 12 CFRP tendons bonding type anchorage system using reactive powder concrete as bonding medium, and applied it in two pairs of CFRP slings of Aizhai Bridge. (Zhang 2013, Fang 2015)

The composite anchorage can be connected in series or parallel with the mechanical clamping anchorage and the bonding anchorage to give full play to the advantages of the mechanical clamping anchorage and the bonding anchorage, but there are relatively few relevant studies.

Mei Kuihua proposed a new CFRP tendons composite anchorage, which is made of aluminum casing as the perfusion vessel inside, uses epoxy resin to bond multiple tendons, and exerts pre-extrusion pressure on the adhesive part outside in the way of mechanical clamping, and good anchoring efficiency is obtained. (Mei, 2021)

To solve the above problems, this paper developed a new type of mechanical grip-bond composite anchoring tool with small size and excellent anchoring performance by optimizing the inner wall Angle and anchoring length of the anchoring tool. Its essence is still the bonding anchorage, which provides extrusion pressure for mechanical clamping to improve the bond strength of the anchorage. Through static load test, the anchoring efficiency coefficient and load-slip performance of the anchorage were studied, as well as the influence of inner wall inclination angle, bonding length and other parameters on the anchoring performance of the anchorage. which proves that the new anchorage has good anchoring performance.

3 ANCHORAGE TEST DESIGN

3.1 Anchorage design

The anchorage is composed of steel sleeve, clip, aluminum casing pipe, colloid, tendons and bolt. The bonding medium of the bonding part is wrapped by aluminum casing pipe, which can effectively transfer the pre-tightening force generated by the clip to the bonding medium,

so as to obtain better anchoring effect. The steel sleeve with external constraints is also shaped like an inner cone to better adapt to the shape of the bonding area.

An inclination angle difference of 0.1 degree is set between the inner wall and the outer wall of the steel sleeve. Due to the existence of the inclination difference, there is a gap between the clip and the steel sleeve near the loading end, which can effectively avoid stress concentration.

3.2 Anchorage test process

Push the anchorage assembled by each part to achieve pretightening at both ends. Push the anchorage in place at one time and the thrust force is 130kN.

Before the formal tensioning, the anchorage was pre-tensioned three times, and the pre-tensioned load was 40% of the theoretical breaking force of the cable.

According to the theoretical ultimate tensile strength of CFRP tendons provided by the manufacturer of 78.68kN, the theoretical ultimate tensile strength of cable anchorage is calculated to be 400kN. The cable anchorage system shall be loaded at a constant speed of 0.1F_{ptk}, (40kN) at the loading grade of 0.5F_{ptk} (200.5kN) for 1 hour, and at other load levels for 5 minutes. If no tendon slips or tension occurs when the anchorage system is stretched to 1.0F_{ptk} (400kN), the load shall be maintained for 1h.

The specific experimental loading time-load curve is shown in the figure.

Figure 1. Static load test time load curve.

This model will be developed on the basis of the above experimental scheme.

4 FINITE ELEMENT MODEL

4.1 Material data

4.1.1 Assembly of anchorage

The material parameters required in the experimental model are shown in the following table

Table 1. Mechanical properties of epoxy resin.

Modulus of elasticity / GPa	Poisson's ratio	Tensile strength / MPa	Shear strength / MPa	Compressive strength / MPa
2.61	0.25	40.5	24.3	73.6

4.2 Original model design drawing

The design drawing uses the steel sleeve with a length of 200mm and the clip with a length of 250mm. A composite anchorage with an inner wall inclination angle of 3.9° is designed, that is,

Table 2. Mechanical properties of steel barrel, aluminium tube and CFRP tendon.

Physical Parameters material	Modulus of elasticity /GPa	Poisson's ratio	Ultimate tensile strength /MPa	Ultimate elongation /%
Steel sleeve	210	0.31	600	-
Aluminium casing pipe	71	0.31	90	-
CFRP tendons	147	-	2300	1.44

the inner wall inclination angle of the steel sleeve is 3.9° , the outer inclination angle of the clip is 4° , the inner inclination angle is 3° , and the aluminium casing pipe inclination angle is 3° .

Figure 2. Original anchorage design drawing.

4.3 Establishment of finite element model

4.3.1 Basic model

Figure 3. Basic model modeling diagram and Grid division diagram.

Each component of anchorage is simulated by solid65 unit, with 136806 units. The surface-to-surface contact element is used to simulate the interaction between the components of the cable anchorage system. Conta173 and Target170 were used for the contact surface and the target surface respectively. There are 23,784 contact elements in total. The friction coefficient between the steel sleeve and the clip is 0.2; The friction coefficient between the clip and the aluminum casing pipe is 0.2, referring to the friction coefficient between steel and aluminum. The contact algorithm adopts the hybrid method combining Lagrange multiplier method and penalty function method, and the contact surface behavior adopts the non-separation (allow sliding) mode. The external load is applied to the end of the tendons in the form of surface load, and the steel sleeve is treated by consolidation at the free end to simulate the constraint conditions of the anchorage.

Figure 4. Original anchorage load-slip curve.

The curve development process of finite element calculation is that at the initial stage of loading, the slip of tendon increases slowly with the increase of load. When the load reaches 100kN, the slip begins to increase significantly. The maximum slip of the inner tendon and the outer tendon of the anchorage is 4.8mm and 4.7mm. The slip amount of the inner tendon is slightly larger than that of the outer tendon, which indicates that the layout of the inner and outer layers of the tendon has a certain influence on the axial force distribution of the tendon.

4.4 Variable parameter analysis

4.4.1 Changing the bond length

In this section, the influence of the bond length of anchorage on the anchorage capacity is investigated.

The anchorage length of the anchorage was increased by increasing the size of all members by 30mm. The load-slip curve is shown in the figure.

Figure 5. Load-slip curve of anchorage after increasing bonding length.

When the ultimate load is reached, the maximum slip of the inner and outer tendon is 4.1mm, which is about 0.5mm less than the original test result, and the slip of the whole loading process is smaller than that of the original design anchorage. Compared with other models, the slip in the second half of the load changes significantly slower, which indicates that the increase of bonding length mainly plays an important role in the later stage of loading, reducing the slip of the tendon relative to the colloid. It can be inferred that: firstly, the increase of bonding length can increase the contact area between the components of the anchorage, increase the friction force, and reduce the relative slip between the components;

Secondly, the increase of bonding length leads to the increase of the contact area between the tendons and the colloid, thus increasing the bonding force between them, and finally reduces the slip of tendon when loading.

4.4.2 Changing the inclination angle of anchorage

In this section, the influence on the anchorage capacity of the anchorage is investigated by reducing the inclination angle of each component inside the anchorage by 0.5° .

Figure 6. Load-slip curve of anchorage after change of inclination angle.

By comparing the figure with the figure, it can be found that reducing the internal inclination angle of the anchorage by 0.5° has no effect on the time when the relative slip of the tendon occurs. The only difference is that after the internal inclination angle is reduced, the maximum slip of the tendon when reaching the ultimate load increases by 0.2 mm. On the whole, it can be inferred that the overall reduction of the inclination angle of each component in the anchorage has no obvious impact on the anchorage performance of the anchorage.

4.4.3 Changing the jacking force

The influence of preload on anchoring effect of five-tendons anchorage was investigated by changing the preload.

Figure 7. Load-slip curve of anchorage after changing jacking force.

The preload value of the original anchorage was 130kN, and the preload was changed to 145kN by variable parameter analysis, and the load-slip curve of the free end of the inner and outer tendon under different preload was plotted in the figure. First, it can be seen that the change of preload does not make a big difference in the load-slip distribution of the inner and outer tendon. However, when the preload is 130kN, the external load of the tendon is 100kN,

and when the preload is 145kN, the external load corresponding to the obvious slip of the tendon is 110kN respectively.

To sum up, it can be analyzed that: (1) the change of preload will make the load slip of the tendon in the inner and outer layers of the anchorage change at the same time, and the change degree of the inner and outer layers is the same, without obvious difference; (2) Within a certain range, the increase of the preload will make the relative slip of the tendon occur later, mainly because the increase of the preload makes the internal parts of the anchorage more tightly squeezed, and the colloid is subjected to greater extrusion pressure, thus producing greater bonding force and friction force on the tendon; (3) Within a certain range, the increase of the preload will reduce the maximum slip of the tendon. According to the finite element simulation results, when the preloading force reaches 145kN, compared with 130kN, the weakening effect on the tendon slip is small, only decreasing by 0.09mm.

4.4.4 Changing colloidal elastic modulus

For the colloid that plays an important role in anchoring tendons, its main physical properties are elastic modulus, tensile strength, shear strength, compressive strength, friction coefficient and so on. Keeping other parameters of the colloid unchanged, the influence of the change of the physical properties of the colloid on the anchoring efficiency of the anchorage device is investigated by changing its elastic modulus. The elastic modulus of the original model colloid is 2.61Gpa, and the colloidal elastic modulus of anchorages was changed to 2.2Gpa in the finite element simulation, respectively. The relative load-slip curve of the free end of the tendon was shown in the figure.

Figure 8. Load-slip curve of anchorage after changing colloidal elastic modulus.

As can be seen from the figure, the change of colloidal elastic modulus has little influence on the inflection point of significant slip of the tendon, and the simulated anchorage has obvious slip of the tendon when the external load reaches 100kN. When the elastic modulus of the model is 2.2Gpa, the slip of the tendon reaches the ultimate load is 0.4mm larger than that of the original model. This shows that within a certain range, when other parameters remain unchanged, the larger the elastic modulus of the colloidal, the better the anchoring performance of the anchorage, mainly because under the same stress conditions, the larger the elastic modulus of the colloidal, the greater the deformation, thus the extrusion pressure and bonding force on the tendon will also increase.

5 CONCLUSION

The finite element model was established according to the size and material parameters of the anchorage, and the load-slip curve of the anchorage under different parameters was compared

by changing one of the parameters of the model for analysis and calculation, and then the influence of different parameters on the anchoring efficiency of the anchorage was deduced.

The conclusions are as follows:

- (1) To a certain extent, the increase of bonding length will reduce the slip of tendon and enhance the anchoring performance.
- (2) On the basis of the original design parameters, changing the internal inclination angle of the anchorage has little effect on the anchoring efficiency of the anchorage, and the inclination angle of the anchorage designed for the static load test does not need to be optimized.
- (3) Increasing preload and colloid elastic modulus has limited effect on improving anchorage performance, so it is unnecessary to greatly increase the cost of anchorage for improving the limited anchorage performance of current anchorage.

Preliminary assessment on the effects of longitudinal cracks on carbonation-induced corrosion

N. Russo, M. Gastaldi & F. Lollini

Department of Chemistry, Materials and Chemical Engineering “Giulio Natta”, Politecnico di Milano, Milan, Italy

L. Schiavi & A. Strini

Construction Technologies Institute, National Research Council of Italy (ITC-CNR), San Giuliano Milanese, Milan, Italy

ABSTRACT: Currently available models for reinforced concrete (RC) durability still lack the inclusion of the effects of cracks, which are inevitable in concrete structures, and literature on the effects of cracks on carbonation-induced corrosion is scarce, especially in case of cracks longitudinal to the reinforcement. This paper presents some preliminary experimental results on the effects of longitudinal micro-cracks on carbonation-induced corrosion, initiation and propagation phases. Experimental tests were performed to evaluate the penetration of carbonation, under accelerated conditions, in cracked and uncracked concrete made with different cement types and *w/c* ratios. Corrosion propagation was monitored, through electrochemical techniques, in longitudinally cracked and uncracked RC specimens subjected either to natural or accelerated carbonation. Results showed a more marked effect of the micro-crack on carbonation penetration in more impervious concretes, while the presence of the micro-crack did not seem to significantly affect corrosion propagation, except when developing to rebar depth.

1 INTRODUCTION

Durability models, based on reliable modelling of the service life of reinforced concrete (RC) structures, are typically performed as a function of the initiation and propagation of corrosion of steel reinforcement, and are of fundamental importance to meet the sustainability targets in the construction field (Bertolini et al. 2013). However, even the most accredited models present some limitations that still need to be addressed to, such as the inclusion of the effects of cracks, which are inevitable in concrete and may alter the corrosive process. The limited knowledge concerning the effects of cracks on durability performances, especially in the case of carbonation-induced corrosion, contributed to slow their improvement at this regard.

Considering the penetration of carbonation in concrete, initially cracks lead to a general increase in the penetration rate of gaseous CO₂ from the environment. Subsequently, as carbonation proceeds, the precipitation of calcium carbonate in the form of calcite, vaterite and aragonite, that occupy a volume about 3 to 20% higher, leads to a partial closure of small cracks with time, as a form of carbonation-induced autogenous healing (Liu et al. 2021). Studies on carbonation penetration in unreinforced specimens and under accelerated carbonation showed that even micro-cracks (width at the exposed surface lower than 100 µm), could significantly affect the resistance to carbonation penetration. In Alahmad et al. (2009), a significant penetration of carbonation perpendicularly to crack walls was reported, similar to uncracked conditions for cracks wider than 60 µm, with a progressive decrease for cracks about 40 µm wide, and negligible for crack narrower than 9 µm. In Bogas et al. (2019), a method was proposed to retrieve the carbonation coefficient inside the crack, founding a carbonation coefficient 3.7 times higher in the crack with respect to uncracked concrete for a 100 µm wide artificial crack (obtained through metallic plates at fresh state), while in specimen with load-induced crack about 150 µm wide the increase resulted of

about 2.7 times. In Carević & Ignjatović (2019), some simulations were performed after carbonation depth measurements under accelerated conditions. It was estimated, according to *fib* Model Code 2010, that in the case of 300 μm wide crack, under natural carbonation, the service life of the structure would have been reduced of about three times with respect to uncracked conditions, assuming depassivation of steel as ultimate limit state.

Considering carbonation-induced corrosion in reinforced concrete, the presence of a crack can alter both the corrosion initiation and propagation processes. In fact, when a crack develops to rebar depth, an alteration in the protective alkaline environment normally provided by sound concrete may occur, and corrosion may preferentially take place where crack tip reaches the steel reinforcement (as observed for chloride-induced corrosion in Leporace-Guimil et al.). Moreover, once corrosion started, corrosion rate could further be increased by the generation of a small anode to large cathode ratio (ACI Committee 201, 2016). Literature on this topic is more limited in the case of cracks in the longitudinal direction of the reinforcement with respect to the transversal direction, which may form in bidimensional elements, or due to shrinkage, or plastic settlement of concrete. Longitudinal cracks may influence the corrosion process to a higher extent, since aggressive species (carbonation, moisture, oxygen, ...) can more easily reach a wider area of embedded steel surface (Shaikh 2018). To conclude, the subject is not only complex due to the number of variables affecting durability parameters, but also to the different experimental procedures and materials used in different studies, which make it difficult to derive unambiguous conclusions.

This paper presents some preliminary experimental results on the effects of cracks on carbonation-induced corrosion initiation and propagation. Experimental tests were performed to evaluate the penetration of accelerated carbonation in cracked and uncracked unreinforced specimens, considering different cement types and *w/c* ratios, and cracked through a specifically developed loading procedure. Corrosion propagation was monitored in cracked and uncracked concrete specimens subjected either to natural or to accelerated carbonation. In this case, concrete was obtained with Portland-limestone cement and *w/c* of 0.45, reinforced with carbon steel bars, and cracked using the same procedure to obtain a longitudinal micro-crack. Electrochemical techniques were used to detect corrosion initiation in specimens subjected to natural carbonation (exposed to outdoor unsheltered environment), and to monitor corrosion propagation in specimens previously subjected to accelerated carbonation and then exposed to outdoor unsheltered environment, considering a different orientation for the cracked surface.

2 MATERIALS AND METHODS

2.1 Specimens layout

Unreinforced specimens were realized considering three different cement types, *i.e.* an ordinary Portland (OPC, type CEM I 42,5R according to EN 197-1), a Portland-Limestone (PLC, type CEM II/A-LL 42,5R), and a Pozzolanic cement (PC, type CEM IV/A(V) 42,5R-SR), and two *w/c* ratios, *i.e.* 0.45 and 0.55. Reinforced specimens were made only with PLC cement type and *w/c* of 0.45. The mixes with 0.45 *w/c* ratio were obtained considering 422 kg/m^3 of cement, 190 kg/m^3 of water and 1731 kg/m^3 of aggregates, while those with *w/c* ratio equal to 0.55 were obtained with 422 kg/m^3 of cement, 232 kg/m^3 of water and 1619 kg/m^3 of aggregates. All the aggregates were crushed calcareous type, subdivided into 5 grain size fractions, with maximum diameter of 9 mm. An acrylic-based superplasticizer was also added to the mixes with 0.45 of *w/c* ratio, to reach, at least, a S3 class of consistency. As reinforcement, carbon steel bars with 16 mm diameters were employed, subject to sandblasting and degreasing with acetone prior casting. Moreover, to avoid side effects, the two ends of each rebar were masked with a styrene-butadiene-modified cement mortar and epoxy, leaving a total length of 80 mm exposed to the concrete.

A total amount of 6 unreinforced specimens per each cement type and *w/c* ratio were realized, out of which 2 in uncracked and 4 in cracked configuration, while a total amount of 16 reinforced specimens were realized, out of which 4 in sound (S), 9 in cracked (C) and 3 in heavily cracked (HC) configuration. All the specimens were characterized by prismatic geometry, with dimensions 120×90×50 mm, as reported in Figure 1. In cracked configuration, specimens presented

a longitudinal notch, about 3 mm depth, to promote the formation of the crack during the cracking procedure. In reinforced configuration, specimens were equipped with one carbon steel rebar (concrete cover thickness of 15 mm), an activated titanium wire (reference electrode) and a titanium wire (counter-electrode) for electrochemical measurements. Both unreinforced and reinforced cracked specimens were subjected to a specifically developed cracking procedure, within 24 hours after casting (thus to have a lower concrete mechanical resistance and a less brittle behaviour). The method was a sort of three-point bending procedure to induce a longitudinal micro-crack in correspondence of the notch. Specimens were encased in a steel confinement system and placed in a universal testing machine with the notch facing downwards, and interposing three stripes of synthetic elastomer membrane, 1.2 mm thick. Two were placed along the downward corners of the specimen, as the supports, and the other in central position on the upward face, as the loading pin. A displacement-controlled load was then applied, equal to 0.5 mm/min in the vertical direction. In unreinforced configuration, the load was applied until an overload level 45-55% higher than that corresponding to the first appearance of the crack was reached. Cracks were measured at the end of exposure to carbonation with the same procedure as in Russo et al. 2020, and resulted 30-160 μm wide and 30-40 mm deep. In reinforced configuration, the load was applied until the simultaneous appearance of the crack on both sides of the specimen, at least one of which was up to the rebar. To the 3 more heavily cracked specimens a further overload of 10 % was applied. For further details on the procedure and on the obtained cracks see past publications (Russo et al. 2020, Russo et al., in press). After the cracking procedure specimens were kept, together with the uncracked ones, in a curing chamber at a temperature of 20 °C and relative humidity higher than 90%, until the starting of tests.

Figure 1. Schematic representation of sound and cracked concrete specimens in reinforced configuration.

2.2 Resistance to penetration of carbonation

Specimens were moist cured for 28 days and subsequently were pre-conditioned and prepared for accelerated carbonation test according to EN 12390-12. All the surfaces of each specimen were then sealed with epoxy, except for the cast surface to be exposed to carbonation. Accelerated carbonation was performed in a chamber with 3% of CO_2 concentration, 60% of relative humidity and 20 °C of temperature for 30 and 70 days of exposure. At each exposure time, one portion of the specimen was split and phenolphthalein was sprayed, in order to highlight the carbonation profile. The split surface of the remaining part of the specimen was sealed again to be exposed for the other exposure time. Carbonation depth measurements were measured with a calliper, and were taken in correspondence of the central point and on three other points on each side, spaced 10 mm each (7 points in total). In cracked configuration the central measurement, *i.e.* in correspondence of the crack, was taken in correspondence of the maximum penetration depth, excluding the notch. The accelerated carbonation coefficient, K_{AC} , was derived according to the formula:

$$x = K_{AC} \cdot \sqrt{t} \quad (1)$$

where x = average carbonation depth; t = time. At each exposure time, in sound configuration a single coefficient was evaluated (K_s), considering the average penetration depth. In cracked configuration two coefficients were evaluated, one in correspondence of the crack (K_{cr}), considering the maximum penetration depth, and the other in the uncracked part of the specimen (K_{uncr}), considering measurements points at ± 20 and ± 30 mm from the central crack.

2.3 Carbonation-induced corrosion monitoring

Reinforced specimens for the monitoring of corrosion were moist-cured for 7 days. After curing, three cracked specimens were exposed to outdoor unsheltered conditions, one with the surface containing the crack oriented horizontally, one vertically and one heavily cracked horizontally. Specimens were periodically monitored, thorough electrochemical measurements, to detect corrosion initiation and monitor corrosion propagation. The other reinforced specimens in uncracked and cracked configurations were exposed to accelerated carbonation to induce corrosion initiation, in the carbonation chamber with 3% of CO₂ concentration, 60% of relative humidity and 20 °C of temperature. Specimens were periodically taken out of the carbonation chamber to electrochemically assess whether corrosion was initiated. After corrosion initiation was detected, specimens were exposed to external unsheltered conditions, considering either horizontal orientation or vertical orientation of the crack (as in a floor or a vertical element, respectively).

As electrochemical measurements, the half-cell potential (E_{corr}) was measured versus a saturated calomel electrode (SCE), placing the electrode on the specimen surface in correspondence of the central part of the rebar, while corrosion current density (i_{corr}) was measured through linear polarization resistance measurement (R_p) according to the equation:

$$i_{\text{corr}} = \frac{B}{R_p \cdot A} \quad (2)$$

where A = surface of rebar exposed to concrete; B = assumed equal to 26 mV.

3 RESULTS AND DISCUSSION

3.1 Effects of micro-cracks on penetration of carbonation

Figure 2 reports the results obtained in terms of K_{AC} , for the different exposure times and for the different concrete types, where histograms represent average values and error bars represent maximum and minimum values. In the Figure, the different mixes are identified with a label recalling the cement type (OPC for Ordinary Portland, PLC for Portland-limestone and PC for Pozzolanic cement type) followed by the w/c ratio. Considering sound and uncracked configurations, a quite good reproducibility of results was obtained in replicate specimens, and, moreover, for each concrete type K_{AC} was very similar for the two configurations. Similar results were also obtained considering the same mix at different exposure times. This result was expected, since carbonation in concrete is generally believed to be not affected by an ageing factor, unlike chloride penetration. To discuss the effect of cement type and w/c ratio, a single value of K_{AC} can be therefore considered, by averaging the values at both the exposure times in sound and uncracked conditions (Table 1).

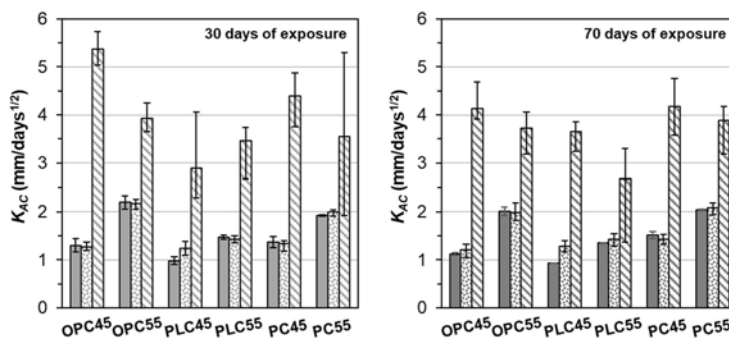

Figure 2. Average accelerated carbonation coefficient (KAC) and variability in sound (K_s, solid), uncracked (K_{uncr}, dotted) and cracked (K_{cr}, hatched) configurations, for different concrete types, after 30 (left) and 70 (right) days of exposure.

Concretes made with w/c equal to 0.45 showed similar K_{AC} in sound and uncracked conditions, except PLC45, for which the sound value unexpectedly resulted lower than $1 \text{ mm/days}^{1/2}$. If for this cement type the value in uncracked condition is considered more accurate, the carbonation coefficient for different cement types resulted quite similar, between 1.2 and $1.4 \text{ mm/days}^{1/2}$. As expected, higher K_{AC} were found for concretes with w/c of 0.55, since these concretes were characterized by higher permeability, which is considered to be one of the main factors affecting the diffusion of carbon dioxide in concrete (Bertolini et al. 2013). K_{AC} for these concretes resulted included between 1.2 and $2 \text{ mm/days}^{1/2}$, showing a percentage increment that depended on the cement type, *i.e.* about 40% for PC, 30% for OPC, and 15% for PLC.

Table 1. Average K_{AC} evaluated considering both the exposure times.

	OPC45	OPC55	PLC45	PLC55	PC45	PC55
$K_s \text{ (mm/days}^{1/2}\text{)}$	1.21	2.10	0.96	1.42	1.44	1.98
$K_{uncr} \text{ (mm/days}^{1/2}\text{)}$	1.24	2.07	1.26	1.43	1.38	2.03

Considering the effect of micro-cracks, these always led to a significant increase in the carbonation depth and therefore in the carbonation coefficient, and in the scatter of data among replicate specimens and for the same concrete type at different exposure duration (hatched histograms and error bars in Figure 2). It is worth noting, however, that this high scatter is also related to the fact that results at different exposure times were obtained on different specimens, characterized by different crack parameters, as well as replicate specimens for the same exposure duration may have been characterized by variable crack widths and depths. Moreover, the adopted cracking procedure did not prove to guarantee replicable cracks widths and depths (Russo et al. 2020). For this reason, the results at different exposure times were not averaged to find a single K_{AC} . To discuss the effects of the micro-crack on the carbonation coefficient, Figure 3 shows the ratio between K_{AC} in micro-cracked and uncracked condition (K_{cr}/K_{uncr}), as a function of K_{uncr} .

Figure 3. Increase in accelerated carbonation coefficient in the crack with respect to uncracked conditions (K_{cr}/K_{uncr}) as a function of accelerated carbonation coefficient in uncracked conditions, for different concrete types and after 30 (left) and 70 (right) days of exposure.

As can be noticed in Figure 3 an increase in the carbonation coefficient in the micro-crack always occurred, at both the exposure times. Moreover, an increasing trend in the ratio K_{cr}/K_{uncr} could be detected, for decreasing values of K_{uncr} (less permeable concretes). This effect was more pronounced for concretes with w/c of 0.45 (filled symbols), showing K_{cr}/K_{uncr} between 2 and 4.5, considering both the exposure times, and less pronounced for concretes with w/c of 0.55 (empty symbols), being K_{cr}/K_{uncr} mostly between 1 and 2.5. Similar results were obtained by the writing Authors with regard to chloride penetration resistance (Russo et al. 2020, Russo et al. 2022), confirming that a more marked effect of the micro-crack on concrete durability may occur for more impervious concretes. However, the presence of micro-cracks may not be of high concern for

concretes characterized by the w/c ratios typically used for structures subject to carbonation-induced corrosion, which according to EN 206 are 0.50 for exposure class XC4 and 0.55 for XC3.

3.2 Effects of micro-cracks on corrosion initiation and propagation

Figure 4 shows the electrochemical monitoring of corrosion potential (E_{corr}) and corrosion current density (i_{corr}), for cracked and highly cracked specimens exposed to outdoor unsheltered conditions. In particular, one cracked specimen was exposed with the crack in horizontal direction (CH), another one in vertical (CV), while one highly cracked with horizontal direction (HCH). The Figure reports also the outdoor climatic conditions, *i.e.* the daily cumulative rain and the daily average temperature (dark and light grey lines respectively). It can be noticed that over almost two years of exposure temperature fluctuated between 0°C and 30°C, while rain was in general quite scarce, with only 56 days with more than 5 mm of cumulative rain recorded. During the first half of exposure period (up to about 200 days of exposure), and especially in correspondence of the more wet days, HCH specimen already showed significantly lower values of E_{corr} (−200 ÷ −250 mV vs SCE) associated to i_{corr} values around 2 mA/m². It is reasonable to assume that in this specimen the crack developed to rebar depth, by analogy with some specimens realized and cracked with the same procedure but exposed to chlorides (Russo et al., in press), which may have led to corrosion initiation within the first 200 days of exposure. Subsequently, however, during the second half of the exposure period, E_{corr} was on average increased, and i_{corr} remained at values around 1 mA/m² or even lower. This may be associated to a drier climate during this period, or, eventually, to a partial or total closure of the crack due to self-healing and re-passivation of steel rebar. Further monitoring as well as destructive tests are needed to further investigate this aspect.

No significant difference in electrochemical behaviour was instead detected between the two cracked specimens with differently oriented cracked surface (CH and CV), whose values of i_{corr} always remained around 1 mA/m² or even lower, suggesting rebar passivity. For these two specimens it is reasonable to assume that the crack (and carbonation) did not reach rebar depth or, at least, did not involve a sufficiently wide area of steel to detect corrosion initiation with linear polarization method.

Figure 4. Trend in time of corrosion potential (left) and corrosion current density (right) for reinforced cracked (C) and highly cracked (HC) specimens subjected to natural carbonation with horizontal (H) or vertical (V) orientation.

Figure 5 shows the electrochemical monitoring for sound (S), cracked (C) and highly cracked (HC) specimens subjected to accelerated carbonation to induce corrosion initiation and external outdoor exposure to monitor natural corrosion propagation, with different crack orientation. In the Figure, the hatched area highlights the period in which specimens were in the carbonation chamber, the solid blue and grey areas highlight the measurements that were taken after 4 days of exposure to partial immersion and after one week in the curing chamber ($T=20^{\circ}\text{C}$, $\text{RH}>90\%$), respectively. These measurements were performed to verify, at two different humidity

contents, the corrosion initiation. Subsequently, the dark and light grey lines report the trend of the daily cumulative rain and the daily average temperature during external outdoor exposure.

Figure 5. Trend in time of corrosion potential (left) and corrosion current density (right) for reinforced sound (S), cracked (C) and highly cracked (HC) specimens subjected to accelerated carbonation and natural corrosion propagation at outdoor exposure with horizontal (H) or vertical (V) orientation.

Figure 6. Corrosion potential as a function of corrosion current density for specimens subjected to natural (left) and accelerated (right) carbonation, in sound (S), cracked (C) and highly cracked (HC) configurations, with horizontal (H) or vertical (V) orientation.

The lowest E_{corr} values ($-300 \div -600$ mV vs SCE), together with the highest i_{corr} values (up to 9 mA/m² for sound, S, 17 mA/m² for cracked, C, and 29 mA/m² for highly cracked concrete, HC), were detected as soon after the end of exposure to the carbonation chamber, at partial immersion conditions, confirming that carbonation arrived at rebar depth causing corrosion initiation in all the configurations. At curing chamber conditions, a neat increase of E_{corr} was detected ($0 \div -100$ mV vs SCE), while i_{corr} decreased of roughly one order of magnitude ($1 \div 5$ mA/m²), due to a lower moisture content in concrete and therefore higher concrete electrical resistivity. Specimens were then moved at external conditions during summer and fall, characterized by mild temperatures ($15 \div 30^{\circ}\text{C}$) and very low cumulative rain. Due to the prolonged drought, the values of E_{corr} and i_{corr} remained stable, at values close to the curing chamber conditions, without any particular difference between the cracked (C) and sound (S) conditions and vertical or horizontal orientation, unless for the two sound specimens exposed with vertical orientation, that showed particularly low i_{corr} (0.5 mA/m²). The latest measurements were performed during winter, characterized by a higher amount of precipitations, but no particular difference in values of E_{corr} and i_{corr} were detected, even though i_{corr} seems to slightly increase in time. Again, specimens characterized by vertical orientation (hollow symbols) seemed on average to be characterized by lower values of i_{corr} , while highly cracked specimens by higher i_{corr} , independently from crack orientation.

The same conclusions can be drawn if considering E_{corr} as a function of i_{corr} (Figure 6), where all the measurements during corrosion monitoring are reported for specimens subjected to natural carbonation, while only measurements during corrosion propagation at external exposure are reported for specimens previously subjected to accelerated carbonation. These results may imply that if a crack develops to rebar depth, not only corrosion initiation time may be reduced (excluding possible self-healing effects, not proved to the writing time), but also the corrosion propagation stage, due to a higher corrosion rate. On the other hand, comparable propagation of corrosion may be assumed in carbonated concrete if the crack does not develop to rebar depth, due to comparable corrosion rate values.

4 CONCLUSIONS

This study reports some preliminary results on the effects of cracks on carbonation-induced corrosion. Penetration of carbonation was tested under accelerated exposure conditions in cracked and uncracked unreinforced specimens, while corrosion propagation was monitored in cracked and uncracked concrete specimens subjected either to natural or to accelerated carbonation, considering different orientations of the cracked surface. The adopted cracking procedure was kept constant, to induce micro-cracks in direction longitudinal to the specimen (and the rebar). Carbonation penetration was evaluated through a colorimetric technique while corrosion was monitored through electrochemical techniques to measure corrosion potential and current density.

Results showed that for cracks 30-160 μm wide and 30-40 mm deep, a more marked effect of the crack on carbonation penetration may occur in more impervious concretes, leading to an increase in the carbonation coefficient up to 4 times. The presence of a crack developing down to rebar depth led corrosion initiation within the first 200 days of exposure, and to higher corrosion rates during corrosion propagation. In specimens where crack was supposed not to develop to rebar depth, no particular effect of the presence of the crack, nor of its orientation, was detected.

Numerical evaluation on electrical resistivity of hardened cement paste using 3D pore model based on X-ray micro-CT images

K. Kawai

Ehime University, Ehime, Japan

T. Nishida

Shizuoka Institute of Science and Technology, Shizuoka, Japan

ABSTRACT: Corrosion resistance against chloride attack and carbonation is essentially associated with electrical resistivity of cover concrete. This study explored numerical simulation on the evaluation of the resistivity of porous materials by FEM analysis. First, 3D model comprised of hardened cement paste and pores fully saturated with pore solution was modelled based on X-ray images taking into consideration the porosity analyzed by mercury intrusion porosimetry. And current flows via ionic conduction through the pores in hardened cement paste are simulated under steady-state condition. And then, the electrical resistivity is evaluated taking into consideration the cell constant in the cubic geometry of 3D model which is of cross section 200 μm each. Based on the results, electrical resistivity is found to be significantly influenced by the presence of connected pores in the hardened cement paste.

1 INTRODUCTION

1.1 Background

The resistance against corrosion is of great importance with regards to durability of reinforced concrete structures (e.g., Kawai et al. 2019). Especially, the resistance against chloride attack is essentially associated with electrical resistivity of cover concrete, which indicates the pore structure. In practice, Wenner method has been widely used for assessing the resistance against the chloride ions in concrete structures as shown in Figure 1. However, the resistivity measured by the method on the actual concrete structure is largely influenced by the water content, the geometry of concrete member, and presence of steel bars. Thus, the measured value would be considered as an indicator for apparent resistivity which should be modified by appropriate cell constant (Morris et al.1996, Minagawa et al. 2022).

On the other hand, the materials property of concrete resistivity is usually measured by the method using cylindrical specimens which are fully saturated (Whiting 1981&1992, AASHTO 2011). The potential difference between the electrodes located at outer sides is measured when constant current is injected between electrodes located at inner sides. And the electrical resistivity (ER) is calculated taking into consideration the cell constant which is $2\pi a$ for most of cases. The cell constant is obtained theoretically; however, it should be modified depending on testing conditions. For example, ionic conduction is essentially limited in cylindrical shape of the specimens. In order to evaluate ER as the materials property of existing concrete structures which possibly have moisture distribution in depth, it is extremely difficult to specify the cell constant depending on many variables as mentioned above. In this study, small samples in 2 mm size obtained from cored concrete are focused on assessing electrical properties associated with pore structure of hardened cement paste. This study utilized X-ray micro-CT images

to model 3D pore structure, which could be a new approach for assessing the mass transport in porous media such as concrete in determining the resistance against ingress of corrosive substances such as chloride ions. This approach is advantageous in assessing the electrical resistance in concrete under dry environment in which the resistivity is not experimentally assessed by the standard method.

Figure 1. Histogram of grayscale pixel values and modeling of 3D pore structure.

1.2 Objective of this study

Based on the background mentioned above, this study explored the numerical evaluation on the electrical resistivity of hardened cement paste based on X-ray micro-CT images. Especially, the current flows caused by ionic conduction through connected pores are simulated in porous cement matrix. And then, this study compares the results of numerical simulation with those of experimental results measured by conventional Wenner methods.

2 METHODOLOGY

2.1 Materials and specimens

Concrete cylindrical specimens with a diameter of 100 mm and height of 200 mm were made with a water to cement ratio of 0.65. Ordinary Portland cement with a specific gravity of 3.16 g/cm³ was used. Table 1 shows mix proportion of concrete mixture. The specimens were cured under room condition controlled at 20°C until the age of 28 days. The small samples comprised of hardened cement paste in size of 2 mm for X-ray CT images were obtained from the specimens.

Table 1. Mix proportion of concrete mixture.

Unit weight (kg/m ³)				(g/m ³)	
W	C	S	G	SP	AE
165	254	913	954	2538	1.015

2.2 Testing methods

The Wenner method was carried out using four probe method comprised of four stainless electrodes located 50 mm apart. Before the specimens were tested, the specimens were immersed in water tank and fully saturated under vacuum conditions. The results of electrical resistivity were converted to material property taking into consideration modified cell constant depending on the geometry of specimens. And then, the samples were tested by mercury intrusion porosimetry. Porosity and pore volumes with respect to pore size diameter were measured in this study. And porosity of the concrete specimens was also tested by Archimedes method.

2.3 3D pore model based on X-CT images

First, the X-ray micro-CT images were analyzed by image analysis software Simpleware. The size of image is comprised of 1.9 μm in this study. The pore models consist of voxels with scalar/vector values such as absorption rate. Darker color indicates air-filled pores, and in contrast lighter color indicates hardened cement paste with finer aggregate in solid. The 3D voxel models should be divided into two regions including air-filled pores and cement paste in solid by threshold value of pixel value as shown in Figure 2. The dividing line could be determined taking into consideration of porosity measured by mercury intrusion porosimetry and Archimedes method. The latter indicate the porosity with regards to water permeable porosity in the hardened cement paste.

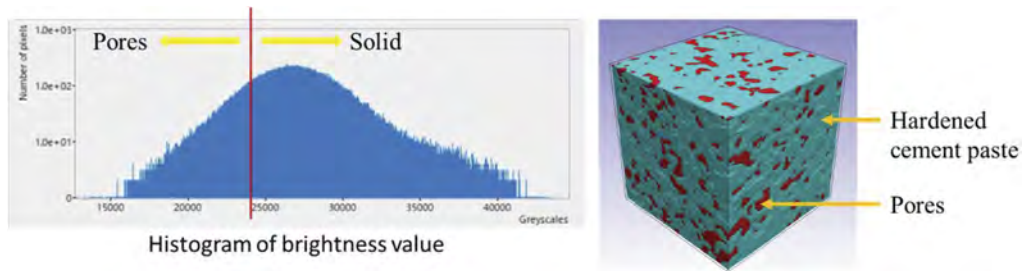

Figure 2. Histogram of grayscale pixel values and modeling of 3D pore structure.

2.4 Numerical simulation

The 3D pore model constructed based on X-CT images as explained in Section 2.3 was further discretized into finite element models using tetrahedral mesh for numerical analysis. The numerical simulation was performed using COMSOL ver. 5.6. When Ohm's law is satisfied and current density is not dependent on time i.e., steady state, and the current density and electric field vector satisfy the following equations:

$$\nabla \cdot J = 0 \quad (1)$$

$$J = \sigma E \quad (2)$$

$$E = -\nabla V \quad (3)$$

where J = current density vector (A/m^2); σ = electro-conductivity (S/m); E = electric field vector (V/m), and V = potentials (V).

As shown in Figure 3, potential difference ΔV is added to the X direction. And the surface integral of current density observed at each plane on the X direction is calculated, which leads to average current I flowing through the porous media. For boundary conditions in the insulation plane, Neumann condition $n \cdot J = 0$ (n : normal vector perpendicular to the plane) is set. Based on the results simulated under steady state, resistivity R can be obtained by the potential V and current I which is known as Ohm's law. In general, the resistivity is proportional to length of the object and inversely proportional to area of the object. The electrical resistivity in terms of volume resistivity without the influence of the geometry can be obtained taking into consideration appropriate cell constant as following equation:

$$\rho = \frac{RA}{L} = \frac{\Delta V A}{I L} \quad (4)$$

where A = area of the object (m^2) and L = length of the object (m).

The calculation is performed in the X, Y, and Z directions in order to confirm the isotropic consistency of the results. the electro-conductivity in the solid and liquid phases is specified as

summarized in Table 2. It should be noted that the electro-conductivity in the liquid phase is largely dependent on the ion concentration and mobility in the pore solution, which meets the requirement of electrical neutrality. The current flows via ion conduction in hardened concrete which is assumed to be fully saturated in the simulation.

Table 2. Electro-conductivity of solid and liquid phases.

Electro-conductivity	S/m
Solid phase (hardened cement paste)	1.0×10^{-12}
Liquid phase (air-filled pores)	5.23

3 RESULTS AND DISCUSSION

3.1 Experimental results of electrical resistivity

Electrical resistivity was measured at the age of 91 days in this study. The values should be converted to volume resistivity without the influence of geometry as mentioned previously. The result was $30.2 \Omega \cdot m$ on average in the case of concrete specimen tested in this study. In addition, mortar specimen was made to measure the resistivity without coarse aggregate, which was $15.7 \Omega \cdot m$ in this study. The difference with regards to the electrical resistance between concrete and mortar is explained by the fact that the aggregate is an electrical insulator in the hardened cementitious materials.

3.2 Porosity and 3D pore models

3D pore model of hardened cement paste is constructed by image analysis using X-ray micro-CT images in this study. The porosity was measured by Archimedes method in the cases of concrete specimens in addition to mercury intrusion porosimetry in the case of small sample obtained from the concrete specimen. Figure 3 shows the porosity measured by the methods,

as can be seen, the porosity 18.51% of hardened cement paste analyzed by mercury intrusion porosimetry ranged between those of concrete and mortar specimens. By setting the porosity of 3D pore model based on the counts of voxels pertaining to each phase of voxel, and the 3D pore models comprising solid and liquid phases are clearly divided. Although the pores especially capillary pores in concrete could range from 3 nm to 30 μm and the gel pores are further smaller than 3 nm, the smaller pores could be recognized as either solid phase or pore phase. The 3D pore model is mostly comprised of larger capillary pores, which could determine the electrical properties by ion conduction in pore solution through connected pores.

As shown in Figure 4, the brightness in determining 3D pore models in cubic shape with a dimension of 200 μm ranged from about 13300 to 13700, which was extracted from 8 locations of original voxel models with a dimension of 2 mm. It should be noted that the locations are mutually exclusive in order to confirm the variations of dividing lines for each phase. As mentioned in Section 2.3, 3D pore models are comprised of two phases such as solid phase and pore phase. Figure 5 shows the regions of pore phase comprising connected as well as isolated pores. As shown in the figure, the pore phase consists of connected pores with 80 to 90% in the total volume of pores.

Figure 4. Porosity and variations of threshold value in dividing solid and liquid phases.

Figure 5. Connected and isolated pores in pore phase.

3.3 FEM analysis on resistivity of porous media

3D pore/voxel model is used for FEM analysis in this study. The FE model comprising tetrahedral mesh was made in this analysis and the number of elements is over 2 million as shown in Figure 6. The mesh size is essentially dependent on the resolution of voxel model made using X-ray CT images. First, a potential difference i.e. 1V is applied between two sides in X, Y, or Z direction as explained in Section 2.4. And then, potential distribution through pores is calculated and is found to be varied depending on the presence of connected pores as shown in Figure 6. It should be noted that the calculation is carried out for total pores (TP) and only connected pores (CP) extracted as mentioned in Section 3.2 to examine the presence of connected pores in pore models.

Figure 6. FE model and potential distribution in steady-state.

3.4 Effect of connected pores on electrical resistivity

Figure 7 shows the results of electrical resistivity calculated based on eq. (4). It should be noted that the calculation is made on X, Y, and Z directions to confirm the isotropic property of hardened cement paste. The results are observed to be comparable among the electrical resistivity calculated for X, Y, and Z directions. Based on the results obtained by FEM analysis, the electrical resistivity is $11.71 \Omega\cdot\text{m}$ on average. This is smaller compared to those of mortar specimen ($15.7 \Omega\cdot\text{m}$) and concrete specimen ($30.2 \Omega\cdot\text{m}$) measured by experiments. Although the influence of aggregates present in mortar and concrete could be illustrated by the experimental results which is an insulator to inhibit current flow, the results of FEM analysis are clearly smaller compared to those with the presence of aggregates. This can be explained by the fact that the pore models are mainly comprised of hardened cement paste which led to underestimate the influence of aggregates with respect to the electrical property of concrete. The results seem to suggest that the electrical resistivity could be estimated based on the results of numerical analysis taking into consideration the influence of aggregates as an insulator in concrete or mortar. It should be noted that the electro-conductivity of interfacial transition zone (ITZ) is higher compared to that of cement paste, which should be explored in future research.

In addition, the comparison in the cases of models with total pores (TP) and connected pores (CP) is examined to investigate the effect of connected pores on the electro-conductivity in total pore model. As can be seen in Figure 7, the electro-conductivity is largely dependent on the presence of connected pores since the variation is marginal between two models analyzed especially in the case of PERM-1. As can be seen in Figure 8, the electrical conductivity in the case of results with connected pores is greater by 20 to 30% at most, thus suggesting that the electro-conductivity is largely influenced by the presence of connected pores in which ion movement takes place via ion conduction. In contrast, the presence of isolated pores which are connected each other would have lesser influence on the ion conduction through the pore structure formed in cementitious mixtures.

Figure 7. FE model and potential distribution in steady-state.

Figure 8. Comparison between ER obtained by TP models and CP models.

4 CONCLUSIONS

This study explored numerical simulation on the evaluation of the resistivity of porous materials by FEM analysis. First, 3D model comprised of hardened cement paste and pores fully saturated with pore solution was modelled based on X-ray micro-CT images with a resolution 1.9 μm . And current flows via ionic conduction through the pores in hardened cement paste are simulated under steady-state condition. It should be noted that 3D pore models are comprised of total pores and only connected pores. And then, the electrical resistivity is evaluated taking into consideration the cell constant in the cubic geometry of 3D model which is of cross section 200 μm each. Based on the results, electrical resistivity is found to be significantly influenced by the presence of connected pores in the hardened cement paste. This study paved the way in evaluating electrical resistivity in existing concrete structure by 3D models analyzed by X-ray micro-CT images.

ABSTRACT: In order to provide basis for service life of steel fiber reinforced concrete engineered for pavements in frigid region. Long-term freeze-thaw cycles were carried out on mill-cut steel fiber reinforced concrete (MFSRC) in 3.5% NaCl solution, taking into account the fiber volume fraction and cycle index under the coupled deterioration mechanisms of freeze-thaw and chloride penetration. The effect of fiber volumes (0.6%, 1% and 1.4% volume content of concrete) was quantitatively analyzed. The performance degradation of MFSRC was evaluated by surface scaling, mass loss, internal damage, relative dynamic elastic modulus and residual compressive and splitting tensile behaviors. The results show that MSFRC are able to withstand 100 freeze-thaw cycles without significantly surface scaling or degradation in mechanical properties. The internal damage degree of MSFRC sample in 200 saline freeze-thaw cycles is within the acceptable range. When the steel fiber content is increased to 1%, the deterioration of concrete is considerably reduced in the same cycle.

1 INTRODUCTION

Degradation of concrete structures caused by the environmental erosion is regarded as an important durability problem. The use of concrete materials in chilly coastal and seasonal frozen areas is challenging, as concrete structures need to withstand harsh environmental conditions during service (Kuosa et al., 2014). Periodic freeze-thaw changes produce additional internal stress, resulting in cracking, spalling and other deterioration behaviors of concrete (Mayercsik et al., 2016). Moreover, concrete suffers the most severe freeze-thaw damage when the medium is a salt solution with concentration of about 3.5% by weight (Marchand et al., 1999). Both deicing salt and seawater contain a large amount of sodium chloride, which also induce corrosion in reinforcing materials such as steel bars and fibers (Tran et al., 2015). Hence, the ability to withstand chloride erosion and freeze-thaw cycle damage is an important index to improve the durability of concrete.

The effective control of cracks is essential for the service life of structure. The unique morphological characteristics of mill-cut steel fiber enable it to give full play to cracking resistance ability in concrete, inhibit the crack development caused by temperature and expansion stress and effectively delay the penetration rate of chloride ions into the structure (Zeng et al., 2020). Additionally, the addition of steel fiber plays the role of air entraining agent, which enhance the internal gas content of concrete and alleviates the internal stress caused by freeze-thaw cycle (Sun et al., 1999). However, corrosion effect of salt solution on steel fiber may affect

durability of steel fiber concrete (Alsaif et al., 2019). For the prospect of better applying mill-cut steel fiber reinforced concrete (MSFRC) in practical engineering, it is necessary to verify its freeze-thaw resistance in chloride ion medium.

This study aims to investigate the effect of freeze-thaw damage on the performance of MSFRC under accelerated conditions in 3.5% NaCl solution. The level of frost damage was quantified by the matrix spalling, mass loss and the dynamic elastic modulus, which represented external and internal damage degrees respectively. The residual mechanical properties of MSFRC including compressive strength and splitting tensile strength was assessed after being subjected to hundreds of freeze-thaw cycles in NaCl solution. The influence of fiber content on the durability and mechanical properties of MSFRC was also explored, which can be used when analyzing the frost-damaged concrete structures of corresponding materials and may shed some light on the service-life prediction model.

2 EXPERIMENTAL PROGRAMME

2.1 Materials

The cementitious materials consists of 42.5 ordinary Portland cement, with fly ash and slag powder as substitute for 15% cement respectively. Polycarboxylate polymer plasticizer with water reducing rate of 25% was used to enhance the workability of concrete. Natural river-sand with an average fineness modulus of 2.35 was used as fine aggregate. Granite gravel with particle size of 5-25mm was employed as coarse aggregate.

Mill-cut steel fiber (MSF) was mixed into the mixture as reinforced material. The morphological characteristics of steel fiber are illustrated in Figure 1 and Table 1. The mill-cut steel fiber was produced by high-speed milling of the steel ingot with a cylindrical milling cutter. These fibers have rough inner surface and smooth outer surface, with radial distortion of about 20°, and crescent shaped cross section.

Figure 1. Morphologies characteristics and cross-section of mill-cut steel fiber.

Table 1. Physical properties of steel fiber.

Fiber Type	Cross-section	Length, l/mm	Diameter, d/mm	Aspect ratio, l/d	Tensile strength (MPa)
Mill-cut steel fiber	Crescent	32	0.91	35	897

2.2 Concrete mix designs and casting procedures

To explore the influence of mill-cut steel fibers contents of MSFRC under salt freeze-thaw condition, three different mixes were prepared in this study as illustrated in Table 2. Considering the toughening effect and dispersibility, the amount of steel fibers added in MSFRC mixtures were 50 kg/m³, 80 kg/m³ and 110 kg/m³. The mix ID contains letter and number, denoting the type and volume of steel fibers respectively.

The production of MSFRC mixture started with dry components such as cementitious materials and aggregate altogether into the single-shaft mixer and mixing for 2-3 min. Half of the

mixture of superplasticizer and water was then introduced to the mixer, continue stirring for about 5 min to make it adequately reacting. After that, added steel fiber and kept stirring for 3 min until the fibers were dispersed homogeneously. Finally, mixing was continued until the mixture completely uniform, during which the remaining plasticizer` solution was gradually added. Concrete was cast in molds and vibrated on a shaking table for 1min. The specimens were demolded after curing with plastic covering for 48h. Subsequently, all specimens were placed in a curing room with humidity of $92\pm 2\%$ and temperature of $23\pm 1\text{ }^{\circ}\text{C}$ for 28 days.

For measuring the properties of MSFRC after freeze-thaw cycles, cube, prism and beam specimens were cast. Cube specimens with the dimension of $100\text{ mm} \times 100\text{ mm} \times 100\text{ mm}$ were cast for split tensile testing. Prism specimens with the dimension of $100\text{ mm} \times 100\text{ mm} \times 300\text{ mm}$ were used for compressive testing. The beam specimens of $100\text{ mm} \times 100\text{ mm} \times 400\text{ mm}$ dimensions were employed to test resonant frequency at every freeze-thaw period. Meanwhile, surface scaling, mass loss and dynamic modulus of elasticity were measured for each specimen to assess the variation of specimens during freeze-thaw process.

Table 2. Mix proportions of the designed specimens.

No.	Mix proportion (kg/m ³)							
	Cement	Aggregate	Fly ash	Slag	Sand	Water	SP	Fiber
MF0.6	380	1040	85	85	610	149	4.4	50
MF1	380	1040	85	85	610	149	4.4	80
MF1.4	380	1040	85	85	610	149	4.4	110

2.3 Test set-up

2.3.1 Freeze thaw testing

The freeze-thaw resistance of the cube, prism and beam specimens of MSFRC was carried as per GB/T 50082-2009 by rapid freezing and thawing method. The specimens were placed in rubber containers with fully immersing in 3.5% NaCl solution. The containers were then placed into a rapid freezing and thawing machine which could apply continuous freeze-thaw cycles with temperature ranging from $-18\pm 2^{\circ}\text{C}$ to $5\pm 2^{\circ}\text{C}$. Each cycle of freeze-thaw process was completed within 2-4h. The temperature was controlled through the thermocouple embedded in the central specimen.

The damage of concrete caused by freeze-thaw cycles was assessed on several aspects. Through the visual examination of appearance to evaluate the matrix spalling and rusting condition of steel fibers. To quantify the spalling condition of specimen, the mass loss was determined at each freeze-thaw stage. Forced resonance method according to ASTM C215 was employed to obtain the transverse frequency to assess the internal damage. The test set-up is shown in Figure 2, the concrete beam was forced to vibrate by a driver transducer fitted at the middle of specimen, and collect data by the pick up transducer fixed near the edge of specimen. The transducers were pressed on the concrete surface, and petroleum jelly was used as the coupling medium to dispel the air between the surfaces. The dynamic modulus of elasticity of specimens can be determined by Equation (1):

$$E_d = 9.464 \cdot 10^{-4} \cdot ML^3 T f^2 / a^4 \quad (1)$$

where E_d is the dynamic modulus of elasticity (MPa); M is the mass of specimen (kg); f is the transverse fundamental frequency of specimen (Hz); T is the correction factor, $T=1.4$ for a beam specimen; L is the length of specimen (mm); a is the width of square section (mm);

2.3.2 Mechanical properties

The cube specimens were used in splitting tensile test assembly as per GB/T 50081-2019 at a loading rate of 0.05 MPa/s. For compressive strength testing, prism specimens were tested under uniaxial compressive loading at a displacement rate of 0.05mm/min with the help of servo hydraulic testing machine of 1000 kN capacity. Beam specimens were used for freeze-thaw nondestructive testing.

Figure 2. Equipment and schematic view of dynamic elastic modulus testing.

3 RESULTS AND DISCUSSION

3.1 Surface scaling and degradation characteristic

Figure 3 shows the appearance of the cube and prism specimens suffered from freeze-thaw cycles in chloride environment. From diagram it is cleared that hole forming and matrix peeling are the main features of appearance destruction during salt-frost damage. As the number of cycles is increased, surface cementitious layer peels off under the internal stress caused by freeze-thaw cycles, along with the exposure of coarse aggregate and steel fibers at the later stage of freeze-thaw cycles. ASTM C672/C672M determines the visual rating of the concrete surface exposed to freeze-thaw cycles depending on the degree of scaling, as show in Table 3. The cementitious matrix is starting to peel off at 25 cycles of freeze-thaw. After 50 cycles, some corroded steel fibers can be observed on the surface, and the surface layer of M0.6 specimens is totally peeled off. At 75 cycles, M0.6 specimens reaches visual rating 3 with some coarse aggregate visible. Subsequently, after 100 cycles, the exposure degree of coarse aggregate of M0.6 specimens is further aggravated, the concrete is rated as 5 and nearly failed. Meanwhile, the M1 and M1.4 specimens just reach rating 3 at 100 cycles, and then further degenerate to rating 4 at 150 cycles. The surface damage and matrix peeling off during the freeze-thaw cycles is slightly lower when the mill-cut fiber content is 1%. This is a consequence of the appropriate amount of steel fibers can resist the expansion stress caused by the conversion from free water to ice, and relieves the damage degree of matrix peeling off. However, the steel fiber exposed to chloride after the surface mortar stripping is tent to rust, resulting in failure of fiber bridging and spalling together with the matrix. Therefore, excessive fiber content will cause further damage.

Figure 3. Appearance of specimens before and after freeze-thaw cycles.

3.2 Mass loss after freeze-thaw cycles

The mass loss of specimens was determined after every 25 freeze-thaw cycles. At each specified cycle, each specimen was brushed to remove loose parts and weighed to the nearest 0.1g

Table 3. Visual rating of the surface according to ASTM C672/672M.

Rating	Condition of surface
0	no scaling
1	very slight scaling (3mm depth, max, no coarse aggregate visible)
2	slight to moderate scaling
3	moderate scaling (some coarse aggregate visible)
4	moderate to severe scaling
5	severe scaling (coarse aggregate visible over entire surface)

during the thawing phase. Comparing with the mass before corrosion, the percentage of mass loss after n cycles was calculated according to Equation (2):

$$\Delta W_n = \frac{W_0 - W_n}{W_0} \cdot 100 \quad (2)$$

where ΔW_n is the mass loss rate of specimens after n cycles (%); W_n is the mass measured after n cycles (g); and W_0 is the initial mass of specimens after curing and before testing (g).

The mass loss of specimens of different size versus the number of freeze-thaw cycles in chloride environment is shown in Figure 4 and Table 4. Considering the mass loss and that of per unit area, it is evident that the size effect doesn't play a key role in the freeze-thaw damage of MSFRC. Despite the damage area of small-size specimens under the same freeze-thaw conditions is relatively large, the specimens are not further deteriorated due to the reinforcement of steel fibers. Throughout the test, M0.6 specimens exhibit maximum mass loss, while M1 and M1.4 shows lower mass loss behavior. The M0.6 specimens display a sudden increase at 75 freeze-thaw cycles, indicating a severe damage of specimen after 75 cycles. The mass loss per unit area occurred in M1 and M1.4 specimens is less than 1.5 kg/m^2 after 125 cycles of salt-freezing, and the mass loss rate is less than 5% within 200 cycles, which indicates that the excellent salt-freezing resistance of the two groups according to the failure standard specified by GB/T 50082-2009. The M1 specimens display the lowest rate of mass loss especially after 100 cycles, which is attributed to the presence steel fiber. The interface adhesion between steel fiber and matrix restricts the peeling of mortar.

Figure 4. Mass loss due to freeze-thaw cycles. a) MSFRC cubes; b) MSFRC prisms; c) MSFRC beams.

3.3 Dynamic modulus of elasticity

The dynamic modulus of elasticity (DME) of beam specimens with different steel fiber content before and after freeze-thaw cycles are calculated from transverse fundamental frequency using the Equation (1) in section 2.3.1, as shown in Figure 5. Due to the high stress and strain measurement conditions, the DME of non-freezing specimens is above 40000 MPa, which is higher than the static elastic modulus measured under normal conditions. As can be seen from the figure, the initial DME of M1 specimens with 1% fiber content is higher than that of other two groups. During the freeze-thaw cycles, M1 and M1.4 specimens exhibit higher DME, while a sudden drop in DME occurs in M0.6 group when the freeze-thaw cycles reach around 100, indicating that the increase of mill-cut steel fiber content is contribute to improve the frost resistance of concrete. In addition, different from the variation trend of mass loss, the DME of M1

Table 4. Mass loss per unit area for all tested mixes.

Mix	Specimens	Mass loss after n cycles (kg/m ²)							
		25	50	75	100	125	150	175	200
M0.6	cube	0.12	0.14	1.43	5.49				
	prism	0.34	0.48	1.24	3.05				
	beam	0.11	0.19	1.83	4.89				
M1	cube	0.10	0.19	0.27	0.53				
	prism	0.24	0.44	0.79	1.06	1.25	1.67		
	beam	0.39	0.60	0.85	0.88	1.12	1.21	1.31	1.39
M1.4	cube	0.19	0.21	0.37	0.62				
	prism	0.12	0.27	0.55	0.99	1.59	2.18		
	beam	0.45	0.64	0.82	1.04	1.40	1.67	2.01	2.36

specimens increases slightly during 125-150 cycles. This is a likely consequence of the intrusion of salt solution into the matrix, the pulse wave passes directly through the solution in the pores without being blocked by the crack interface. Meanwhile, the steel fiber in the matrix also plays a conductive role, so that the wave velocity presents a rising trend and the DME increases.

Figure 5. Dynamic modulus of elasticity of MSFRC after freeze-thaw cycles.

3.4 Relative dynamic modulus of elasticity

In this section, the variation of DME after saline freeze-thaw cycles was used to evaluate the internal damage of concrete. As stipulated in ASTM C666, the relative dynamic modulus of elasticity (RDME) after n cycles was calculated by Equation (3):

$$P_n = \frac{f_n^2}{f_0^2} \cdot 100 \quad (3)$$

where P_n is the relative dynamic modulus of elasticity after n cycles of freeing and thawing (%); f_0 is the fundamental transverse frequency at 0 cycles (Hz); f_n is the fundamental transverse frequency after n cycles (Hz).

Figure 6 shows the RDME of the concrete beam specimens as a function of the number of freeze-thaw cycles applied. As a key index reflecting the freezing resistance of concrete, when the RDME drops to the threshold value of 80% defined by GB/T 50082-2009 and RILEM 2004, the specimen can be considered to have reached the freeze-thaw limit. In general, the RDME decreases with the number of freeze-thaw cycles increases. The M1 and M1.4 specimens survived 200 freeze-thaw cycles and their RDME are above 80%, showing good durability. At 100 cycles, M0.6 and M1.4 specimens have a prominent decline stage which represents relatively obvious matrix damage. In particular, the RDME of M0.6 specimens drops below 80% after 100 cycles, indicating that the specimens have failed. Whereas, similar to the DME, M1 specimen shows a special rising stage after 100 cycles. This is mainly due to the invasion of chloride solution, which generate crystalline substances such as Friedel's salt to fill the internal pores and cracks and increase the bonding effect between fiber and matrix.

Figure 6. Relative dynamic modulus of elasticity during freeze-thaw cycles.

3.5 Compressive strength

The compressive behavior of the specimens after freeze-thaw cycles are summarized in Figure 7. As can be seen from the figure, with the content of steel fibers increases from 0.6% to 1%, the compressive strength of specimen is raised to 56.9 MPa. However, no further increase in compressive strength is observed when the content reaches 1.4%. Previous studies have also shown that excessive steel fiber content tends to cause uneven fiber dispersion, which leads to the decline of compressive strength (Hasan-Nattaj and Nematzadeh, 2017). As the freeze-thaw cycle proceeds, the compressive strength of M0.6 and M1.4 specimens decreases gradually. Whereas after 75 cycles, M0.6 and M1.4 specimens suffers significant strength loss during 75-100 cycles, while M1 enters a special plateau with strength loss rate remains below 30% until 150 cycles, which is similar to the change trend of RDME. This indicates that the 75th freeze-thaw cycle is the critical point of freeze-thaw damage of MSFRC specimens. According to the previous appearance damage analysis, the external matrix begins to peel off after 75 cycles, lacking or excessive fiber content would aggravate this damage. Meanwhile, too many fibers will cause additional internal initial defects, which weakens the durability and compressive strength of specimens. In conclusion, the content of steel fiber has an obvious effect on the compressive strength of concrete after saline freeze-thaw cycles. The content of mill-cut steel fiber is recommended to be controlled at 1%, which is conducive to improving the frost resistance and compressive strength of concrete, so that the specimen can maintain good durability after 150 cycles.

Figure 7. Compressive strength of MSFRC before and after freeze-thaw cycles.

3.6 Splitting tensile strength

Figure 8 shows the split tensile strength of MSFRC specimens under different freeze-thaw cycles. It shows that the splitting tensile strength increases by 11% and 20% respectively, when the fiber content is 1% and 1.4%, compared with M0.6 specimens. The splitting tensile strength loss rate of M0.6 specimen reaches 30% when the freeze-thaw cycle is only 25 times, and the strength deteriorates rapidly after 50 cycles, with the loss rate exceeding 60%. It might be due to the low fiber content has no inhibiting effect on the spalling of the matrix under the freeze-thaw cycle, resulting in serious damage of the small-volume specimen and early entry into the failure stage. In the case of M1 and M1.4 specimens, the splitting tensile strength sustains above 5 MPa during 100 freeze-

thaw cycles, and the strength loss rate is less than 20%, indicating that the material still have good mechanical properties. The results show that the saline freeze-thaw cycle has slight effect on the steel fiber inside the specimen, and the fibers can still play the bridging role and improve the tensile properties of the matrix after the cumulative damage of multiple cycles. The strength loss rate of splitting tensile strength is less as compared to that of compressive strength of MSFRC at their respective freeze-thaw cycles, the presence of fibers has a more obvious effect on the improvement of tensile performance. When the fiber content reaches 1%-4%, MSFRC can be considered to still have good splitting tensile strength after 100 freeze-thaw cycles.

Figure 8. Splitting tensile strength of MSFRC before and after freeze-thaw cycles.

4 CONCLUSIONS

This study assessed the saline freeze-thaw performance of mill-cut steel fiber reinforced concretes (MSFRC). Based on experimental results, some conclusions are as follow:

- 1) The inclusion of mill-cut steel fiber mitigates the negative effects of freeze-thaw, MSFRC with fiber content between 1% and 1.4% can tolerate more freeze-thaw cycles without severe damage. The mass loss rate of specimens is less than 5% after 200 cycles, which is acceptable according to the GB/T 50082-2009.
- 2) Dynamic elastic modulus reflects the changing trend of compressive strength. Within a reasonable steel fiber content range (1-1.4%), the relative dynamic elastic modulus maintains above the critical value (80%) for internal damage during 200 cycles.
- 3) Mill-cut steel fiber is effective to enhance the tensile behavior of concrete, up to 11% and 20% with the increase of fiber content. The presence of steel fibers significantly reduces the loss rate of splitting tensile strength due to the saline freeze-thaw, compared to that in compressive strength.

Construction of hydrogen pipeline utilizing communication pipeline and experimental study on its utilization

T. Ishikawa & K. Itasaka

NIPPON Telegraph and Telephone Corporation, Tsukuba-city, Ibaraki, Japan

ABSTRACT: In this report, we report on hydrogen transportation using a communications infrastructure to achieve a decarbonized society. Due to a reduction in communication cable diameter, the space in the conduit to accommodate the cables has increased. To make effective use of this space, efforts are being made to transport hydrogen by using a double pipeline system. At present, the transportation of hydrogen is mainly carried out by tanker trucks, and further reduction of transportation costs and CO₂ emissions are required in the future. As a solution, transporting by pipeline utilizing existing transmission lines is demonstrated. Hydrogen transportation by pipeline requires airtight transportation, because it is assumed that the gas is supplied under high pressure. Therefore, in the verification, a flexible stainless steel tube will be constructed in an existing communication tube and used as a pipeline for hydrogen transportation.

1 BACKGROUND AND PURPOSE

The 2050 Carbon Neutral Declaration announced by the Japanese government set a goal of achieving a decarbonized society and net-zero greenhouse gas emissions by 2050, and NTT is also considering expanding its efforts to achieve carbon neutrality to society as part of its efforts to achieve the Declaration. As one effort to achieve a decarbonized society, a verification was conducted on a hydrogen transportation initiative using existing communication pipes.

At present, delivery of hydrogen by tanker truck is the mainstream transportation method in Japan, but further reduction of transportation costs and carbon dioxide (CO₂) emission are required in the future. As a solution, we aimed to demonstrate a transportation method by pipeline using a previously-constructed 75-mm communication pipe.

Communication cables have changed from metal- to optical-based ones, and as their diameters have become smaller, the space in communication pipes to accommodate the cables has increased, so we are focusing on that space (Figure 1).

To make effective use of this available space, we aim to design a double pipeline system that enables hydrogen to be transported in a pipeline installed in the empty space. We also aim to conduct various technical demonstrations.

Since transporting hydrogen by pipeline is assumed to be carried at a high pressure, the airtightness of the hydrogen pipeline must be ensured. Generally, hydrogen is said to be highly permeable, and we decided to use a stainless steel tube with less hydrogen permeation.

In this demonstration, the existing communication pipe was constructed using flexible stainless steel pipe, which was assumed to enable it to flexibly deal with both straight and curved cables. Hydrogen is pumped into the pipeline to confirm its workability and operability as a hydrogen pipeline, and to confirm whether transporting hydrogen using a double piping system is possible (Figure 2).

Figure 1. The space in communication pipes to accommodate the cables.

Figure 2. Stainless flexible pipe.

The construction of the double pipeline system can effectively utilize the preexisting pipeline and can maximize the use of existing facilities by eliminating the need for road excavation to resolve any impact of life cycle cost. (Figure 3)

Generally, communication pipes are classified as metal and vinyl pipes. In this demonstration, vinyl conduits were used for the communication pipes as it was assumed that the surface friction force was lower than that of metal.

The constructed pipeline houses a flexible stainless steel tube in an existing vinyl pipe, which is towed through the pipe by a winch from a nearby manhole.

Figure 3. Double piping system.

Since some friction with the pipeline will occur, in this demonstration, the pipe will be towed in a section of up to 150 m to determine its feasibility.

In addition, friction between the vinyl pipe and flexible stainless steel pipe is expected. Therefore, both the communication and flexible stainless pipes are checked for damage by laboratory tests.

The content of the report is as follows:

- 1: Examine whether construction of a double pipeline system is possible that accommodates flexible stainless steel pipelines in communication pipes
- 2: Determine if it is possible to transport hydrogen after construction
- 3: Determine if metal pipe and flexible stainless steel pipe are affected by friction during construction

2 VALIDATION (1)

The verification was carried out to determine whether a double pipeline system could be constructed in which a flexible stainless steel pipeline was housed in the communication pipe.

During construction, plastic elongation is expected to occur when the flexible pipe stainless steel is pulled. In addition, construction with a winch is assumed to not be possible due to plastic deformation, and this will also be confirmed.

As a result of towing the flexible stainless steel tube at a speed of 3 m per minute as shown in Figure 4, the following points were confirmed: construction was possible without any problems with tension, horizontal and vertical bend sections could be constructed without any problems, and the stainless steel flexible tube was stretched because it was pulled during construction but shrank when the winch was removed; this effect would be negligible in future construction.

Figure 4. Construction.

3 VERIFICATION (2): HYDROGEN TRANSPORT VERIFICATION

An airtight check was conducted to ensure that no gas leakage occurred in the system constructed in the verification (1). For confirmation, nitrogen gas with no risk of explosion was pumped to a constructed double piping system, and pressure drop measurements were performed on the supplying and receiving sides under the conditions shown in Table 1. The test pressure was held for 120 minutes, after which a foaming agent was used to detect any leaks or pressure drops.

The airtightness with nitrogen confirmed the possibility of transporting hydrogen using a hydrogen pipe. The pressure during transportation was at 0.95 Mpa. We also determined whether hydrogen was leaking by installing a hydrogen sensor.

Table 1. Pressure drop measurements result.

Normal pressure (MPa)	Test pressure (MPa)	Measurement time (minutes)	Results	Judgment
0.95	1.05	120	No leakage	OK

We confirmed that the stainless steel flexible tube was stretched during hydrogen transportation. In particular, since the extended force is concentrated at a fixed point, problems such as the elongation and meandering of the flexible stainless steel tube between the fixed position in a manhole and the duct opening were confirmed (Figure 5).

Figure 5. Result.

In response to these problem, we confirmed that the stainless steel flexible pipe extends 5 mm/m at a pressure of 0.95 Mpa when checking how long the pipe extends during hydrogen transportation. Depending on where the extension force is applied, the stainless steel flexible pipe was at risk of buckling, so countermeasures were considered.

We confirmed that the extension of the flexible pipe into the manhole could be suppressed by fixing the pipe at the connection between the manhole and pipeline. When hydrogen was transported at a pressure of 0.95 MPa as in the previous experiment, the elongation of the stainless steel flexible tube was suppressed by the fixation effect.

From this result, it is assumed that since elongation occurs when hydrogen is transported using flexible stainless steel tubes, it is necessary to first fix them in manholes, and any damage to them must be suppressed by countermeasures.

4 VERIFICATION (3): EFFECT OF FLEXIBLE STAINLESS STEEL PIPE INSTALLED IN A METAL COMMUNICATION PIPE

As a number of communication pipes are made of metal, the stainless steel flexible pipe may be damaged due to contact with rust or the like in the metal pipe when towed through it by

a winch. This test confirmed any scratches or breakages when the stainless steel flexible pipe was laid using metal tubing intentionally constructed with rust.

The conditions for the test are as follows. A rusted metal communication pipe (5 m) was prepared, in which a flexible stainless steel tube cut to 30 cm is reciprocated. On the basis of the number of reciprocations, the distance of the flexible stainless steel pipe laid in the metal pipe is calculated. The flexible stainless steel tube is then visually checked for scratches at each distance. The distances verified were between 250 and 2,500 m.

Conclusion:

When the stainless steel flexible tube was pulled for a length equivalent to 2,500 m, a slight scratch occurred on its surface. However, it had no effect when hydrogen was passed it, indicating that the metal tube did not affect the flexible stainless steel tube. (Figure 6)

Figure. 6. Result.

5 CONCLUSIONS

We verified whether a hydrogen transportation system could be constructed by utilizing the empty space in existing communication pipes.

- The purpose of this study was to confirm the possibility of constructing a stainless steel flexible conduit for communication pipes in a research facility in Tsukuba City using a double conduit system. It was confirmed that stainless steel flexible tubes can be constructed without any effects even if horizontal or vertical bend sections are present.
- When pumping hydrogen through the constructed system, it was found that the stainless steel flexible tube extends in the manhole space. Therefore, it was confirmed that it was possible to suppress the elongation by taking measures such as fixing it in a manhole.
- A verification was carried out to see if a flexible stainless steel pipe could be laid on a rusted metal communication pipe. It was confirmed that the effect was minor even when towing the pipe over 2500 m.

On the basis of the aforementioned points, the construction of hydrogen facilities that contribute to the reduction of life cycle costs and carbon dioxide generated in construction, is possible by utilizing existing systems, resources, and limiting construction by excavation.

Modelling the thermal response of firestop sealant exposed to standard fire

Z. Ye, A.K. Abu, C.M. Fleischmann & R.P. Dhakal

University of Canterbury, Christchurch, New Zealand

ABSTRACT: Firestopping systems are non-structural passive fire protection elements which are used to seal service penetrations through fire-rated assemblies. They are designed to restrict fire spread for durations of exposure following the standard fire test. Depending on the material used, different firestopping configurations can behave very differently even when exposed to the same heating environment. However, current understanding of fire performance of firestopping systems is based on standard fire testing, without a full appreciation of thermal behavior of the firestopping material (called firestop). As an initial assessment to identify thermophysical properties for firestop materials, this sensitivity study investigates how variations of temperature-dependent thermal property inputs affects the results of the numerical analysis in comparison to test data. The close comparison between the experimental results and numerical prediction highlights the extreme importance of gathering the right fundamental properties for fire behavior modelling.

1 INTRODUCTION

In modern fire safety engineering design, the concept of compartmentation plays a significant role. As a general design principle, a building is considered as composed of multiple fire-protected zones, in which each zone is capable of containing a fire for a reasonable duration (Soja, 2022). Thus fire-resistive barriers, which are used to separate fire compartments, are required to maintain their integrity during their service life in order to prevent flame and smoke passage during fire events. However, in real applications non-structural services, such as piping and electrical communication systems, are run from one part of the building to another; these systems sometimes need to go through fire-rated walls and floors. The existence of these penetrating building components could undermine the physical integrity of original fire separation. To cope with this problem and ensure the overall effectiveness of fire compartmentation, firestops have been well-applied to protect penetrations in fire separations. These firestops are designed to firmly seal installation gaps between penetrations and fire barriers. In theory, they do not fail earlier than the main body of the protected fire-rated assemblies during real fires (The Ministry of Business Innovation and Employment, 2020). Various fire-stop solutions are available in today's market to respond to the demand for different characteristics of protected penetrations (e.g. size of cable bundles, plastic pipe versus metallic pipe, etc.) and fire-rated wall/floor assemblies (e.g. dimensions of apertures, drywall versus concrete wall, etc.). For example, firestop wrap and collar are frequently used for filling the gaps caused by the melting of plastic pipes under heat (Sędłak et al., 2017) while high thermal conductive metal penetrations rather use porous firestop mastic or high-density board systems to retard the heat transfer at contact faces (Soja, 2022). The holistic fire separation assembly is called as a firestopping system. For cases where fire-rated substrate are completely penetrated by service installation (as illustrated in Figure 1) they are known as through-penetration fire-stopping systems (ASTM International, 2017).

Figure 1. Three main components of a typical through-penetration firestopping system.

Firestopping systems are classified as passive fire protection (PFP) systems which are usually not designed with any load-bearing capacity. Similar to most other PFP systems, their fire performance is rated by a period of time that the systems survive under exposure to a conventional standard fire. The tested performance is standardized as a Fire Resistance Rating (FRR) usually in multiples of 30 minutes. The assessment criteria considers integrity (E) and insulation (I), which examine the capability to block flame propagation through the medium and restrict a rapid temperature rise on the non-fire-exposed side of the medium (International Organization for Standardization, 1999; European Committee for Standardization, 2009; Standards Australia, 2014). Additional criteria such as air leakage (L) and water rating (W) may also be required in certain regions (International Code Council, 2021). Nevertheless, the traditional standard furnace tests never consider performance deterioration nor effects of consequences during service life. For instance, significant seismic damage has been recorded on firestopping systems in recent earthquakes (Baker et al., 2012; Federal Emergency Management Agency (FEMA), 2012). Considering that not all buildings are likely to be fully inspected after every seismic event, especially if only minor and medium earthquakes occur, seismic-induced openings around service penetrations could act as potential paths which channel fire and smoke between adjacent compartments. Namely, the fire protection systems would be left vulnerable and may fail earlier than expected in a future potential large fire. As observed above, this fire safety issue is particularly important for seismically active countries, such as United States, Japan, New Zealand and so on. However, the effective performance of earthquake-damaged firestopping systems has not yet been studied.

During initial investigations of the residual functionality of general firestopping systems in the aftermath of earthquakes, the authors realized that there is a significant lack of knowledge, including the transient thermal behavior of firestop materials at elevated temperatures. This is because the fire engineering design industry focuses on systems that meet a minimum fire resistance rating to the standard fire, which never occurs in a real building fire, to meet standardized design requirements. As such, there is no understanding of the reactions involved and heat transfer mechanisms of various firestop materials in fires. On the other hand, the lack of property information of common firestops also increases the difficulty to simulate the associated thermal behavior through numerical modeling. As a result, it becomes a challenge to predict the actual performance of firestopping systems when exposed to both standard and non-standard fire conditions.

As a credible numerical benchmark model does not yet exist for any firestopping system, largely rooted in the deficiency of fundamental material properties, this paper aims to utilize thermal property inputs to develop a preliminary finite element (FE) heat transfer model for a commonly used firestop acrylic sealant. The model is built based on a standard fire test (Warrington Fire Research Consultancy, 1996). Among all related material parameters, conductivity (k), specific heat capacity (c_p) and density (ρ) are the most important ones that govern the temperature

rise within solids (Wickström, 2016). Information is provided by the product manufacturer on the change in density with temperature. As such the research mainly probes into the impacts of pseudo thermal conductivity (k) and specific heat (c_p) inputs on the accuracy of surface temperature estimates. The thermal response of the firestop solution was modelled in comparison to well-established material models of timber, gypsum board and intumescent paint. The thermal properties of these three materials have been relatively better understood in contrast. A comparison of corresponding numerical results based on different thermal property models is also drawn in this paper.

2 FINITE ELEMENT MODELING

2.1 Description of the simulated fire test

The numerical model presented in this paper was developed based on a standard fire test conducted by Warrington Fire Research Consultancy (1996). The tested assembly consisted of two identical lightweight autoclaved aerated concrete (AAC) substrates, which had dimensions of 0.15×0.15×0.95 m. A rockwool insulation and a non-intumescent firestop acrylic sealant were applied to fill a 30 mm wide gap between the substrates. There was no penetrating element included in the test to avoid any ill-defined thermal interactions. The overall structure of the tested system can be seen in Figure 2a. During the experiment, the rockwool insulation was fully exposed to the hot gases and flame, while the firestop sealant sat behind the rockwool layer. It did not receive any direct heat flux from the furnace. The test strictly followed the normative assessment requirements stipulated in BS 476-20:1987 (British Standards Institution, 1987). The test started at room temperature of 18 °C. The monitored furnace temperature throughout the four-hour test is plotted in Figure 3.

A corresponding three-dimensional thermal model was analyzed by using the finite element solver ABAQUS/Standard (Dassault Systèmes, 2020). In the present model, all solids were discretized into eight-node linear heat transfer bricks (DC3D8) for an uncoupled heat transfer analysis. A fine mesh size of 0.005 m was assigned on each side and it showed an overall good quality of results.

By following the instructions for modelling a standard fire scenario suggested in the standard BS EN 1991-1-2 (European Committee for Standardization, 2002), a convective heat transfer coefficient (h_c) of 25 W/m²K with a emissivity factor (ε) of 0.8 was assigned at the fire-exposed boundary, which is labelled and shaded in Figure 2a. These two parameters help model the incident convective (\dot{q}''_{conv}) and radiative heat flows (\dot{q}''_{rad}) produced by the furnace respectively, and they are assumed to be applied uniformly across all heating boundaries. Overall, the net heat flux ($\dot{q}''_{\text{total,fire}}$) received on the fire-exposed surfaces can be then represented as following equation:

$$\dot{q}''_{\text{total,fire}} = \dot{q}''_{\text{conv}} + \dot{q}''_{\text{rad}} = h_c(T_g - T_s) + 5.67 \times 10^{-8} \Phi \varepsilon \left[(T_g + 273)^4 - (T_s + 273)^4 \right] \quad (1)$$

where Φ represents the view factor, with a default value of one for surface radiation. T_g and T_s stand for the transient furnace temperature (i.e. Figure 3) and surface temperature of element respectively in degree Celsius. The value of T_s at each time step was estimated by solving the related heat balance equations using ABAQUS (Dassault Systèmes, 2006; Nithiarasu, Lewis & Seetharamu, 2016). The convective heat transfer coefficient was set to 9 W/m²K to account for combined heat loss through both convection and radiation on the unexposed surface (ambient side) of the AAC slabs. The other boundaries of the AAC slab were all assumed to be adiabatic.

Besides, a uniform thermal conductance of 3 W/m²K was defined at all contact surfaces in accordance with a battery of sensitivity analysis. This is because the value of thermal conductance is highly variable to the conditions at the contact surfaces (e.g. pressure and gap distance between solids (Dassault Systèmes Simulia Corp, 2011)). However, it is unable to know the exact surface conditions based on the limited information in the original test report. From this, the authors conducted a separate sensitivity analysis and tried to input different thermal

conductance values, like $10^6 \text{ W/m}^2\text{K}$ (an idealized condition which assumes there is no temperature gradient and two contact surfaces achieve the same temperature at the interface), $100 \text{ W/m}^2\text{K}$, $10 \text{ W/m}^2\text{K}$, $5 \text{ W/m}^2\text{K}$, $4 \text{ W/m}^2\text{K}$, $3 \text{ W/m}^2\text{K}$ as well as $1 \text{ W/m}^2\text{K}$, in order to see the difference between the corresponding temperature estimates. Through comparing with the thermocouple data obtained from the original test, it was found that a better agreement could be generated when define the thermal conductance to be $3 \text{ W/m}^2\text{K}$.

Above all, the selections of appropriate material property inputs always play a critical role in simulating the elements behavior. As a result, the authenticity of the overall model also relies on this factor. For numerical heat transfer analysis, the essential property inputs are conductivity (k), specific heat capacity (c_p) and density (ρ). In the current model, the thermal properties of AAC slab and rockwool insulation can employ the material data from the previous research (Hakmi et al., 1993; Benichou et al., 2001; Ghazi Wakili et al., 2015). Nevertheless, the fundamental properties of common firestop acrylic sealants are uncertain. To conquer the problem, this study attempted to use fictitious property values to model the thermal behavior of the tested firestop sealant. The creation of the ‘artificial’ properties is grounded on the test observations, as interpreted below. The reliability of the overall model is justified through comparisons of the simulated temperatures on the unexposed surface of the firestop acrylic sealant to corresponding measured thermocouple data (as indicated in Figure 2b) during the actual test.

Figure 2. Configuration of tested firestopping specimen: (a) overall dimensions; (b) Thermocouple measurements on non-fire side.

2.2 Thermophysical property inputs for firestop acrylic sealant

In the original test report, visible charring was noticed on the unexposed surface of the firestop acrylic sealant at 146 minutes after the experiment began. This phenomenon was considered as a basis for drawing reference from the temperature-dependent thermal properties of other common charring materials, like timber, gypsum board and organic intumescent polymers.

Figure 3. Recorded furnace temperature during the test.

A parametric analysis was therefore conducted to select representative values to adopt. These were developed from variations of combinations of thermal property inputs (i.e. k and c_p). The property combinations were:

- Case 1: Constant thermal conductivity ($k=0.179$ W/mK) and specific heat ($c_p = 1500$ J/kg °C) values for general acrylic materials at ambient condition (Plastic Service Centers, 2021). It is assumed that both properties are completely insensitive to changes of temperature. This case is depicted by the solid black lines in Figure 4.
- Case 2: Apply temperature-dependent thermophysical property ratios following timber properties, as given in Eurocode 5 (European Committee for Standardization, 2004) to the ambient values of general acrylic materials given in Case 1. The modified thermal property results are plotted as per long dash lines in Figure 4.
- Case 3: Employ the same method in Case 2, but use the thermophysical property growth ratios of gypsum board instead (Wang et al., 2012). These modified property profiles are drawn in dash-dot lines in the same plots below.
- Case 4: The last scenario was built based on the thermal property growth patterns of intumescent coatings. The variation of thermal conductivity under high temperatures references a validated effective conductivity model for a solvent-borne acrylic intumescent paint (Nørgaard et al., 2016). The suggested analytical model considered a combined heat transfer effect inside both virgin material and carbonaceous char layer at different temperatures ranges, while the evolution of specific heat employed experimental measurements of a disparate intumescent material as collected by Tabeling (2014). These parameters were represented by the dot lines in the same figure.

Figure 4. Difference between four different combinations of thermal property inputs.

3 RESULTS AND DISCUSSION

The experimental thermocouple measurements and their corresponding numerical results are plotted in Figure 5. The numerical estimates show a close agreement to the experimental data only within the first 90 minutes. Among the four numerical cases, Case 2 displayed a better consistency to the test results in comparison to the other cases. It can well predict the temperature at center of the sealant until about 130 minutes. But meanwhile, the results at the interface between the sealant and concrete substrate were noticeably overestimated. In contrast, the third model (i.e. Case 3) presented more accurate temperature estimates at this interface up to 180 minutes. However, the temperature outputs at the center of the fire-stop material were consistently underestimated since around 70 minutes. This discrepancy could be due to a significant increase of specific heat in gypsum at about 100 °C (see Figure 4b).

Figure 5. Comparison between temperature measurements and simulation results of surface on non-fire side: (a) at center of sealant; (b) at interface between sealant and AAC substrate.

The results show that none of these models can predict the surface temperature history of the firestop acrylic sealant throughout the four-hour exposure. This could be due to uncertainty around the chemical mixtures of actual firestop sealant product and their sensitivity to changing temperatures. Thermal-induced reactions, such as dehydration, change of internal pore structures, charring and even ignition, can therefore occur at very different times (Mouritz & Gibson, 2007). As a result, the overall heat transfer mechanism is difficult to model accurately without specialized experimental support to determine the temperature-dependent thermophysical properties, e.g. use differential scanning calorimeter (DSC) technique to extract the effective specific heat capacities at elevated temperatures (Daw, 2008).

Moreover, the appropriateness of the experimental data may need some confirmation by additional test data. For instance, the apparent soar of the sealant temperature beyond 100 °C may be as a result of thermal response of the rockwool insulation on the fire-exposed end. Leppänen & Malaska (2019) found that smoldering combustion of mineral wool insulation can contribute to an increase of temperature around 115 to 165 °C. Nonetheless, this hypothesis needs further assessment to confirm its validity.

Based on the above discussion, the authors would like to underline the considerable need to gather the right fundamental properties of frequently used firestop materials. It is only by obtaining the correct thermal properties, a reliable benchmark numerical model is likely able to be generated. On that basis, further research to analyze the heat transfer interactions between different firestopping components as well as comprehend variations in response of identical fire-stop products under distinct fire regimes can then be possibly investigated in the future.

4 CONCLUSIONS

Based on a concern of modelling the behavior of firestopping materials with unknown thermal features, this paper has presented four different sensitivity analyses to simulate the fire response of a typical firestop acrylic sealant with fictitious thermal property inputs. A finite element model was built based on a real standard fire test conducted in 1996. The development of the ‘fictitious’ conductivity and specific heat capacity results were based on the similar attributes between the acrylic sealant and known materials. The materials were charring materials, including timber, gypsum board and intumescent paint. However, none of the cases showed a consistent good agreement to the test data for the entire duration of fire exposure. Thus, in order to realistically model the thermal response and ensure fire safety even under non-standard fire conditions, the authors suggest the acquisition of large pools of experimental properties data of firestops for further development of future numerical models.

Dynamic chain reaction analysis of a cable-stayed bridge by sudden loss of stays considering cable corrosion

Y. Aoki, H. Tsunoda, T. Akiyama & H. Gotou
Akita university, Akita-city, Japan

S. Nakamura
Tokai university, Hiratsuka-city, Japan

ABSTRACT: Regarding design of cable-stayed bridges, cable breakage must be considered as one of the significant events. Therefore, sudden loss of cables is normally considered when a new bridge is designed or built. On the other hand, aging of bridges is getting considerable in recent world. Especially some bridges built during 80s and 90s showed some unexpected damages such as corrosion of cables. Therefore, cable breakage of these old bridges also must be considered. In this study, hypothetical cable-stayed bridge is designed to investigate the possible chain reaction considering and not considering cable corrosion. Also, a new analysis method of chain reaction, which can include the dynamic response, is suggested.

1 INTRODUCTION

In suspension type of bridges, loss of cable should be considered in the design phase. Several research have been proposed and couple of effective numerical methods were introduced (Aoki, et al., 2012; Wolff & Starossek, 2009), regarding to the loss of cable by using dynamic response. However, since previous studies have been conducted on bridges at the time of design phase, cable corrosion or and other factors caused due to aging have not been considered. In recent years, corrosion and deterioration of cables in suspension and cable-stayed bridges, which were built mainly in the 1980s and 1990s, have been recognized as significant issues. The most recent example of the tragic event was collapsed of the Nanfangao Bridge in northeastern Taiwan in October 2019. During the large trunk drove on the bridge, one cable in the center of the span ruptured due to corrosion, and other cables ruptured one after another, like an opened-up zippers (so called as zipper type collapse as well), that caused the arch ribs to collapse and the entire bridge to collapse. This tragedy warned the world that cable corrosion would lead the structures to significant damage. Regarding this accident, some researches were carried out to investigate the situation (Nakamura & Miyachi, 2021).

In this study, a new method is proposed to analyze the chain reaction of the entire bridge subjected to sudden loss of cable with and without cable corrosion. Specifically, this proposed method attempts to dynamic analysis using FEM to investigate whether the possible progressive analysis would simulate rupture of a particular cable or not.

2 BRIDGE MODEL

2.1 *Bridge design concept*

In this study, hypothetic steel cable-stayed bridge model was designed to investigate the chain reaction of this type of bridge. While the concrete superstructure is more commonly used than

steel superstructure, this research focus on aging cable-stayed bridges that are mostly made of steel. The model is shown in Figure 1. This bridge model is assumed as a road bridge, where the main span length as 300 m and total length is 540 m (see in Figure 1(a)). The steel box girder with two vehicle lanes shown in Figure 1(b) is adopted in this research, where the width is 22 m and the web height is 3.0 m. Cables are connected at the center of the deck as it is shown in Figure 1(a), since a single stay cable arrangement is adopted in this study. The displacement at both ends of the main girder are restrained vertically but not horizontally. The tower is A-shaped consisting of three members as shown in Figure 1(c) and the cross section of members is rectangular with several ribs to avoid buckling as shown Figure 1(d). The displacement at the bottom of the oblique members of the tower are restrained in all directions including rotation. For the cables, parallel wire strand (known as PWS) is used (see in Figure 1(e)). The cable consists of steel wires, and it is assumed that the tensile strength is 1,570 MPa. The cable location and the name of cables (such as C1) for the bridge model is shown in Figure 1(a). The cable are connected to the deck mostly at 20 m intervals, while at 10 m intervals at the both ends and outer sides of the towers.

Figure 1. Bridge configuration.

2.2 Dimensions and material properties of numerical bridge model

For the numerical analysis, beam elements are used for all the components (see in Figure 2 (a)). The cross section of the bridge deck is shown in Figure 2(b). The size of deck is same as those of design, while the U-ribs and horizontal stiffeners are abbreviated to reduce the amount of calculation load. In order to avoid the local bending deformations of plates caused by abbreviation of ribs and stiffeners, the thickness of composed plates of deck and tower are increased from 11 mm to 12 mm for upper flange and webs, 14 mm to 16 mm for lower flange and 23 mm to 25 mm for the tower cross section, respectively.

Figure 2. Numerical model.

The PWS cables are modeled by cylinder solids, where the radius of the cables r have variations depending on the position of each, cables, shown in Figure 2(d).

The stress-strain relations of the materials are shown in Figure 3. The stress-strain relation of the steel plates used for main girder and tower, whose steel grade is SM400, is bi-linear with Young’s modulus of 200 GPa, Poisson’s ratio of 0.3, yield stress of 235MPa, and other properties as shown in Figure 3(a). The stress-strain relation of the cables is tri-linear with Young’s modulus of 195 GPa, Poisson’s ratio of 0.3 and other properties as shown in Figure 3(b).

This model calculation is performed by the commercial FEM software Marc Mentat 2021.4.

Figure 3. Stress-strain relations of materials.

2.3 Design load and verification of safety of structural members

In this study, design load is decided in accordance with ‘Japanese Road Bridge Specification’ (Japan Road Association, 2014), which is shown in Figure 4.

Figure 4. Design loads.

Cable prestress (Pr) is applied for each cable to create the pre-camber. The dead load (D) consists of the steel girder weight (69.7 kN/m), curbs and guardrails (24.5 kN/m), and asphalt (28.4 kN/m). A counter wights (CW , 60 kN/m) are loaded at the side spans to suppress the uplift at the end supports and decrease the bending moments of the girder and the towers. The design live load (L) is assumed the ‘B live load’ which consist of the concentrated load (p_1) represented as heavy vehicle and distributed load (p_2) represented the traffic by normal cars. The load p_1 of 10 kN/m² is applied to a length of 10 m and a width of 5.5 m at the center of the span. The other area of this 10 m span length x 5.5 m width the p_1 is applied as half of 10 kN/m². The distributed load p_2 of 3.5 kN/m² is applied to a width of 5.5 m and half of it for the other part along the entire bridge.

Sectional forces due to design load ($Pr + D + CW + L$) is obtained by numerical analysis and summarized in Table 1. According to this table all the verification value are less than 1.0, which show the assumed member are safe and the bridge model is within the allowable stress range.

3 ANALYTICAL METHODS

3.1 Cable corrosion

In this study, cables are considered as corroded and the assumption of cable corrosion in numerical analysis is explained in this section.

Table 1. Sectional force and stress of critical members.

Model-300		N	M	σ_n	σ_b	γ
Girder	Tower	-31	-59	-45	-89	0.95
	Center	2.8	79	0.2	118	0.85
Tower	Base	-28	19	-82	45	0.93
	Anchor	6.1	0	505	0	0.80
Cable	Center	6.4	0	532	0	0.85

※N :Axial force (MN), M : Bending moment (MN.m), σ_n Axial stress (MPa), σ_b : Bending stress (MPa), γ : Verification value

During corrosion is progressing, corrosion pits would be deepened, and cracks would be occurred, which would lower the ductility and decrease the cable strength. According to Nakamura and Suzumura (2013), the average elongation of the healthy steel wires used for bridge cable is over 4.0%, however the elongation will be decreased to less than half due to corrosion.

On the other hand, Mitamura et al (1992) tested PWS with/without corrosion, which research is only one experimental work of real cable. They reported that the elongation of PWS would be dropped by almost $\frac{1}{4}$ of healthy and yield stress is also decreased by about half according to their experimental work. Also, the corrosion of cable leads to not only reduction of elongation but also reduction of effective cross-sectional area (Nakamura & Suzumura, 2013).

Regarding to these previous researches, the constitutive law of corroded cables is assumed. The Stress-strain relation of healthy cable and corroded cable are presented in Figure 5. The yield stress is reduced by 60% of healthy cable and breakage strain is decreased by 80%, namely 628 MPa for tensile stress and 0.8% for breakage strain. This condition is quite harsh since the main objective of this research is considering the effect of cable corrosion.

Figure 5. Assumed constitutive laws of cable.

3.2 Numerical method of chain reaction due to loss of cable(s)

A new chain reaction analysis is suggested and introduced in this study. The chain reaction of entire bridge will be occurred due to loss of cable(s). The methodology used in this study is explained in this section. For this analysis, transient (time-history) analysis of the bridges is carried out using Newmark-beta method.

Step 1: In this method, the bridge model having all cables is called as *initial model* shown in Figure 6(a). At first, as shown in Figure 6(b), the combination of design load ($Pr + D + CW + L$) is gradually applied on the bridge model. By doing so, the bridge model is allowed to reach equilibrium state which is basically equivalent to the result of static analysis. After this analysis, time history of tensile force of C1 is taken and plotted shown in Figure 6(c).

Step 2: At this step, a subject cable (C1 or C 14) element is removed from the bridge model (called *cable loss model*) shown in Figure 6(d). For this breakage model, the combination design load is applied, which is same as step1 (see in Figure 6(e)).

In this method, after the bridge model reached the equilibrium state, the cable loss is simulated by the reducing force, which means cable tensile force shown in Figure 6(f) is down to zero over a time step of $\Delta t=0.01$ sec at analytical time of 250 sec. The removal timing against the analysis time is arbitrary. In this research, first 200 sec is used for loading time, 200 sec to 250 sec is for steady state, and cable C1 is lost its tensile force at 250 sec and dynamic transient analysis is carried out during and after removed cable. The time history load shown in Figure 6

(f) is used as applied load on the point of cable connected with the deck and the tower. The applied load has to be applied opposite sign since the time history load is the internal axial force of the removed cable.

Dynamic response of the vertical deflection at the mid-span and tensile force of cable C2 (next to the removal cable) are plotted in Figure 6(g) and (h), respectively. As it can be seen, the tensile force of C2 is decreased to zero at around 255 sec. According to the constitutive laws of cable, shown in Figure 6(i), the corroded cables would be lost their ability to carry tensile stress when they reached to breakage strain. By setting of constitutive law shown in Figure 6(j) to all the cables, cable loss can be calculated such method automatically.

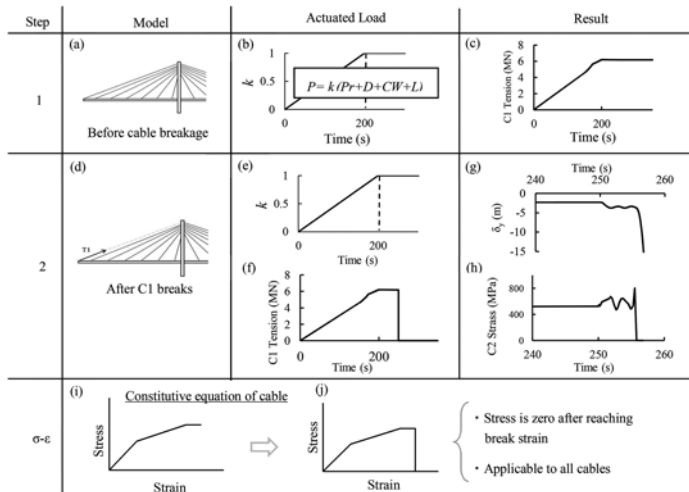

Figure 6. Chain reaction method.

4 RESULTS AND DISCUSSION

In this section, the results of chain reaction are presented. There are three scenarios considered in this research and shown in Table 2.

Table 2. Scenarios considered.

Name	Loss of cable	Corrosion	2 nd yield stress (MPa)	Breakage strain
Scenairo-1	C1	-	1570	0.04
Scenairo-2	C1	○	628	0.008
Scenario-3	C14	○	628	0.008

4.1 Loss of cable C1

Scenario-1

In Figure 7, Deformation diagram of entire bridge at critical timing with sudden loss of C1 is shown. As it is shown in Table 2, all cables are not corroded in this scenario. At 0 sec-ond of analysis time, the bridge was not applied any load. At 250 sec, C1 element is re-moved from the model and maximum deflection at mid-span is obtained at 253sec (see in Figure 7 stage I). The model was fluctuated vertically, and maximum deflection was about 1.77m downwards. At stage II in Figure 7, the model was converged. When all cables are not corroded, single cable loss does note leads to entire bridge collapses. Moreover, all the component of this bridge model was still under yield stress, therefore, the redundancy of this model was also demonstrated.

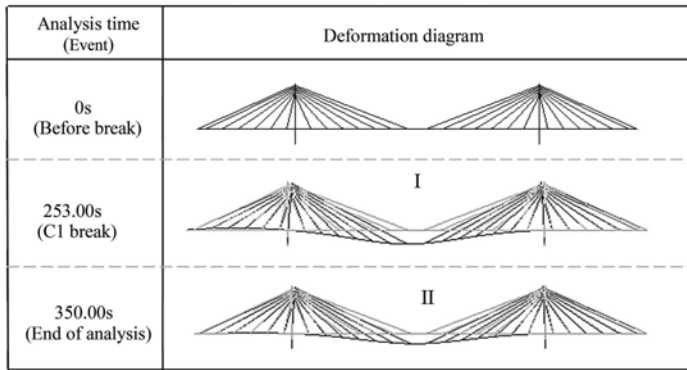

Figure 7. Deformation diagram of entire bridge at critical timing for scenario-1 (scale factor 10).

Scenario-2

In this scenario, the bridge is considered aging and all cables are assumed as corroded.

In Figure 8, deformation diagram of critical timing are shown. At 0 sec, there is no load applied and design load will be applied gradually till 200 sec. At Stage I, the analysis time is at 250 sec, C1 cable element is taken from the bridge model instantly and transient analysis is continued. At Stage II, (time as 251.01 sec), cable C2 and C3 reached to the second yield stress as 628 MPa and lost their elasticity. In Stage III, the deflection is getting significant since cable C4 and C5 are also reached to yield stress and lost their elasticity. Just before the Stage IV in timing of 256 sec, C2 and C3 cables finally reached to breakage strain and eliminated from the bridge model automatically. By this phenomenon, the plastic-hinge is occurred around C5 cable, and the entire bridge is collapsed.

Figure 8. Chain reaction process for loss of cable C1 (scale factor 10).

Figure 9. Time history of cable total strain (C2 to C7).

Figure 10. Time-history of stress at the C5 cable anchorage zone (the location plastic hinge was occurred).

In Figure 9, time-history of cable total strain for (a) timing between 240sec to 260sec (before C1 removal till the bridge collapse) and (b) timing between 254.4 to 255.0 (at the cables exceeded the breakage strain) are shown. Cable C2 to C5 reached to the yield stress at 251.1sec and started to increase the strain with fluctuation and reached at the breakage stress almost all together see in Figure 9(b).

The time-history of stress at the critical location, where is around C5 cable anchorage zone is shown in Figure 10. As it can be seen in Figure 10(a), deck around C5 became plastic hinge, which means upper, lower edge and even neutral axis are yielded, just after cables are ruptured at 255 sec.

4.2 Loss of cable C14

Scenario-3: In scenario-3, cable C14 which is connected at the center of main span is eliminated at 250sec in analysis time. The deformation diagram of the entire bridge at critical times are shown in Figure 11. As it was seen in scenario-2, the same trend is detected. After removing cable C14, cable C13 and C12 reached to the second yield stress as 628 MPa at 251.18 sec which is seen in Figure 11 stage II. At 254.58 sec, three cables, named C13, C12 and C11, reached to the breakage strain as 0.008, and these cables are eliminated from the structure automatically (see in stage II in Figure 11). After that, the other cables connected to the left side of main span (named C 10, C9 and C8) are also reached to the breakage strain and removed from the bridge model. According to losing 7 cables, the entire bridge model was collapsed having with plastic hinge seen around the C12 anchorage zone.

In Figure 12,(a) the time-history of cable strain during 240 sec to 260 sec, and (b) time-history of cable strains focused during 254.0 to 255.0 sec are shown. According to Figure 12 (a), all the cables reached to breakage strain almost simultaneously. It can be seen more details in Figure 12(b) that C 11 to C 13 are exceeded the breakage strain during 0.2 sec and the other three cables exceeded the value by 0.1sec delaying respectively.

The time history of stress around the C12 is shown in Figure 13. According to this graph, the stress is fluctuated after removing C14 cable and suddenly reached to the yield stress at the

Figure 11. Chain reaction process for loss of cable C14 (scale factor 10).

Figure 12. Time history of cable total strain (C8 to C13).

Figure 13. Time-history of stress at the C12 cable anchorage zone (the location plastic hinge was occurred).

bottom of deck and top of the deck at the same time. Moreover, the stress around the neutral axis exceeded to the tensile stress.

5 CONCLUSIONS

In this research, a new chain reaction method by dynamic transient analysis is introduced and considered. As it can be concluded that

- Chain reaction of cable-stayed bridge could be conducted by this introduced method.
- The cable corrosion could be presented by using introduced constitutive laws.
- Chain reaction can be occurred by the rupture of cable connected at the anchorage zone and assumed all the cables were connected.
- Also, the chain reaction was happened when the first ruptured cable was the one connected at the center of the girder, even all the cables were assumed as corroded.
- However, the chain reaction was not occurred when the cable is not corroded.

For the further research, these factors should be considered;

- Confirm the constitutive law assumed in this research by experimental work.
- Calculate the impact from the force created by ruptured cable instantly.
- Confirm the most significant cable related with the loading patterns.

Since the assumption of PWS corrosion in this study is only related to one reference, therefore, it should be updated. It is important to know the actual material characteristics of corroded PWS for the future bridge maintenance.

ABSTRACT: The mechanism of concrete shrinkage is mainly controlled by the relative humidity (RH) gradient in its pore-structure. The change in the RH in the long term is mainly controlled by moisture diffusivity and saturation degree, which are affected by many internal and/or external factors. In this paper, the impact of size and shape of the concrete member on the RH gradient and hence the shrinkage behaviour of the member, is explored. Generally, there are many engineering 1D models for time-dependent deformation that can predict the size/shape effect on concrete shrinkage using a parameter called the notional size (h_0) defined by the ratio between the total area of the member's cross-section to the perimeter of the surface that is in contact with the outer environment. A key contribution of this paper is re-examination of the capability of Eurocode 2 to capture shape and size effects that has so far not been accounted for. This is achieved via computationally intensive 3D numerical analysis of different shapes and sizes of concrete members. For the numerical analysis, a Hygro-Thermo-Chemical (HTC) model with elasticity is used, which essentially incorporates heat diffusion, moisture diffusion, hydration reaction and shrinkage. 3D simulations of different shapes and sizes of concrete structural members suggest that the notional size parameter in its present form may be insufficient and does not capture the shape effect, leading to a proposal of shape factors.

1 INTRODUCTION

Much research work has been done since time-dependent deformations, creep and shrinkage, of concrete were discovered early last century. However, creep and shrinkage phenomena of cement-based concrete are still far from being fully understood and modelled (Bažant et al., 2001). This is attributable to the complexity of the phenomena and the nonlinear interaction between internal and external factors affecting time-dependent deformations. Examples of external factors are gradients in the relative humidity and temperature, different shapes and dimensions. Examples of internal factors are concrete the concrete composition and curing procedures (ACI 209R 2008). The complexity of this phenomenon leads to inaccurate predictions of the long-term behaviour of concrete. This may lead to a loss in the functionality of concrete structural members, especially, shrinkage of pre-stressed concrete structures, which can have a significant impact on the prestressing forces in the long term (Gan et al., 2019; Li et al., 2019; Raphael et al., 2012).

There are different types of time-dependent deformations of unloaded-specimens (shrinkage), such as autogenous shrinkage, drying shrinkage and carbonation shrinkage. In this study, the main concern is concrete drying shrinkage and the impact of size/shape of the member on it. The mechanism of drying shrinkage is mainly controlled by the relative

humidity gradient within the concrete pore-structure. This change in the RH in the long term is mainly controlled by the moisture diffusivity and capacity (Bažant et al., 2015; Bažant and Najjar, 1972; Rahimi-Aghdam et al., 2019).

Generally, there are many engineering 1D-prediction-models for time-dependent deformation that can reflect the size/shape effect on concrete shrinkage using a parameter called the notional size such as the Eurocode model included in prEN1992-1-1, the CEB-FIB model (fib 2010), the ACI model (ACI 209R 2008) and the B3 model (Bažant and Baweja, 1995) and B4 model (RILEM, 2015). The notional size is the ratio between the total area of the member's cross-section to the perimeter of the surface that is in contact with the outer environment. In this study, this notional size parameter of the prEN1992-1-1 (designated Eurocode 2 in the remaining of this paper) is revisited using numerical analysis of different shapes and sizes of concrete members. For the numerical analysis a Hygro-Thermo-Chemical (HTC) model with elasticity is used, which essentially incorporates heat diffusion, moisture diffusion, hydration reaction and shrinkage (Di Luzio and Cusatis, 2009a, 2009b). Many investigations and attempts were done to modify the notional size of different codes and to add a shape factor parameter to it (Bažant et al., 1976; Dönmez and Bažant, 2016; Hubler et al., 2015; TC-242-MDC, 2015; Wendner et al., 2015a, 2015b), however the performance of Eurocode 2 in this regard has not been addressed in the studies. Thus, in this study, 3D simulations of different shapes/sizes of concrete structural members are considered to modify the notional size parameter in the Eurocode 2 and to add a shape correction factor to it.

2 PREDICTION OF LONGITUDINAL STRAINS OF A CONCRETE MEMBER DUE TO DRYING SHRINKAGE IN EUROCODE

In the upcoming 2nd generation of Eurocode 2, an averaged cross-section approach is followed for predicting the time-dependent deformation of the member. The total shrinkage is the summation of autogenous shrinkage and drying shrinkage. The drying shrinkage strain can be expressed as follows:

$$\varepsilon_{cd}(t - t_s) = \varepsilon_{cdsfm} \cdot \beta_{RH} \cdot \beta_{ds}(t, t_s) \cdot \alpha_{NDP,d} \quad (1)$$

$$\beta_{ds}(t, t_s) = \left[\frac{(t - t_s)}{(t - t_s) + 0.035 \cdot h_0^2} \right]^{0.5} \quad (2)$$

Where ε_{cdsfm} is the notional drying shrinkage coefficient, β_{RH} is a coefficient to consider the RH effect, $\beta_{ds}(t, t_s)$ is a function that describes the development of drying shrinkage strains with time, t_s is the age of concrete (days) when drying starts, and $\alpha_{NDP,d}$ is considered. As for Equation (2), t is the age of concrete at the considered moment (days). h_0 is the notional size of the cross-section which can be calculated as follows: $h_0 = 2 \cdot A_c / u$ where A_c is the cross-sectional area of the member (mm²), and u is the perimeter of the cross-section that is exposed to the drying environment (mm).

3 NUMERICAL ANALYSIS OF DRYING SHRINKAGE USING HTC MODEL

The HTC model can model the spatial and temporal field of relative humidity RH, temperature T and the overall hydration reaction degree over the structural element. Based on this model, the T and RH can be computed using the enthalpy balance equation and the moisture mass balance equation, respectively (Abdellatef et al., 2019).

The RH of the pore structure is governed by the combination of Fick's law of diffusion and the sorption isotherms of water (Dönmez and Bažant, 2016) as follows:

$$\frac{\partial RH}{\partial t} = \nabla [D(RH, T) \cdot \nabla RH] \quad (3)$$

$$D(RH, T) = \exp\left(\frac{E_{ad}}{R \cdot T_0} - \frac{E_{ad}}{R \cdot T}\right) \cdot D_1 \cdot \left[1 + \left(\frac{D_1}{D_0} - 1\right) \cdot (1 - RH)^n\right]^{-1} \quad (4)$$

where RH is the pore relative humidity (%), t is the time (days), $D(RH)$ is the moisture diffusivity, D_1 and D_0 are the maximum and minimum moisture diffusion coefficient (kg/mm h) at saturation and fully dried state, n is an exponent that governs the transition between D_1 and D_0 , T_0 is the room temperature and $\frac{E_{ad}}{R} \approx 2700K$.

The temperature of the pore structure is governed by the combination of Fourier's law and the enthalpy balance equation as follows:

$$\rho \cdot c_t \cdot \frac{\partial T}{\partial t} = -\nabla \cdot \mathbf{q} + \dot{Q}_c \quad (5)$$

where ρ is concrete density, c_t is specific heat capacity of concrete, q is the heat flux, \dot{Q}_c is the rate of heat generation due to cement hydration, silica fume polymerisation and pozzolanic reactions.

The time-dependent deformation of the unloaded-specimens as a result of the drying process is mainly linked to the diffusion process of concrete or the related change of the RH distribution in the pore network. The free local shrinkage strain rate $\dot{\epsilon}_f$ can be assumed to be proportional to the local rate of RH change (Abdellatef et al., 2019):

$$\dot{\epsilon}_f = \alpha_h \cdot \dot{RH} \quad (6)$$

where α_h represents the hygral shrinkage coefficient.

This 3D numerical work considers concrete members with different cross-section types and sizes as shown in Table 3. The mechanical boundary conditions of this 3D model ensure consistency with the hypothesis of Navier-Bernoulli, which is demonstrated in Figure 1. To this end rigid plates are attached onto both end faces with statically determinate boundary conditions. In addition, it should be noted that creep has been ignored in this instance as a first approximation. In fact, creep plays an important role at high drying shrinkage stresses, which is usual for thinner cross sections.

Figure 1. Conceptual model used in the analysis.

4 EUROCODE MODIFICATION PROCEDURE

In this section, the methodology for the modification of $\beta_{ds}(t, t_s)$ is presented. Firstly, numerical analyses of drying shrinkage of real experiments are carried out based on published

experimental data (Bryant and Vadhanavikkit, 1987) for the purpose of validating the Lattice Discrete Particle Model (LDPM). LDPM is a discrete model that represents heterogeneity of concrete by introducing coarse aggregate particles to the mortar. Thus, LDPM is capable of simulating the mechanical interaction between the randomly placed particles and the cement mortar (Cusatis et al., 2011b, 2011a). The input parameters that are used here are based on (Abdellatef et al., 2019) as shown in Table 1. After successful validation by the experiments (see Figure 2), numerical simulations for different shapes and sizes are performed, as shown in Table 2. The specimen sizes and shapes are chosen such that a range of real structural conditions and not only laboratory specimens are covered. The length of all specimens is assumed to be 500 mm. As the functional dependence of drying shrinkage on the shape and size of the cross-section is considered uncertain, the horizontal scaling parameter of the Eurocode time function is replaced by a variable ψ to be determined inversely, resulting in an analytical surrogate model with $\beta_{ds}(t, t_s) = \left[\frac{(t-t_s)}{(t-t_s)+\psi} \right]^{0.5}$. Then, using the least square method, the optimum values of ψ are determined for each cross-section shape and size by fitting the results of the 3D numerical simulations.

Table 1. HTC input parameters.

	Parameter (Units)	Value
Rate of hydration	A_{c1} (h^{-1})	42.55×10^7
	A_{c2}	375×10^{-4}
	η_c	9.3
Heat specific capacity	C_t (kJ/kg°C)	1.1
Thermal conductivity	λ_t (W/m°C)	2.3
Moisture permeability	D_0 (kg/mm h)	0.036×10^{-9}
	D_1 (kg/mm h)	6.5×10^{-7}
Sorption/desorption isotherm	n	6.5
	g_1	1.75
	g_2	0.025
Shrinkage coefficient	α_h	1.4×10^{-3}
Thermal coefficient	A_t	10×10^{-6}
Compressive strength	F_c' (MPa)	50.1

Table 2. Considered shapes and sizes and their corresponding notional size.

Shape (symbol)	Dim. (mm)	h_o (mm)
Circle (D)	D=150, 200, 400	75, 100, 200
Rectangle ($Rec L W$)	Length(L):width(W) $L:W=1$	75, 100, 200
	$W=150,200,400$

	$L:W=4$	120,160,320
	$W=150,200,400$	

Table 3. Prism sizes for autogenous and drying shrinkage of Bryant experiment.

	Dimensions
Autogenous shrinkage	150mm × 150mm × 600mm
Drying shrinkage 100	100mm × 100mm × 400mm
Drying shrinkage 150	150mm × 150mm × 600mm
Drying shrinkage 200	200mm × 200mm × 800mm
Drying shrinkage 300	300mm × 300mm × 1200mm

4.1 Validation of the numerical approach (Bryant experiment)

Bryant conducted a series of shrinkage experiments under sealed and drying conditions (RH=60%, T=20 °C) for different prism sizes as shown in Table 3. The prisms were cured for 9 days, then exposed to the outer environment. The constituents of the cement were as follows, 1985 kg/m³ of crushed basalt, 390 kg/m³ of ordinary Portland cement (CEM I) and a water-to-cement ratio of 0.47 by weight (Bryant and Vadhanavikkit, 1987). Figure (2) shows good correspondence between the numerical simulations and Bryant's experimental results, thus giving confidence in the use of the numerical model for further examining the shape effect.

Figure 2. Experimental and numerically simulated shrinkage strain (Bryant and Vadhanavikkit, 1987).

4.2 Predictive numerical simulation for different shapes and sizes

A series of numerical simulations were considered for different shapes and sizes as shown in Table 2 using the same calibrated parameters of Bryant's experiments. All simulations are performed on samples cured for 28 days and then either exposed to drying conditions (RH=75%, $T=20^{\circ}\text{C}$) or completely sealed to capture the autogenous shrinkage. Figure 3 shows the evolution of total shrinkage strains obtained from the numerical analysis for different shapes and sizes.

Figure 3. Total shrinkage development for different cross-sections and sizes: (a) Circle, (b) Square, (c) Rectangle with aspect ratio 1:2, (d) Rectangle with aspect ratio 1:3, (e) Rectangle with aspect ratio 1:4.

Figure 3 shows that the evolution of total shrinkage depends not only on notional size but also on the shape of the cross-section. Each subplot represents geometrically similar cross-sections of different size. This is elaborated further in Figure 4, which shows the drying shrinkage development for 2 different shapes predicted by the numerical analysis in comparison to the Eurocode 2 prediction which is shape-independent. The 2 shapes possess the same notional size ($h_0=200$ mm). Eurocode 2 fails to capture the difference in shapes, as shown in Figure 4. Hence, it is recommended to introduce a shape parameter to Eurocode 2.

Figure 4. Shape effect on shrinkage behaviour of members with $h_0=200$ mm.

Figure 5. Total shrinkage, autogenous shrinkage and drying shrinkage of a cylinder with 400 mm diameter and 500 mm height.

4.3 Determination of shape factor

The simulations for sealed conditions are considered to capture autogenous shrinkage. Hence, the predicted autogenous shrinkage strains are subtracted from the total shrinkage strains. Consecutively, the drying shrinkage can be extracted as shown in Figure 5. The figure shows the autogenous shrinkage, total shrinkage and the estimated drying shrinkage from the numerical analysis and Eurocode 2 of a cylinder with 400 mm diameter under sealed and drying conditions (RH=75%). Additionally, the figure also shows that Eurocode underestimates the drying shrinkage rate. Using the least-square-method, a ψ value with the least error for each simulation is calibrated.

Figure 6 shows a relationship between ψ and h_0 for each shape/size. From this figure, a shape factor S_f can be derived as shown in Table 4 so that ψ can be expressed as follows: $\psi = 0.0021 \cdot S_f \cdot h_0^2$.

Table 4. Proposed shape factor for different shapes.

Shape	Shape Factor (S_f)
<i>Rectangle</i>	1
<i>Circle</i>	1.33
<i>Square</i>	1.62

Figure 6. ψ of each shapes/sizes and their corresponding h_0 : (a) Square (b) Circle (c) Rectangle.

5 CONCLUSIONS

In this paper, the impact of size/shape of the concrete member on the relative humidity distribution and in turn the drying shrinkage behaviour has been investigated numerically by a 3D hygro-thermo-chemical analysis and compared to predictions according to the upcoming 2nd generation Eurocode 2. This work concludes the following:

- 1- The used multi-physics framework model succeeds in simulating experiments on concrete prisms with different sizes.
- 2- Virtual tests of different shapes and sizes can be simulated using the multi-physics numerical framework.
- 3- The shape of the cross-section has a noteworthy influence on the development of drying shrinkage, which is not covered by Eurocode 2.
- 4- An approach is presented that allows the development of shape and size-effect correction terms based on elastic 3D multi-physics simulations, which can later be extended to consider damage, creep and reinforcement.

Guided tour of the pathological manifestations found at Rossio's historical train station

C. Carvalho & N. Bento

Infraestruturas de Portugal, Lisboa, Portugal

A. Silva

CERIS, Instituto Superior Técnico, Lisboa, Portugal

ABSTRACT: The present study is a guided tour of the pathological manifestations found at Rossio's historical train station, located in the centre of Lisbon, Portugal. Built in the late 19th century, this station is classified as a Monument of National Public Interest, being one of the most visited stations in the country. In this paper, the characterisation of the existing building is presented, based on visual inspection. The most common types of anomalies were identified, as well as some proposed rehabilitation techniques. Some of the most relevant restraints are the fact that the building is classified, its location in Lisbon's downtown and, finally, the lack of information about existing infrastructures, structures, and water courses. The conclusions drawn intend to raise awareness to the importance of regular and adequate maintenance among the industry actors and minimize the development of anomalies and their causes, at the design and application stages.

1 INTRODUCTION

In this study, a guided visit is made to the pathological manifestations found in a Lisbon's historic train station, classified as a Monument of National Public Interest (Figure 1a and 1b). This station was built in the late 19th century, being one of the most visited stations in the country, with approximately 14.5 million annual passengers in 2019 (according to data from the management entity). The station has undergone several interventions over the years, including the installation of electric lighting in 1894, the electrification of the railway in the 1950s and the connection to Restauradores Metro Station in the 1990s.

Since the last general renovation in 2006, the station has been subjected to a natural process of degradation, with the appearance of several anomalies, from the wear of the station's equipment to infrastructural anomalies. Despite some actions of local maintenance that took place over the years, a general rehabilitation is needed, to guarantee the safety of its users and workers, as well as to protect and maintain this national historic building.

In this paper, the characterization of the existing building is presented, based on the visual inspection. The most common types of anomalies were identified, as well as some proposed rehabilitation techniques.

1.1 *Main restraints*

Since the Rossio train station is a historic building with heritage value, some restrictions were found to its rehabilitation. Moreover, the station is in Lisbon's downtown, which implies some access barriers and some caution with the surrounding structures and infrastructures. There is also a lack of information about the existing infrastructures, structures, and water courses around the train station.

Figure 1. Site location and conditioning (a - source: adapted from Google Maps); main façade (b).

2 CHARACTERISATION OF THE BUILDING: EXISTING ANOMALIES

The buildings' deterioration process occurs as soon as they are put into use. Deterioration is a gradual phenomenon associated with physical, chemical, and mechanical degradation agents and with the natural ageing process (Silva et al. 2016a). In this chapter, the characterization of the train station is presented, by identifying the most common types of anomalies identified.

2.1 Exterior

The exterior façade of the station was refurbished in 2019, restoring all the natural stone claddings. These claddings raise the value of buildings while representing the first layer of protection against weather-related agents (de Brito et al. 2020). However, the existing obsolete pest bird's deterrents were not replaced. Due to the constant exposure to weather conditions, and absence of maintenance actions, the actual system is composed of deformed stainless-steel spikes and a deactivated low voltage bird scarer (Figure 2a and b). The deterioration of these systems results in the permanence of pigeons and seagulls on exterior façades and roof. Also, the skylights are devoid of any system that prevents landing and permanence of birds, which leads to being permanently dirty with bird droppings, aiding a negative visual impact for the station (Figure 2c) as well as promoting the corrosion and degradation of the building.

Birds can affect monuments in many ways, causing a lot of alterations: aesthetic, physical, mechanical, chemical, or biological. One of the degradation factors that has more incidence in monuments is bird nesting and the accumulation of bird droppings. Besides the aesthetic effect, bird droppings deteriorate stone substrate and, if not removed periodically, can obstruct the drains, which increases the presence of humidity. The growth of plant roots that germinate on the nests can also cause damage, as well as nests can create stability problems both in structural elements and in ornamental elements. Both can promote the disintegration of stone ornaments, and hence the risk of them falling on people passing by.

Finally, bird control is important not only for the protection of buildings, but also for preserving public health and prevention of spread of diseases (Rodríguez 2022; Spennemann, 2017, 2018).

Figure 2. Existing bird deterrent system (a, b); skylight with permanence of seagulls (c).

Figure 3. Roof handrails (a); brise-soleil and polycarbonates (b, c); paths and stairs (d).

Regarding the roof, part of the existing paths structures must be rehabilitated. Also, there are paths that are dangerous to go through, not having an adequate structure, which does not allow the maintenance plan to be carried out as planned. In addition to that, the glass fibre reinforced polyester handrail structure is severely degraded due to the exposure to weather and UV radiation. The fiberglass is already on the surface, preventing the use of the handrail since it causes irritation when in contact with the human skin (Figure 3a), putting the maintenance workers at risk of falling.

Moreover, the waterproofing capacity of the roof is compromised, with water penetrating inside. Also, the level of luminosity is low, since the translucent polycarbonate elements are dirty with high presence of lichens (Figure 3b and c), as well as the paths and stairs (Figure 3d).

Finally, the paint from iron doors and windows is peeling, resulting in spots of rust and corrosion in the welds of elements connections, which promote the loss of resistance of these materials. Regarding the wooden windows, the paint is also peeling, and the dried wood is cracking, which promotes its rotting as well as infiltrations in the interior of the monument, increasing the risk of deterioration.

2.2 Interior

The interior of the Station has three base levels: ground floor; first floor; and second floor (Figure 4). Some common anomalies to all spaces are the general peeling of paint of ceilings and walls, as well as cracking and leak/infiltration stains. Regarding the Station's illumination, most lights need cleaning, as their level of luminosity is low. The spaces were divided in the categories described in detail in the next sections.

2.2.1 Ticketing atrium

The ticketing atrium presents accumulated dirt on the existing skylights and degradation of its rubbers and silicones, which allows rainwater to enter the atrium, also promoting eventual falls of the station's users and workers due to slippery floors (Figure 4, green area).

Figure 4. Transversal cut of the station.

Figure 5. Rossio's station platforms (a,b).

2.2.2 Platforms

Regarding the platforms zone (Figure 5a and b), the wall stones present infiltration stains (Figure 6a and b), jeopardising the integrity of the historic tile panel. There is an exterior wall above the north tile panel that shows signs of water entrance, as well as plant growth. The north tile panels present several anomalies, namely the presence of humidity, which promotes paint cracking and blistering due to saturation of the wall (Figure 7a), as well as the growth of salts (Figure 7b), and the opening of joints and support breakdown (Figure 7c). Also, some tiles present glaze loss, dirt, cracking in the ceramic tiles' glazed layer and microcracks. In some of the tiles it was possible to observe surface water run-off.

Regarding the roof, since its waterproofing capacity (Figure 4, yellow area) is compromised, water penetrates inside, resulting in corrosion of the metallic structure, including pillars.

Moreover, the stained-glass window presents dirt, also some glasses are broken or cracked, allowing the rain to enter the building. The false ceiling, as well as the stainless-steel surrounding pillars and wall present punctual spot rust and corrosion.

Regarding the pavements of the platforms, both granite (Figure 6c) and “calçada portuguesa” (Figure 6d) are used. The traditional “calçada portuguesa”, is an artistic typical Portuguese pavement mainly made with white and black limestone or basalt (da Silva et al. 2022). However, an adequate soil compaction is crucial for the efficiency and safety of the pavement's use (DGEG 2009). The pavement shows lack of polishing, as well as punctual lack of material. Also, the pavement shows clear signs of wear and present signs of differential settlements, which increases the risk of tripping of the station's users and workers.

Regarding the tunnel entry, the roof shows infiltrations, which allows water to flow through the tunnel wall, deteriorating the stone claddings.

Figure 6. Interior infiltrations (a, b); worn out pavements (c, d).

2.2.3 Gallery

Regarding the gallery behind the store (Figure 4, red area), it is possible to observe rising damp and efflorescence (Figures 8a and b), due to humidity by capillarity. These anomalies promote salubrity problems since mould can cause respiratory problems. The constant presence of water, and the absence of a functional drainage system, promotes the mechanical degradation

Figure 7. Anomalies on the historic tiles (a, b, c).

Figure 8. Gallery (a), rising damp and efflorescence (b) and orange-coloured run-off (c).

of the existing structures. Finally, the water run-off is orange coloured (Figure 8c), which could indicate the corrosion of the existing steel reinforcement bars.

3 PROPOSED REHABILITATION TECHNIQUES

Repairing an anomaly should always begin with eliminating its cause. If not possible, an attempt must be made to avoid the growth of the anomaly and consequent degradation of the element. The purpose of periodic maintenance is to identify the anomalies and degradation condition of buildings and their components, correcting the anomalies and causes, while preventing, or mitigating the occurrence of new anomalies (Carvalho et al. 2018). The maintenance activities allow maintaining the building's performance in adequate levels over its service life. Although there are different definitions in the literature, these interventions can be programmed or not. Generally, maintenance policies can be of many types, preventive, proactive, condition-based, prescriptive, curative or improvement repair techniques (Ferreira et al. 2022).

In this chapter some rehabilitation techniques are proposed, separated by the zones defined in the previous chapter.

3.1 Exterior: Pest birds deterrents

As referred, the exterior façade, composed by stone claddings, was renovated in 2019, therefore it does not need immediate rehabilitation. However, regular maintenance should take place, since it is a relevant factor for the performance and durability of the cladding. Simple planned maintenance works, such as cleaning and inspecting the façade are useful to avoid expensive late repairs (Snethlage 2014; Amaral et al. 2015).

Since Rossio’s station is located near the river, allied to the fact that it’s an extremely touristic place, with unlimited food supply for the birds, both pigeons and seagulls affect the building and its surrounding area. The mentioned animals have great reproductive potential; therefore, the actions must aim to achieve a lasting effect (Rodríguez 2022).

In order to avoid the permanence of the birds on the exterior façade, skylights and ticket hall, the following bird deterrent devices were proposed:

- Roof/skylights: spring-tensioned netting system (Figure 9a);
- Ticket offices hall: spring-tensioned wire; bird netting system; bird gel (Figure 9b);
- Exterior façade: stainless steel spikes and low voltage bird scarer (Figure 10).

According to Spennemann et al. 2018, “the highest-ranking deterrents were bird netting and bird spikes, but they were only considered moderately effective. The costs of installation and maintenance, as well the ease of installation, were all deemed significantly less important than the physical impact, the aesthetic sympathy and the effectiveness of a deterrent method.”

The spring-tensioned wire and netting system are designed to create an unstable landing area, thus avoiding the permanence of birds.

Figure 9. Proposed bird deterrent solutions: ticket offices hall (a); skylights (b).

Figure 10. Proposed new roof paths (a,b,c) and gallery drainage solution (d).

3.2 Exterior/Roof: Safe accessibility

Regarding the roof, to assure the conditions to safely carry out a planned maintenance program, new paths should be executed (Figures 10a, b and c). Also, a new paint-based coating should be applied on the degraded handrail structure, to safeguard the safety of those who use it.

In order to control the existing infiltrations, a full review of the roof should take place, with treatment of infiltration areas, replacement of silicones, rubbers and fasteners. This will avoid future deterioration of the interior metallic structure, as well as eventual falls of the station users and workers due to slippery floors.

Regarding the interior part of the roof, a cleaning of the metallic structure, including pillars, and an evaluation of the existing corrosion points with proper treatment is proposed, in order to safeguard its bearing load capacity.

At last, to increase the luminosity of the station, the translucent polycarbonate elements should be cleaned and restored, with an adequate anti-fungus solution. This will allow to take fully advantage of the solar natural light, being an environment-friendly solution and avoiding extra energy costs.

3.3 *Interior of the station*

To eliminate stains and paint peeling, a general painting of the ceilings and walls of the Station is proposed. Regarding the Station's illumination, all lights will be substituted by LED lamps, to increase the efficiency and become more environment friendly. Moreover, as part of the maintenance plan, all light structures should be cleaned periodically, to maintain the highest luminosity possible.

3.3.1 *Ticketing atrium*

A full inspection and rehabilitation of the existing skylights will take place, as well as a full replacement of all its rubbers and silicones, in order to cease the infiltration of water in the station's atrium, and thus preventing eventual falls of the station users and workers due to slippery floors (Figure 9a).

3.3.2 *Platforms*

Regarding the platforms zone, the exterior wall above the north tile panel will be fully waterproofed, to avoid future infiltrations and thus protecting the historic tiles. Moreover, the stained-glass window will be repaired and broken or cracked glasses will be replaced. The false ceiling, as well as the stainless-steel surrounding pillars and wall will be cleaned, and the punctual spot rust and corrosion will be treated.

Considering the anomalies present in the historic tiles, these need an urgent intervention, in order to safeguard the tile patrimony. Therefore, a specific intervention plan will be developed and carried out by entities specialized in conservation and restoration, equipped with specialized human resources and adequate means.

Regarding the worn and uneven pavements of the platforms, these will be polished, considering an adequate slip resistance of the material. A monitoring plan will be developed, in order to understand if more invasive measures should take place in the near future, such as the total replacement of the pavements with the execution of a new substrate.

Finally, regarding the tunnel entry, the roof will be repaired, in order to cease the infiltrations, and thus eliminating the presence of water into the tunnel wall.

3.3.3 *Gallery*

Regarding the gallery, an insulation and drainage solution will be designed, to ensure the drainage of the groundwater streams that flow from the existing anchored wall, and then accumulate in the gallery behind the train station's assistance/service spaces (Figure 10d). Further studies will be needed in to order to obtain the actual conditions of the existing anchors.

4 CONCLUSIONS

Several difficulties were found during the research, mainly the lack of information about some of the existing structures, infrastructures and water courses. This paper contributes to the dissemination of knowledge on the maintenance of train stations infrastructures, as the presented information may be used to improve and increase the effectiveness of maintenance plans. As future developments, a system that classifies the causes associated with anomalies should be created, as well as a system of classification of the diagnosis methods associated with the characterization of anomalies and causes should be designed. Finally, based on the system, a proper maintenance program should be developed for the station.

ABSTRACT: When water enters the bottom of the concrete slab of an airport pavement through the joints, aircraft loads can cause granulated grout material particles to erupt from the joints and create voids at the bottom of the concrete slab. The ejected granulated grout causes equipment damage due to suction into the engine. In addition, loss of support and pavement failure can severely affect aircraft navigation, therefore early detection is critical. Therefore, in this study, voids were fabricated in a specimen simulating airport pavement concrete, and various nondestructive investigations were conducted. As a result, it was found that defects could be properly detected by using electromagnetic radar and ultrasonic tomography. Based on the above results, an investigation was conducted at an actual airport pavement to verify the results.

1 INTRODUCTION

When prestressed concrete pavement (referred to as PC pavement) is used for airport pavement, a grout layer is generally injected between the roadbed and the PC pavement to eliminate the unevenness between them. when water penetrates the bottom surface through the joints of PC pavement, the grout material is granulated by the aircraft load and spurts out from the joints of the PC pavement. The granulated grout material is then ejected out of the joints, creating a void at the bottom of the PC pavement (Tanaka et al. 2008) as shown in Figure 1. The grout ejected from the joints can be sucked into aircraft engines, etc., and may have a serious impact on the running of the aircraft. Therefore, it is necessary to identify the areas where grouting has occurred or is likely to occur at an early stage.

In this paper, the possibility of detecting these voids by nondestructive testing was experimentally investigated using a specimen simulating airport PC pavement concrete. Based on the above results, an investigation was conducted at an actual airport to verify the results.

Figure 1. Ejection of granulated grout at airport PC pavement.

2 INVESTIGATION USING SIMURATED SPECIMENS

2.1 *Outline of specimens*

The specimens were prepared based on the design drawings of actual airport PC pavements. The water cement ratio was set to 0.34 in consideration of the mix ratio of prestressed concrete. The specimen is reinforced concrete, 300 mm thick, and its shape and dimensions are shown in Figures 2. During concrete placement, styrene foam was partially placed at thicknesses of 5 mm, 10 mm, 20 mm, 30 mm, and 50 mm as a simulated void (referred to as the “simulated void”). The location of the simulated void was 250 mm from the top of the specimen, considering that the actual thickness of the airport PC pavement is 250 mm. For specimen (1), after repeated nondestructive investigation of the void, the Styrofoam was removed from the red frame (50 mm thick) shown in Figure 2, and saturated sand and soil were re-laid to assume granulated grout (see Figure 3, refer to as “simulated granulated grout”). The non-destructive investigation method considered for this simulated granulated grout was chosen considering the results of the aforementioned investigation using Styrofoam.

2.2 *Types and methods of nondestructive investigation methods*

The nondestructive inspection methods were the rebound hammer method, impact echo method (Sansalone & Streett 1997), electromagnetic radar method (Maeda et al. 2015), and ultrasonic tomography method (ACS Website 2022). The rebound hammer method was conducted in accordance with Japan Industrial standards (JIS A 1155 2012). The impact echo method was conducted in accordance with the iTECS method (i-TECHS website 2022). The electromagnetic radar method and ultrasonic tomography were performed using commercially available equipment. The locations of the simulated voids were searched using various nondestructive investigation methods to detect the void locations and evaluate their accuracy. Figure 4 shows an example of the measured positions.

2.3 *Results and discussions*

Table 1 shows the detection results of voids by various nondestructive inspection methods. Figure 5 shows an example of the measurement results of electromagnetic radar and Figure 6 shows an example of the measurement results of ultrasonic tomography.

(1) Rebound hammer method

Voids with an area of approximately 1 m² (1000 x 1000 mm) or a thickness of 30 mm or more tend to have a rebound force 10 to 20 points lower than the area without voids, and it is generally possible to detect voids with a large area or thickness, but not with a small or thin void. The results are shown in Table 1.

(2) Impact echo method

When the void area was about 1 m², a void with a thickness of 5 mm could be detected. However, when the area was small and the thickness was thin, it was difficult to detect it.

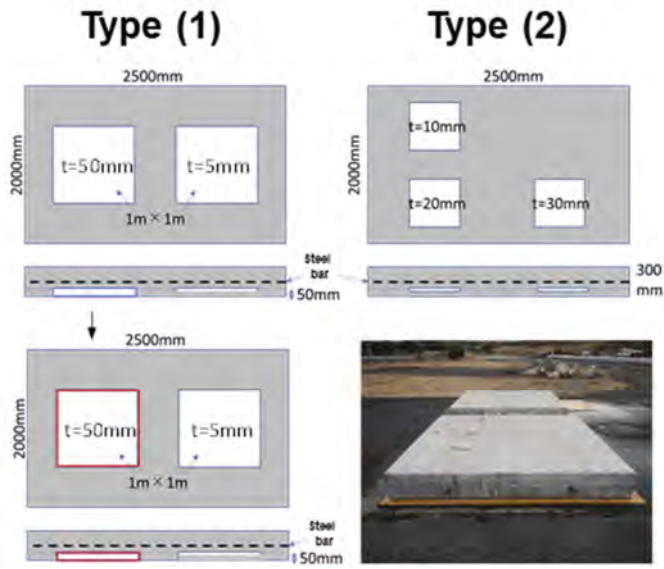

Figure 2. Outline of specimen.

Figure 3. Simulated granulated grout.

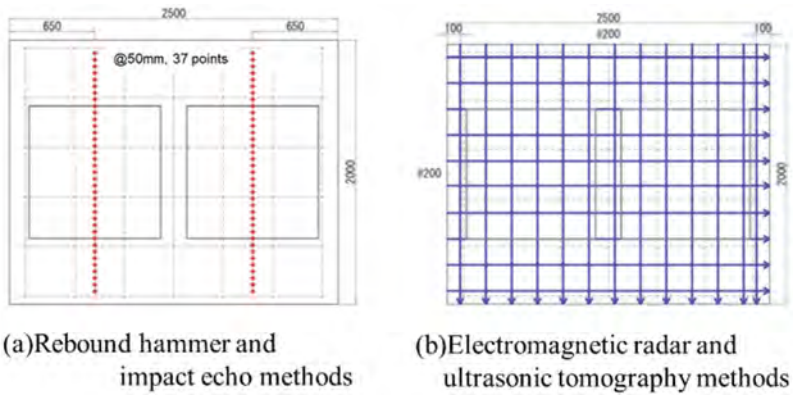

Figure 4. Outline of measurement points.

Table 1. Availability of void detection.

Non-destructive tests	Availability of void detection				
	1000×1000		500×500		
	(area mm)				
	50	5	10	20	30
	(thickness mm)				
Rebound hammer	○	○	×	×	○
Impact echo	○	○	×	×	○
Electromagnetic					
400MHz	○	×	×	×	×
600MHz	○	×	×	○	○
900MHz	○	×	○	○	○
1600MHz	○	○	○	○	○
2000MHz	○	×	○	○	○
2700MHz	○	×	×	○	○
Ultrasonic tomography	○	○	○	○	○

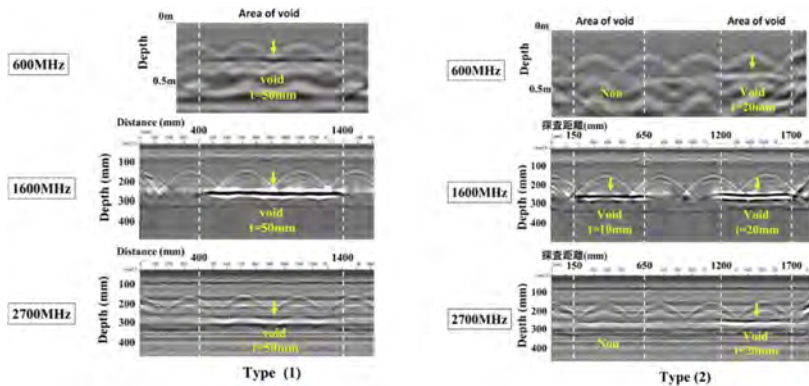

Figure 5. Results of electromagnetic radar.

(3) Electromagnetic wave radar method

In the electromagnetic wave radar method, the thickness of voids varies depending on the antenna frequency; Radar using 1600 MHz electromagnetic waves was able to detect all simulated voids, but radar using 2000 MHz electromagnetic waves was unable to detect small voids due to attenuation of the electromagnetic waves.

(4) Ultrasonic tomography

All voids were detectable in the 3D images, but the smaller the void thickness, the smaller the red and yellow areas with stronger ultrasonic reflections tended to be.

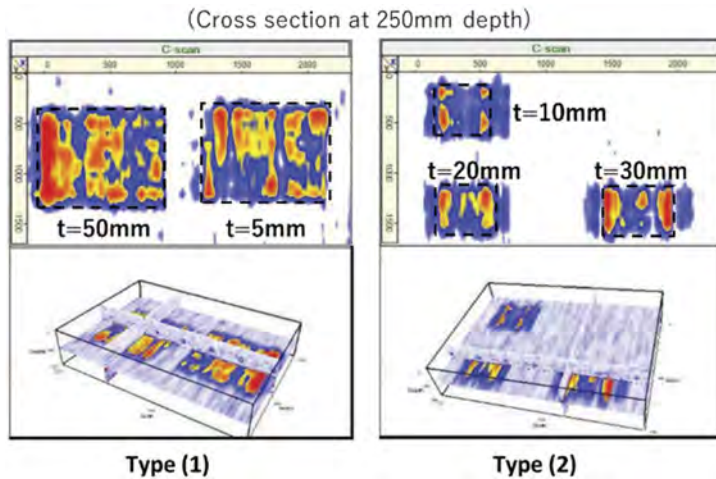

Figure 6. Results of ultrasonic tomography.

The accuracy of void detection in various nondestructive testing methods was determined as follows.

- (1) Rebound hammer method
The ratio of the rebound force at the void location divided into three ranges (30-40, 40-50, 50-60), with 30-40 being the rebound force.
- (2) Impact Seismic Method
Ratio of the length of void detection to the length of the void installation against the length of the void installation.
- (3) Electromagnetic Radar Method
Ratio of the length of void detection to the length of void installation against the length of void installation.
- (4) Ultrasonic tomography method
Ratio of the area of void detection to the area of void installation against the area of void installation.

Figure 7 shows the average detection accuracy of the simulated void locations for each NDT method. The NDT methods with average void detection accuracies exceeding 50% were the electromagnetic radar method and the ultrasonic tomography method. Among the investigated items used in this study, the 1600 MHz electromagnetic radar was found to be the most accurate in detecting voids 250 mm deep placed in specimen.

Figure 7. Accuracy of void detection.

The electromagnetic wave radar method and ultrasonic tomography, both of which have high accuracy of void detection, were employed as nondestructive investigation methods for the simulated granulated grouted area.

Two frequency bands, 600 MHz and 1600 MHz, were used for the electromagnetic radar. After about one week of curing, the specimens were turned over again with the defects on the underside of the specimens.

The results of the electromagnetic radar and the ultrasonic tomography at the location of the defect were shown in Figure 8 and 9.

(1) Electromagnetic wave radar method

Both 600 MHz and 1600 MHz electromagnetic wave radar were capable of detecting defects, and the location of defects was clear in the 1600 MHz image.

The detection range of the contour of the simulated granular grout tended to be slightly smaller than that of the void.

(2) Ultrasonic tomography method

The ultrasonic tomography method was also able to detect the simulated grout.

The 3D image of the simulated grout did not differ significantly from the void detection image and was almost the same.

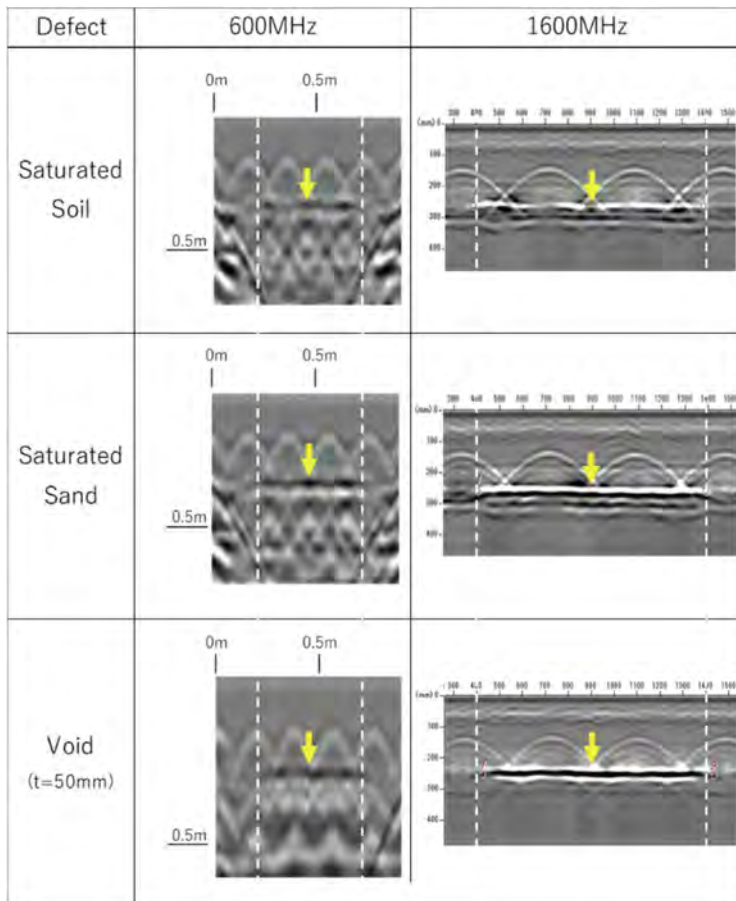

Figure 8. Detection of simulated granulated grout by electromagnetic radar.

Figure 9. Detection of simulated granulated grout by ultrasonic tomography.

3 IN-SITU INVESTIGATIONS

Following the results of the study using the specimens, verification was conducted on an actual airport pavement. Electromagnetic radar and ultrasonic tomography methods were applied as nondestructive testing methods as shown in Figure 10.

The actual airport is the one operated in Japan, and the white granular grout jet was observed as shown in Figure 1.

Figure 11 shows the results of electromagnetic radar measurements. Note that there were some points where it was difficult to distinguish voids due to the influence of moisture. The results indicate that some of the measured points have signals that appear to be voids.

Figure 12 shows the results of ultrasonic tomography. The ultrasonic tomography results showed signals that were probably due to reflections from the steel and the bottom surface, so it was not possible to detect voids in the lower part of the PC plate, which was the subject of this study.

Figure 10. Measurement at actual airport.

Figure 11. Results of electromagnetic radar in actual airport PC pavement.

Figure 12. Results of ultrasonic radar in actual airport PC pavement.

4 CONCLUSIONS

The results obtained in present paper are as follows;

- 1) The detection accuracy of the electromagnetic radar method and the ultrasonic tomography method was high and suitable for nondestructive inspection of simulated specimen.
- 2) The electromagnetic radar method was able to detect defects in simulated specimen more accurately than any other methods used in this study at the frequency of 1600 MHz.
- 3) Ultrasonic tomography was able to roughly determine the location and size of defects from the three-dimensional images.

These results suggest that the electromagnetic radar and ultrasonic tomography methods are effective in detecting defects in the lower part of concrete slabs of airport pavements.

A future challenge is that the antenna frequency suitable for defect detection may vary depending on the measurement environment and conditions, and a device is needed for each frequency used. Therefore, it would be desirable to verify electromagnetic radar measurements of concrete on airport pavements using devices with broadband antenna frequencies or devices that can change frequencies.

ABSTRACT: Structural applications of advanced cementitious materials such as Ultra High Performance Concrete (UHPC) have been already assessed in harsh exposure conditions with presence of chlorides or sulfates. Nevertheless, the limited availability of design standards has not favoured so far a widespread use of these materials. Moreover, previous studies employed a constitutive model only partially representative of the real behavior of such materials when exposed to aggressive conditions. Therefore, this work, employing a “scenario dependent” constitutive law, estimates the serviceability limit state in correspondence of which it is needed to carry out the maintenance activities and investigates, through the Life Cycle Assessment (LCA) methodology, the ecological and economic profile of a UHPC water basin structure subjected to chloride and sulfate attack. The CML impact assessment method has been employed for the specific purpose to compare such structure to one made with ordinary reinforced concrete (ORC) using as system boundary the A1-B7 stages indicated in EN 15804.

1 INTRODUCTION

The construction sector, due to its social and economic impacts in the modern society (e.g. 9% of the gross domestic product of European Union and 18 million of people employed), requires a particular attention to be paid to its overall sustainability (Ortiz et al, 2009) (Oloke et al., 2022). The latter should encompass, from a holistic point of view, environmental, economic and social aspects. This challenge may represent an opportunity for the involved supply chain that has to be, then, rethought within a more sustainable framework starting from the extraction of the single constituent raw materials until the dismantling/recycling of the final product or structure. This means that also the design process of structures/infrastructures has to be based on a Life Cycle Assessment (LCA) approach to predict the future environmental and economic performances of a specific solution in comparison to another. Thus, the designers must be helped to also account the needs of the final users (long durability, reduced maintenance costs, adequate environmental performances) within the intended Service Life (SL). This is also in line with the path outlined by the European Commission action plan adopted in 2020 to favour a transition from linear towards circular production and consumption models. The latter represent a driving force to turn, what has been so far considered as a waste product,

into a secondary raw material and keep (even if modified) its value in the economy as long as possible (European Commission, 2020). These concepts can then be transferred to the design of concrete structures employing a methodology such as the Durability Assessment Based Design (DAD) especially for advanced cementitious based materials such as the Ultra High Performance Concrete (UHPC) accounting for, “a priori”, the interaction of the material with the surrounding environment (Kannikachalam et al., 2022) (di Summa et al., 2022) (Al-Obaidi et al., 2021) (Al-Obaidi et al.2022). This approach can overcome the limitations of the current standards that simply provide prescriptions, such as minimum cement content and maximum water to cement ratio, aimed at implicitly guaranteeing a target service life without considering the evolution of the behavior of the material over time, within the life span of the structure and as a function of its service scenario. In this framework, this work presents as case study a water basin structure aimed to contain geothermal water, characterized by the presence of sulphate and chloride ions. Different degradation phenomena have been taken into consideration, including sulphate attack, leaching and chloride penetration. Then, LCA and Life Cycle Cost (LCC) analysis have been carried out to investigate the potential sustainability of such construction technology in comparison to an ordinary reinforced concrete based solution.

2 DESCRIPTION OF THE CASE STUDY AND DEGRADATION MECHANISMS

2.1 Description of the case study

The analysis has been carried out assessing the case study of a basin aimed at containing the geothermal water coming from the condensation of the vapor extracted from the soil and cooled in a cooling tower and designed for a target service life of 50 years. The structure is 18 m long and 5 m wide, with a height of the compartment walls varying from 3 m up to 4.87 m, depending on the boundary morphological conditions since the structure itself is designed to be partially underground. Two different structural solutions are compared, characterized by two different design philosophies due to the different performance of the employed construction material. In the first scenario, the basin is built with ordinary reinforced concrete (ORC), including steel bars while the second design uses UHPC. They are hereinafter referred as ORC_basin and UHPC_basin, respectively. The mix designs for both cases are reported in Table 1. Figure 1 details the cross section of the vertical elements of both solutions. As it is possible to observe, the structural performance of UHPC (such as its compressive and tensile strength that can reach values around 150 MPa and 10 MPa respectively, much higher than the one of ORC) allowed to shift from the 0.4 m thickness of the ORC_basin to the 0.05 m thick UHPC_basin walls designed as supported by ORC buttresses. Similarly to other works (di Summa et al., 2022) (Kannikachalam et al., 2022) while the first implies the use of reinforcement bars (details shown in Figure 1), the second one has been designed as UHPC slabs supported by 2 m spaced reinforced ORC buttresses, without any reinforcement bars in the slabs. The latter was possible

Table 1. Mix design for ORC_basin and UHPC_basin.

Constituents [kg/m ³]	ORC	UHPC
CEM I 42.5 R	350	-
CEM 52.5 R	-	600
Slag	500	-
Water	207	200
Aggregate 7/12	600	-
Aggregate 4/7	300	-
Sand (0-2 mm)	950	982
Limestone filler	60	-

Steel fibers	-	120
Crystalline admixture	-	4.8

employing, within the model code 2010 (Fédération internationale du béton, 2012), the mechanical properties of UHPC identified in (Lo Monte and Ferrara, 2020) and (Davolio et al., 2022).

Figure 1. Cross section of ORC_basin (left) and UHPC_basin (right).

2.2 Sulphate attack

The sulphates penetrate into the concrete matrix reacting with the hydration products and causing expansion phenomena which have been here accounted according to the study by Jian et al. (Jian et al., 2018). The latter assessed the behavior of 54 mix designs defining in total three macro groups characterized by different expansion kinetics due to the chemical composition of the cement. Due to its mix design, the ORC_basin belongs to the group characterized by an expansion (EXP) as reported in Equation 1 while the UHPC_basin follows Equation 2, where C_3A is the C_3A cement content expressed in percentage (7.6% for the case of this study), T the time and w/c the water to cement ratio. In both cases, for this type of damage, the ultimate limit state has been defined by the attainment of an expansion ratio equal to 0.5% which is calculated to be reached, for the case of ORC_basin after 38 years and which is even not reached at 100 years for the UHPC_basin as detailed in Figure 2.

$$EXP = 0.0293 \left(\frac{W}{C} * T \right) + 0.000975 (C_3A) * T + 0.0216 \quad (1)$$

$$EXP = 0.0157 \left(\frac{W}{C} * T \right) + 0.0305 \quad (2)$$

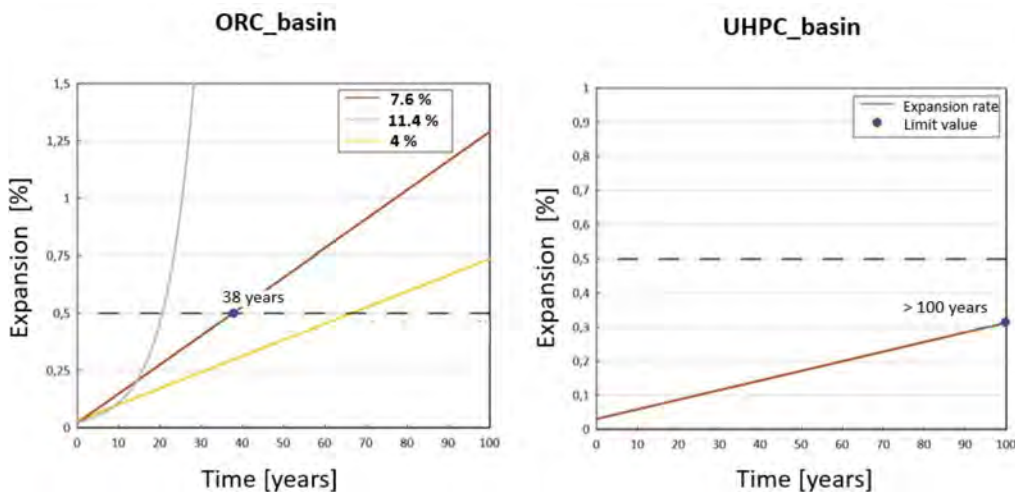

Figure 2. Expansion within a timeframe of 100 years. The graphs referring to the ORC_basin also contain the behaviour that the material would have had in the case of a C_3A content: 7.6%, 11.4 % and 4%.

2.3 Leaching phenomena

The $\text{Ca}(\text{OH})_2$ leaching phenomena are mainly dictated by the permeability of the material itself and by the pressure of the water against the structure, with a consequent reduction of the cross section corresponding to the depth of the leached zone. Therefore, the process has been assessed according to Fagerlund (Fagerlund, 2021) according to Equation 3 where X corresponds to the depth of the leached area, t is the time, while a and k_e are the leaching coefficients considered as equal to $0.1385 \text{ mm/day}^{0.5}$ and 0 mm/day for ORC_basin and $0.0072 \text{ mm/day}^{0.5}$ and 0.006 mm/day for UHPC_basin respectively as in (Fagerlund, 2021).

$$X_{crit} = a\sqrt{t} + k_e * t \quad (3)$$

Therefore, to identify the serviceability limit state for the case of this degradation mechanism, the time when the acting bending moment (M_{Ed}) is equal to the resistant bending moment (M_{Rd}) has been calculated according to the section which is reduced with time for each wall of the ORC_basin. It has been then estimated that for one of the walls of that structure, M_{Rd} and M_{Ed} are equal at 27 years. The same calculation has been performed for UHPC_basin where the limit is observed to be reached only after 58 years. In this regard it must be specified that M_{Ed} was calculated employing a cantilever scheme for ORC_basin while a plate analysis was adopted for UHPC_basin. Figure 3 reports the results above described.

Figure 3. Variation of M_{Rd} according to the leaching phenomena for both ORC_basin and UHPC_basin within a timeframe of 100 years.

2.4 Chloride penetration and steel corrosion

The chloride penetration has been estimated employing the second Fick's law. With regard to ORC_basin both the initiation and propagation times have been estimated as in di Summa et al. (di Summa et al., 2022) and Van Belleghem (2018) obtaining a value lower than 6 months for the initiation. Then, considering for the propagation a localized damage such as a hemispherical pit, the serviceability limit state is assumed to be reached at the moment when 20% of the cross section is lost which is calculated to occur after 3 years for at least one of the walls of ORC_basin. This is in line with previous studies which demonstrated how 20% degree of corrosion can cause significant reduction in terms of strength capacity (Noh et al., 2018) (di Summa et al., 2022) (Bossio et al., 2017). With regard to UHPC_basin, other works already assessed case studies similar to the one here presented (di Summa et al., 2022) (Kannikachalam et al., 2022) but still employing a constitutive law not perfectly representative of the behaviour of the material when exposed to a chloride environment. Such studies considered the cross section, for the sake of simplicity, as progressively reduced along time accordingly to the chlorides penetration and supposed the steel fibers immediately corroded. In this respect, this study takes advantage

of more recent studies (Davolio et al, 2022) (Al-Obaidi et al., 2022) where for the cross sectional equilibrium, the contribution of the region in tension affected by chlorides penetration follows a constitutive law as function of the crack opening and as function of time based on the experimental results and their extrapolation along time. This constitutive law has been obtained in (Davolio et al., 2021) who employed UHPC specimens characterized by the same mix design as the one here employed, and tested them in four point bending and direct tension after having subjected them to simultaneously acting sustained loads and exposure to either XA (acid) or XS (chloride) environment. Employing the constitutive law coming from both the aforesaid experimental campaign M_{Rd} always reaches the value of M_{Ed} after more than 100 years. Figure 4 better explains where the new constitutive law was employed also detailing M_{Rd} of UHP_basin within the time.

Figure 4. Representation of a generic UHPC cross section with the identification, in red, of the area affected by chlorides in which the new constitutive law can be used to better describe the behavior of the material (left) and M_{Rd} over time for UHPC basin (right).

3 LIFE CYCLE ASSESSMENT AND LIFE CYCLE COST

3.1 The system boundary of the analysis

The LCA analysis has been carried out hypothesizing a cradle to grave system boundary in which the basin is considered as demolished at the end of its service life and treated as a waste material except for the steel scraps which are always considered as recycled according to the European regulations. The maintenance activity hypothesized for the ORC elements consisted in the removal of the damaged concrete cover and reinforcement bars, followed by the replacement of the latter and the realization of a new concrete layer after having applied a primer to favor its adhesion to the substrate. According to what has been stated in 2.2, 2.3 and 2.4, the most severe damage is represented by chloride attack, reason why one maintenance activity every 3 years has been considered for ORC_basin and for the ORC buttresses of UHPC_basin. No further repairing activities were calculated to be needed for UHPC_basin. The 10 CML IA impact method has been employed with the scope to describe all the implications at a global, regional and local scale. The LCC has been further developed according to the construction rates reported in (Regione Toscana, 2022) and (Regione Lombardia, 2022) referring to the Tuscany area, where the basin is supposed to be located. Moreover, a discount rate for the activities that have to be carried out in the future has been accounted for according to Caruso et al. (Caruso et al, 2020) and di Summa et al. (di Summa, 2022).

3.2 LCA and LCC outcomes

The environmental analysis demonstrated a consistent reduction for all of the ten impact indicators when the UHPC_basin is compared to the ORC_basin with advantages of around 80% as for the case of the terrestrial ecotoxicity and 70% as for the case of eutrophication, marine aquatic ecotoxicity, fresh water aquatic ecotoxicity and human toxicity. In general, it is possible to observe that cement and steel have the highest influence, reason why the impacts related to ORC_basin are so high, due to the raw materials needed to restore the functionality of the structure through the maintenance activities. More specifically, the greatest influence is represented by the steel for 6 out of 10 impact indicators of ORC_basin. On the opposite, UHPC_basin, due to the reduced amount of steel ($1.24 \cdot 10^4 \text{ kg}$ in comparison to $3.39 \cdot 10^4 \text{ kg}$ for ORC_basin) registers a higher influence of cement. With regard to the cost analysis, it has been calculated that the maintenance activities affect the overall costs of ORC_basin by about 39% while the overall difference between the two compared solutions is assessed at around of 37%. Figure 5 summarizes these results.

Figure 5. Percentage reduction of impacts of UHPC_basin compared to ORC_basin (left) and total costs within the SL (right).

4 CONCLUSIONS

This work has presented and assessed the implications of a design methodology aimed at including the use of advanced cementitious based materials with a structural design based on the durability of the material and on the life cycle implications, regarded as a pillar concept that should drive the construction sector within the near future. Differently from other recent works, the current study has analyzed not only the chloride penetration phenomena, but also the sulphate attack and the leaching degradation, due to the service scenario of the selected case study, consisting of a basin containing geothermal water. This approach, more structured than a prescription-based one which is normally employed whenever the current standards are simply followed, allowed to figure out the benefits of UHPC in comparison to a traditional solution, based on ordinary reinforced concrete, due to the total absence of maintenance activities for the first. In this regard, the Life Cycle Cost analysis has highlighted a relevant influence of the repairing activities whose reiteration for the ORC elements not only generates an increase of the total expenses but also the need to use more raw materials such as cement and steel whose environmental consequences are well known. Thus, this investigation represents a milestone to support and corroborate the efficacy of advanced cementitious materials even with the absence of the traditional reinforcement steel bars whenever aggressive structural service scenarios have to be met. These improvements are often disregarded in the current design and construction practice due to the false idea that a comparison between ordinary materials and innovative ones has to be based on a cubic meter scale, not taking advantage of durability and structural performance of the materials. This is also due to the absence of appropriate

durability-based design approaches together with the further need to employ tailored, time- and scenario-dependent constitutive laws, which would require additional care in the design phase. In view of this, the DAD, together with LCA and LCC can be a driving force to shape differently the evolution of the construction sector.

ACKNOWLEDGEMENTS

This project has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 860006.

Durability of residential construction in a marine environment

I.N. Robertson

University of Hawaii at Manoa, Honolulu, Hawaii, USA

ABSTRACT: Single and multi-family housing in the United States of America typically consists of timber or cold-formed steel (CFS) framed structures on reinforced concrete foundations with a design life of 40-50 years. Often these houses outlive that period but require considerable maintenance and repair to extend much beyond the design life. This is particularly true for coastal communities exposed to high humidity, airborne salts and termites. Building on 30 years of experience in durability research and design of residential structures in Hawaii, this paper presents some of the best practices for enhancing durability, building performance, reducing maintenance and repair costs, and significantly increasing the life expectancy of residential construction. With a relatively low premium on the initial capital investment, these measures greatly reduce the life-cycle costs and carbon footprint of residential construction in harsh coastal environments.

1 INTRODUCTION

Single and multi-family housing constitutes most of the buildings stock in the USA and many countries worldwide. In the USA, most of this construction is based on timber framing with timber or cement board products as exterior cladding. These buildings are typically supported by slab-on-grade foundations, and less commonly on elevated post-and-pier or cripple wall systems where the first level is a structural floor over a crawlspace or basement. The life expectancy of these buildings is typically assumed to be 40 to 50 years, though they are often utilized for up to 100 years with consistent maintenance.

The annualized life cycle cost of a constructed facility is a function of the initial cost, the maintenance cost and the demolition and disposal cost, divided by the useful life of the facility. One effective way to reduce the annualized life cycle cost of residential construction is to extend the useful life of the building beyond 50 years, while limiting the amount of maintenance required each year.

The life expectancy and anticipated maintenance costs of a building will depend on the building location. For example, in relatively arid environments it is not unusual for timber framed buildings to survive far beyond their design life. On the other hand, coastal environments are particularly harsh on built infrastructure because of the increased humidity and potential for chloride deposition on the building leading to corrosion of metal components. Tropical areas in the southern US states are also exposed to termites that can rapidly consume timber framing if the building is not regularly treated, or other termite control measures implemented. Because of this threat to timber framed homes, many communities in tropical environments are turning to cold-formed steel (CFS) framing to replace timber framing. In the US state of Hawaii, over 50 percent of new residential single- and low-rise multi-family housing is now constructed of CFS instead of timber.

This paper focuses on measures to increase the longevity of residential buildings in Hawaii and provides recommendations for both the concrete and framing elements used in residential construction. Reference is made to two research projects, one relating to the performance of cold-formed steel framing members and connectors in a marine environment, and the other relating to mitigation of reinforcing bar corrosion in concrete foundations and other structural members.

2 CORROSION OF GALVANIZED FASTENERS USED IN COLD-FORMED STEEL FRAMING

This research program investigated the potential for corrosion of galvanized fasteners used in cold-formed steel framing by exposing test samples to a variety of environmental conditions frequently found in Hawaii and elsewhere. The results of this research will aid in the protection of galvanized fasteners and associated framing in various exposure conditions.

Five field enclosures were constructed on the island of Oahu at coastal locations on both windward and leeward shores, and in the interior of the island (Figure 1). Each field enclosure represented various aspects of typical cold-formed steel construction and was equipped with a complete weather station. The full report contains greater detail regarding atmospheric conditions at the field enclosure sites, screwed connection test results, and provides complete photographic documentation of the progression of corrosion at various locations in all field enclosures. A full copy of the final report is available from the Steel Framing Alliance.

Standard cold-formed steel connections with galvanized screws were placed in various locations within each of the field enclosures as a controlled study of the performance of galvanized fasteners in typical CFS framing construction (Figure 2). Identical screwed test connections were subjected to a cyclic salt spray routine in a corrosion chamber to induce accelerated corrosion (Figure 3).

Based on the results of this study, recommendations were made for the protection of cold-formed steel framing and fasteners in coastal environments.

Figure 1. Corrosion field sites on the Island of Oahu (left) and typical field enclosure at location 4 (right).

2.1 Summary of field test observations

After 20 months of field exposure, the interior enclosure at location 5 and the coastal enclosure at location 4 (on the leeward side of the island) showed only minor signs of corrosion of framing fasteners in the fully exposed crawl space. No corrosion was noted in the exposed floor joists, vented attic or enclosed wall framing. After the same exposure, the coastal enclosure at location 3 (on the leeward side of the island) exhibited similar behavior, with the addition of the initiation of corrosion of fasteners and cut ends of CFS framing in the vented attic.

In contrast, fully exposed CFS members and fasteners in the crawl space of the coastal enclosure at location 1 (on the windward side of the island) showed initiation of corrosion after as little as 5 months exposure. This corrosion proceeded rapidly so that by 28 months, the exposed floor joists and supporting posts and cripple wall have experienced severe corrosion. Areas of the floor joists that were enclosed by plywood sheathing show very little signs of corrosion except where exterior air has leaked into the enclosed space through unsealed edge joints.

After 28 months, fasteners in the vented attic at the enclosure at location 1 experienced significant corrosion. The CFS roof framing members were tarnished with some cut end

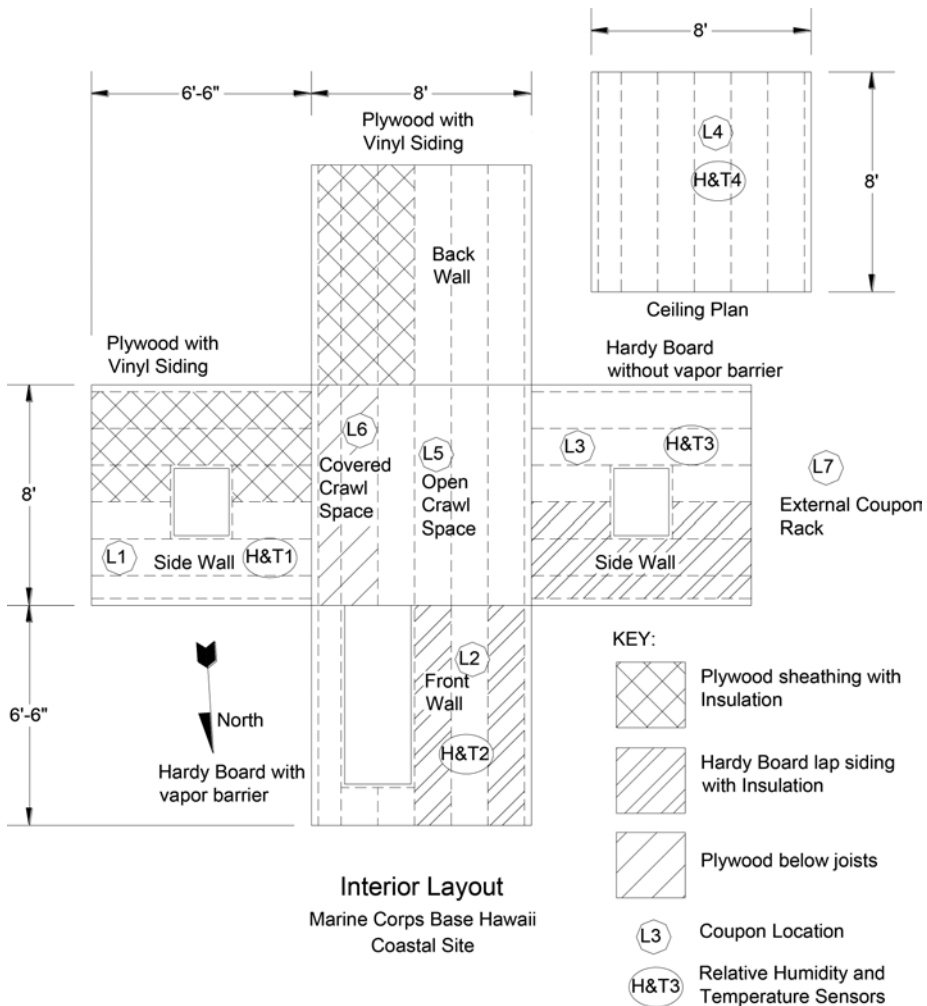

Figure 2. Typical wall layout to study corrosion within walls, floor and ceiling with different exterior coverings.

corrosion. Similar corrosion was noted in the wall with lap siding and no vapor barrier, while the walls with lap siding and vapor barrier, or plywood sheathing, only showed signs of corrosion at the top plate that was exposed to air in the vented attic.

The inland enclosure at location 2 exhibited corrosion levels significantly less than the coastal site at location 1, but more severe than any of the enclosures at locations 3, 4 and 5. The additional distance from the coastline, and the intervening vegetation appear to have provided significant protection for this enclosure.

2.2 Recommendations for improved durability of cold formed steel framing and fasteners

The following recommendations are based on the results observed in this study.

Guidelines for protection of CFS framing and fasteners from atmospheric corrosion induced by air-borne chlorides are presented for the following three exposure categories:

- Category A: Extreme exposure.
- Category B: Moderate exposure.
- Category C: Mild exposure.

Figure 3. Salt spray corrosion chamber with screwed connections (left) and typical connection specimen test (right).

Each building location should be assigned to one of these exposure categories based on geographical location, surrounding features and meteorological records. Table 1 gives suggestions for this assignment:

Table 1. Exposure category assignment.

Distance from shoreline (m)	Site characteristics			
	Onshore wind		Offshore wind	
	Unshielded	Shielded	Unshielded	Shielded
$L \leq 200$	A	A	A	B
$200 \leq L \leq 500$	A	B	B	B
$500 \leq L \leq 1000$	B	B	C	C
$L \geq 1000$	C	C	C	C

Distance from shoreline is the straight-line distance measured perpendicular to the coast.

Onshore and *offshore* wind refers to the predominant wind direction for the building location. If winds are variable or unknown, *onshore* wind should be assumed.

Shielded refers to the presence of vegetation and/or structures, at least as tall as the proposed building, located between the coast and the proposed site. Sites that do not satisfy these conditions are considered to be *Unshielded*. Shielded conditions are afforded by medium to dense vegetation covering at least 25 meters of the straight line distance from the coast. Shielded conditions are also afforded by two or more rows of housing between the proposed site and the coast. A single barrier, such as a wall, fence, or hedge, should not be considered to provide shielded conditions. A small hill or rise with no vegetation should not be considered to provide shielded conditions.

2.2.1 Category A design recommendations

The following recommendations are made for CFS framing in category A exposure conditions:

- No CFS members or fasteners should be exposed to ambient atmospheric conditions. This includes both sheltered and non-sheltered exposure.
- Exposure to atmospheric conditions during construction should be limited. If such exposure is expected to exceed 2 months, protective measures should be taken to prevent chloride accumulation on the CFS members.

- No CFS framing should be exposed in sheltered locations such as crawl spaces or the interior of garages, carports and other unfinished spaces. Plywood sheathing or gypsum board, with sealed joints, is effective for protection of CFS in these locations.
- Protection of CFS framing and fasteners in interior walls and floor systems can be provided by gypsum board coverings on both sides of the wall cavity, and as a ceiling below elevated floor framing. The drywall joints should be taped and all openings sealed. The top of the wall should be sealed from any vented attic space above.
- Attic spaces require particular attention because of the need for venting to prevent moisture accumulation and potential mold development. However, venting in exposure category A conditions permits the ingress of air-borne chlorides. Two options are proposed for these conditions:
 - the attic space can be designed as a sealed environment with insulation placed directly under the roof sheathing (a.k.a. cathedral ceiling), and the area underneath designed as a conditioned space.
 - attic venting, particularly on the coastal elevation, can be kept to the minimum permitted by the applicable building code, while extra protection can be provided for the framing members and fasteners in the attic space through increased galvanizing thickness and/or the addition of zinc rich coatings after fabrication.

Neither of these options was evaluated in this study.

Similar but less restrictive recommendations were provided for Category B and C exposure.

3 PERFORMANCE OF CORROSION INHIBITING ADMIXTURES IN A MARINE ENVIRONMENT

Single- and multi-family homes are generally supported by concrete foundations or slab-on-grade. These foundations are typically reinforced with steel reinforcing bars. When subjected to coastal or marine environments, chlorides will penetrate the concrete and initiate corrosion of the reinforcing steel, leading to concrete spalling and high maintenance costs, or reduction in the useable life of the buildings.

A multi-year study was performed to study the efficacy of corrosion inhibiting admixtures used in reinforced concrete specimens. Accelerated laboratory corrosion testing was performed on 660 concrete specimens and a field study exposed 25 concrete panels to a marine environment in Honolulu Harbor, Oahu, Hawaii (Figure 4) (Robertson and Newton, 2019). Seven different corrosion inhibiting admixtures and two pozzolans were used to compare their effectiveness at preventing or delaying onset of corrosion. This study was funded by the Hawaii Dept. of Transportation, Harbors Division, to evaluate commercially available corrosion inhibiting admixtures when used in concretes made with basalt aggregates common to Hawaii and other Pacific Islands.

The corrosion-inhibiting admixtures included in this project were Darex Corrosion Inhibitor (DCI), Rheocrete CNI, Rheocrete 222+, FerroGard 901, Xypex Admix C-2000, Latex-modifier, Kryton KIM, and the pozzolans were fly ash and silica fume.

After approximately 8 years exposure in a marine environment, the panels were removed and returned to the laboratory for dissection. The mass loss of the test layer of reinforcing steel with 38 mm clear concrete cover to the top surface of the panel, was recorded for each specimen (Figure 5).

Based on the results of both the laboratory and field studies the following conclusions were drawn:

- The control mixture with water/cement ratio of 0.35 showed improved corrosion protection compared with the control mixtures with 0.40 water/cement ratio.
- Mixtures with DCI or Rheocrete CNI at doses of 20 liters per cubic meter showed superior corrosion inhibiting performance compared with the corresponding control specimens. The same admixtures at doses of 10 liters per cubic meter had less satisfactory performance in both laboratory and field specimens.

Figure 4. Fabrication and location of Phase III field corrosion panels in a marine environment.

Figure 5. Mass loss due to corrosion of test layer of reinforcing steel.

- Mixtures with 15 percent replacement of cement with Fly Ash or Silica Fume showed superior corrosion inhibiting performance compared with the corresponding control specimens.
- Concrete mixtures using Rheocrete 222+, FerroGard 901, Xypex Admix C-2000 or Latex-modifier showed mixed results.
- Kryton KIM performed well in a field panel, but was not included in the laboratory study.
- A recommended concrete mixture for use in marine environments in Hawaii would have a 0.35 w/c ratio with either DCI or CNI at 20 //m³ and either Fly Ash at 15% cement replacement or Silica Fume at 5% cement replacement. Although this combination was not tested in this study, it is believed that the admixture attributes will complement each other when combined in a concrete mixture.

4 GOLD STANDARD FOR RESIDENTIAL CONSTRUCTION IN A TROPICAL MARINE ENVIRONMENT

Based on the two research projects described above, and decades of inspections of residential buildings exposed to a tropical marine environment, the following measures are recommended to significantly extend the useable life expectancy of residential construction.

4.1 *Framing material*

Both timber framing and cold formed steel framing can provide extended life expectancy if they are protected from termites for the former and corrosion for the latter. Regular tenting of timber framed structures in tropical environments is required to control both ground and aerial termites. Sealed wall and floor cavities and careful venting of attic spaces is required to protect CFS framing from exposure to airborne chlorides.

4.2 *Foundation concrete*

The ACI 318-19 standard (American Concrete Institute, 2019) requires that concrete used in marine and coastal environments exposed to “sea spray” utilize concrete with a water-to-cementitious material ratio of 0.4 or less. This essentially ensures a relatively dense concrete with high compressive strengths. The addition of Fly Ash with 15% more replacement of cement will significantly reduce the concrete permeability and enhance the protection offered to the reinforcing steel. Ensuring 50 mm or greater clear cover to the reinforcing steel will also improve performance. The use of stainless steel bars, particularly when located close to exterior exposed surfaces, will greatly reduce the likelihood of corrosion. Ultimately, replacing the reinforcing steel with bars made of non-corrosive materials such as glass fiber reinforced polymer (GFRP) bars, Aramid FRP (AFRP), basalt FRP (BFRP), or carbon FRP (CFRP) bars will remove the threat of corrosion entirely, though structural members subject to deflection may not perform adequately with these FRP materials because of their relatively low modulus of elasticity compared with steel bars.

4.3 *Concrete placement*

During placement of the concrete in residential foundations and slab-on-grade construction, there is a tendency to overlook the need for consolidation and adequate curing. Poor consolidation of the concrete can provide easy access for chlorides and other corrosive products to the embedded steel components. Lack of adequate curing of concrete can result in shrinkage cracking which again provides entry points for corrosive chemicals. It is therefore essential that concrete be properly consolidated and cured to ensure the required concrete strength, density and low permeability are achieved.

4.4 Exterior CFS wall framing

Cold formed steel used in exterior walls in coastal environments must be well protected from airborne chlorides. This can be achieved by paying close attention to the installation of exterior vapor barriers and the use of holddowns located inside the wall cavity, with stainless steel anchors embedded in the concrete slab (Figure 6, left). A common area of exposure of the CFS is the wall bottom track which is exposed to the concrete slab below and potential air entering between the exterior cladding and the side of the concrete slab. Installation of a protective wrap around the bottom and sides of the track significantly reduce the potential for this source of corrosion (Figure 6, right).

Figure 6. CFS framing in exterior wall cavity with interior holddown (left) and bottom track protective wrap (right).

5 CONCLUSIONS

This paper presents the results of two corrosion studies studying the performance of cold formed steel framing and reinforced concrete to coastal marine environments in Hawaii. The following conclusions are drawn based on these studies and field inspections on numerous residential structures:

- Care must be taken with the concrete mix design, concrete placement, and protection of the reinforcing steel to ensure adequate life expectancy of the foundations with limited maintenance and repair.
- Cold formed steel framing elements, holddowns and fasteners in the exterior walls require particular design and installation attention to reduce the potential for corrosion. Any exposure of these materials to air borne chlorides will lead to rapid corrosion and ultimately loss of structural function.

Predicting the military load class from bridge data with a multilayer perceptron

M. Haslbeck, J. Flotzinger & Th. Braml
University of the Bundeswehr, Munich, Germany

ABSTRACT: Assessing the load bearing capacity of civilian bridges is a challenging task for routine reassessment jobs, especially in the military context. In order to ensure mobility of troops, the load bearing capacity of bridges needs to be assessed to make the safe crossing of military vehicles possible at home and abroad. For this reason, rapid assessment methods have been developed that allow for classification of civilian bridges after a quick visual reconnaissance. In the absence of verifiable calculations or drawings, the applied methods need to be based on geometrical data that is suspected to be correlated to the military load class of a structure. Current approaches are based on simplified assumptions such as correlations between dead loads and live loads or consist of simplified calculations assuming conservative material properties. In order to improve the current classification method, a Machine Learning (ML)-based methodology is given that classifies slab to a particular military load class without human intervention using a correlation between measured geometrical data and classification result. It is concluded that the usage of ML models is very promising for rough classifications of bridges with unknown military load class (MLC). However, the available training data is insufficient to train reliable models and an expanded amount of training data will be needed for deployment as a software package in the armed forces.

1 INTRODUCTION

1.1 *Importance of bridge assessment*

The assessment of the load bearing capacity of existing bridges is a challenging task when no verifiable calculations or as-built drawings are available. The development of methodologies to assess the maximum bearable traffic load is thus of special interest when the rapid assessment of the bridge geometry is the only source of information. For military bridge assessment, this is the case when convoys have to be guided through unknown terrains or when supply routes have to be planned. Use cases such as these have already been encountered in stabilization missions or similar military operations. (Haslbeck, Hertle & Braml, 2021; Haslbeck, Vallée & Braml, 2021).

Based on those experiences, bridge assessment codes have been developed independently by several nations to ensure a safe crossing of military vehicles over civilian bridges. The approach of most of these methods is to derive the maximum allowable Military Load Class (MLC) of a bridge from geometric parameters of the main structural parts. In order to enable soldiers to classify a bridge in the field, the tablet-based application BRASSCO-NG has been developed by the University of the Bundeswehr that allows for a rapid assessment on site.

For the application of BRASSCO-NG and the user interface please refer to (Haslbeck, Hertle & Braml, 2021; Haslbeck, Vallée & Braml, 2021).

1.2 *Introduction to military load classes and STANAG2021*

As the main output of the presented methodology using machine learning (ML) is the attribution of a military load class (MLC) to a specific bridge in the field, the system of matching vehicle MLC and bridge MLC needs to be discussed briefly.

The framework of STANG2021 (NATO) describes a system of hypothetical vessels that shall reflect the true loading of military vehicles. Due to the different nature of the load distribution, each class comprises a load model for wheeled and for tracked vehicles. Due to reasons of brevity, the reader is referred to (Geissler, 2014) for further information on the MLC system and the attributed load models.

The system of load models describes the shape and the weight of the assumed vehicles both for structural analysis and the classification of the carrier to a certain MLC. Using the load scheme, each bridge can be sorted into a MLC class using the maximum bearable bending moment and shear force. Interpolation between different load classes is permitted, so intermediate MLCs are allowed. As the load bearing capacity for one-way and two-way traffic, the allowable load class is commonly split into a one-lane and a two-lane MLC.

As verifiable calculations are in many cases not available, the attribution of a MLC to a specific bridge often requires the assumption of a correlation between certain observable properties of a structure to its MLC class.

1.3 *Current approach*

Reconnaissance of civilian bridges is based on the recording of geometrical data using folding rules or laser distance meters. From this data, a correlation function is applied that exploits the assumed correlation of dead load and the ultimate load from military vehicles expressed by the capacity to resist a certain unit bending moment. This method for regression relies very much on engineering experience. The correlation function for the ratio of moment from dead load and moment from live load has been calibrated by a large number of verifiable calculations for bridges of different span length and construction types. However, the assumed relation might be improved by a more sophisticated regression using machine learning techniques.

1.4 *Potential of machine learning for bridge assessment and scope of this contribution*

In order to implement a regression for the maximum MLC depending on a set of geometrical input parameters, Artificial Intelligence (AI) can help to go beyond engineering experience and to find correlations that are not visible at first sight.

Using a limited data set available from a NATO database, the potential of machine learning techniques is revealed in this contribution using the example of slab bridges.

After a brief review on the theoretical background of the applied machine learning technique, the required input for the graphical user interface of BRASSCO-NG is depicted. Subsequent to the description of the implementation, several worked examples are given in order to present the results and to discuss the pros and cons of this new approach to military bridge assessment.

2 RELATED WORK

2.1 *Machine learning*

Neural Networks (NNs) are able to solve very complex problems more accurately than other algorithms in the field of machine learning, e.g. linear regression, decision tree (Wu et al., 2008) or random forest (Ho, 1995). The regression of tabular data can be a complex task, for the solution of which the NNs can be particularly suitable. The architecture of Neural Networks is inspired by biological neurons, in the ML context also called nodes. The special feature of NNs compared to other algorithms in the ML domain, is the contained weighted information in nodes forwarded to neighboring neurons. These weights (synapses) are trainable, whereby a transmitted signal can be amplified or attenuated (Goodfellow et al., 2018).

Figure 1 shows the sequence of the forward process that is carried out during inference of tabular data from a bridge. The model that will be used in this work is a multilayer perceptron (MLP), a neural network consisting of linear layers. Each input parameter is fed into the NN. Subsequently, the inputs are multiplied by weights. After having summarized all weighted

inputs of one node, and biases were added, the activation function is applied. The aforementioned operations and the application of the activation function will be executed for all nodes in the hidden layer. For the nodes in the output layer, no activation is applied in order to obtain the result of the regression describing the military loading class.

Figure 1. Feed-forward process of the MLP calculating MLC from tabular data.

2.2 Machine learning models for load-carrying capacity

Truong et al. (Truong et al., 2022) have analyzed the applicability of ML models for the estimation of the load-carrying capacity of semi-rigid connected steel structures. They evolved a dataset using the advanced analysis based on beam-column and zero-length elements. The model's input layer consists of member cross-sections and parameters of the high-order non-linear functions characterizing the semi-rigid connection behaviors. They evaluated multiple ML methods: linear regression models, support vector machines, tree-based ensemble algorithms and models from the field of deep learning. The most performant model for solving the problem of depicting the load-carrying capacities of semi-rigid connected steel frames is XGBoost (Chen & Guestrin, 2016).

3 METHODOLOGY

3.1 General

The collection and preparation of data for later evaluation by AI represents a crucial step in the process chain of developing a military AI. The reliability of the trained model depends crucially on the data provided. For the model to be trained within the project, the collection of design drawings with associated MLC classification provided by the Military Engineering Centre of Excellence (MILENG-COE) will be used. In particular, the use of intermediate MLCs representing not only the load models depicted in STANAG 2021 (NATO) but also values representing interpolation between them, could find use in the training process. The geometric dimensions were taken manually from the design drawings.

The modeling of the neural network requires knowledge of the problem and the algorithms to be used as well as insight into the existing dataset. Especially the complexity of the regression model depends on the available data and the correlations. In the context of the investigations, a linear neural network is used, whose theoretical background is discussed in Section 3.2. For the training of the NN and the test of the regression, a MATLAB script has been used where the input is read directly from the NATO database provisioned for the testing of MLC classification methods.

3.2 Multilayer perceptron

The operating principle of the neural network is explained in the following. The geometry information stored in the input variables is summed up in the neurons after the multiplication

by their weighting factors to represent the importance of the information. To this, the bias b is added, which is trained as a parameter.

The nodes in the hidden layer are activated by the sigmoid function according to Equation 1.

$$y = \frac{1}{1 + e^{-\left(-\sum_j c_j x_j - b\right)}} \quad (1)$$

$$y = f(c_1 x_1 + c_2 x_2 + \dots + c_n x_n + b) = f\left(\sum_j^n c_j x_j + b\right) \quad (2)$$

The multilayer perceptron includes one hidden layer with three nodes. The activation function in the hidden layer is the sigmoid function. During one training step all samples are fed into the network. Thus, the batch size corresponds to the number of data points in the training split. The default value of the learning rate of 0.001 is chosen. In total the training process is repeated for 100 epochs.

Table 1. Hyperparameters and architectural parameters of the network.

Parameters	Value
Hidden layers	1
Nodes in hidden layer	3
Activation function	Sigmoid
Batch size	37
Learning rate	$1e^{-3}$
Train epochs	100

4 IMPLEMENTATION OF A NEURONAL NETWORK FOR SLAB BRIDGES

4.1 Engineering background

For the purpose of this paper, the automatic evaluation of slab bridges shall be used as they are common on side roads with few heavy traffic to span over small and medium gaps.

The cross section of a slab bridge is formed by the slab itself and two cantilever arms at both outer faces. Figure 2 shows (a) a slab bridge as it has been found in the KFOR mission in Kosovo and (b) the schematic representation of the cross section with its major parts.

Figure 2. (a) slab bridge in the regional road network in Kosovo from (KFOR) and (b) illustration of the cross section and its parts.

4.2 Input values and dataset

In order to exploit the assumed correlation of maximum load bearing capacity of a bridge and its physical dimensions, data from the cross section and the civil engineering system in

longitudinal direction are part of the input into the BRASSCO-NG code. Figure 3 shows the GUI of the software package and the required dimensions. Especially challenging for the determination of the input was the need to choose a representation that corresponds to the various construction types for slab bridges in different regions. It should be noticed that the evaluation is based on a symmetrical cross section as the load bearing capacity is evaluated for the most unfavorable position of load, so only the weaker half of the superstructure's cross section is shown in the GUI. For the evaluations of this paper, only the height of the slab and the span length has been used as input because these values appear to be the most influential.

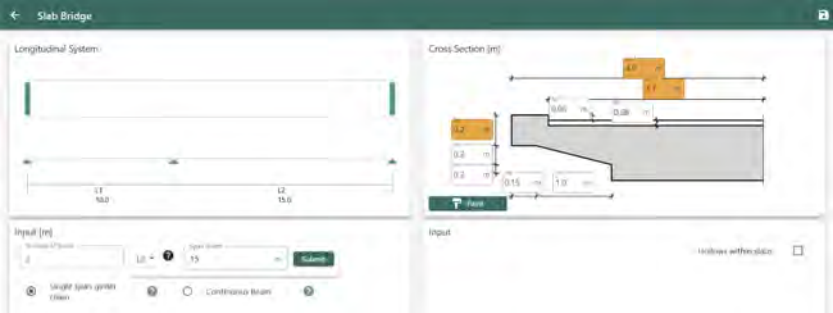

Figure 3. GUI of BRASSCO-NG for slab bridges with the required input L_1 , L_2 , ..., h_e , h_v , h_s , w_e , w_v , h_c , t_p , $w/2$, $w_r/2$.

In order to achieve the best possible result from the training of the neuronal network, a set of data has been chosen that represents a large spectrum of bridges. Figure 4 shows a histogram of the set of MLC for single lane crossing of wheeled vehicles in the training data of size 37.

Figure 4. Histogram of the target MLC for the classification of slab bridges for single lane traffic of wheeled vehicles.

The bridges' heights range from 3.7 to 25 meters while the widths and spans range from 0.20 to 0.80 and 4 to 17 meters (Table 2). Generally, the variety in geometries indicates a strong heterogeneity of the underlying data.

Table 3 shows the sample distribution over the data splits. In total the dataset includes information of 40 bridges. The size of the dataset can be considered as small compared to others,

Figure 5. Histograms for the input parameters.

Table 2. Minimum, median and maximum for the input parameters of slab bridges, dimensions in in [m].

Parameter	Min	Median	Max
Height	3.7	7.4	25
Width	0.20	0.44	0.80
Span	4	8.8	17

such as the ones named in chapter 2.1. Therefore, the data was split in into two packages, the training and validation split. The validation split also represents the test data. Usually, datasets consist of a training, validation and test split. The three samples included in the test package approximately describe the whole range of bridges in the dataset regarding the MLC.

Table 3. Train and validation splits for the MILENG plate dataset.

Split	Count
Train	37
Validation/Test	3
Total	40

4.3 Results and discussion

In order to show the applicability and the advantages of machine learning techniques to the subject of military bridge classification, the results of the process of training are presented and discussed.

Figure 6 shows the progress of the loss during training. It can be stated that the loss continually decreases without significant variability and the patterns in the training data are well recognized by the network.

Regarding the differences between predictions and targets in Figure 7 an acceptable performance is observed. Only six predictions differ more than 10 MLC from the target. Most prognosticated samples have a difference, compared to the target, of less than five MLC.

The neuronal network was tested using three examples of bridges that were not part of the training data. To show the applicability, the test set of bridges was chosen such that the lower, medium and higher range of the MLC spectrum is covered. The target values for the three examples can be given by MLC 55, 95 and 20. Table 4 gives the design values, the result from the approach currently implemented in BRASSCO-NG and the result gained from the regression done by machine learning. The results of this small control sample indicate that the application of neuronal networks might be a significant advance for the classification of civil bridges. Even though the classification result does not show perfect agreement to the target values of the structural analysis, the results fit better than the currently implemented approach using the bending moment from dead load or the linear fit of the parameters to the target

Figure 6. Loss during the training process for slab bridges.

Figure 7. Differences between predictions and targets for slab bridges.

values. However, a larger sample set and a wider range of MLCs is required to improve the regression. This is especially true for the lower part of the MLC spectrum (test sample #3).

Table 4. Comparison of the results for slab bridges (single lane, wheeled vehicles).

Test Bridge no.	Structural analysis (target)	Current approach	ML-approach	Linear regression
#1	55	100	76	86
#2	95	150	81	140
#3	20	80	50	47

5 CONCLUSIONS

In this contribution, a new approach for the classification of civil bridges for military purposes is presented utilizing Machine Learning techniques instead of state-of-the-art engineering approaches. The results show that the methodology is superior both to the current method and a simple least squares regression that was performed for reasons of comparison. It can be reasoned that the application of the presented approach is very promising. However, the data set used for training is not yet sufficient for application in the field and needs further

enlargement. What is more, an analysis of sensitivities for the applied input as well as the amplification of the studied input parameters may give further insights into the correlation of certain features and the load bearing capacity. Supplementary to the measurable geometrical dimensions, the inclusion of the material strength, the percentage of reinforcement or the design load model are very promising for further investigations. Further improvement may also be made when other Machine Learning methods are applied and compared to the implemented linear neuronal network, e.g. decision tree, support vector machines or random forest.

Elaboration of a truncated probability function for the Young's modulus of concrete

M. Haslbeck & Th. Braml

University of the Bundeswehr Munich, Bavaria, Germany

ABSTRACT: The necessity of recalculating existing engineering structures has inspired a bunch of methods to ensure reliability. Among them is probabilistic modelling of material properties for the probabilistic structural analysis or methods of Bayesian System Identification that allow for the verification of the model parameters in a finite element calculation. Both methods rely on probability distribution functions to describe scatter in the behavior of an engineering structure. Of special interest in this field are concrete structures as they show a great variance in the material characteristics. Using a Monte-Carlo-Simulation, an approximate lower bound for the truncation of the probability function for compressive strength is given, based on the regulations of conformity testing that were in effect at the time of construction. The introduced methodology is elaborated using examples from different periods of quality management. The lower bound provided by the methodology avoids excessively low values of compressive strength in the probability distribution as they exist in boundless functions. The results of this simulation are afterwards transferred to the concrete's Young's modulus, so that the truncated probability function can be used as a prior in a Bayesian system identification framework.

1 MOTIVATION AND SCOPE

1.1 *Motivation*

The evaluation of failure probabilities and uncertainty quantification for the purpose of statistical modelling for engineering structures by means of uncertainty propagation, variance-based sensitivity analysis and Bayesian updating very much rely on (prior) assumptions, i.e. probability distribution functions to describe uncertainty.

The introduction of additional knowledge, e.g. from quality testing can help to lower uncertainty attributed to parameters in probabilistic calculations.

1.2 *Research question*

As numerical simulations often require the restriction of possible parameter values to a feasible parameter space and as advanced statistical assessment necessitates the introduction of all available knowledge for the assignment of a distribution function to uncertainty in general, this contribution deals with the elaboration of a lower bound for the compressive strength and Young's modulus of concrete from (historic) regulations on quality management.

The presented contribution is an extension and further development of the author's suggestions in (Haslbeck & Braml, 2021) in order to extend the application to other quality standards, to compare the results and to show how the conclusions can be transferred to stiffness parameters.

2 CONFORMITY TESTING AND REGULATIONS

The assessment of conformity is a central element of the concept of quality control in most design standards. Most testing procedures rely on a random sample of at least three specimens from a selected number of charges for concrete and a decision rule on the conformity that has been elaborated based on statistical considerations. In most cases, several criteria have to be considered.

The intention of the regulation is to control the quality of the produced concrete by accepting or rejecting the hypothesis of conformity for a certain concrete strength class and sorting out those charges that do not pass the quality check and are thus of inferior quality. Hence, conformity testing serves as a means of filtering out those lots of concrete below a certain limit value and should thus be considered in the statistical models of strength and stiffness parameters.

As it is the case for every statistical testing procedure, each single criterion for acceptance or rejection has an operational characteristic curve that shows the probability of rejection for every possible realization of any parameter of the distribution function. Due to the limited number of specimens tested, the operational characteristic curve does not show a perfect slope at the intended limit value, but reveals some inaccuracy in the sharpness of separation (DAfStb, 2003). In order to give a sharp boundary for the truncation of the probability distribution function, this contribution assumes an idealized operational characteristic curve of the testing procedure.

As most tests are based on a multi-criterion decision rule, the evaluation can no longer be done analytically, but the assumption shall be based on a numerical experiment using a Monte-Carlo-Simulation. In accordance with the regulations, it is assumed that those structures that do not meet the requirements are demolished or checked by more sophisticated methods of quality assessment. This assumption is consistent with the idea of quality testing and has already been applied by previous work, e.g. in (Loch, 2014; Schnell et al., 2010).

3 RATIONALE OF THE SIMULATION AND ALGORITHMIC IMPLEMENTATION

The general rationale of the procedure originally proposed in (Haslbeck & Braml, 2021) and extended in this contribution is to determine a lower bound of the concrete strength distribution function based on the notion that those samples not passing the test on conformity are considered to be those of lowest quality.

The Monte-Carlo-Simulation is initiated by drawing a number of N samples (f_{c1}, f_{c2}, f_{c2}), where each f_{ci} is a realization of the probability distribution function of the compressive strength of concrete described in section 5.

In a loop, the different criteria to accept or reject the hypothesis of conformity is applied to each sample (f_{c1}, f_{c2}, f_{c2}) sequentially. If a sample does not pass, the counter for rejected samples, called 'num_reject' is increased by 1, otherwise it remains unchanged.

As the operational characteristic curve is assumed to be ideal in its sharpness of separation, those samples sorted out are assumed to be those of inferior quality. In consequence, the ratio between the number of rejected samples after the total number of iterations N is the quantile applied for the truncation of the parent distribution before conformity testing has been carried out.

The transfer of the results to stiffness values can scientifically be reasoned when assuming a monotonic relation between strength and stiffness properties, e.g. Young's modulus. The correlation of these properties is discussed further in section 6.

The algorithmic implementation of the procedure has been carried out using MATLAB. As the number of rejected samples is stored in 'num_reject', the ratio of deficient samples can be expressed by num_{reject}/N . As soon as an appropriate convergence is reached, this proportion shall be seen as the quantile where the original distribution function of concrete strength from section 5 can be cut off at its tail. Figure 1 shows a flowchart of the algorithm which has been implemented in the template.

The idea of this simulation is rather universal and needs only slight adaptation for the implementation of other standards than those described briefly in section 4.

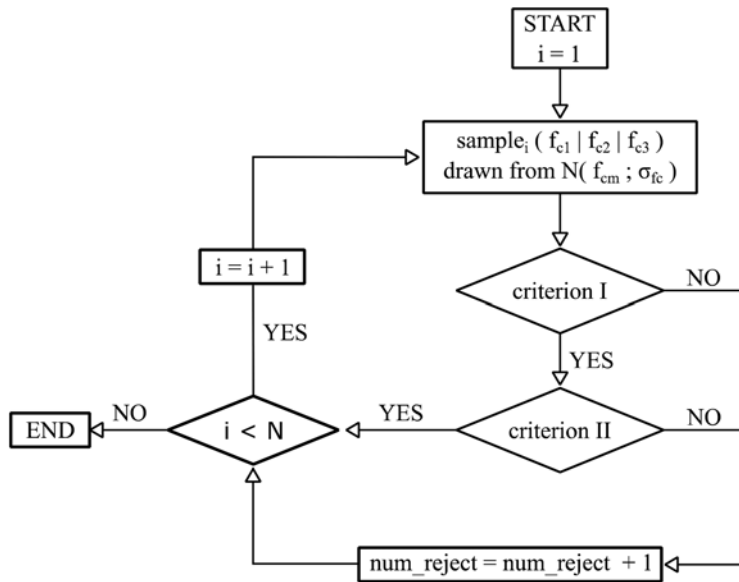

Figure 1. Flowchart of the proposed numerical computation.

4 REGULATIONS

The core of the proposed approach is the numerical replication of the instruction on conformity testing according to the respective applicable standard. The respective regulations for the examined standards are given in the subsequent sections.

DIN 1045:1959-11 (in effect 1959 – 1972) applies the following rules for concrete of strength class B300:

- Three test cubes of edge length 200 mm are tested on their strength after 28 days → (cube compressive strength)
- Criteria I: The mean of the compressive strength values, $mean(f_{c1}, f_{c2}, f_{c3})$ is to meet the compressive strength of the strength class W_{28} , here: $300 \text{ kpl/cm}^2 = 30 \text{ MPa}$
- Criteria II: The minimum of the strength values, i.e. $\min(f_{c1}, f_{c2}, f_{c3})$ must not be less than 85 % of the compressive strength of the strength class W_{28} , here: $0.85 \cdot 300 \text{ kpl/cm}^2 = 255 \text{ kpl/cm}^2 = 25,5 \text{ MPa}$

The implemented regulations in DIN 1045:1972-01 (in effect: 1972 – 1978) for a Bn450 (concrete group B II) can be summarized as follows:

- Three test cubes of edge length 200 mm are tested on their compressive strength after 28 days → f_{c1}, f_{c2}, f_{c3} (cube compressive strength)
- Criteria I: The mean of the compressive strength values $mean(f_{c1}, f_{c2}, f_{c3})$ is to meet the serial strength of the strength class β_{wS} , here: $500 \text{ kpl/cm}^2 = 50 \text{ MPa}$
- Criteria II: The minimum of the strength values, i.e. $\min(f_{c1}, f_{c2}, f_{c3})$ is to meet the nominal strength β_{wN} (5%-fractile), here: $450 \text{ kpl/cm}^2 = 45 \text{ MPa}$

5 COMMON PROBABILISTIC MODEL OF CONCRETE STRENGTH

5.1 General remarks

Scientific studies on the assumable statistical parameters of the concrete compressive strength are plenty and can be found, e.g. in (Hansen, 2004; Murdock, 1953; Six, 2003). However, there are still significant differences in the proposed statistical parameters.

A short literature study on the measures of location and dispersion is given in the following subsections that serves to justify the choice made for the examples of this paper. However, the given values are meant as input for the simulations from section 7 and should be reconsidered for each specific use-case of the presented procedure.

5.2 Type of distribution function

A common assumption for the type of distribution function is a Gaussian one following e.g. the description in (Östlund, 1991; Rüsç, 1969). The assumption of an unbounded normal distribution also reflects best practice in quality testing applications (DAfStb, 2003) and is thus adapted in this paper.

5.3 Standard deviation

The aspired or commonly achieved standard deviation has a major influence on the design of concrete mixtures and vice versa (Rüsç, 1969).

Investigations on the coefficient of variation (abbreviated: COV) for concrete with strength classes according to DIN 1045:1959-11 indicate that a variation coefficient of 5 % has only been reached in rare cases of optimal conditions at site, so coefficients of 15 to 20, up to 25 % are proposed (Graf, 1950). For a B300, standard deviations of 4.5 MPa to 6.0 MPa (COV \approx 0.12 to 0.16) should be assumed for the cube compressive strength.

For DIN 1045:1972-01, (Blaut, 1968) proposes a standard deviation of 5.5 MPa in combination with a normal distribution where the denomination of the strength class can be interpreted as a 5% quantile.

The synopsis of the literature review for the different periods of standardization and the state of the art in concrete production over the last 70 years results in a standard deviation of $\sigma \approx 5$ MPa. This seems appropriate for each of the examined standards. Differing geometry of the reference specimen shall be neglected due to the high range of suggested values from literature.

5.4 Expected value

The assumption of the mean value of compressive strength is a major part of modeling as the targeted compressive strength is very influential in computing the ratio of samples that do not meet the requirements. Of special interest in this field is the allowance to the minimum value when designing the mixture to minimize the number of rejected samples. Therefore, a review on the dimensioning aids of the different time periods was conducted, but could not give consistent advice on an adequate allowance.

For DIN 1045:1959-11 advice is given in (Blaut, 1968). The reference recommends a value of 1.645σ for the allowance to the normative value. This results in an expected value of $1.645 \cdot 300 \text{ kp/cm}^2 = 382.2 \text{ kp/cm}^2 \approx 38.2 \text{ MPa}$ for the considered B300. In comparison, the author reports a value of 340 – 350 kp/cm^2 from experience which corresponds approximately to this value.

For concrete produced after the introduction of DIN 1045:1972-01, the minimum value of β_{wS} should be seen as the 5 %-quantile for a normally distributed probability function and reflects the upcoming statistical quality control at that time. This assumption is consistent with the recommendations of (Blaut, 1968) and exceeds the minimum value of $50 \text{ kp/cm}^2 = 5 \text{ MPa}$ reported in (Rapp, 1971; Walz, 1972). For the example of a Bn450, the assumed value is $\mu = 1.645 \cdot \sigma + \beta_{wS} = 1.645 \cdot 50 \text{ kp/cm}^2 + 450 \text{ kp/cm}^2 = 532.25 \text{ kp/cm}^2 = 53.2 \text{ MPa}$.

6 DISTRIBUTION FUNCTION OF YOUNG'S MODULUS FOR CONCRETE

6.1 Type of distribution function

In most of the studied reference books, the type of distribution function is given as a normal distribution. In contrast to this, it is in a minor number of studies given as a log-normal

distribution function, e.g. in (Six, 2003), or as a Student-t-distribution, e.g. (JCSS, 2001). For this contribution, the probability function is assumed to follow a Gaussian distribution for all the examples of section 1.2.

6.2 Coefficient of variation

Because of the many different strength classes in different standards worldwide and the intermediate values between the strength classes, the scatter in the elastic stiffness is commonly expressed by its coefficient of variation v_E . Table 1 gives a short summary of values taken from different textbooks.

Table 1. Summary of COVs from different references.

Reference	Coefficient of Variation
Six2003(Six, 2003)	0.15
(Rüsch, 1969)	0.12
(Östlund, 1991)	0.10

6.3 Expected value

The assumption on the mean value for the different classes is made according to the current state of the art, i.e. the expression from Eurocode 2 (DIN EN 1992:2004) according to equation (1). For those regulations that are based on cubes of 200 mm edge length, the values need to be converted.

Therefore, a factor of 0.8 is applied, which is approximately the value used in the current standard of Eurocode 2. The mean value of concrete compressive strength for the different standards and the assumed values of Young's modulus are summarized in Table 2.

$$E_{cm} = 22,000 \cdot \left(\frac{f_{cm}}{10}\right)^{0.3} \quad (1)$$

Table 2. Assumed values for the mean of the probability function of elastic stiffness before incorporating information from conformity testing.

Concrete Strength Class	Mean Value of Concrete Strength	Expected Value of E_{cm} after 28 days
B300	$f_{cm} = 38.2 \text{ MPa} \cdot 0.8 = 30,6 \text{ MPa}$	$E_{cm} = 30765 \text{ MPa}$
Bn450	$f_{cm} = 53.2 \text{ MPa} \cdot 0.8 = 42,6 \text{ MPa}$	$E_{cm} = 33977 \text{ MPa}$

6.4 Transferability of the results to the elastic stiffness

Even though the strong connection between the concrete compressive strength has become obvious in section 6.3, the transferability of the simulated quantile needs further justification.

The rationale for the direct adoption of the simulated ratio to the quantile of the lower bound of elastic stiffness is that the monotonic relation between these two properties legitimates the simplified assumption that those charges sorted out for the reason of their low strength are exactly those that have lowest stiffness properties. Scatter in the simultaneous growth of strength and stiffness should be comprised in a larger coefficient of variation of Young's modulus compared to the compressive strength.

6.5 Post hardening

All the standards reviewed in this contribution apply in a strict sense to concrete properties as they are 28 days after production. As the process of hardening is not yet finished at that point

of time, effects of post hardening can be incorporated in the assumed probability function. Experimental studies on the long-time development of the elastic stiffness after 50 or even 100 years are very rare. For the purpose of this contribution, the results presented in (Walz, 1977) were evaluated which leads to an increase of about 15 % in stiffness after 50 years. This time period shall be assumed for the examined standards. In consequence, it is proposed to multiply the expected value of the probability function by 1.15. The scatter that lies in the process of post hardening should be respected by an increase in the coefficient of variation for the distribution function of the Young's modulus described in section 6.2.

For the simulations in this contribution, a value of $\nu_E = 0.20$ is applied that respects the large spectrum of processing, incorporates different qualities of production facilities and comprises uneven post-hardening.

Figure 2. Truncated Probability distribution function for (a) B300 and (b) Bn450 and (c) C20/25.

7 RESULTS

7.1 Concrete compressive strength

The results of the procedure described in section 3 are given in Figure 3 using the examples presented in section 4 and a number of 10^5 simulation runs. For the B300 tested according to the procedure described in DIN 1045:1959-11, a ratio of 0.017 of the tested samples were rejected which corresponds to a lower bound of 27.7 MPa (cube compressive strength). The evaluations result in a decrease in standard deviation after truncation of 5 %.

A stricter rule for rejection seems to be described in DIN 1045:1972-01, where an amount of approximately 21 % of the samples failed. The corresponding limit value for the cube strength was computed as 49.0 MPa. Using the truncation, the standard deviation can be lowered by 24 %.

Figure 3. Simulation results for the truncated probability density function elastic stiffness taking post-hardening into account.

7.2 Elastic stiffness

As one of the objectives of this contribution is to transfer the results to stiffness properties, the results of the simulation were used to truncate also the probability distribution for the Young's modulus. Figure 3 shows the result for the two examples. The transfer of the lower bound was done using the quantile of rejected samples and a slightly higher coefficient of variation of $v_E = 0.20$. The expected value of the initial distribution function, i.e. before truncation, was calculated according to equation (1). Post hardening has been taken into account using an increase in the expectation of 15 % and a slightly higher coefficient of variation compared to the experimental studies or theoretical derivations presented in section 6.2. The simulated lower bounds also show that the computed bounds are very promising in terms of computational issues caused by very unequal values in the stiffness matrix when used for the numerical simulation. In most cases, the assumption of a quantile less than the calculated one may be sufficient to ensure numerical stability.

Table 3. (Initially) Expected Value of Young's Modulus after 50 years for the three examined examples.

Concrete Strength Class	(Initially) Expected Value of Young's modulus after 50 years
B300	$E_{cm} = 35379 \text{ MPa}$
Bn450	$E_{cm} = 39073 \text{ MPa}$

8 CONCLUSIONS

Most modern recalculations of existing structures are based on statistical evaluations of certain properties describing a structure's behavior. Therefore, a reduction of uncertainty in the input to such evaluation is of tremendous help.

In order to better describe the uncertainty of a parameter, a procedure is proposed that includes additional information from quality control of concrete to the process of statistical model building by deriving a lower bound for the assumable concrete strength. The developed template is universally applicable for different classes of concrete compressive strength and standards for quality testing.

Additionally, the derived quantile was used to transfer the gained results to elastic stiffness of concrete which is of special interest for the statistical modeling of structures in numerical calculations, e.g., in a finite element analysis.

The impact of surface aspect ratio on the embodied energy, embodied carbon, and embodied water of a building structure

M.K. Dixit

Texas A&M University, College Station, TX, USA

P. Pradeep Kumar

Texas A&M Transportation Institute, Bryan, TX, USA

ABSTRACT: Nearly 48% of the yearly global energy supply is consumed by buildings during their construction and operation in the form of embodied and operating energy, which is responsible for nearly 40% of global carbon emissions. Building materials used for the superstructure, substructure, envelope, and interiors of a building contribute to over 90 percent of the embodied energy. Concrete and structural steels are two major materials used in bulk quantities in the construction industry, which can adversely impact the environmental sustainability of buildings. Concrete alone is responsible for 5-9 percent of the global carbon emissions. The ratio of horizontal to vertical surface area of the building known as the surface aspect ratio is an important parameter for the sustainability of a building because it affects its structural design and the quantities of materials such as steel and concrete. In this study, we analyzed how aspect ratio of a building impacts its structural design and material use in the foundation, framing, and slab of the building, and how it eventually affects the embodied energy (EE), embodied carbon emission (EC), and embodied water (EW). Five different building configurations of a generic reinforced concrete building with 12, 9, 6, 3, and 1 floor/s are modeled, and input-output based hybrid (IOH) models are used to determine the total EE, EC, and EW requirements for concrete and steel for different surface aspect ratios. The results show that for a 12-story building, there is *ca.* 34% increase in EE and EC and *ca.* 27% increase in EW as compared to a 1-story building. These results signify the importance of selecting horizontal vs. vertical building configurations in urban areas to potentially help reduce the environmental footprint of the building construction sector.

1 INTRODUCTION

Nearly half of global energy supply can be spent in buildings' construction and operation alone, which may attribute to up to 40% of global carbon emissions (Baum, 2007; Dixit, 2017). The building sector also consumes extensive amounts of fresh water (Stephan and Crawford, 2014). Looking at the intensifying construction activities and radical weather events causing water scarcity around the globe, shrinking the water footprint of buildings is essential for long-terms environmental sustainability of the building sector (Stephan and Crawford, 2014; Dixit, Kumar and Haghghi, 2022). These extensive energy, carbon and water footprints of the building sector are becoming a big concern (Stephan and Crawford, 2014; Rasmussen *et al.*, 2018; Hong *et al.*, 2019; Dixit, Kumar and Haghghi, 2022). Most of the energy and water impacts come from building operation activities, whereas a sizable portion from embodied impacts due to buildings' construction activities (Stephan and Crawford, 2014; Dixit, Kumar and Haghghi, 2022). The embodied impacts include embodied energy (EE), embodied carbon (EC), and embodied water (EW) (Stephan and Crawford, 2014; Rasmussen *et al.*, 2018; Hong *et al.*, 2019; Dixit, Kumar and Haghghi, 2022). The amounts of

energy and water used directly in construction activities and indirectly by using materials is termed EE and EW, respectively (Stephan and Crawford, 2014; Rasmussen *et al.*, 2018; Hong *et al.*, 2019; Dixit, Kumar and Haghghi, 2022). The EE and EC, therefore, have a direct and an indirect component (Stephan and Crawford, 2014; Rasmussen *et al.*, 2018; Dixit, Kumar and Haghghi, 2022). Because energy sources consumed as EE also incur water use in their generation, extraction, refinement, and delivery, there is a third EW component called the energy related embodied water (EREW), which must also be added to the total EW use of a building (Hong *et al.*, 2019; Dixit, Kumar and Haghghi, 2022). The resulting carbon emission due to the use of EE is termed EC (Rasmussen *et al.*, 2018).

Most EE, EC, and EW impacts stem from the use of construction materials such as steel, concrete, brick, aluminum, and glass, which are highly energy and water intensive (Stephan and Crawford, 2014; Dixit, 2017; Rasmussen *et al.*, 2018). Steel and concrete are two materials that are installed in bulk in buildings' structural systems and can greatly influence the environmental sustainability of buildings (Dixit and Pradeep Kumar, 2022). Concrete, specially is more concerning due to its share of 5-9% in the total global carbon emissions (Benghida, 2017; Cramer, 2019; Di Filippo, Karpman and DeShazo, 2019). Most of these emissions (74%-81%) comes from the production of Portland cement, whereas just 13%-20% from coarse aggregates (Minunno *et al.*, 2021). Likewise, astounding 2 tons of carbon dioxide is released by the production of one ton of steel (Pradeep Kumar *et al.*, 2021). The energy, carbon emission, and water footprints of reinforced concrete structures can be reduced by either lowering the energy, carbon, and water footprints of the production of cement and steel or shrinking the bulk use of concrete in building structure (Benghida, 2017; Monteiro, Miller and Horvath, 2017; Wangler *et al.*, 2019). One of the aspects that may affect the amount of concrete put into a building is the aspect ratio of the building (Beghini and Sarkisian, 2014; Pradeep Kumar *et al.*, 2021). In other words, a building designed for the same floor area can be constructed horizontally and vertically. The big question is which of these configurations may consume more reinforced concrete, answer to which would potentially help urban planners, developers, and policymakers create future city plans and developments that, through design, can help reduce environmental impacts. This paper presents an analysis of how a building's aspect ratio may influence the concrete use and eventually the amount of embodied energy (EE), embodied carbon (EC), and embodied water (EW).

2 SUSTAINABILITY OF REINFORCED CONCRETE

Portland cement and steel are the two most embodied energy (EE), embodied carbon (EC), and embodied water (EW) intensive materials in reinforced concrete structures (Benghida, 2017; Pradeep Kumar *et al.*, 2021). Concrete alone can consume 1 GJ/ton, 35 kgC/ton, and 290 liter/m³ of EE, EC, and EW, respectively (Hammond and Jones, 2008). On average, steel and cement production can incur up to 24.4 GJ/ton, 482kgC/ton, 2.6 kiloliter/ton and 4.6 GJ/ton, 222 kgC/ton, 1.0 kiloliter/ton of EE, EC, and EW usage, respectively (Hammond and Jones, 2008). In fact, steel is found to have the largest EW footprint among common construction materials (Crawford and Treloar, 2005; Choudhuri, 2015; Bardhan and Choudhuri, 2016; Dixit, Kumar and Haghghi, 2022). Key techniques to shrink the energy, carbon, and water impacts of cement mainly strive to reduce or replace the use of Portland cement (Benghida, 2017; Javadabadi *et al.*, 2019). This can be done by either adding materials such as clay and lime that may require lesser processing or replacing cement with pozzolanic materials like natural pozzolans, silica fumes, fly ash, and granulated blast furnace slag (GBFS), which may help shrink the CO₂ emissions by 13%-15% (Naik, 2008; Benghida, 2017; Monteiro, Miller and Horvath, 2017; Javadabadi *et al.*, 2019). Other types of concrete such as fiber-reinforced concrete (FRC) can not only reduce the usage of steel but also time (37% less) and cost (12% less) yielding more savings in carbon emissions (de la Fuente *et al.*, 2019). Other materials such as calcined clay and geo- or inorganic polymers are also added by some studies to replace cement in reinforced concrete (Monteiro, Miller and Horvath, 2017). Recycling is another approach to lower the energy, carbon, and water footprints of reinforced concrete, especially by using recycled concrete aggregates (RCA)

(Javadabadi *et al.*, 2019). Design optimization can also be used to develop mixes that reduce the quantity and improve the quality of concrete in terms of higher durability and strength (Monteiro, Miller and Horvath, 2017; Javadabadi *et al.*, 2019). The size and shape of aggregates as well as packing factor of concrete mix designs can be explored to improve the concrete quality (Monteiro, Miller and Horvath, 2017; Javadabadi *et al.*, 2019). Construction automation technologies such as additive and subtractive construction (e.g., large-scale 3D printing) can be other approaches to reduce the use of concrete (Dixit, 2019). One of the key design parameters that may influence a building's structural design is the aspect ratio of the building (Waldron *et al.*, 2013; Beghini and Sarkisian, 2014; Quaglia *et al.*, 2014; Shadram and Mukkavaara, 2019). The aspect ratio can be defined as a ratio of a building's height to its width or depth (Benghida, 2017). Studies have discussed and analyzed how aspect ratio may impact a building's structural design eventually affecting the use of structural concrete and steel, which apparently has embodied impact implications (Waldron *et al.*, 2013). The aspect ratio of buildings, therefore, can influence their energy and environmental sustainability (Waldron *et al.*, 2013).

3 METHODOLOGY

The primary objective of this study is to evaluate the impact of surface aspect ratio on the total embodied energy, carbon, and water of a building structure. The key objectives are as follows:

3.1 Objectives

- 1) Compute a building's total concrete and steel quantity takeoff based on structural analysis for each defined surface aspect ratio.
- 2) Determine the total embodied energy (EE), carbon (EC), and water (EW) using an input-output based hybrid (IOH) method for each defined surface aspect ratio.
- 3) Compare the results of EE, EC, and EW to understand the impact of surface aspect ratio on these three environmental indicators of the building structure.

3.2 Surface aspect ratio and material takeoff

In this study, aspect ratio is defined as surface aspect ratio (AR_s) which is the ratio of the total horizontal surface area and the total vertical surface area of a building structure. To study the impact of surface aspect ratio, a structural load analysis is conducted on a 12-story commercial building. The surface aspect ratio is varied by changing the total height of the building i.e., by reducing the number of floors while keeping the floor area the same. For this study, a total of five different cases with 12, 9, 6, 3, and 1 floor/s are considered to investigate the impact of AR_s . However, to ensure consistency among the cases being compared, the buildings' total floor area of 10,600 m² is kept constant for all the cases considered. Therefore, the horizontal dimensions are varied to accommodate for the reduction in the height and thereby, the AR_s is varied. Thus, the AR_s increases with decrease in the numbers of floors, i.e., for the buildings with 12, 9, 6, 3, and 1 floor/s the AR_s is obtained to be 0.14, 0.21, 0.37, 0.99, and 4.19, respectively.

The floor plans distinguished by surface aspect ratio are analyzed using ETABS v18 and Rapid Interactive Structural Analysis (RISA) Foundation for evaluating the superstructure and sub-structure, respectively. The structural model is prepared using beam and column assignment for the horizontal and vertical members subjected to standard ASCE7 (ASCE7-16, 2016) loading. The self-weight of the 9-inch-thick exterior wall is applied as a uniformly distributed load along the wall periphery. 104 pounds per linear foot (plf) dead load is assigned to the walls assuming a normal partition stud wall with half inch-thick gypsum board on each side for a wall/floor height of 13 ft. as per ASCE7. The live load is assumed to be 100 pounds per square foot (psf) for the floor and 20 psf for roof in accordance with ASCE7. This analysis does not consider variation in the wind directions and parameters. The structure is analyzed using the standard beam and columns available in the software list for optimal structural design.

The material properties of the elements are assumed as 4 kips per square inch (ksi) for concrete and 60 ksi for rebar steel. RISA Foundation is used for designing the substructure. The base reactions that are computed from the superstructure serve as the input parameters of dead and live load on the foundation. The amounts of concrete and steel used is obtained from the quantity take-offs and are plotted against the surface aspect ratio for several alternatives with differing number of floors and surface aspect ratio. More details of the model, loading and assumptions may be found in Dixit and Pradeep Kumar (Dixit and Pradeep Kumar, 2022).

3.3 *Input output-based model*

The raw *Use* and *Make* tables from the latest United States (US) benchmark input-output (IO) accounts were utilized to develop two input-output-based hybrid (IOH) model. One model is developed for embodied energy (EE) calculation, whereas the other for embodied water (EW). The *Use* table indicates the consumption of different commodities for producing a unit of the output of an industry, whereas the *Make* table the production of commodities by an industry sector. The *Use* and *Make* data are converted into *Use* and *Make* coefficients that are then used to quantify the direct requirements matrix, which listed the direct input of commodities needed to generate a unit of a commodity's output. *Leontief's Inverse* matrix is used to generate the total requirements matrix that showed the total commodity inputs required to produce a unit output of a commodity (Pradeep Kumar, Venkatraj and Dixit, 2022). To compute EE and EW intensities of commodities without using energy and water prices, data of energy and water use by each industry sector was gathered and integrated into the *Use* table in physical units.

3.4 *Computation of Embodied energy (EE) and carbon (EC)*

Energy use data from United States Census Bureau (USCB), United States Department of Agriculture (USDA), and United States Department of Energy (USDOE) is collected for each industry and integrated into the *Use* table. Primary energy factors are then sourced from Dixit et al. (Dixit, Culp and Fernandez-Solis, 2014) and used to convert the energy values into primary energy units. The total EE intensities for concrete and steel (MBtu/\$) commodities are converted into energy per unit weight (MJ/kg) of the respective materials based on their unit weight prices. Using the density of these materials the energy per unit weight is converted into energy per unit volume (MJ/ft³), which is then used to calculate the total EE.

Embodied carbon refers to the total carbon emissions and is directly related to the EE. The coefficients of carbon dioxide emission (kgCO₂e/MBtu) for each energy source are obtained from the United States Energy Information Administration (USEIA) and used to compute the energy source specific carbon emissions per unit volume (kgCO₂e/ft³). These values for both concrete and steel are used to determine the total EC for these two materials.

3.5 *Computation of Embodied water (EW)*

Total water used by all industry sectors of the United States economy that produce different commodities was gathered from USCB and United States Geological Survey (USGS). The collected water use data in physical unit was inserted into the *Use* table. The calculated direct and total requirement matrices now provide EW intensities of a given commodity in gallon/\$. Detailed procedure to determine the embodied water is given in Dixit et al. (Dixit, Kumar and Haghghi, 2022). Unlike EE, EW not only includes direct and indirect embodied water components but also the water used by the energy sources that contribute to the EE, which must be counted as energy related EW (EREW). The EREW of the two materials is determined using the energy source-specific EE for each energy source, a water factor is determined and multiplied with the source specific EE to calculate total EREW. To avoid double counting, EREW is separated from the indirect water component. The total embodied water requirement (Gal./\$) is converted into water per unit weight (Gal./kg) for both concrete and steel based on their respective unit weight prices. Like EE, the density of the materials is used to determine the water per unit volume (Gal./ft³), which is used to calculate the total embodied water (EW).

4 RESULTS

Figure 1 presents the total quantities of concrete and steel used in a building structure with different surface aspect ratio. The figure shows that the total quantity of materials is inversely proportional to the surface aspect ratio of the building. As the number of floors reduces from 12 to 1 i.e., as the surface aspect ratio increases from 0.14 (12 floors) to 4.19 (1 floor), the quantity of concrete decreases by *ca.* 17,000 ft³, whereas the quantity of steel by *ca.* 400 ft³. This reduction in the total structural material usage generated proportional EE, EC, and EW savings.

Figure 1. Variation in quantity of the two materials for different surface aspect ratio values.

The EE of both concrete and steel decreases with an increase in the surface aspect ratio. In other words, the EE increases with increase in the number of floors. It is important to note that the contribution of the EE of steel decreases with the increase in the surface aspect ratio. Contribution of steel decreases from 28% for AR_s of 0.14 to 21% for AR_s of 4.19.

Figure 2(A) shows the total embodied carbon of buildings with different surface aspect ratios. The plot shows that the EC due to concrete and steel decreases with increase in the surface aspect ratio. Therefore, with the increase in the number of floors the embodied carbon increases and thus, adversely affects the environment. Like the EE, the contribution of the EC of steel decreases with the increase in the surface aspect ratio. Contribution of steel decreases from 27% for AR_s of 0.14 to 20% for AR_s of 4.19. Figure 2(B) also presents the total embodied water of buildings with different surface aspect ratios. Like the EE and EC, the EW of both the materials decreases with increase in the surface aspect ratio. Although, like EE and EC, the contribution of the EW of steel decreases with the increase in the surface aspect ratio, the variation is relatively lower as compared to EE and EC. The contribution of EW of steel decreases from 14% for AR_s of 0.14 to 10% for AR_s of 4.19.

Figure 3 presents a comparison of the results with respect to a one-story building structure. Figure 3(A) shows the variation in the contribution of material quantities for the different surface aspect ratio cases in comparison with the one-story building with a surface aspect ratio of 4.19. The variation in the quantity of steel for 12, 9, 6, and 3 floors is *ca.* 82%, 64%, 30% and 8%, respectively, while the variation in concrete is *ca.* 21%, 18%, 13% and 9%, respectively. This indicates that the

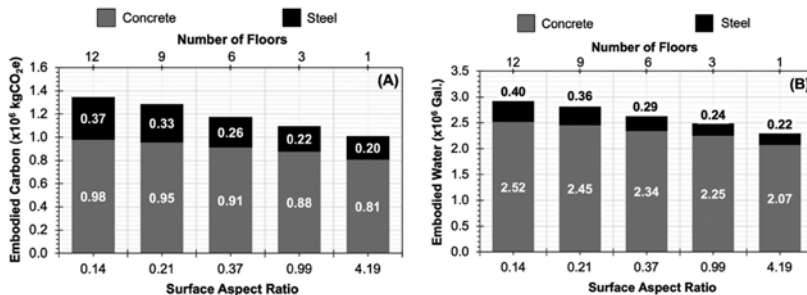

Figure 2. Total embodied carbon and water of buildings with different surface aspect ratio values.

Figure 3. Contribution of (A). steel, concrete, and total quantity of materials, (B). embodied energy, carbon, and water of buildings with different surface aspect ratios with respect to a one-story building.

quantity of steel significantly reduces with the decrease in the number of floors while the decrease in the quantity of concrete is slight. One of the reasons for this could be that the size of the floor slab/s is kept constant for all surface aspect ratio cases since reducing the size of the slab may cause vibration issues that may adversely affect the serviceability of the building structure.

Figure 3(B) shows the variation in the total EE, EC, and EW for the different surface aspect ratio cases in comparison with the one-story building with a surface aspect ratio of 4.19. Results show that the variation in EE and EC for 12, 9, 6, and 3 floors is *ca.* 34%, 28%, 17% and 8%, respectively, while the variation in EW is *ca.* 27%, 23%, 15% and 9%, respectively. The variation is similar for EE and EC since they are related by a constant carbon emission coefficient. However, the difference in the variations between EE and EW increases with decrease in the surface aspect ratio. Since the embodied energy, carbon, and water for each material are directly calculated using the material quantities, the variation in the contribution of EE, EC, and EW of steel and concrete individually is similar to Figure 3(A).

5 DISCUSSION

Results show a reduction in the total quantities of concrete and steel required as the surface aspect ratio of the structure increases i.e., with the reduction in the number of floors. This may be attributed to the fact that the total load on the footings/foundation of a taller building structure is higher as compared to a short building thereby requiring larger size footings that use more concrete and steel. Furthermore, the size of the beams and columns of a tall building increases from the topmost to the bottommost floor. Therefore, the total quantity of concrete and steel required by the structural components of a taller structure is more than that of its shorter counterparts.

The total embodied energy, carbon, and water decrease with an increase in the surface aspect ratio. This is directly related to the total quantity of each material and the contribution of the materials to the total. The contribution of embodied energy, carbon, and water due to steel decrease with increasing surface aspect ratio, i.e., as the number of floors goes up, EE, EC, and EW increase due to the increased use of steel for taller structures attributed to a higher load transferred to the structural components. Reducing the number of floors from 12 to one decreases the share of EE, EC, and EW from 28% to 21%, 27% to 20% and 14% to 10%, respectively. It is important to highlight that the steel contributes to *ca.* 20% to 28% of the building's total EE and EC while it contributes to only 10% to 14% of the buildings total EW, i.e., the contribution of concrete is 86% to 90% of the total EW of a building. This clearly shows that concrete relatively consumes more water than steel as compared to its energy consumption. However, it may be due to the lower volume of steel installed in the structure as compared to concrete. The trade-off between the material level contribution of EE and EW highlights the importance of evaluating the EW in addition to EE since a reduction in EE may not indicate the same reduction in EW.

The results suggest that there is *ca.* 34% increase in EE and EC and *ca.* 27% increase in EW for a 12-story building structure as compared to a 1-story building structure. Evidently, EE

and EW are independent indicators that must be evaluated separately to ensure judicious use of not just energy resources but also water. The variation in material quantities impact the EE, EC, and EW. With an increase in surface aspect ratio, a significant reduction in the usage of steel is seen as compared to concrete, which in turn reduces EE, EC, and EW. Furthermore, the total EE, EC, and EW requirements per unit volume of both steel and concrete vary considerably and thus impact the total EE, EC, and EW differently. The EE and EC requirements per unit volume of steel is *ca.* 40 times that of concrete while the EW requirement per unit volume of steel is only *ca.* 17 times that of concrete. This variation is highly sensitive to the uncertainties associated with the unit weight price of each material. Although the unit volume requirements are huge for steel as compared to concrete, the quantity of steel is typically 2 orders of magnitude lower than concrete. Thus, the variation in total material quantity is often similar to that of concrete as shown in Figure 3(A). The results may indicate that, at the structural level, the horizontal construction may help save materials as well as EE, EC, and EW. However, EE, EC, and EW of a building are also impacted by other building systems such as the building envelope, interiors, and mechanical, electrical, and plumbing (MEP) systems, which may influence these findings. For instance, as compared to vertical structure, a horizontal structure has much larger roof area that may not just influence EE, EC, and EW but also the operational energy used in heating, cooling, and lighting the interior spaces. More detailed study covering all building systems may be needed to understand the effect of an aspect ratio on the use of building materials and embodied and operational impacts.

6 CONCLUSIONS

This paper analyzed the impact of a design parameter, surface aspect ratio, on EE, EC, and EW of a building structure. The results show a decrease in the environmental impacts with an increase in the surface aspect ratio. In other words, horizontal construction seems to favor environmental impacts as compared to vertical construction at the structure level. By increasing the surface aspect ratio, the reduction in EE and EC is observed to be slightly different from that of EW. This highlights the importance of analyzing EE as well as EW to ensure a sustainable built environment. Although the results suggest the use of buildings with higher surface aspect ratio for environmental sustainability, the main aim of the study is to highlight the impact of a design parameter such as surface aspect ratio on the EE, EC, and EW of a building. Therefore, results may be skewed to account for only material level variability which may be misleading from a community level analysis where use of buildings with higher surface aspect ratio may adversely impact the environment if other factors such as flash flood, urban heat island effect, and ground permeability are considered. Nevertheless, studying horizontal vs. vertical construction has profound policy- and planning-level implications for redesigning existing and creating new urban areas to reduce the environmental impacts of built environments.

Performance assessment of existing prestressed concrete bridges utilizing distributed optical fiber sensors

H. Burger, T. Tepho & O. Fischer

Technical University of Munich, Munich, Germany

N. Schramm

Büchting + Streit AG, Munich, Germany

ABSTRACT: Many existing prestressed concrete bridges are currently in a poor structural condition with calculative deficits concerning the load bearing. To extend their service life, structural health monitoring could be an effective method. In addition to the permanent surveillance of damage, structural performance could be monitored. Through distributed fiber optical sensing technology, the change of strain along a defined sensor length is measured. Especially local unexpected crack formation can be detected as it can occur on prestressed bridges due to the fracture of single wires in a tendon. On two prestressed highway slab bridges, fiber optical sensors were applied as a part of a major infrastructural monitoring project. An evaluation of the data was made with the help of calibration tests in the laboratory and in in-situ load tests. Furthermore, the influence of temperature on measurements and the accuracy of the measurement system were analyzed.

1 INTRODUCTION

The utilization of distributed fiber optical sensors (DFOS) for structural monitoring has increased in the last few years. There are different sensing technologies and various application methods of DFOS. Recent technical developments make measuring and application easier and more efficient. An overview is given in the research conducted by Bado & Casas (2021). To choose the right measurement system, technical and economic aspects have to be considered. Its choice depends on the needed and expected measurement data. The structural performance of an existing prestressed concrete bridge has to be evaluated by considering its expected behavior. Often, the evaluation of a concrete structure is based on the detection of cracks. The exact location of a crack is often not known in advance, especially in prestressed structures where the potential damage of tendons can lead to cracks or high strain in unexpected locations. Brittle fractures of the prestressing steel can occur due to stress-corrosion cracking, which depends on the corrosive environment, the tensile stress and the steel properties.

With the help of fiber optic technology, it is possible to record the strain distribution along a defined sensor length. Approved measurement systems based on Rayleigh backscattering are limited to obtain data on a sensor length of 50 m with a spatial accuracy down to 0.63 mm (Luna 2020) and allow the detection of small changes in crack width. However, even if a general measurement accuracy and uncertainty is specified, the recording of reliable data is not guaranteed. Depending on various factors such as sensor selection, sensor application, measurement settings, load effects etc., measurement results may deviate from the true value. To avoid discrepancies in a monitoring project, a redundant measurement system should be used and the values of the gathered data should be verified. An evaluation of the data must be done critically and should consider already known results.

As part of a major long-term monitoring project of two existing prestressed concrete bridges DFOS are used to detect cracks and strain changes due to tendon failure. Since the beginning of the monitoring at the end of 2021, various calibration tests were carried out in the laboratory and on the bridges themselves. These generated data under known boundary conditions are used to successfully evaluate the monitoring data. The experience gained over time in the monitoring project simplifies the collection, analysis and interpretation of the data, thus facilitating the application of structural monitoring. In addition to detecting cracks, the detection of the global structural behavior of bridges is possible with DFOS.

Furthermore, the application of DFOS for monitoring generally has to be non-destructive or minimally invasive. These properties cannot be at the expense of the measurement results. Parts that are sensitive to maintenance, such as plug connections or termination of the DFOS, must remain reachable and accessible after installation. Besides that, durability of the components plays a very important role regarding long-term monitoring, which influences the type of the DFOS and its application.

2 APPLICATION OF DISTRIBUTED FIBER OPTIC SENSORS

DFOS are specially sheathed optical fibers. Their design varies according to application type and manufacturer. They can be inserted into concrete while concreting, consequently being bonded to the surface or applied into a milled groove. It is also possible to bond such sensors on the reinforcing bars and in case of post-tensioning concrete structures, DFOS can be inserted in the duct before grouting (Fischer et al. 2019).

For existing structures, sensors are applied superficially or into a groove milled into the structure. In the latter case, the sensor is completely embedded in the adhesive. Consequently, the sensor is better protected from external influences and it is easier to establish a complete bond between the sensor and the measured object. Figure 1 shows a detail of this application method.

The different layers, from the host material (concrete) to the optical fiber, have a significant influence on the measured data. For example, when the host material is subject to mechanical stress, constant strain transfer between the individual layers is not guaranteed. Especially at a very high strain, a slip occurs, which can be locally observed in cracks (Bassil et al. 2020). Furthermore, temperature loads not only cause strain in the concrete component, but also have an influence on the sensor and its sheaths. Therefore, the expected strain change of a structure at different temperatures does not always correspond to the measured one. Due to these influences, it is necessary to perform different calibrations for every sensor application. Hence, the influence of mechanical and thermal stress must be quantified to interpret the measurement data (see Chapter 3).

In addition to the type of application, the correct sensor position must be determined to assess a structural performance and detect signs of tendon fractures. Consequently, the structural behavior must be known in advance and the geometry of the existing bridge identified as precisely as possible. Prestressed cross sections are usually completely under compressive stress in the serviceability limit state (SLS) and the bending moment from the prestressing counteracts the external loads. Fractures of the prestressing steel can occur in older existing bridges due to stress-corrosion cracking, which cause strain changes. The location of these fractures is normally unknown. When one or multiple tendons fail, tensile stress up to cracking in a cross-section can occur. Cracks clearly stand out in the measurements and thus serve as the measurement target. Furthermore, the strain change due to a prestressing steel fracture does not change linearly over the cross-section height (König et al. 1996). Therefore, a crack in the concrete may occur at the level of the tendon. If the steel fracture minimizes the counteracting normal stresses in a section with a high bending moment, the concrete instead cracks at the top or bottom of the cross-section. For this reason, it is often useful to use more than one DFOS per tendon layout.

The position of a sensor on longitudinally prestressed bridges depends on the bridge's cross section. Figure 2 gives possible locations for DFOS in three different cross-section types. At the bottom of the cross-section, where tension due to positive moment appears, an application of the sensors at relevant locations is usually possible without any problems. In the area of negative bending moments (in general the support area), tension, cracks and thus locally high strain are expected on the top side. However, it is usually not possible to apply to the upper surface of the concrete. A possible solution is to open the road and install the sensors on the top side. In the case of T-beams and box girders, sensors can alternatively be attached to the web or at the bottom of the roadway slab. Regarding the web, the position over the height can vary along the span.

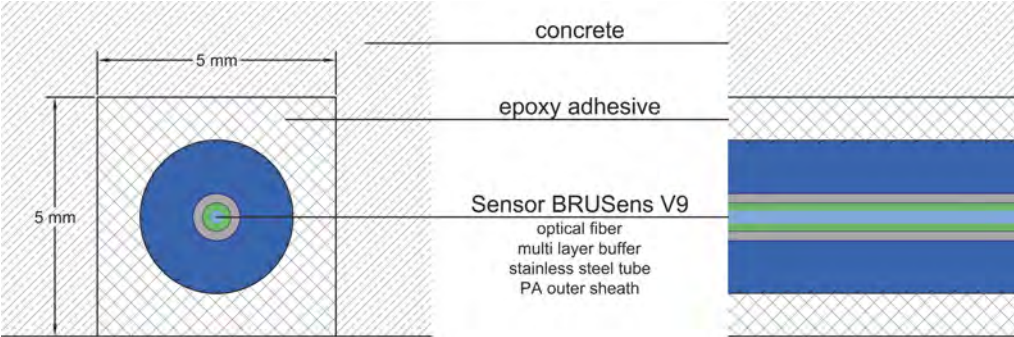

Figure 1. Detail of a BRUSens V9 sensor embedded in a groove; cross-section (left) and longitudinal section (right).

Figure 2. Possible location of the DFOS (blue circles) w. r. t. positive bending moments for various cross-sections of prestressed concrete bridges (tendons shown as black circles).

Once the DFOS have been applied, the exact location of the sensor on the bridge has to be identified. The beginning and end of the sensors are recorded by the measurement system, but noticeable locations, such as the end of bonding, existing imperfections in the concrete or the adhesive matrix, etc. cannot be clearly assigned to the sensor position without prior referencing. Artificially generated local temperature effects can be used to allocate the sensor coordinates in the global coordinate system of the structure. If the sensor is no longer accessible after installation but is still visible, a scale should be applied in the longitudinal direction. This simplifies the detection of cracks at a later stage.

3 CALIBRATION OF THE MEASUREMENT TECHNOLOGY

Fiber optical measurement systems based on Rayleigh backscattering use an active tunable laser and a spatially resolving reflectometer. The emitted light beam is coupled into a reference arm with a fixed path length and into the sensor fiber using a Mach-Zehnder

interferometer. Backscattered light from the sensor fiber is superimposed with the light component from the reference arm. From the interference between reference and measurement signal, a local frequency shift can be derived. This frequency shift is proportional to the strain or temperature change. A relative strain or temperature change can be calculated from these results in consecutive spatial windows along the fiber. (Fischer et al. 2019)

Separate recording of strain change and temperature change on the same bonded sensor is not possible. When DFOS are installed, they have to be specified as strain or temperature sensors. Therefore, Luna (2014) suggests reference values for the calibration constants to convert the frequency shift into strain or temperature change. These conversion factors vary depending on the material properties of the fiber core and the sensor type.

Various tests have to be carried out to ensure the reliability of the calibration constants and the measured strain or temperature change. Known boundaries can be created in a laboratory. These allow researchers to investigate the influence of mechanical and temperature induced loads separately. As an example, the calibration tests carried out in a monitoring project and their results are shown for the sensor application type according to Figure 1.

Before measuring, the distance between centerpoints of consecutive spatial windows along the fiber has to be selected as a general setting. This distance influences the measurement uncertainty of the sensing technology (Luna 2020). Depending on the DFOS type and its strain transfer through the sheaths, the width of the spatial windows has to be chosen. For an application as shown in Chapter 2 and to obtain data with a minimum of general uncertainty, a spatial window of 2.6 mm is chosen for the calibration tests. Additionally, information was gathered on the probation and performance of the application method during the test execution.

3.1 *Strain measurement under mechanical load*

The expected strain at the concrete surface in SLS can be estimated on the basis of the material behavior and mechanical laws. The following considerations apply only to normal strength concrete up to class C50/60 and assume a material behavior according to Eurocode 2 based on average values. Furthermore, influences from prestressing, creep and shrinkage have already been concluded. This represents the case of sensor application on existing bridges. Compressive strain for a cracked section is reasonable up to approximately $-1160 \mu\text{m/m}$ (-1.160 ‰) under only bending moment loading and considering the safety concept according to Eurocode 0. Since 40 % to 60 % of the total load is already present as a dead load before sensor application, a maximum of $-660 \mu\text{m/m}$ (-0.660 ‰) compressive strain is expected from live load in a cracked section.

Tensile strain in concrete without prestressing can increase linearly only up to $100 \mu\text{m/m}$ (0.100 ‰) on average, calculated from the tensile strength divided by the Young's modulus. After exceeding the tensile strength, cracks occur. On prestressed concrete bridges, higher tensile strain from live loads is possible before cracking due to the present compressive stresses, because of prestressing. The compressive stresses are limited at approximately 40 % of the average compressive strength. At the most favorable stress distribution, the tensile strain at the non-cracked cross-section reaches a maximum of $365 \mu\text{m/m}$ (0.365 ‰).

If a crack occurs and crosses the sensor, the maximum strain is only limited by the sensor sheath. BRUSens V9 sensors measure the strain up to $10,000 \mu\text{m/m}$ (10 ‰) according to the manufacturer. In reinforced concrete, however, cracks are measured with their crack width. A crack is present only when the crack edge is completely displaced. This corresponds to a crack width of 0.1 mm (Röhling & Meichsner 2018). According to Eurocode 2, calculated crack widths are limited to 0.2 mm, 0.3 mm or 0.4 mm (Eurocode 2). For prestressed structures, cracks of this size must be detected. The values shown above do not consider extreme events, such as an overload.

The measurement results must be reliable for the mean strain from compression, tension and crack widths. This was investigated in calibration tests using independent reference

measurement technology as strain gauges and displacement transducers. The following calibration tests were carried out under a constant temperature:

- 4-point bending test on prestressed precast hollow core slab
- Crack formation on the tensile test of a concrete bar
- Compression and bending tests on concrete beams

In these various tests, the accuracy specified by the manufacturer was achieved for tensile and compressive strain in comparison to strain gauges on the concrete surface. Luna (2020) gives a system accuracy of 30 $\mu\text{m}/\text{m}$ (0.030 ‰) using the manufacturers' sensors compared to NIST-traceable extensometer measurements. Figure 3 shows the results of the 4-point bending test on a prestressed precast hollow core slab. The diagram shows the strain of strain gauges and the DFOS shortly before first cracking. Furthermore, the measurement of the crack formation is illustrated in this figure, which was only detected by DFOS. When first crack formation was initiated, no significant strain change was recorded by the gauges. Even though data from DFOS show indications for probable microcracks, it is not possible to definitively predict macrocracks in a certain location.

Figure 3. Crack formation on a prestressed hollow core slab.

As shown in Figure 3, a crack generates a strain peak. Nevertheless, it is necessary to ensure that a crack is present at the respective peak. Disruptions in the adhesive or in the concrete can manifest themselves in such strain peaks. In a tensile test of a concrete bar, the crack formation was investigated and the crack width compared with a displacement transducer. It was found that in an opened crack, the crack width change can theoretically be traced down to 0.001 mm by integrating over a peak. In contrast, with conventional techniques, such as a steel ruler, it is possible to record ideally changes of 0.05 mm or with a magnified graticule down to 0.01 mm. (Fischer et al. 2022)

In the case of cyclical loads, a problem occurred. When cracks between 0 and 0.5 mm were repeatedly opened and closed, the crack width change could no longer be reliably recorded by the DFOS. A peak was still displayed, but the crack width measured with DFOS did not match the referenced measurement of the displacement transducer. This might be the cause of a slip.

3.2 Influence of temperature on strain measurement

Since the sensors on the bridge are exposed to the weather, additional tests were carried out on the influence of temperature on the measured data. Uncracked concrete beams and cracked concrete bars were loaded with temperatures ranging from -35°C to $+23^{\circ}\text{C}$. The DFOS were

also embedded into a groove as shown in Figure 1. Mechanical loads were minimized by placing the test samples vertically. Selected results on the cracked concrete bar test are given in Figure 4. At high temperature differences of more than 20 Kelvin, the strain scatters in a range of $\pm 50 \mu\text{m/m}$ ($\pm 0.050 \%$).

The mean value of the recorded strain along the DFOS deviates considerably from the expected values. The coefficient of thermal expansion of concrete is between 8 and $12 \times 10^{-6}/\text{K}$. The value measured in the test is between 15 and $19 \times 10^{-6}/\text{K}$. This result corresponds with the thermal expansion coefficient of the inner stainless steel tube of the BRUSens V9 sensor. According to the manufacturer Solifos AG, the average value is $16 \times 10^{-6}/\text{K}$. For this reason, it can be assumed that the temperature-induced loads cause strain changes in the sheath of the DFOS. This influence must be considered when evaluating measurement data on a supporting structure.

Figure 4. Results of the DFOS on the cracked concrete bar at different temperatures without mechanical loading.

4 RESULTS OF IN-SITU MEASUREMENTS

Due to the results obtained in the calibration tests (see Chapter 3), a differentiation is made between results from long-term and short-term measurements on bridges. In the case of short-term measurements, it is assumed that the temperature remains approximately constant over the measurement period. At two existing prestressed bridges, measurement data was collected on several days for more than one year. These three-span slab bridges are part of the feeder to the German highway network. DFOS were bonded to the bottom of the bridge cross-section as shown in Figure 2 on the left. Sensors were applied along several tendon axes in each span. This results in a total length of 60.5 m of bonded sensor per axis. Their function is to detect cracks or strain changes resulting from possible wire fractures as a part of a major monitoring project.

Short-term measurements for two to ten minutes are carried out at intervals of four months and as a control measurement after an alarm from acoustic emission sensors. Between the individual short-term measurements, referencing is performed and long-term strain changes are recorded. In order to calibrate the monitoring system and to assess the structural behavior, static load tests on the bridges were carried out.

4.1 Static load tests and short-term measurements

The structural performance of the bridges was investigated during two static load tests. In order to analyze the impact of the seasonal effects on short-term measurements, the two tests

were carried out on two different days at an interval of six months. Two 40-ton trucks were used as proof loads. One truck stopped at defined locations on a closed traffic lane. The second truck made simultaneous passes in the flow of traffic in the lane next to it.

Between the two single tests, no significant impacts on the short-term data were observed. In Figure 5, the results of one load test are given. The strain on two different time steps are plotted in this diagram:

- Stop of one truck in the center field on the closed lane (total load ~400 kN)
- Stop of one truck in the center field on the closed lane and passing of the second truck on the lane next to it (total load ~800 kN)

The measured strain is quite low because of the slab load-bearing effect. Tensile strain reaches a mean high of 20 $\mu\text{m/m}$ (0.020 ‰). This strain correlates with parallel recorded strain gauge measurements. During the tests, strain peaks with a maximum prominence of 40 $\mu\text{m/m}$ (0.040 ‰) appear. In the location of most peaks, irregularities were found in the bonding or concrete surface.

Figure 5. Measurement results on a prestressed hollow core slab bridge obtained from static load tests with two 40-ton trucks (longitudinal section top).

4.2 Long-term measurements

The measurement data (including a temperature change) shows much higher peaks than those due to the test load. At a uniform heating of approximately 8 Kelvin, the prominence of peaks reaches up to 200 $\mu\text{m/m}$ (0.200 ‰). In laboratory tests, such peaks were indicators for cracks. These locations were visually inspected. In the case of the highest peaks, offsets were detected in the concrete surface. This offset causes a local deflection of the sensor's position. Thus, a linear strain transfer between the concrete and optical fiber is not possible at this point, which leads to the above-mentioned results.

Along the remaining area the same influence of temperature was observed as in the laboratory tests. Figure 6 shows the raw data of a measurement at a uniform heating temperature of approximately $\Delta T_N = 7.7$ K and a vertical temperature difference of $\Delta T_{M,heat} = 5.0$ K (warmer on top). If the strain peaks are neglected, a scatter in the range of ± 20 $\mu\text{m/m}$ (± 0.020 ‰) is observed. The diagram in Figure 6 shows the calculated ideal strain on a simple structural model due to the specified temperature load. The corrected data corresponds to the raw data with an offset correction of $-\Delta T_N \times 8 \times 10^{-6}/\text{K}$. The linear trend of both curves essentially coincides.

It is necessary to determine the temperature load of the structure to calculate the right correction factor. This determination is very difficult, as the bridge surface temperature can vary by ± 1.5 K at the same time in different locations. Furthermore, the concrete temperature on the section's top can only be approximated because of traffic on the road. This temperature approximation also includes a time-delayed heat transfer, which depends on various material parameters.

Figure 6. Measurement results on a prestressed hollow core slab bridge from temperature-induced loads: uniform heating $\Delta T_N = \sim 7.7$ K, $\Delta T_{M,heat} = \sim 5.0$ K (top warmer than bottom; longitudinal section top).

5 CONCLUSION

The application of quasi continuous fiber optic sensing technology based on Rayleigh backscattering achieves useful results in the monitoring of existing prestressed bridges. The application has to be evaluated and planned individually for each structure, considering the advantages and disadvantages of the technology. DFOS record strain along the sensor length. Cracks or superficial damages can be monitored, in addition to the assessment of the structural performance. A major advantage of DFOS is the detection of strain changes that cannot be detected visually and aren't known in advance, such as those that occur due to prestressing steel fractures.

There are many different DFOS types on the market as well as different application types. The measurement data varies significantly for different sensors and application types. For this reason, calibration tests must be carried out for each configuration in order to determine the measured data under mechanical and temperature induced load.

At the Chair of Concrete and Masonry Structures at TUM fiber optic strain measurements are used for a various experimental research. Furthermore, it is currently being investigated which further applications are possible in the monitoring of real structures. Considerations are made about automated evaluation and permanent long-term monitoring. The aim is to incorporate the data obtained into a realistic computational assessment of the existing structure.

Life-cycle assessment of crack repair systems for fire-damaged concrete

R.M. Galano, R.S. Chan & J.M. Ongpeng
De La Salle University, Manila, Philippines

ABSTRACT: Despite its durability, exposing concrete to excessive changes in temperature causes it to crack. To seal these cracks, repair systems, which can be categorized as active repair and passive self-repairing systems, can be applied. In this study, the potential environmental benefits of passive repair systems were evaluated by comparing traditional mortar filled concrete against two types of self-healing concrete (SHC), namely SHC with *Bacillus subtilis* and SHC with superabsorbent polymers and superplasticizer. Life cycle assessment (LCA) revealed that cement production has the highest contribution across all repair systems, accounting for 62.1% to 81.1% of the overall impact. The polymer based SHC is the most damaging, especially in terms of resource consumption, while the mortar filled concrete has the lowest impact among the three. The bacteria based SHC performs better than mortar filling in categories like terrestrial, marine, and freshwater ecotoxicity. However, active repair is generally better for thicker concrete components.

1 INTRODUCTION

1.1 *Background of the study*

Concrete is one of the most widely used building materials in the world. In fact, the global consumption of concrete is twice as much as the consumption of all other building materials combined (Gagg, 2014). Concrete is used in a wide variety of infrastructure projects such as buildings, bridges, and dams. Its popularity in the construction industry is mainly due to its strength as it is one of the most durable construction materials (Van den Heede et al., 2018). However, concrete has a few limitations. For example, it is susceptible to cracking due to various factors such as tensile forces, shrinkage and creep effects, and temperature (Leonhardt, 1988). Consequently, concrete is a poor conductor of heat. When it is exposed to high temperatures like during a fire, its properties deteriorate (Georgali & Tsakiridis, 2005). Some significant examples are the decrease in compressive strength, spalling and cracking of concrete, the progressive deterioration of the hardened cement paste, and the destruction of the bond between the cement and the aggregates.

1.2 *Significance of the study*

Fire incidence in the Philippines is relatively high, especially during the dry season. These incidents are continuously rising with the first few months of 2022 already experiencing a 13% increase (Caliwan, 2022). Managing the damage caused by fires to concrete is a must as most structures in the country are made from reinforced concrete. In particular, cracks in the concrete must be sealed to hinder structural issues like the accelerated corrosion of embedded steel reinforcement. Hence, it is necessary to compare concrete crack repair systems. However, one area that is often overlooked when comparing these repair systems is their environmental impact.

2 MATERIALS AND METHODS

2.1 Crack repair systems

Table 1 shows the composition and mix design of three concrete repair systems. The conventional method of using mortar filler is compared to two types of SHC. The bacteria based SHC contains *Bacillus subtilis* (*B. subtilis*) with calcium chloride serving as the nutrient source. This spore-forming bacteria induces calcite precipitation which can seal cracks and pores up to 0.5 mm in width (Nikhil et al., 2020). The bacteria is obtained by cultivating cells in an agar culture plate containing distilled water, sodium chloride, yeast, glucose, and peptone from fish protein. On the other hand, the polymer based concrete incorporates superplasticizer and superabsorbent polymers (SAP) at 2.2% and 1.0% of cement by weight respectively. The expansion of SAP when exposed to moisture allows this SHC to seal cracks up to 0.2824 mm in width (Sidiq et al., 2020).

Table 1. Description of concrete crack repair systems.

Repair System	Sealable Crack Width (mm)	Item	Quantity (kg/cum.)	Reference

Superplasticizer	9.12			

2.2 Life cycle assessment

The objectives of this study are to (1) compare the environmental impacts of three concrete crack repair systems, namely (a) SHC with *B. subtilis*, (b) SHC with SAP and superplasticizer, and (c) ordinary Portland cement (OPC) concrete with mortar filler; (2) assess the suitability of using

SHC for the slabs and walls of a classroom in terms of carbon dioxide emission. To achieve these, the slabs and walls of a classroom in De La Salle University – Manila were used as the functional unit. A case study was conducted in order to quantify the amount of concrete and mortar filler required to construct and repair the damaged classroom. The columns and beams were not considered because the exposed surface is small relative to their volume; hence, the benefits of SHC are less significant. The cradle-to-gate system boundary was applied which covers raw material extraction and production of each type of concrete.

2.3 Structure of microcracks

Cracks can propagate in varying ways depending on the forces applied to the concrete. To conduct LCA on a theoretically damaged classroom, the study of Georgali and Tsakirdis (2005) on the microstructure of fire-damaged concrete was used. By analyzing concrete specimens from an actual fire-damaged building, the researchers showed how crack density varies with depth. The datapoints from this study can then be used to create a function

$$\rho = 34.207x^{-0.1581} \tag{1}$$

where ρ = crack density in meters per square meter; and x = depth of crack in meters
 However, information regarding the crack width and how it varies with depth was lacking. Since cracks typically taper with depth, this study assumes that the crack contracts linearly thereby forming a V shape (Figure 1). Hence, the relationship between crack width and depth is attained

$$w = w_0 - \frac{w_0}{x_0}x \tag{2}$$

where w = crack width; w_0 = crack width at concrete surface; x = depth of crack; and x_0 = total depth of crack. In this study, two values were used for the crack width at surface (w_0), namely 0.2824 mm and 0.50 mm corresponding to the maximum sealable crack widths of the polymer based and bacteria based SHC respectively. Normal strength concrete heated at 600°C, the typical temperature during real case fires, tends to develop cracks ranging from 0.28 mm to 0.94 mm in width (Poon et al., 2001). Therefore, the chosen SHC are capable of repairing some fire-damaged concrete. On the other hand, a total depth (x_0) of 49.6 mm was used as Xu et al. (2020) has found that the damage zone of microcracks in SHC reaches this depth.

In line with these assumptions, the total volume of cracks can be obtained by integrating the product of crack width and crack density with respect to depth.

Figure 1. Cross section of crack.

$$dV = w \rho dx \tag{3}$$

By substituting Equations 1 and 2 to make width and density a function of depth, the equation for volume can be obtained

$$V = 40.631 w_0 x^{0.8419} - 18.572 \frac{w_0}{x_0} x^{1.8419} \quad (4)$$

where V = volume in cubic meters per square meter. When depth (x) is equated to total depth (x₀), the resulting volume represents the volume of mortar required to seal 1 sqm. of damaged concrete.

2.4 Methodology

A 53.14 sqm. (5.4 m x 9.8 m) classroom served as the theoretically fire-damaged classroom. The wall thickness was kept constant at 100mm as these are non-load bearing. However, slab thicknesses of 100 mm, 125 mm and 150 mm were used as this can change based on design loads. This was done to establish the thickness of the slab at which SHC would be more sustainable than regular concrete. Overall, LCA was conducted on six cases corresponding to two crack widths and three slab thicknesses. The volume of concrete needed to construct the classroom varies between 19.138 m³, 21.795 m³, and 24.452 m³ while the mass of mortar needed to fill the cracks varies between 191.504 kg and 339.065 kg. The latter was calculated using Equation 4 and based on a dry density of 2014 kg/m³ (Thamboo, Bandara & Jayarathne, 2018).

3 RESULTS AND DISCUSSION

3.1 Impact assessment

The process networks of the three concrete crack repair systems are shown in Figures 2 to 4. It was found from the three networks that concrete, specifically cement, mainly contributes to the overall environmental impact of each of the crack repair systems. The production of cement accounts for 79.3%, 62.1% and 81.1% of the overall impact of the regular concrete, bacteria based SHC, and polymer based SHC respectively. On the other hand, the contributions of mortar filler and *B. subtilis* individually account for only less than 1% of the impact of their respective product systems. Relatively higher contribution of both SAP and superplasticizer was observed as these two individually account for 9.87% and 12.4%, respectively. Hence, if the impact of the concrete crack repair systems is to be reduced, the proportion of the cement should be reduced. Although the process networks shown only represent case 1, similar results were obtained for other cases since only the volume of concrete changes with varying slab thickness and not the composition of the product itself. Nonetheless, the contribution of mortar filler varied slightly based on the crack width used.

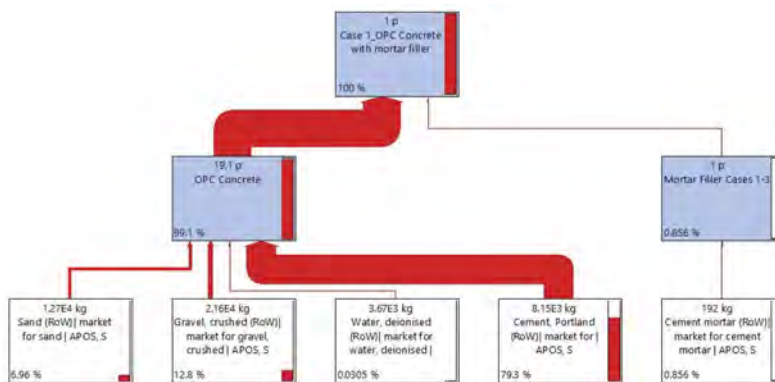

Figure 2. Process network for concrete with mortar filler.

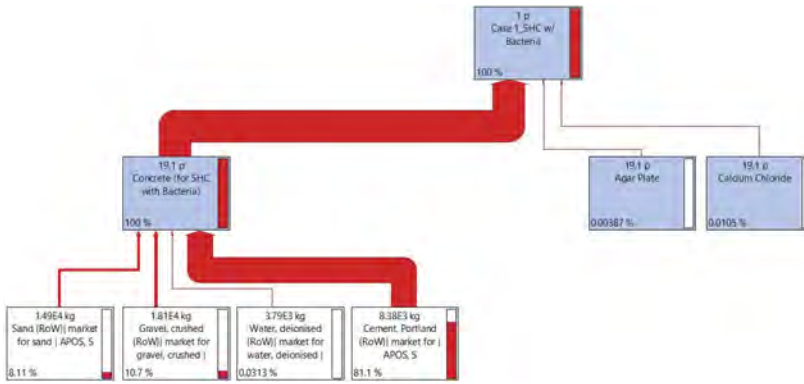

Figure 3. Process network for SHC with *B. subtilis*.

Figure 4. Process network for SHC with SAP and superplasticizer.

Figure 5 shows the damage assessment of cases 1 to 3 in terms of human health, ecosystem, and resources. The impact of the mortar filled concrete and SHC with *B. subtilis* are almost equal in case 1. However, the difference between the two increases with slab thickness due to the constant amount of mortar filler needed in contrast to the increasing amount of bacteria additive needed with increasing slab thickness. Moreover, the SHC with SAP and superplasticizer is consistently the most damaging out of the three. Despite this, the difference between the percent damage of the polymer based concrete and the other two systems do not exceed 5% in terms of human health and ecosystems damage. For damage to resources however, the difference was around 20%. Hence, the addition of SAP and superplasticizer causes a significant increase in damage to resources. Specifically, the polymer based SHC performed worse in terms of fossil resource scarcity and water use. The latter can be attributed to the need for more water in concrete with SAP due to the tendency of SAP to absorb water from the concrete mix which reduces its workability (Poornima et al., 2020). Overall, mortar filling was found to consistently cause the least damage to human health, ecosystems, and resources considering all slab thicknesses.

The same damage assessment was conducted for cases 4 to 6 as shown in Figure 6. Considering human health and ecosystems categories, the mortar filled concrete was found to cause less damage than the bacteria based concrete. Although the difference is only less than 1% in most cases, this difference increases minimally with the slab thickness. When the resources category is analyzed however, the bacteria-based concrete initially causes less damage than the mortar filled concrete. As slab thickness increases however, the two values converge. This implies that regular concrete is less impactful when thick slabs are to be constructed. Overall, the conventional method of mortar filling is generally more sustainable than the bacteria-

based concrete even though the crack width is increased to 0.500mm. Nonetheless, the findings from Figures 5 and 6 have shown that SHC can be more sustainable than mortar filled concrete if SHC capable of sealing larger cracks is used.

Figure 5. Damage assessment of crack repair systems with 0.2824 mm crack width.

Figure 6. Damage assessment of crack repair systems with 0.50 mm crack width.

3.2 Carbon dioxide emissions

Cement production accounts for roughly 7% of the world’s GHG emission (Busch et al., 2022). As such, reducing the carbon dioxide emission of concrete production is a relevant problem in the construction industry. In this study, airborne emissions of carbon dioxide from land transformation and biogenic sources were analyzed and are shown in Table 2. The carbon dioxide emission of each repair system were then plotted against the slab thickness in Figures 7 and 8. Based on the three datapoints originating from the three slab thicknesses used, linear regression was applied to show the trend and to identify the range of slab thickness where each type of repair systems performs best. SHC with SAP and superplasticizer, SHC with *B. subtilis*, and mortar filled concrete were represented by the blue, green, and orange trendline respectively.

Table 2. The carbon dioxide emissions of concrete crack repair systems.

Crack Repair System	CO ₂ (kg)					
	1	2	3	4	5	6
OPC Concrete with Mortar Filler	134.43	153.18	170.82	136.46	155.21	172.96
SHC with <i>B. subtilis</i>	134.49	153.25	172.02	134.49	153.25	172.02
SHC with SAP and Superplasticizer	147.74	167.53	188.33	-	-	-

Figure 7 shows the trend given a crack width of 0.2824 mm. The blue trendline reveals that SHC with SAP and superplasticizer has the highest carbon dioxide emission. Given that both the slope and intercept of SHC with SAP and superplasticizer are higher than the conventional mortar filled concrete, it can be concluded that the latter will always emit less carbon dioxide regardless of slab thickness. This is further supported by the fact that the highest sealable crack width for the polymer based SHC was already considered. As for SHC with *B. subtilis*, it was

found that the green and orange trendline intersect at a slab thickness of 105.57 mm. Given the larger slope of the green trendline, the figure shows that SHC with *B. subtilis* emits less carbon dioxide for slab thicknesses below 105.57 mm while mortar filled concrete is more ideal for higher slab thicknesses. Nonetheless, a thickness less than 100 mm would be a better estimate since Table 2 has shown that the OPC concrete with mortar filler still emits slightly less carbon dioxide at 100 mm (case 1). This inconsistency is caused by residuals in the trendline.

Figure 7. Carbon dioxide emission versus slab thickness with 0.2824 mm crack width.

Figure 8 shows the trend given a crack width of 0.50 mm. In this figure, only SHC with *B. subtilis* and OPC concrete with mortar filler were compared as the crack width is beyond the capability of the polymer based SHC. It can be seen that SHC with *B. subtilis* now emits less carbon dioxide within the considered range of slab thickness. This is due to the fact that a larger crack volume is used which necessitates a higher amount of mortar filler. Equating the orange and green trendlines shows that they intersect at a slab thickness of 203.83 mm. Therefore, it can be concluded that mortar filled concrete always emits less carbon dioxide if the slab thickness is above 203.83 mm given that the maximum sealable crack width of the bacteria based SHC was already considered. On the other hand, SHC with *B. subtilis* is preferred for slab thicknesses below 203.83 mm; however, this is a conservative estimate and would decrease depending on the considered crack width which must be less than or equal to its maximum sealable width of 0.50 mm.

Figure 8. Carbon dioxide emission versus slab thickness at 0.50 mm crack width.

Moreover, the aforementioned slab thicknesses where bacteria based SHC outperforms conventional mortar filled concrete would vary based on the sealable width of the concrete mix used.

4 CONCLUSIONS

The results have shown that for all crack repair systems, cement has the highest environmental impact among the inventory inputs. Moreover, the damage assessment yielded consistent results wherein the mortar filled concrete was the least damaging across almost all impact categories regardless of slab thickness and crack width. In terms of carbon dioxide emissions however, mortar filled concrete is less sustainable than SHC with *B. subtilis* when a slab thinner than 203.83 mm is to be constructed. In contrast, there is no clear environmental benefit of using the polymer based SHC as the SAP and superplasticizer contribute greatly to the environmental impact and the sealable crack width is too small to justify the use of additives instead of mortar filler.

ABSTRACT: Performance-based design concepts are a key tool to ensure the durability of reinforced concrete structures. Their application relies on the definition of limit states, for which defined limit state functions represent the probability of exceeding a particular condition. Such limit state functions are available for depassivation (initiation of reinforcement corrosion) in case of concrete carbonation and/or chloride-induced corrosion. Moreover, not only the knowledge about the exceedance of a certain limit state is of interest, but also the related consequences such as the costs for the subsequent repairs. This contribution analyses the inspection reports and the tendering documents of well-documented rehabilitations of parking garages. The focus was set on chloride-induced corrosion since it is the main cause of the rehabilitations. The analysis focused on the following aspects: the estimation of the reliability index value that led to the rehabilitation, the rehabilitation method used, and finally an indicative estimation of the incurred costs. The results unveil that for both conventional and cathodic protection rehabilitations, the reliability index had similar ranges for columns. Furthermore, in one meticulous project, a clear relationship between the estimated reliability index and the incurred costs was observed. However, this finding was less evident in other projects, for which a step cost function was more suitable.

1 INTRODUCTION

1.1 Background

Recently, great focus has been set on developing performance-based design concepts for durability assessment of concrete structures. For example, engineering models for the initiation phase have been developed for carbonation and chloride-induced corrosion (DURACRETE 2000, Gehlen 2000). Three basic principles constitute the base of these concepts: the use of validated material laws (or models); the adequate quantification of both the material resistance and the acting environmental loads or stresses; and finally, a safety concept on a probabilistic basis. This safety concept sets a maximum allowed probability of occurrence of a selected, undesired limit state.

In Germany, the German Committee for Reinforced Concrete (DAfStb) provided in (DAfStb 2008, Gehlen *et al.* 2008) the concepts for the application of this performance-based approach. Here, models for both, carbonation and chloride exposure classes (XC and XS/XD respectively), are given for the initiation phase, i.e., depassivation of the steel reinforcement.

Depending on the exposure class, a maximum allowed probability of reaching the depassivation of the reinforcement is suggested at either 10 or 30%, or in terms of the reliability index $\beta = 1.5$ or $\beta = 0.5$, respectively (DAfStb 2008). These values were set initially based on common targets for

serviceability limit states based on qualitative considerations of economic aspects. Similar to a cost-benefit analysis, the risk associated with the exceedance of these values during the structure service life and the costs of minimizing the risk during the design and construction phase were considered (DAfStb 2008). The present work focuses on the quantification of the risk associated with the exceedance of these limit values. In other words, the costs of the structural rehabilitation that result from the exceedance of the defined limit values.

1.2 Motivation and scope

Recent studies have shown, that in certain cases with a high chloride exposure (e.g. XD3) and an unfavorable material selection (low chloride penetration resistance), structures may not reach the targeted 50 years of service life, even if they have been built in accordance with the standards (fib Bulletin 76 2015). Cases observed in praxis provide evidence supporting this statement (Kessler 2020, Kessler & Gehlen 2020, Lozano Valcarcel *et al.* 2022), thus highlighting the advantage of the use of performance-based approaches for assessing the durability of reinforced concrete structures. By applying this approach, not only the need for (unexpected) premature and costly repairs can be avoided, but also the total costs for the construction and operation of a structure may be optimized. This may also lead to a more efficient and sustainable use of construction materials.

Motivated by this, this contribution analyses a set of rehabilitations of underground garage structures carried out in southern Germany. (Lozano Valcarcel *et al.* 2022) provides a first attempt at estimating the reliability index at which these structures had been rehabilitated. Therein, the difficulties of comparing the resulting costs on a global (building) level for this kind of structure have been discussed. In the present work, the focus is set on the analysis at the structural element level for the repair of column bases (exposure class XD3) for six selected projects. The aim is to study both the values of the reliability index that lead to corrective actions (rehabilitation alternatives) and the resulting incurred costs.

2 METHODOLOGY

Figure 1 shows the general framework of the present work. The inspection reports were analyzed for acquiring relevant information necessary to estimate the reliability index at the time of inspection i.e., just before the rehabilitation. The tender documents were analyzed for information regarding the type of intervention (action taken) and the resulting costs. The objective is to generate pairs consisting of reliability indices and resulting costs to study the relationship between them. The hypothesis was that the resulting costs increase with decreasing reliability index. The analysis focuses on the (structural) element level for column bases (further referred to only as “columns”).

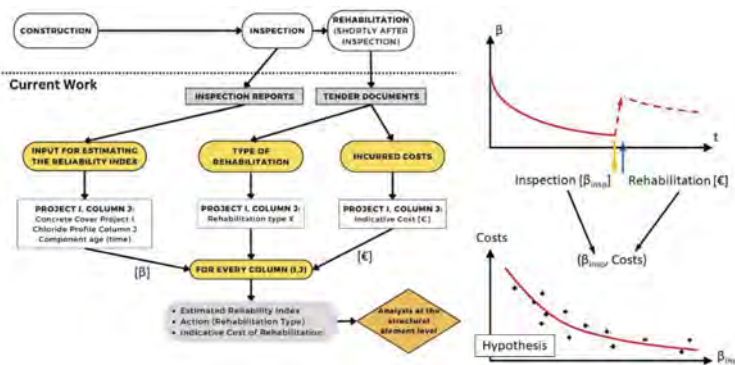

Figure 1. General framework of the present work (left) and initial hypothesis (right).

2.1 Selected model and available information

A modified version of the Duracrete Model based on Fick’s second law of diffusion (DURACRETE 2000, Gehlen 2000) is used to calculate the reliability index. Here, the limit state

function for depassivation is evaluated employing a critical chloride content at the level of the steel reinforcement, as shown in Equation 1:

$$LSE = C_{crit} - C_{S,\Delta x} \cdot \left[\operatorname{erfc} \left(\frac{d_c - \Delta x}{2 \cdot \sqrt{D_{app}(t) \cdot t}} \right) \right] \quad (1)$$

Where C_{crit} = critical, chloride content required to initiate corrosion (depassivation); $C_{S,\Delta x}$ = the substitute surface chloride content; $\operatorname{erfc}()$ = complementary error function; d_c = concrete cover; Δx = depth of the convection zone; $D_{app}(t)$ = apparent chloride diffusion coefficient of concrete (as a function of time); t = time of exposure (Gehlen 2000, fib Bulletin 76 2015).

The inspection reports constituted the information base to quantify the relevant model parameters. A consulting company based in Munich, Germany carried out the inspections. The inspected garages were rehabilitated shortly after the inspections. The reports include normally a visual inspection at points of interest, i.e., corrosion hotspots, the sampling of depth-staggered drill-dust samples, and the determination of the concrete cover, among others. From these measurements, the chloride profiles and the measurements of the concrete cover are highly relevant. Additional information about the type of binder and other parameters regarding the concrete mix was unfortunately not available, since usually, the project owners do not document this kind of information. Therefore, the information available was insufficient to estimate the reliability index following methods found in the literature (Gehlen 2000, Kapteina 2011, Rahimi 2016).

For this reason, the unknown model variables (the substitute surface chloride content and apparent chloride diffusion coefficient) had to be quantified. To achieve this, a Metropolis-Hastings (MET-HAS) algorithm was implemented to estimate these variables using the reported chloride profiles. Since the initial chloride content of the concrete elements was unknown, it was assumed as zero based on (fib Bulletin 76 2015). Values for the other variables were taken from the literature or the reported measurements, as in the case of the concrete cover.

2.2 Estimation of the unknown model variables

Due to limitations in the available information, the distributions of the substitute surface chloride content and the apparent diffusion coefficient (main unknown variables) were estimated using a MET-HAS algorithm. The algorithm was first proposed by (Hastings 1970) based on (Metropolis *et al.* 1953). A detailed description can be found in (Robert & Casella 1999). The reported chloride profiles constituted the base for the analysis. Each of the profiles included usually three points in depths from 0-10, 10-30, and 30-50 mm, which is common practice in Germany. The point near the surface is usually not used for mathematical regressions since it is located in the so-called convection zone, and thus, its behavior deviates from Fick's second law of diffusion (Gehlen 2000). Therefore, only two points were left to estimate the two selected variables for each of the analyzed columns. To overcome this limitation, the algorithm implementation required additional assumptions. The subtrahend of Equation 1 is used as the regression equation, since it describes the diffusion process of chloride into the concrete, as shown in Equation 2:

$$C(x, t) = C_{S,\Delta x} \cdot \left[\operatorname{erfc} \left(\frac{x - \Delta x}{2 \cdot \sqrt{D_{app} \cdot t}} \right) \right] \quad (2)$$

Where $C(x, t)$ = chloride content at depth x and time t ; x = depth measured from the concrete surface; D_{app} = apparent chloride diffusion coefficient of concrete (at the time of the inspection); all other variables as described in Equation 1.

Based on Equation 2, the MET-HAS algorithm was used to estimate the distributions of $C_{S,\Delta x}$ and D_{app} which best fit the observed data. Since the analysis focuses on the structural element level, each column is analyzed individually. For the implementation, a 2-dimension joint normal distribution was used as the proposal distribution for $C_{S,\Delta x}$ and D_{app} . The variance of the proposal distribution was set as a diagonal matrix and calculated in every step of the Markov-Chain using a fixed coefficient of variation. The selected likelihood function

bases on the sum of the squares error (Smith 2014), assuming that the error residuals are homoscedastic and follow a zero-centered normal distribution. Equation 3 shows the used likelihood function (Smith 2014):

$$L(C_{S,\Delta x}, D_{app}|X, \sigma) = \frac{1}{(2 \cdot \pi \cdot \sigma^2)^{n/2}} e^{-\frac{SSE}{2 \cdot \sigma^2}} \quad (3)$$

Where σ = standard deviation of the Gaussian error; n = number of observations (chloride analysis) per chloride profile; SSE = Sum of Square Error, calculated by Equation 4:

$$SSE = \sum_{i=1}^n [C(x, t|C_{S,\Delta x}, D_{app}) - C_{meas}(x, t)]^2 \quad (4)$$

With n = number of observations (chloride analysis) per chloride profile; $C(x, t|C_{S,\Delta x}, D_{app})$ = calculated chloride content with the current Markov Chain values for $C_{S,\Delta x}$ and D_{app} ; $C_{meas}(x, t)$ = measured chloride content reported in the inspection reports.

Because most profiles had only two viable points for the regression (likelihood based on the sum of least squares), the standard deviation of the Gaussian error could not be properly quantified and, therefore, had to be assumed. The assumption was based on the fit of a profile with four viable points and was set constant for the analysis of all the chloride profiles. The authors are aware that this assumption may not hold valid in all cases but consider that the approach is sufficient for the analysis in the present work. Finally, the posterior distribution for the unknown model variables $C_{S,\Delta x}$ and D_{app} is estimated for each of the analyzed profiles. The left side of Figure 2 shows the estimated posterior distribution of the target variables for the profile with four viable points for regression. The right side of Figure 2 shows the estimated 95% credible interval (ETI: Equally Tailed Interval) of the chloride content for this same profile.

Figure 2. Estimated posterior distribution of the target model variables (left) and resulting 95%-Credible interval of the chloride content as function of the depth from the surface (right).

2.3 Calculation of the reliability index

After the estimation of the two main unknown model variables, the next step is the estimation of the reliability index. To do so, the limit state equation for depassivation (Eq. 1) is evaluated using Monte Carlo Simulations sampling from the posterior space generated with the MET-HAS algorithm. For the other model variables, literature reference values are used. Table 1 shows the variables and their corresponding distributions used to estimate the reliability index for each column.

The reliability index is calculated for each of the columns individually. For a limited number of columns, several chloride profiles were available. Since the chloride exposure varied significantly, only the most critical chloride profile (with the highest chloride content at the reinforcement) was considered. The quantification of the concrete cover (d_c) was not possible at the element level, since in most cases the information was not documented element-wise. Therefore, the parameters of the distribution for the concrete cover of the columns of each project (garage) had to be

calculated globally. It was assumed, that the concrete cover followed the same distribution for all columns of the same project. This assumption may not necessarily hold valid in all cases.

Table 1. Model variables used for calculating the reliability index.

Variable	Unit	Distribution	Parameters				Reference
			Mean	Std. Dev.	a*	b*	
C_{crit}	[wt.-%/b]	Beta	0.60	0.15	0.20	2.0	(Gehlen 2000)
$C_{S,\Delta x}$	[wt.-%/b]	Sampled from MET-HAS space					
d_c	[mm]	Normal	**	**	0	-	(Gehlen 2000)
Δx	[mm]	Deterministic	10				(Rahimi 2016)
D_{app}	[mm ² /a]	Sampled from MET-HAS space					

*a and b are the lower and higher limits (constraints)

**Parameters estimated for each parking garage based on the reported concrete cover measurements

2.4 Rehabilitation alternatives

The following actions or rehabilitation alternatives were found in the tendering documents:

- Conventional: the chloride-contaminated concrete is partially demolished and recast with a repair material. Method 7.2 in (*DIN EN 1504-9:2008-11*, DIBt 2020).
- Cathodic Protection: a cathodic protection system is usually installed without the need of invasive concrete demolitions. This method is referred to as method 10, i. e., 10.1 in (*DIN EN 1504-9:2008-11*, DIBt 2020).
- No (substantial) Intervention: refers to the columns, which were neither repaired using the other two methods. Here, only a surface protection system or coating was applied. Since a similar coating was also applied to columns repaired under the other categories, this method can be seen not as a corrective measure, but rather as a protective measure. Therefore, one could consider this alternative as the zero-alternative: no intervention.

3 RESULTS AND DISCUSSION

3.1 Actions taken at different levels of reliability

Figure 3 shows the estimated reliability indices and the actions taken for the 89 analyzed columns from six different projects. From these, 44 columns were repaired using the conventional method; 29 were repaired using a cathodic protection system; and 16 did not undergo any substantial intervention. The following aspects of Figure 3 are analyzed: the ranges for the “no intervention” category, and the ranges of the conventional and cathodic protection.

To begin with, Figure 3 reveals that columns without rehabilitation (no substantial intervention) presented high values of the reliability index (> 1.5), agreeing with the values recommended by (DAfStb 2008). Nonetheless, a few columns rehabilitated with the other two methods fall also into this range of reliability index. In the case of cathodic protection, an explanation for this can be that cathodic protection systems are usually installed on all the elements of the garage. Hence, it acts not only as a corrective measure for columns with high chloride concentrations but also as a preventive measure for those with little or no exposure so far. On the other hand, marginal repairs could explain the high value of the reliability index on some conventional interventions. Marginal repairs refer to the intervention of a non-critical (or not-so-critical) column, due to the low individual costs in comparison to the total costs. Another explanation is the avoidance of potential future damage in the element, thus avoiding another intervention of the facility and all related consequences (additional costs, partial closure, etc.).

Cathodic protection systems are usually carried out when no substantial damage, like high loss of reinforcement cross section, cracking, or spalling of the concrete cover is present. Conventional rehabilitations can be carried out when substantial damage is present or not. In the case of chloride-induced corrosion, the damage phase takes place rather quickly after the reinforcement is depassivated (fib Bulletin 76 2015). Therefore, it can be expected that the estimated reliabilities for

Figure 3. Histograms of the estimated reliability index by rehabilitation method executed for the analyzed repaired columns.

cathodic protection are higher than for conventional interventions. However, no significant difference in the ranges of the estimated reliabilities for cathodic protection and the conventional intervention was found (see Figure 3). This suggests that depassivation as a limit state may not be a proper criterion to define ranges, for which these two alternatives should be executed within the decision-making process. Other limit states in the damage phase (cracking or spalling) may be more suitable for defining target values of the reliability index for these two repair alternatives.

3.2 Cost function in terms of the reliability index

In underground garage rehabilitations, several elements are usually addressed simultaneously. For instance, some columns may need to be repaired due to chloride-induced corrosion, but also other elements like wall segments, the drive-in ramp, and areas near joints or even slabs. The need for repair is very individual for each garage and depends on how it was built, its current condition state and user frequency. Moreover, the rehabilitation works may be used simultaneously for refurbishment or upgrading purposes. Therefore, identifying the relevant cost positions is subject to certain difficulties. Some cost positions are very specific for a certain element, like the depth of the intervention, but others like the site equipment or logistic positions are not. For this reason, the focus is set on two main cost-driving positions that are usually well documented in the analyzed projects: concrete demolition and retrofitting. Both of these positions depend naturally on the depth of the intervention and can be expressed in terms of the intervened area (unit prices).

For one very detailed project rehabilitated with conventional methods, enough information was available to quantify the unit cost of the repair in terms of these two cost positions: demolition of the contaminated concrete and retrofitting of the structural elements. Other cost positions were unfortunately not so well documented and could not be allocated element-wise. Therefore, the reported costs for these two activities were used to build a function in terms of the repaired depth.

In five out of the six analyzed projects, columns were repaired using the conventional rehabilitation method. Figure 4 shows the costs of the concrete (partial) demolition and concrete retrofitting in terms of the repaired depth for one well-documented project. In Figure 4, the y-axis is left without values on purpose due to the approximations taken, which allow only for a qualitative analysis. Figure 4 shows that with increasing depth of the repair, the costs for demolition and retrofitting increase.

Figure 5 presents the calculated reliability indices together with the corresponding indicative costs. The left side of Figure 5 shows the indicative costs of the repair against the estimated reliability index for project C. In this particular case, a clear relationship between the repair costs and the estimated reliability index is found. The lower the reliability index values are, the higher the cost of the repair is. In project C, the depth of the intervention was determined for each of the columns individually and therefore detailed information about the inspection was available at the structural element level. Nonetheless, to achieve this level of detail, expensive inspections are required, such as numerous chloride content analyses and individual concrete cover measurements. The right side of Figure 5 shows a different case. Here, the relationship between the costs and the reliability index for the other four projects takes the shape of a step function: after a certain threshold is surpassed, the decision to repair a column is taken. However, the depth of the repair is left equal, or quite similar, for all repaired columns within a project and thus the unit costs are the same (or similar). This is often the case in column rehabilitations in parking garages.

Figure 4. Indicative cost function for demolition and retrofitting of concrete in terms of the repaired depth.

Figure 5. Indicative costs in terms of the estimated reliability index (left: Project C, right: all other Projects).

4 CONCLUSIONS

The inspection reports commissioned for the condition assessment and planning of the subsequent rehabilitation of underground garage structures were analyzed. Based on the available information, the reliability index with depassivation as the limit state was estimated for each of the columns of the garages at the time of inspection (shortly before the rehabilitation). The estimated values of the reliability index were analyzed given the type of repair executed. No significant differences were found in the ranges of the reliability index value for which conventional rehabilitations and the installation of cathodic protection systems were carried out. This result suggests that selecting depassivation as the limit state may not be adequate to define target values for the reliability index in which one of these alternatives should be carried out or not. Nonetheless, a threshold that leads to the decision of “repair” (conventional and cathodic protection) or “not repair” (no substantial intervention) was found to be more evident (around 1.5). Nonetheless, the authors consider that the results of the present work should be considered qualitatively for the time being since only a limited number of projects were analyzed and the reliability indices were calculated using limited data and approximate methods.

Furthermore, an indicative cost function was defined considering two activities that were well documented for each of the structural elements analyzed, in the case of the projects repaired using the conventional method. This cost function was expressed in terms of the depth of the repair, using costs for the (partial) demolition of the concrete and the retrofitting of the columns. As expected, the function showed increasing costs with increasing intervention depth. For a project with a very detailed level of information, a clear relationship between the repair costs and the reliability index was found. This relationship was, in contrast, not so evident for the other analyzed projects, for which a threshold or stepwise function was observed. This outcome suggests that if the reliability index of each column were to be determined, the expected costs would theoretically increase with decreasing reliability index. Nonetheless, this requires very detailed and thus expensive inspections, which are not usually done in practice. It seems that in practical applications a more pragmatic approach is followed, in which a certain threshold is defined for which the columns are either

repaired or not, while the depth of the repair is left constant for all repaired columns. These practical considerations complicate the derivation of a cost function in terms of the reliability index.

Interesting research questions remain open. For instance: what would have been the optimum time of intervention to minimize the repair costs? Which measures during the design and construction phase could have been taken, in avoidance of the need for a costly rehabilitation?

FUNDING NOTE AND ACKNOWLEDGMENT

The IGF project no. 21828 N of the Research Association of the German Concrete and Precast Industry was funded by the German Federal Ministry of Economic Affairs and Climate Action (BMWK) through the German Federation of Industrial Research Associations (AiF) within the framework of the program for the promotion of joint industrial research and development (IGF) on the basis of a resolution of the German Bundestag. The authors gratefully acknowledge the financial support. Furthermore, the authors would like to thank the German Committee for Reinforced Concrete (DAfStb) for the valuable exchange of experiences and ideas in numerous discussions and the Engineering Consultancy Schiessl-Gehlen-Sodeikat for providing us with the documented rehabilitation reports.

The potential for direct reuse of precast concrete slabs in buildings with “wet” joints

P.S. Halding & K. Negendahl

Technical University of Denmark, Kgs. Lyngby, Denmark

ABSTRACT: Today, many buildings are built with precast concrete slabs each year, and as per tradition, these slabs are joined by pouring in-situ mortar in the joints between the slab elements. This is typically done to ensure the structural performance when the entire level of a building needs to perform as one rigid body. However, the consequence of the mortar-joints is that future dismantling is difficult as it requires extensive and costly use of diamond saws. Therefore, disassembly and direct reuse of concrete slab elements are rarely seen. Instead, the concrete is often crushed and used for, e.g., road filling. The global focus on reducing carbon dioxide from cement production and challenges with limited natural resources means that the production of new concrete must be reduced in the future. Direct reuse of concrete elements is essential to this transformation. More recently, methods have been employed to apply “dry” mechanical joints (e.g., steel brackets) specifically to enable a simpler disassembling process after end lifetime of buildings. Several challenges exist for the dry connections, such as more complex elements, labour-demanding assembly, higher cost, and problems with local damages, fire protection and robustness in service. Despite the trend in development and research activities in dry connection joints, the opportunity of modifying the simple, traditional “wet” mortar joints to create Design for Disassembly (DfD) has only been superficially investigated. The article unfolds the potential of a new type of wet concrete joints with a review of the challenges and limitations. The proposed solution to achieve DfD for wet connections is to reduce the mortar strength and stiffness and disassemble by pulling with a crane.

1 INTRODUCTION

Concrete elements from precast buildings are rarely reused. In developed countries, concrete buildings are crushed after the end of life to be used as a substitute for gravel in road filling or, on rare occasions, as aggregates in new concrete. But the direct reuse of entire concrete elements is almost nonexistent even though there is a global potential for enormous savings in the emission of CO₂ by doing so. Eberhardt et al. (2018) showed that 80% of the CO₂ is saved when an entire precast concrete building is reused once.

Worldwide, the construction industry accounts for 38% of the emission of CO₂ (UN, 2020), whereas cement production alone is 5 to 8 % (Figueira, 2021). As the main contributor of carbon emission from concrete, cement accounts for about 0.9 kgCO₂e per kg cement, depending on the specific cement factory (Hertz and Halding, 2021).

Furthermore, the resources to produce concrete are already scarce in many areas worldwide. Continuing the current production trend will accelerate the problems related to climate change and loss of biodiversity (UN, 2019).

To lower the consumption of cement for concrete structures, researchers investigate solutions such as “Green concrete” with less cement, minimal structures with less volume of concrete, and structural elements with combinations of different grades of concrete. However, considering the direct reuse of precast concrete elements is relevant in combination with any other technological gain in concrete buildings if the required forces can be transferred via the joints during the service of the building.

In this article, the emphasis is on the direct reuse of concrete slabs. They are often made with a relatively higher compressive strength (more cement) and constitute a large percentage of the overall volume of a concrete element building. The building industry is often considered to be conservative. Therefore, the scope is to investigate solutions within the current practice regarding erection methods – this means creating “design for disassembly” solutions with cast joints (“wet” joints) between slabs and adjacent elements. The proposed solutions are at a conceptual level. An example of a typical pouring of mortar/concrete over the reinforcement in joints between precast concrete slabs is seen in Figure 1.

Figure 1. Ordinary pouring of joints in a precast concrete building.

1.1 Existing DfD-solutions

The primary research in DfD revolves around mechanical “dry” joints that can typically be disassembled by loosening some bolts or similar steel connectors. Examples of proposed mechanical connections for DfD of precast concrete buildings are presented by, e.g., Kang et al. (2013), Witzany et al. (2015), Aninthaneni et al. (2017), Xiao et al. (2017), Aninthaneni et al. (2018), Ma et al. (2019) and Balineni et al. (2020). All the above research has in common that the DfD solutions rely on alterations of the concrete elements and hence require new processes at the factory and building site.

The only “wet” joint DfD-solutions available in the literature and online are based on cutting with a diamond saw around the slabs’ perimeter. Such methods are cumbersome and expensive, which is why it is not already done in practice.

2 BUILDING DFD-REQUIREMENTS AND LIMITATIONS

To investigate DfD-solutions for “wet” joints, limitations for the type of precast concrete buildings and a location have been chosen as an example. The case study building is positioned in Denmark, with low seismic activity and dominating wind load conditions.

Horizontal load from the wind on the façade is transferred to the stabilizing walls via the slabs and into the foundation. The magnitude of the transferred force to each wall is directly related to the wind pressure and the geometry of the building (the façade area, the position and sizes of the stabilizing walls, etc.). The wind load must be transferred via the joints between the slabs and the stabilizing walls. Hence, a conservative design approach is to dimension the structural system with the largest possible transfer of force in the connections, meaning the following two considerations are taken:

1. Apply the largest wind load on each floor (extra-large storey heights and a very long building).
2. Have the fewest possible stabilizing walls and use only short walls (increasing the shear stress in the joints).

2.1 Case study

2.1.1 Transfer of maximum shear force to stabilizing walls in service

A case study of a “conservative” building is made to show a critical case of load transfer from slabs to walls during use. Figure 2 shows a model of the structural system.

Figure 2. 3D view of the structural system of a precast concrete building with a maximum storey height of 5 m.

The building has a storey height of a maximum of 5 m, a façade length of 41.7 m, and only two transversely positioned stabilizing walls of 5.15 m in length positioned in each gable (stabilizing walls 1 and 3). This setup is more critical regarding the magnitude of transferred shear into the stabilizing walls compared to a similar building with less storey height, smaller façade length, more stabilizing walls, or with longer stabilizing walls.

Requirements for robustness (CEN, 2004) of the structural system means that reinforcement is positioned along the edges of the building and - when applying hollow core slabs - also to some extent in the joints between the slabs. Pure cement-based mortar is usually used in these reinforced joints along the perimeter of each slab, and the compressive cylinder strength is often above 40 MPa.

The slabs' size depends on the building's applied vertical loads for the case building. A maximum design load of 6 kN/m^2 is chosen, including safety factors, self-weight of slabs, services etc. It corresponds roughly to the expected imposed loads for an apartment. 180 mm hollow core slabs (HCS) are used to resist loads and deformations sufficiently, and a cross-section of the slabs and beams of the building is shown in Figure 3, including the pre-tensioning strand positions (red dots) and sizes.

Figure 3. Cross-section of HSCs and rectangular beams in the building designed to resist the applied vertical loads, and self-weights.

According to the Eurocodes (CEN 2005), the wind load can be found as maximum positive and negative pressure on different building surface areas. When distributing the wind load on the façades as a line load on the floors, the force becomes 3.33 kN/m (except for the roof and

ground floor). Since the case building façade is 41.7 m long, the total load from the wind on each floor is $3.33 \text{ kN/m} \cdot 41.7 \text{ m} = 138.9 \text{ kN}$.

This force is evenly distributed to the two transverse stabilizing walls at the gables, and each wall will receive 69.4 kN in each storey. It is now possible to investigate the occurring stresses in the local area with the mortar joint between slabs and stabilizing walls to determine the minimum requirement for the strength of the mortar.

2.1.2 Local investigation of the required mortar strength

FE-models were created to investigate the maximum occurring stresses in the mortar between slabs and stabilizing walls coming from the dominant wind load in combination with self-weight and imposed load.

Autodesk Robot Structural Analysis was used to model the geometry of the structural system of the entire building (see Figure 4 left). The material stiffnesses were given as input to the different members. This was to verify the assumption that the critical wind load would be evenly distributed to the two transversely positioned stabilizing walls. It was again assumed and modelled that the columns did not participate in resisting the wind load. The model also provided the maximum shear stress's location over the stabilising wall's length, which was utilized in a local investigation of the mortar joint between slab and wall.

The program ABAQUS was used to model the local (0.6 m x 0.3 m x 0.3 m) detail where the slab transfers the wind load via the mortar to the stabilizing wall. In Figure 4 (right), the simple ABAQUS model is seen. The right part of the figure shows an example of the distribution of the stresses in the mortar when the relevant load was applied to the local detail. The slab was only supported vertically by the stabilising wall, and all critical combinations of shear, bending moment and normal force from the slab were modelled to be transferred through the mortar.

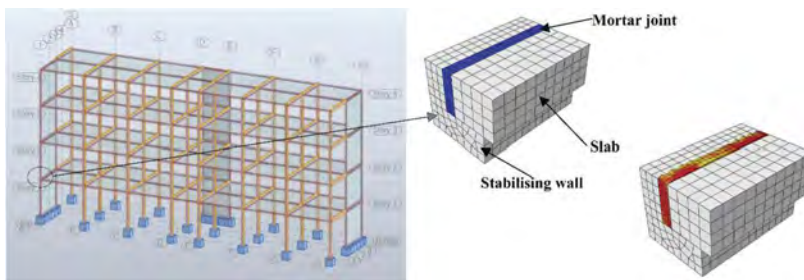

Figure 4. FE-model setup of global and local investigation to find the maximum stress in the mortar based on dominant wind load.

In the local FE-model, the stabilizing wall was fixed at the bottom.

To study the distribution of the stresses in the mortar and to find the largest stress, the model showed the numerically largest 1st and 3rd principal stresses in the mortar part of the assembly.

Based on this approach, the minimum required compressive design strength of the mortar could be determined directly when comparing different mortars with various strengths and stiffnesses, see Table 1. In all cases, the Poisson's ratio was 0.2, and the safety factor when calculating the design strength was 1.45.

Table 1. Mortar properties and maximum stress.

Compressive strength (char.)	Young's modulus	Tensile strength (char.)	Applied max stress	Compressive design strength
8 MPa	25.3 GPa	0.8 MPa	11.0 MPa	5.5 MPa
10 MPa	26.3 GPa	1.0 MPa	11.3 MPa	6.9 MPa
12 MPa	27.0 GPa	1.2 MPa	11.5 MPa	8.3 MPa
16 MPa	29.0 GPa	1.6 MPa	11.9 MPa	11.0 MPa

The small change in the maximum stresses was due to the small deviations in the stiffness. The goal was to determine the required mortar design strength to resist the maximum stress from the applied wind load. The setup from Figure 4 is very conservative since there will also be a contribution to the shear transfer in the surface between slab and wall, which has not been accounted for here. But with this conservative approach, the minimum limit for the strength of the mortar can be determined from Figure 5, where the “mortar design strength to max stress ratio” is plotted against the “mortar design strength”. The linear trendline crosses the ratio = 1 for a design strength of approximately 12 MPa, which corresponds to a characteristic strength of 17.5 MPa.

Figure 5. Mortar strength to max stress ratio with the minimum mortar strength limit location at 12 MPa.

If the slabs were higher, the maximum stress is expected to become smaller (if the mortar joint height follows the slab’s height).

The 17.5 MPa compressive strength of the mortar is less than half of what is ordinarily used for precast concrete buildings, and it enables the opportunity for DfD of slabs.

2.1.3 Design for disassembly of slabs with “wet” (poured) joints

The simplest method to remove whole slabs from precast buildings after end-of-life would be to pull out the elements one by one with a crane. The requirement for such method would be:

1. The slab can resist the pulling-out loading scenario and is free to move without significantly deforming adjacent building parts.
2. The crane has the capacity to pull with the required force in a controlled and safe way.
3. The lifting chains and the anchors embedded in the decks have sufficient capacity.
4. There is access to lifting anchors on the surface of the slabs.
5. The joints are weak and will crack along the slab’s edge when pulled up.

To ensure that the slab for disassembly is free to be moved up, one side of the slab must always be free. The edge beam on the side of the first slab to be lifted must be removed first.

Now, one side edge of the slab is exposed, and the longitudinal reinforcement (if present) must also be cut by a diamond saw in the joints in the two opposite corners of the free edge (Figure 6).

The lifting process can be initiated, and if the mortar in the three attached sides is weak enough, it will start cracking around the slab periphery.

Suppose the lift is performed with ordinary lifting chains. In that case, it can be conservatively chosen to use chains with an inclination of 45 degrees vertical and four lifting anchors positioned 300 mm from the ends of the slab and 150 mm from each side of the slab.

The shear resistance can be calculated in the interface and inside each of the materials (concrete and mortar). Along the smooth surfaces of the slab, the interface will be dimensioning for the shear resistance when pulling the slab up. At the ends of the slab, where the holes are located, the shear force must overcome the shear resistance of the mortar in the location of the holes.

Figure 6. Disassembly setup with the location of reinforcement in mortar joints.

The shear resistance in the interface can be found by e.g., Eurocode 2 (CEN, 2004), and the calculation procedure is not shown here. For further information, the authors can be contacted. In the calculation of the shear resistance, it is assumed that there is no normal force in any of the joints (no wind during disassembly).

In the case building, the slabs have a 6.3 m span, a width of 1.2 m, and a height of 180 mm. Calculating the shear resistance and lifting force from the three sides with mortar joints of 12 MPa compressive strength (found earlier), the result becomes:

- Total shear resistance from holes at the ends of the HCS: 61.5 kN
- Total shear resistance from the remaining part of ends of the HCS: 44.9 kN
- Total shear resistance from the longitudinal joint of the HCS: 166.7 kN
- Self-weight of HCS to be lifted: 19.2 kN
- Total lifting force to overcome shear resistance and self-weight: 292.3 kN

The total load is possible to lift by a mobile crane. A solution for lifting is shown in Figure 7.

Figure 7. Disassembly setup with crane lift.

If no lifting anchors are available, it may be necessary to lift by applying another method, for instance, special lifting straps around the slabs. When this method is applied, the slabs and surrounding elements should always be checked for sufficient resistance to the disassembly load.

2.1.4 Carbon footprint comparison

Considering only the structural system of the case building, the direct saving of CO₂ by direct reuse of the slabs can be calculated. The concrete of the slabs accounts for 72% of the consumption of concrete in the building, and the concrete grade is higher (55 MPa) than for the columns and stabilizing walls (35 MPa). If we consider only the CO₂-emission from the materials manufacturing, the slabs account for 76.5% of the total emission of the system.

Of course, the dismantling and other processes require emission of CO₂ as well, so a more precise calculation is required when such numbers are available. Still, there is a saving of about ¾ of the emission available by directly reusing the slabs in a new similar building in the future.

3 DISCUSSION AND PROSPECTS

The erection method of the building will remain the same as for an ordinary precast concrete building, with the only difference being the application of a weaker mortar in the joints between the elements. The 12 MPa compressive strength mortar could be created from either a pure cement-based recipe or a combined lime- and cement mortar. Note that the hardening of the mortar is not complete after 28 days (ordinary design assumption). This means that the mortar is slightly stronger than anticipated at the end-of-life of the building if this is not accounted for.

Most of the shear resistance comes from the longitudinal side of the slabs. Therefore, it could be a future investigation to develop a method to “pre-crack” the joints along the longitudinal side to reduce the required lifting force. This could especially be interesting for larger slabs with a bigger self-weight and longer sides. The potential of such a solution could be to develop a disassembly method for slabs from existing precast concrete buildings with stronger joint mortars. This would fast forward the CO₂-saving so that society will benefit immediately.

Another promising future development of the DfD method could be creating a “hybrid” DfD-building with a combination of dry mechanical and wet joints. By doing so, it is possible to achieve the benefits of both methods in combination and create a simpler and more inexpensive way to assemble and disassemble.

The disassembly method also requires a check of the capacity of the slabs for the pulling-out load scenario. It may be necessary to put in slightly more pre-tensioning steel in some new slabs to avoid problems with cracking during disassembly.

To verify the proposed DfD-method, full-scale tests will have to be performed. Especially the sequence of the crane pulling regarding the safety of the workers on the building site and the possible concentration of stresses in the slabs or neighbouring elements are issues that need to be proved in the lab.

Many other aspects are important before we can begin to have large numbers of direct reused concrete slabs, e.g.:

- Documentation of the carrying capacity of the slabs and the remaining component life.
- Check chemicals to ensure contamination is not transferred to new buildings via slabs.
- Where to store the elements before they are reused in a new project.
- Evaluation of the economic consequences.
- Regulations that require reuse at an element level to lower future emissions of CO₂.
- All precast concrete buildings should be designed with a solution for both the erection and disassembly methods.

4 CONCLUSIONS

A new method for Design for Disassembly (DfD) of slabs in precast concrete buildings is proposed. The method relies on the mortar in the poured joints being optimized to have the minimum required strength and stiffness to transfer the required force from the load on the building during service. With the much lower mortar strength, the building can more easily be disassembled after the end of life so that the slab elements can be directly used in a new building without being harmed and without the costly and slow process of cutting all edges with a diamond saw.

The outlined method relies on an ordinary crane to pull out the slabs one at a time. The low strength of the mortar means that the mortar is the weak point in the joined structure, and cracks and later separation failure will occur in the joints. The elements should always have one free side to ensure that the slabs are not interlocked during the crane pull. Therefore, the method relies on removing reinforcement or edge beams along the side of the building before dismantling the first slab. Furthermore, the longitudinal reinforcement in the joints between slabs must be cut locally by using a small diamond saw to ensure a restraint-free removal process. With such a setup, the only resistance towards the crane pull is the shear capacity of the interface between the slab and the mortar.

A conservative case building with a critical loading scenario is presented to show the method. An FE model of the local detail between slab and wall provides a minimum mortar compressive strength of 12 MPa. This strength is determined to be sufficient to transfer the wind load.

Subsequently, the required crane pulling force is found by calculating the shear resistance around the three sides of the slab with a mortar joint. The total required pulling force is 292 kN, which is manageable for a normal mobile crane.

The case building clearly shows that the method is a promising step towards an easier process for disassembling concrete decks in future precast concrete buildings to create CO₂ savings (up to ¾ for future buildings from slabs alone). Nevertheless, several obstacles must be overcome to apply such a method in practice. For instance, full-scale laboratory tests are necessary to prove the concept and to show that the method is safe for the workers on the building site.

ACKNOWLEDGEMENTS

The authors wish to thank the M.Sc. students at DTU Construct who were involved in the case study. The investigations are part of a project funded by the “Ingeniør Kaptajn Aage Nielsen” family fund.

Life-cycle assessment of concrete hollow blocks and autoclaved aerated concrete blocks

J.M. Ongpeng & M.V. Umali

De La Salle University, Manila, Philippines

ABSTRACT: The global shortage of natural resources and its effects on the environment are both adversely affected by the construction industry. Environmental criteria must be considered when it comes to selecting sustainable building materials. In this paper, two models for interior wall systems were investigated, the use of conventional concrete hollow block (CHB) and the alternative autoclaved aerated concrete block (AACB). A life cycle assessment (LCA) considering a school building in the Philippines with a cradle-to-gate boundary and a functional unit of 10.5m² was performed to compare the environmental impacts of these walls. In the endpoint categories, the use of AACB resulted a decrease in human health, ecosystems, and resources while in the midpoint categories, the use of AACB walls resulted a decrease in CO₂ emission, fine particulate matter formation, and human carcinogenic toxicity. It is therefore concluded that AACB interior wall systems have substantial potential to reduce the environmental burden caused by the building construction.

1 INTRODUCTION

In comparison to other industries, the construction sector consumes 60% of the world's raw materials (Broun & Menzies, 2011) and is the largest user of materials by weight in the US (Ferrández-García et al., 2016). It has significant effects on the use of energy, production of solid waste, pollution, and greenhouse gas emissions (Broun & Menzies, 2011; Condeixa et al., 2015; Mateus et al., 2013). Additionally, as people's knowledge of environmental issues rises, sustainable construction practices receive increasing attention (Buyle et al., 2013). It is important to use appropriate building design and technology, as well as acceptable construction materials while creating effective buildings. Wasted materials and handiwork result from poor management decisions, suppliers' unreliable performance, and incorrect selection of material parameters (Ferrández-García et al., 2016). As the sustainability concept has grown in construction, there is a popularity of using locally available materials, which establishes the need for more sustainable solutions for construction materials.

A partition wall is a crucial building element that divides a building's interior space into rooms or regions to facilitate better space usage (Broun & Menzies, 2011). Stability to self-weight, eccentric vertical loads, out-of-plane horizontal loads, visual, acoustic, thermal, and water resistance are the key functional criteria for partition walls (Vasconcelos et al., 2013). These interior walls have an impact on the environment depending on the material used, its thermal qualities, and how it is constructed and maintained.

Blocks have been widely employed as a popular option in structures and are one of the essential materials for walls and partitions. Because they dissipate less heat and need fewer resources to produce voids, hollow or solid blocks are more common in developing nations (Wu et al., 2015). Blocks are selected because they can improve aesthetics and lower costs by reducing the number of cut units needed on-site. Grades of partition blocks are determined by the structural and functional performances of the partition and the degree of care the partition is likely to receive (*Build SG - BCA*, n.d.).

The life cycle assessment (LCA) of recycled materials can help in material selection. For the environmental assessment of items covered by the International Organization for Standardization (ISO) 14000 standard series, specifically ISO 14040, LCA methodologies are frequently used (*ISO*

14040:2006, 2014). It plays an important role in the evaluation of environmental impact to enable the selection of environmentally suitable materials (Cabeza et al., 2014). Using all phases of a product's life cycle, the LCA is a scientific methodology that enables the identification and quantification of inputs and outputs linked to a product in accordance with its primary function (Agarski et al., 2016; Frenette et al., 2010). The comparison of various building materials, their embodied energy, CO₂ footprint, and the comparison of material performance within construction are all topics covered by LCA research (Agarski et al., 2016; Frenette et al., 2010). The environmental impact of materials can be reduced by selecting more environmentally acceptable materials, particularly if the sources are sustainably managed or the products have renewable sources.

In this LCA study, the two selected models for interior wall systems (IWS) will be investigated and compared as shown in Figure 1. The first one is the traditionally built non-load-bearing concrete hollow blocks (CHB) with dimensions of 0.40 m (length) by 0.20 m (height) by 0.10 m (thick), three (3) cores jointed and built with 12.5mm of cement mortar and 16mm of cement plaster on both faces (Fajardo, 2000). The second one is the alternative autoclaved aerated concrete blocks (AACB) with dimensions of 0.60 m (length) by 0.20 m (height) by 0.10 m (thick) jointed and built with 5.0mm of adhesive mortar.

Figure 1. Concrete Hollow Blocks (CHB) and Aerated Autoclaved Concrete Blocks (AACB).

2 MATERIALS AND METHOD

2.1 Building interior wall system

The structure considered in this study is a 2-storey school building in Bulacan State University (BulSU) located in City of Malolos, Bulacan, Philippines. The building made up of reinforced concrete has a total area of 355 m² as shown in Figure 2. The elevation and section of CHB and AACB wall systems are shown in Figures 3 and 4 respectively. The building was constructed in accordance with the 2015 National Structural Code of the Philippines (NSCP, 2015).

In the first model, as shown in Figure 3, blocks of CHB wall were laid in the running bond method. The reinforcing steel bar used is 10mm in diameter. As illustrated, the vertical bars are installed at every 600mm on the center and the horizontal bars are installed at every 3 layers of CHB. Mortar beds of 12.50mm thick and 16mm thick cement plastered at both faces of CHB were applied. In the second model shown in Figure 4, blocks of AACB wall were also laid in the running bond method. As illustrated, the vertical bars are installed at every 2 units of the blocks of the first row. Horizontal bars are installed on the side at every 3 layers of AACB. The 10mm diameter dowels used for both vertical and horizontal have a length of 200mm where the 50mm length of rebar was drilled in the concrete while the remaining 150mm length was exposed. An adhesive mortar 5.0mm thick was patched in between the blocks and no cement plaster was required since both faces of the block were already smooth and ready to receive paint.

To ensure a direct comparison, the equal compressive strength of the mortar in both walls has been considered. It is assumed that installation procedures will not vary in significant ways. The secondary sources of data are utilized as shown in Table 1.

2.2 Life Cycle Assessment (LCA)

LCA studies should consist of four separate phases: goal and scope definition, life cycle inventory, life cycle impact assessment, and interpretation. This document is organized in accordance with these recommendations. SimaPro 9.3.0.3 software was used to conduct an LCA (Pré, 2014). The definition of the goal and scope establishes the parameters and limits of the study, while LCIA

Figure 2. Structural plan of the building.

Figure 3. Elevation and section of CHB wall system.

Figure 4. Elevation and section of AACB wall system.

measures the impacts in terms of damage categories and the interpretation is present throughout all phases and influences the choice of data (*ISO 14040:2006*, 2014b). LCI provides information about the input and output of processes. Cost analysis was also added to the LCA.

Table 1. Data for interior wall system based on secondary sources.

Model of Wall System	Compressive Strength	Composition	Design Mix (kg/m ³)	Reference
Concrete Hollow Blocks	3-5 N/mm ²	Cement	415.84	(Dolores et al., 2020)
		Sand	1610.56	
		Water	207.92	
Autoclaved Aerated Concrete Blocks	3-5 N/mm ²	Cement	384	(Kumar et al., 2021; Sethy, 2018)
		Sand	298.67	
		Lime	50.371	
		Aluminum Powder (600 kg/m ³)	0.13%	
		Water	296.3	

The main aim of this study is to conduct a comparative LCA study on the environmental impacts of two models of interior wall systems, CHB and AACB. The aim is also to come to conclusions and make recommendations that will help in the decision-making process for choosing the most cost-effective and environmentally friendly building material for internal partition walls.

The functional unit is defined as the measure applied in evaluating the performance of systems or products (ISO 14040, 2006). In this study, a functional unit considered is a 10.50 m² (3.0mW x 3.5mH) interior wall represented in Figures 3 & 4 with a thickness of 0.10 m for the single-layer walls, excluding paint. The area is calculated by multiplying the width by the height of the wall.

The system boundaries are represented in Figure 5. The performance of IWS is primarily examined in this research from the viewpoint of cradle-to-gate boundaries. The pre-construction phase took into account the extraction of raw materials and the production of essential products, while the construction phase evaluated the preparation and installation processes. It was also considered how the products would get from the location of material extraction to the project site and its corresponding transportation distances. The effects of each of these processes on the environment are evaluated. The use phase has been excluded from this study.

The LCA methodology mandates the establishment of a life cycle inventory for the specific product or process after defining the purpose and scope. Comprehensive tracking of all flows into and out of the product system, including those of raw materials, energy by type, water, and emissions of a given substance into the air, water, and land, constitutes a life cycle inventory. A bill of materials was also created and converted into the functional unit described in this study. SimaPro version 9.3.0.3 is used to execute each approach with varied material needs for evaluation and interpretation (Ortiz et al., 2010). Data consistency was maintained using the Ecoinvent 3 library and the ReCiPe 2016 Endpoint H/World 2010 H/A endpoint method. The LCA software integrates the supplied data with data obtained from the background database to get an accurate picture of the effects of a specific product. Characterization results for each midpoint category are analyzed as the obligatory level of impact assessment.

3 RESULTS AND DISCUSSION

3.1 Life Cycle Inventory (LCI)

Table 2 summarizes the material quantities required for each of the IWS. These material quantities are used as input to SimaPro.

In the life cycle inventory for CHB and AACB, the input data for the Ecoinvent 3 library's materials and processes are based on Rest-of-the-World (RoW) or global (GLO) geographic locations. The GLO dataset refers to cover the average global production, but the RoW dataset reflects the world minus all local geographies for which a process is recorded in the database (Ecoinvent, 2021). The typical GLO dataset selections include tap water, diesel, heat, and electricity. For portland cement, sand, rebars, adhesive, blocks, and transportation, the RoW dataset was selected. The midpoint categories with the most impact are shown as output in the inventory.

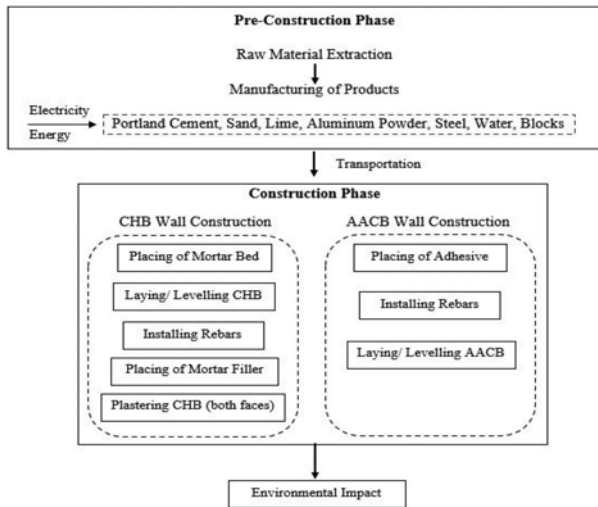

Figure 5. System boundary used in the study.

Table 2. Summary of the bill of materials for each IWS, per functional unit 10.5m² area.

Interior Wall System	100 mm Blocks	Portland Cement*	Sand*	Adhesive*	Rebars	Water
CHB	1056	380	1539		23.61	114
AACB	630			63	2	19

All quantities are expressed in kilograms. *The background color denotes non-included materials.

The three categories that have the greatest impact are (1) human carcinogenic toxicity (measured in kg 1.4 DCB released eq), (2) particulate matter generation (measured in kg PM_{2.5} eq), and (3) global warming potential (measured in kg CO₂ eq). Human carcinogenic toxicity is noted to risk an increase in cancer and non-cancer disease incidence (Huijbregts et al., 2016). Air pollution that results in primary and secondary aerosols in the atmosphere and can have a significant detrimental effect on human health, ranging from respiratory complaints to hospital admissions and mortality, is accounted for by particle matter formation (Lelieveld et al., 2015). The rise in temperature known as “global warming” ultimately harms ecosystems and people’s health.

3.2 Process network

The process network illustrates the materials used in the assembly or the flow of any process. As shown in Figure 5, using SimaPro to analyze the process network in CHB, portland cement production contributes the highest impact with about 42.1%. The next contributor is concrete block production with about 28.4% then followed by reinforcing steel with about 22.4%. The impacts of the other materials such as sand and water including the transportation process, electricity, diesel, and heat are negligible compared to the major environmental contributors.

As illustrated in Figure 6, AACB production contributes the highest impact with about 63.6%. The next contributor is the adhesive mortar with about 31.5% then followed by reinforcing steel with about 3.06%. The reduced impact of cement as compared to the CHB wall is due to the application of adhesive as a replacement for the cement mortar.

3.3 LCA comparison

As shown in Figure 7, the midpoint categories are first evaluated to identify which are considered problem-oriented categories (Bautista et al., 2022). The results demonstrate that AACB has the least impact in almost all the midpoint categories except for the ionizing radiation and mineral resource scarcity wherein AACB has more impact than CHB. Ionizing radiation in human health disperses the radionuclide throughout the environment and exposure to the radiation will damage

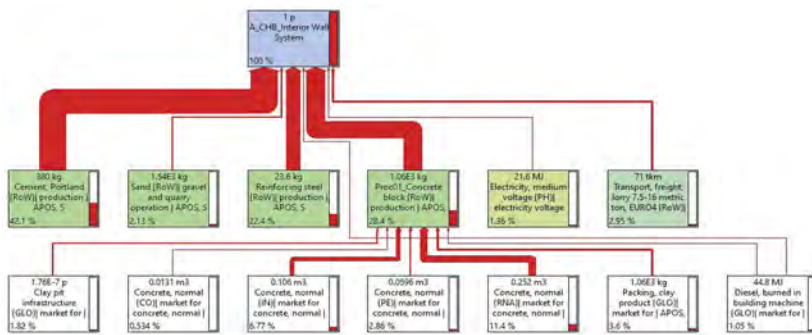

Figure 6. CHB wall process network.

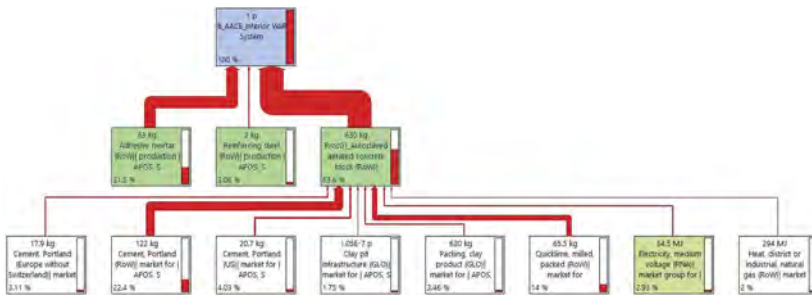

Figure 7. AACB wall process network.

DNA-molecules of a person which can lead to a certain illness (Huijbregts et al., 2016). A higher impact in this category is primarily due to the materials such as lime and aluminum powder added to the block and the higher power generation stage in the curing process of AACB. Meanwhile, the categories which obtained the most variation of CHB vs. AACB are human carcinogenic toxicity and water consumption. AACB uses a lesser amount during block production and installation. After the midpoint categories, the comparative endpoint categories or damage-oriented parameters are evaluated by investigating the impacts on human health, ecosystem, and resource availability as shown in Figure 8 with tabular results in Table 3. LCA results show that

Figure 8. Comparison of impact assessment characterization for CHB and AACB.

the method with the least impact on the endpoint categories is AACB. This means that the installation of an interior wall system using CHB yields a higher impact compared to AACB. As was mentioned, out of all the components taken into consideration, cement is the biggest contributor. AACB wall is considered as the model with the least environmental impact.

The analysis of the results revealed that the cost per square meter of the CHB wall (₱ 966.00) was lower than the AACB wall (₱ 1,462.00). AACB leads to faster and easier installation thus showing lower labor cost but the results depict that CHB cost has reduced by 34% and therefore conclude more advantageous in terms of the total cost in wall construction.

Figure 9. Comparative endpoint LCA results for concrete and autoclaved blocks.

Table 3. Tabular impact assessment comparison of endpoint categories for two models.

Damage Category	Units	CHB Wall	AACB Wall
Human Health	DALY	0.00112	0.000693
Ecosystems	species.yr	2.3E-6	1.54E-6
Resources	USD2013	22.8	22.7

4 CONCLUSIONS

Results of the LCA process network show that cement production has a greater environmental impact than the production of adhesive, steel, sand, and other energy sources like electricity, fuel, and freight transportation, aside from the production of the blocks themselves.

In the endpoint categories, the use of AACB in the interior wall of a building resulted in a 38% decrease (DALY units) in human health, 33% decrease (species.yr units) in ecosystems, and 0.61% decrease in resources. Regarding the midpoint categories, the study also confirms that CO₂ emission, fine particulate matter formation, and human carcinogenic toxicity are the environmental impact categories with the highest impact. Installing of AACB interior wall resulted in a 35% decrease in kg CO₂ eq, a 40% decrease in kg PM 2.5 eq, and 63% in kg 1.4-DCB emitted to urban air eq. It is therefore concluded that AACB walls have a lesser environmental impact between the two models. In terms of cost, it validates that the use of CHB interior walls in the construction of a building is more advantageous than the use of AACB. But in terms of its lightweight property, durability, fire resistance, fast installation, and most especially environmental impact, AACB is still beneficial in the overall design and construction of the building.

Both systems have areas that might be strengthened in terms of production, transport, and installation. The CHB supply chain's construction features must be adjusted to reduce environmental impacts across its lifecycle, particularly in terms of human health, ecosystems, and resources, while the output of by-products in the AACB must be enhanced. In the course of future work, it is recommended to further investigate the process or material production improvements as they can be the source of environmental impact mitigation. The use of recyclable materials in material development can also be explored to reduce costs and negative impacts.

ABSTRACT: The performance of bridge damage assessment based on model updating approaches relies on correctly identifying the structural responses in the undamaged state. However, environmental uncertainties, such as temperature changes, influence structural responses in the same order of magnitude as damages. Therefore, a prestressed concrete bridge beam is studied in this paper. Temperature influences on static experiments in 2 test periods are minimized with physical temperature compensation technique. Displacement fluctuations decrease at least 60% after temperature compensation, making the summer and winter measurements comparable. Next, temperature-compensated Influence Lines (ILs), static flexibility and stiffness matrices are obtained. Comparing the results reveal the importance of performing measurements only on cloudy days. This paper contributes to differentiating between temperature effects and damages, which is crucial for a successful damage assessment.

1 INTRODUCTION

Bridges play a crucial role in connecting transport networks. Bridge safety and integrity are a fundamental concern of Structural Health Monitoring (SHM) as failures result in excessive losses. SHM should not merely rely on numerical models since the results differ from the measurements due to environmental and operational uncertainties (Dakhili et al. 2022; Ozer & Feng 2020).

Damage assessment can be achieved by tracking the stiffness matrix changes. In practice, flexibility is calculated first based on experimental data, and the stiffness matrix is obtained by calculating the inverse of the flexibility matrix. Despite numerous studies on dynamic flexibility matrix (Catbas et al. 2008; Schommer et al. 2017; Zhang & Moon 2012), the static flexibility matrix should be further investigated.

Among the environmental factors, temperature changes are a dominant component in bridge responses. Daily and seasonal temperature changes influence dynamic (Cross et al. 2013; Hu et al. 2018; Nandan & Singh 2014) and static measurements (Kromanis et al. 2016; Kulprapha & Warnitchai 2012; Nguyen et al. 2016) in the same manner as damages. Therefore, it is important to minimize temperature influence to distinguish damages from environmental uncertainties.

(Kulprapha & Warnitchai 2012) developed an analytical model of a small-scale prestressed concrete bridge to study nonlinear temperature distributions. Although the measured and predicted deflections and strains matched well for the scaled-down bridge, any mistakes in predicting thermal responses lead to unsuccessful damage identification (Xu et al. 2019).

(Nguyen et al. 2016) proposed a physical temperature compensation method to reduce the effect of temperature variations on the Deflection Lines (DLs). The proposed method was later combined with Principal Component Analysis (PCA), and the two-step temperature compensation technique

was utilized to compensate for the temperature effects from experimentally acquired natural frequencies of two different bridges (Nguyen et al. 2020).

As mentioned, the effect of temperature changes on the static flexibility and stiffness matrix should be further investigated. This paper studies the structural responses of a prestressed concrete bridge beam under outdoor conditions. The displacements and temperatures at different points are measured. Static and quasi-static experiments are performed using a trolley that moves along the beam. The static flexibility and stiffness matrices are calculated with temperature-compensated data. The reference static structural matrices in the undamaged state can be later implemented in damage assessment techniques based on model updating approaches.

2 EXPERIMENTAL SETUP

The experimental setup and the Finite Element (FE) model are described in this section.

2.1 The investigated beam

The prestressed concrete bridge connecting Mersch – Luxembourg was demolished in 2016, and a $24.9 \times 1.45 \times 2.10$ m (L×W×H) T-beam was transported to the University of Luxembourg. The beam was prestressed with 8 steel tendons in the longitudinal direction. An asphalt layer with a thickness of about 0.07m is still on the bridge beam. The beam is simply supported similar to the original setup. Figure 1 shows the investigated beam.

Figure 1. The prestressed bridge beam under study.

Seven displacement sensors (SV_i) measure the vertical displacements at different locations, while SH8 measures the horizontal displacements at the movable bearing. Additionally, temperature sensors (T1 – T4) record the concrete temperatures. Sensors T5 and T6 measure the asphalt and ambient temperatures, respectively.

The static and quasi-static experiments are performed with the help of a trolley that can move along the bridge. The trolley weighs about 8.8t, and it has an approximate speed of 1m/min. The schematic diagram of the beam, the sensor, and the trolley positions is shown in Figure 2.

Figure 2. The schematic diagram of the beam.

2.2 The numerical model

The Finite Element (FE) model is created with Ansys Parametric Design Language (APDL). A linear model with mapped mesh is used to reduce computational costs. The trolley is modeled as 2 cuboids each with a different density to stimulate the weight distribution. Table 1 provides a summary of the material properties. Figure 3 demonstrates the FE model.

Table 1. Material properties of the FE model.

Material	Young's modulus [MPa]	Poisson's ratio	Density [kg/m ³]
Concrete	30e3	0.16	2500
Prestressed steel	205e3	0.3	7850
Asphalt	2e3	0.4	2350
Trolley	210e3	0.3	2440 – 5244

Figure 3. The FE model with the trolley over the fixed bearing.

3 METHODOLOGY

The flexibility and stiffness derivation together with the physical temperature compensation method is briefly explained.

3.1 Flexibility and stiffness matrix

A flexibility component is defined as the deflection at point i when the unit force is applied to point j . The static flexibility matrix is formulated as below (Thorby 2008):

$$\{x\} = [F]\{f\} \quad (1)$$

where $\{x\}$ = displacement vector, $[F]$ = flexibility matrix, and $\{f\}$ = force vector.

The Influence Lines (ILs) are measured during quasi-static tests. To do so, the trolley starts moving from the fixed bearing to SV1. It stops over SV1 for a few minutes, then it moves to SV2. This process is repeated to measure the ILs when the trolley is above SV3, SV5, and SV6. The flexibility matrix can be easily determined as each IL corresponds to one column of this matrix. Nevertheless, damage localization with $[F]$ is only indirectly feasible (Schommer et al. 2017). Thus, the inverse of the flexibility, i.e. the stiffness matrix should be obtained ($[K] = [F]^{-1}$). Local decrease in stiffness can be directly associated with damage location.

3.2 Physical temperature compensation

Static and quasi-static experiments are performed in two periods. The temperature data and the temperature difference between the upper and lower part of the beam, ΔT is plotted in Figure 4. The temperatures vary differently during the winter and summer. Hence, the measurements in two different seasons cannot be compared unless the temperature effects are compensated.

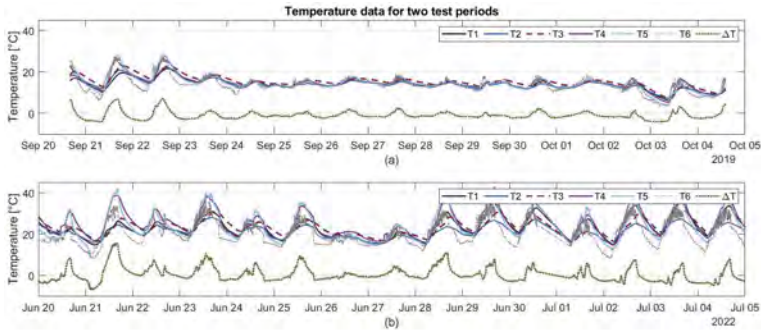

Figure 4. Temperature measurement ($\Delta T = T_5 - T_3$) a) winter b) summer.

Vertical deflection in the middle of the beam (SV3) and horizontal displacement at the movable bearing (SH8) are observed during one (un)loading state. These movements occur due to temperature changes. Figure 5 indicates that SV3 and SH8 are correlated with the temperature at the bottom of the beam (T3), and the temperature difference between the top (T5) and bottom of the beam. Since the linear relation between the SH8 and T3 is pronounced, this information is used to obtain the regression line slopes required for temperature compensation. The average regression line slopes are utilized to map the displacement data from the measured T3 temperature to $T_{ref} = 16^\circ\text{C}$ (Nguyen et al. 2016).

Figure 5. Displacement and temperature scatter plots – unloading state 20.06.2022 – 28.06.2022.

In this study, physical temperature compensation is only performed for the periods after the peak temperature of the day, when T1, T2, and T4 temperatures are almost equal according to Figure 4. For instance, one of the selected data segments is highlighted in Figure 5. As can be seen, for these data series there is no considerable between the displacements and the temperature difference of the top and bottom of the beam (ΔT).

The performance of this method highly depends on correct data selection, and it must be carefully handled to ensure successful damage detection. For instance, if the displacement information at the hottest time of the day is selected, the slope of the regression lines increases. This results in an increase of the scatter in the temperature-compensated displacements. In that case, the physical temperature compensation technique cannot fully reduce the temperature effects.

4 RESULTS

The FE model is verified with the experimental results by comparing deflections when the trolley is over the fixed bearing. As Table 2 indicates, the FE model is validated with the experimental results. Nevertheless, this validation is achievable only after temperature compensation.

4.1 Loading/Unloading states

Figure 6 depicts raw and temperature-compensated SV3 values. Loaded and unloaded states correspond to the trolley in the middle of the beam and the trolley over the fixed bearing, respectively. The results confirm that without considering the temperature effects, one might

Table 2. Comparison of simulated and measured deflections – trolley over fixed bearing.

Sensors	SV1	SV2	SV3	SV5	SV6
Simulation	0.82	3.13	4.18	3.13	0.82
Measurement	0.84	3.14	4.14	3.22	0.87
Error	2.3%	0.3%	1.0%	2.8%	5.7%

associate the increase in the displacements in summer with damage. However, the temperature-compensated values confirm that the bridge beam is still in the healthy state during these two periods. Table 3 presents a summary of the results.

Figure 6. Raw and temperature compensated SV3 values a) winter b) summer.

Table 3. Summary of temperature compensation effect on static data.

	Winter		Summer	
	Loaded state	Unloaded state	Loaded state	Unloaded state
Raw SV3 [mm]	3.63 – 5.47	-0.66 – 3.37	1.89 – 7.21	-3.03 – 3.37
Temp. comp. SV3 [mm]	3.86 – 4.61	0.14 – 1.28	3.28 – 4.27	0.70 – 2.86
Range Decrease (%)	59.2	71.7	81.4	66.2

4.2 Quasi-static experiments

Flexibility is calculated based on the Influence Lines (ILs). Several experiments are performed in the winter and summer. As an example, Figure 7 illustrates the raw and temperature-compensated ILs measured with SV3 for two tests. Although the results are only shown for SV3, temperature compensation is performed on every sensor data. In order to better explain the results, the asphalt temperature at the top (T5) and the concrete temperature at the bottom of the beam (T3) are plotted in Figure 8.

Figure 7. Raw and temperature-compensated IL measured with SV3 at different trolley positions.

Figure 8. T5 and T3 during the quasi-static tests.

As stated, the reference temperature is chosen to be $T_{ref} = 16^{\circ}\text{C}$. Figure 8 indicates that when the difference between T3 and T_{ref} is bigger, the effect of temperature compensation becomes more apparent. The temperatures are closer to T_{ref} during the winter, and they are more consistent. In contrast, being considerably higher than T_{ref} , the temperatures change sharply in the summer. Therefore, not only temperature compensation is recommended, but also experiments should be performed on cloudy days when there is no or little solar radiation to avoid considerable nonhomogeneous temperature distributions over the bridge beam.

4.3 Flexibility and stiffness matrix

The beam deflection due to its weight is subtracted from the Influence Lines (ILs) in the previous section. Then, the results are divided by the trolley weight, 8.8t to calculate the flexibility matrix. As explained, the stiffness matrix is obtained by calculating the inverse of the flexibility. Figures 9 and 10 show the temperature-compensated flexibility and stiffness matrices for the tests in the previous section.

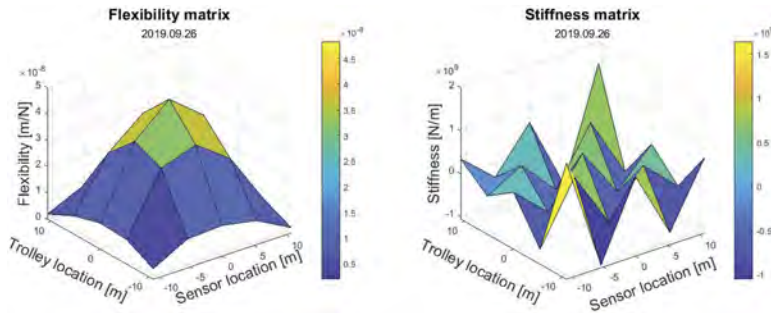

Figure 9. An example of the flexibility and stiffness matrix for a test in winter.

Figure 10. An example of the flexibility and stiffness matrix for a test in summer.

Although there is a similarity between the flexibility matrices in winter and summer, the difference between the stiffness matrices in these two seasons is noticeable. In order to better analyze the results, the diagonal arrays of these matrices are compared in Figure 11.

Figure 11. Comparison of diagonal arrays of the flexibility and stiffness matrices.

According to Figure 11, although flexibility matrices in summer and winter may be comparable with a difference of about 10%, the difference between the diagonal arrays of the stiffness matrices cannot be neglected. Therefore, it is suggested to either perform the 2-step temperature compensation proposed by (Nguyen et al. 2016) or to perform measurements only on cloudy days with minimum solar radiations.

5 CONCLUSIONS

Establishing an accurate model to represent the undamaged state is critical to guarantee a successful damage assessment. This paper demonstrated that daily and seasonal temperature change influences may be mistaken for damage. Therefore, this study aimed to minimize temperature effects with a physical temperature compensation method.

Firstly, the horizontal movement of the bridge beam was shown to be strongly correlated with the concrete temperature in the middle of the beam. The displacements for loaded (trolley in the middle) and unloaded (trolley over the fixed bearing) states were temperature compensated. The results showed that although temperatures are considerably different in summer and winter, physical temperature compensation could reduce the fluctuations for the selected segments.

Secondly, the temperature compensation of the Influence Lines (ILs) was investigated. This information was required to calculate the static flexibility matrix. Being more consistent, the temperatures were closer to the reference temperature in winter, while the temperatures changed sharply during the tests conducted in summer. Thus, it is suggested to implement a 2-step temperature compensation or perform measurements only on cloudy days.

Finally, flexibility and stiffness matrices in summer and winter were compared with two tests as examples. In practice, the flexibility matrix is calculated based on the ILs, which is a straightforward procedure. However, tracking the changes in the stiffness matrix by comparing the undamaged and damaged states provides information about the damage location. Therefore, the stiffness matrix should be obtained by calculating the inverse of the flexibility.

The results showed that although the diagonal arrays of the flexibility matrices vary by roughly 10% in the summer and winter, the stiffness matrix arrays are not comparable. Thus, it was confirmed again that the cloudy days with minimum solar radiation should be selected as test days.

Robot-BIM integration for underground canals life-cycle management

H. Pourhosseini, F. Zahedi & J. Majrouhi Sardroud
Central Tehran Branch, Islamic Azad University, Tehran, Iran

ABSTRACT: Today, global warming causes unpredictable climate changes and issues, such as torrential rains, that leads professionals to anticipate future needs to control sudden floods. In this regard, to reduce the impacts of these consequences, and secure residents, a perfect surface water collection system is crucial. In this paper, the application of building information modeling (BIM) in the entire life cycle of underground surface water collection canals has been reviewed. Then a new-emerged robotic innovation is presented that exploits various technologies to monitor and evaluate channel health in the presence of flammable gasses and moisture. And finally, an integration framework is presented. Based on field verifications, it has anticipated that employing this technology will provide a trustworthy platform for predictive maintenance throughout the whole life-cycle of the underground channels. Meanwhile, during the pre-construction phase, BIM and other technologies integration assist the engineering teams in striding toward the best design output.

1 INTRODUCTION

Underground utility infrastructures create a complex system that needs a comprehensive understanding and reliable tools to manage it throughout the life cycle. Any error during infrastructure engineering, construction, and operation will lead to critical consequences, which could influence urban areas (Chong *et al.*, 2016). Infrastructure management has been facilitated by exploiting recent technological advancements, such as BIM (Hijazi and Omar, 2017). For instance, BIM benefits are five times more than conventional approaches, such as employing CAD-based applications (Kumar *et al.*, 2017). Also, applying BIM to infrastructure management allows operation teams to identify the exact location of underground facilities over a shorter period (Wang *et al.*, 2019). Infrastructure BIM (I-BIM) has developed more in Asia and America compared with other regions. One of the advantages of employing I-BIM in the design stage is that it provides an intelligent model which enables designers to maintain automatic changing interoperability. In contrast, conventional CAD models require controlling the impacts of a change on other dimensions. Stakeholders would also manage and review the 3D virtual model of the built environment, and the model allows them to make-do decisions (Vignali *et al.*, 2021). An intelligent mobile robot has been invented to facilitate periodic infrastructure health monitoring, making well-grounded decisions, exploring any defect in the infrastructure, and reporting it through various technologies.

2 BIM CONTRIBUTION TO INFRASTRUCTURE

The crucial value of BIM lies in generating information iteratively and producing a persistent flow of updated information to project participants (Vignali *et al.*, 2021). To enhance the data gathering accuracy, researchers and practitioners turned to exploit automatic processes. Employing robots

allows teams to access real-time data to compensate for a lag between construction or maintenance and models (Alonso *et al.*, 2019; Lu *et al.*, 2019; Lundeen *et al.*, 2019).

BIM provides several benefits to the construction industry. BIM could improve pre-construction activities in designing, programming, estimation, and planning, and helps engineering teams to design efficiently with fewer conflicts and lower time. Also, BIM enables teams to make required redesigns and reviews employing a 3D virtual model and explore any clashes (Anumba *et al.*, 2010; Azhar, 2011; Barlish *et al.*, 2012; Latiffi *et al.*, 2013; Shou *et al.*, 2015). Meantime, it prepares cost and time estimation to enable project managers to make pragmatic decisions (Anumba *et al.*, 2010; Azhar, 2011; Latiffi *et al.*, 2013; Shou *et al.*, 2015; BorjeGhale *et al.*, 2016; Sardroud, Ghaleh, *et al.*, 2020; Sardroud, Mehranpour, *et al.*, 2020). On the other hand, the 3D model could provide not only an accurate quantity survey but also a practical schedule for anticipating and planning the resource flow throughout the construction phase (Anumba *et al.*, 2010; Latiffi *et al.*, 2013; Shou *et al.*, 2015; BorjeGhale *et al.*, 2016; Sardroud, Ghaleh, *et al.*, 2020). Before starting construction, BIM assists teams in deciding on the site usage and occupation for building, facilities, and mobilization. During the construction phase, the seamless flow of information enhances and facilitates communication between stakeholders. Due to BIM applicability for as-built construction, shop drawings will be practical with less material loss, rework, and waste. Cash flow is accurately controlled, and risks are dramatically reduced. Project managers, on the other hand, will trace material flow and could monitor the site's commutes and material flow (Anumba *et al.*, 2010; Barlish *et al.*, 2012; Bennett *et al.*, 2013; Latiffi *et al.*, 2013; Shou *et al.*, 2015; BorjeGhale *et al.*, 2016; Sardroud, Ghaleh, *et al.*, 2020). BIM could pursue any component and its life cycle to provide continuous operation. In case of crisis, operation teams could react abruptly and efficiently (Anumba *et al.*, 2010; Latiffi *et al.*, 2013; Shou *et al.*, 2015; Kameli *et al.*, 2021).

Infrastructure BIM (I-BIM) concentrates on horizontal construction to monitor and predict infrastructure construction and operation precisely (Vignali *et al.*, 2021), which is neglected in building construction. Fanning *et al.* juxtaposed two similar bridge construction projects and deduced that applying I-BIM lessens construction costs by 5 to 9% (Fanning *et al.*, 2015), but the critical aspect to consider is the level of detail defined in the model to exploit the full potential of I-BIM. (Kim *et al.*, 2014) showed in tunnels, a high level of detail is required. Considering the time and cost involved in I-BIM models, stakeholders could identify upcoming conflicts to assess the construction procedure, measure the schedule alteration impacts, observe project progression at any stage visually, and prevent teams' interference. On the other hand, any model modification will result in a real-time error-free automated bill of quantity, time, and cost update, as well as the plans and sections' automatic update (D'Amico *et al.*, 2020). Expanding the I-BIM application requires the addition of two more dimensions; 6D, for instance, represents the application of geographical information of the construction site and components, and 7D applies to facility management to associates throughout the whole infrastructure life-cycle (Samimpay and Saghatforoush, 2020). On the other hand, construction 4.0 is an integration of different emerged technologies such as the Internet of Things (IoT), Simulating (BIM), Augmented and Virtual Reality (AR/VR), Robotics and Automation, and 3D printing (Turner *et al.*, 2020) (Figure 1).

Figure 1. Construction 4.0 components.

In the proposed robotic system, to detect and locate defects accurately, several technologies are integrated with the robot (e.g., geographical information system (GIS), augmented reality (AR), and sensors.)

3 I-BIM'S LOD

For ease of assessment, a Norwegian standard project phase identification, called “Next Step,” selected in Figure 2, and the LoD (Level of Details) could have developed in each phase with the aim of the BIM efficient application proposed (Knotten *et al.*, 2016).

Figure 2. Life-cycle phases using the Next Step method.

The level of graphic details defined in a 3D BIM-based software has divided into five steps. LOD 100 is a conceptual volumetric model of the built environment used for quantity survey and cost estimation (Coates, 2013) and is usually utilized for feasibility study, pre-planning, or rough cost estimation (Latiffi *et al.*, 2015). At LOD 200, the model has mobilized with approximate geometry, including accurate values, size, shape, and position (Coates, 2013; Latiffi *et al.*, 2015). LOD 300 provides accurate geometry suitable for conventional construction drawings (Coates, 2013), which results in cost and time-precise estimation with more accurate quantity, shape, size, and location and will reflect employer requests. Also, the required performance defined by the owner could be considered in the model (Latiffi *et al.*, 2015). LOD 400 is suitable for construction and installation, which is usually related to shop drawings (Coates, 2013). And LOD 500 consists of construction as-built drawings suitable for operation and maintenance (Coates, 2013), which is the most accurate digital model of the building (Digital twin) (Latiffi *et al.*, 2015). Figure 3 presents the graphical LOD of each defined step.

Figure 3. Steps' graphical LOD.

4 ROBOTICS

The first step is examining common approaches used globally. It is necessary because operators must have up-to-date information to control and manage structures and devices, including underground and open channels. The data should then be processed, and the best strategies and methods adopted to manage it. Three approaches have generally been proposed for gathering information from any facility presented in Table 1 below.

According to Table 1, Industry 4.0 technologies contribute to imagining a machine that can enter the channel instead of personnel; and they can be controlled by an expert or programmed

Table 1. Methods of collecting data from each structure.

Methods	Description	Problems	Result
Visual inspection	An expert personally enters the site and inspects the equipment, facilities, and structure.	Lack of oxygen, the presence of flammable gases, insects and vermin, and the difficulty of carrying the device inside and other dangers for humans	Lack of adequate conditions to have enough concentration to identify and fix anomalies, and also the unsuitable situation for a human visit.
Field impression	An expert or a representative of this person enters the channel and takes photos and videos.	Same problems as visual inspection.	An unsuitable situation for a human to visit.
Automatic system	A series of surveillance cameras are placed inside the canal to monitor the canal.	Cannot be done due to environmental conditions, the number of required cameras, and high maintenance costs.	Using other 4 th generation of the industrial revolutions.

to perform the mission automatically. According to the data taken by the device, specialists can design strategies to repair and preserve the canal without going into the channel and being in this predicament. In addition, experts can use the device as often as they need and whenever they want to update information in the fastest, safest, and most efficient way possible.

This study focuses on using Industry 4.0 technologies to efficiently collect data and maintain underground water channels. The proposed method involves creating a machine that alerts the operator of maintenance needs in the canal and takes action. While drones equipped with lasers and cameras are suitable for monitoring open canals, it is difficult to use them for underground canals due to the risk of explosion from the drone's sparks. Therefore, a different device that can capture the canal path and relay information to the operator without producing sparks is necessary.

A prototype has been developed to test for defective areas within water canals while addressing safety and cost concerns. It is a scaled-down version of the life-size robot, designed to ensure safety in the presence of gas. System requirements include non-explosiveness, waterproofing, obstacle bypass, video and image capturing, remote control, maneuverability, pressure, height, and temperature measurement.

5 PROPOSED FRAMEWORK

To prevent soil and groundwater pollution caused by sewage leakage in underground storm-water canals, detecting defects early is crucial. A proposed integration framework between BIM and a newly invented robot, as shown in Figure 4, enables the exchange of information for a deeper understanding and necessary actions. The framework supports technology integration throughout the canal's life cycle. In the pre-construction phase, engineering teams create a detailed 3D virtual model using BIM software like AutoCAD 3D.

Then they could upload layouts, plans, and cross sections into I-BIM for a comprehensive 3D smart model with automatic updating capability. Adding cost and time features allows teams to employ a 5D I-BIM; enables stakeholders to make any desired changes and explore its effects on the final deliverables and related time and cost. Therefore, making do-decisions will be facilitated during engineering.

GIS technology applied to I-BIM allows for real-time tracking of resources during construction, controlling conflicts and interference. A robot using 7D I-BIM measures construction quality and reports errors with location and images. 7D I-BIM also supports sustainable maintenance through periodic inspections. Integrated with the 3D model, GIS identifies locations, and IoT assesses defect characteristics, while AR aids decision-making with a realistic defect representation.

Figure 4. Proposed BIM-Robotics framework.

6 FINDINGS AND DISCUSSION

The research identified the need for canal harvesting devices in buried canals. The first phase gathered information on management methods and device requirements, including the need for non-sparking, non-explosive devices in the presence of combustible gases and waterproofing due to moisture in the canals.

For monitoring buried water canals, the device needs to be waterproof, spark-free, and obstacle-friendly, with video recording and remote control. It should move on a 20-degree incline, monitor pressure, height, and temperature, detect anomalies, and alert the operator.

The aim was to use point cloud scanners to measure a tunnel's dimensions and compare them to a 3D model to detect any inconsistencies. However, since the scanners were costly and not readily available, alternative solutions were explored. The necessary equipment was obtained by researching available tools. The robot's controller was programmed using Python software, allowing for remote operation and monitoring via a mobile phone's web browser. The robot's internal components were identified and connected before being modeled in Solid software and 3D printed. Figure 5 illustrates a sample modeled in Solid software, and Figure 6 depicts the robot's final appearance.

To test the robot's functionality, a prototype duct was created using Sketch-Up software and five 20 cm diameter tubes, and four 45- and 90-degree elbows. Artificial anomalies were added to the floor and ceiling using sand, stone, and wood to challenge the robot. The results showed that the robot was able to move effectively through the obstacles and identify anomalies, demonstrating acceptable performance.

This study employed Industry 4.0 technologies for continuous monitoring and control of water channels, which can improve their maintenance. The robot developed in the study was tested and found to be able to easily navigate obstacles in gas and moisture-filled environments and detect anomalies using sensors and cameras. The study concludes that the use of Industry 4.0 technologies in water channel maintenance can help prevent sediment accumulation and disturbances, which can cause blockages and failures in the channel. By detecting and addressing these issues early, the costs and damages associated with flooding and other dangers can be minimized. The robots developed can also be used to efficiently create as-built drawings of the channels. Overall, the study suggests that Industry 4.0 technologies can improve the speed and efficiency of information retrieval compared to traditional methods.

Figure 5. The modeled robot in solid software.

Figure 6. Final view.

A proposed framework is intended to guide the robot's application through the pre-, post-, and construction stages and facilitate communication and information exchange among stakeholders throughout the life cycle of an underground infrastructure. The integration of innovative robots, automation, and other technologies could ensure the continuous real-time monitoring of canals, which is crucial for public safety. The framework aims to create a reliable information platform for teams to explore the current state of the built environment and to provide accurate time and cost estimates during the engineering phase. During construction, the framework allows teams to control construction quality, detect defects in real-time, and inform construction teams for corrections and repairs. Additionally, the technology could accelerate the as-built drawing process. During maintenance, the study assists operators in finding defects in the canal, their location, and characteristics, and transferring the information to an I-BIM-based virtual model.

7 CONCLUSIONS

This research proposed a robot to monitor and maintain buried canals. The robot provides online real-time about the current state of canals, including any structural defect through measuring defects and obstruction on the channels by measuring any change in diameter. Hopefully, through its performance, during operation, teams can detect any defect in the early stages of happening and take preventive action to predict future problems, such as blocking the canal due to sediments or disruption of operation due to destruction or leakage. Also, toward nD I-BIM, a framework is proposed to work closely with the robot. The framework aims to create a seamless flow of information and a reliable platform to notify maintenance teams to take any required action to avoid crucial problems. Meantime, it could provide reliable reports through augmented reality in a 3D virtual environment that can show the exact location and dimension of the damage.

Although this research concentrated on the operation phase, it could be extended into the engineering and construction phases, when teams could exploit its advantages. The proposed hardware can monitor and measure quality during construction. AR feature will transfer a high-resolution picture of the defect and any error with the exact location, characteristics, and an augmented defect image. And before construction, teams could fully understand the project deliverables by creating a realistic model with a walking-through ability. Overall, it is expected that the proposed technology aims projects teams toward the following achievements:

- Exporting a reliable time and cost estimation and scheduling ability
- Quality control measures during construction
- Construction progression control
- As-built drawing
- Defect detection
- Maintenance monitoring
- Environmental issues management

To perform this research, due to restrictions, researchers could not provide the required technologies for Big Data. Therefore, the authors suggest developing the proposed robot by using Big Data to collect cloud point data for analysis.

Life-cycle cost analysis of possible solutions for converting existing single-family house into nZEB

C. Marincu & D. Dan

Department of Civil Engineering and Building Services, Politehnica University Timisoara, Timisoara, Romania

ABSTRACT: The obligation of the nZEB building standard has become a certainty of almost two years for all new buildings in Romania. This is even more relevant in the current context of the energy price crisis, as more and more building owners become aware of the importance of energy efficiency and the use of renewable energy systems. Thus, in this paper possible solutions for converting an existing single-family building into a nearly zero-energy building are analyzed and presented. The building has been designed and executed in such a way as to have an energy performance above the minimum required according to the technical regulations in force at the time of design. The current energy performance of the building has been evaluated both theoretically using a dedicated calculation program and based on energy bills for one year period. Based on the current energy performance, a series of solutions have been proposed to increase the energy performance up to the nZEB level. Analyses in terms of energy consumption and life-cycle cost were performed to identify the cost optimal solution that leads to the nZEB upgrade.

1 INTRODUCTION

1.1 *General information*

The building sector, due to its major share in total energy consumption and CO₂ emissions at a global level, plays a key role in the long-term strategy of greenhouse gasses reduction assumed by the European Union (EU). Improving energy efficiency in buildings represents a mandatory action towards the carbon-neutrality goal by 2050 (European Commission, 2019). A major step in improving the energy performance of buildings in the EU was the adoption of Directive 2002/91/EC (The European Parliament, Directive 2002/91/EC, 2002) which introduced energy certification of buildings, minimum energy requirements for new buildings and the promotion of energy renovation of existing ones. In the interest of clarity, the EPBD was recast in 2010 (The European Parliament, Directive 2010/31/EU, 2010), with the main purpose of strengthening the energy performance improvement of buildings in the EU. The latter introduced the nearly zero-energy building (nZEB) concept as the mandatory standard of energy performance for new public and private buildings after 2018 and 2020. In Romania, up until recently, the investment in energy conservation measures have been seen as a burden for most building owners and investors, due to the higher initial costs. However, in the context of significant increase and instability of energy prices, ways of reducing the energy consumption costs of buildings in the operational phase has become a common preoccupation amongst building owners/users and investors. Thus, the life-cycle costs approach has become more and more relevant rather than choosing options with lowest initial investments. This is a tendency that is not limited to the new buildings or in the case of major rehabilitation interventions, becoming interesting also for buildings that are relatively new, built in the past 10 years, when the nZEB standard was not yet mandatory. This paper explores the possibilities of increasing the energy performance of a typical Romanian single-family house up to the NZEB standard. These possibilities are analyzed in terms of both energy use and life-cycle cost.

1.2 Nearly zero-energy building definition in Romania and reference values for residential

As of 2021, all new buildings must be nZEB, in Romania as well as in all the Member States of the EU. EPBD recast does not give a uniform approach for implementing nZEBs, allowing the Member States to develop definitions that reflect the national, regional, or local conditions, including a numerical indicator of primary energy use expressed in kWh/m² per year (The European Parliament, Directive 2010/31/EU, 2010). In Romania, nZEB is defined as a building with a very high energy performance, where the energy requirement to ensure the comfort conditions and energy performance is almost equal to zero or is very low and is covered in proportion of at least 30% with energy from renewable sources, including energy from renewable sources produced on site or nearby, within a radius of 30 km from the GPS coordinates of the building (Romanian Law No. 372/2006, republished). If the renewable energy share has a fixed value, independently on the building category and climatic zone, the level of energy performance that must be achieved in Romanian nZEB's is given through maximum admissible specific total primary energy consumption and CO₂ equivalent emissions, differentiated on building category and climate zone, presented in Table 1 (Mc001, 2022).

Table 1. Maximum values of total primary energy consumption and of equivalent CO₂ emissions for NZEB single-family buildings.

Climatic zone	Specific total primary energy [kWh/m ² ,year]	CO ₂ equivalent emissions [kg/m ² ,year]
I	120,1	14,7
II	127,9	16,0
III	133,3	17,1
IV	140,6	18,5
V	147,9	19,9

2 METHODOLOGY

2.1 nZEB characterization: Primary energy, CO₂ emissions and renewable energy share

The methodology applied in the present paper includes energy and life-cycle cost assessment of a relatively new building for which energy performance solutions are proposed to reduce the energy related costs of the building and to achieve the nZEB standard as it is defined in Romania. In order to compare the energies from different energy vectors, it is necessary to convert the final energy consumed into primary energy. Primary energy can be renewable primary energy and non-renewable primary energy. The total primary energy of a building includes both. As explained in the previous chapter, in Romania, one of the indicators for nZEB is the amount of specific total primary energy, which includes typical uses of the building for heating, domestic hot water, cooling, ventilation, lighting and auxiliary energy (measured in kWh/year or kWh/m².year in the case of specific primary energy). More precisely, the energy performance will be quantified in terms of specific total primary energy consumption, CO₂ emissions and renewable energy share as these are the main indicators in defining nZEB's in Romania. The conversion of final energy of a building to primary energy is made by means of primary energy factors, which indicate the amount of primary energy used to provide a unit of end use energy. These conversion factors are usually different for each country in the EU, reflecting national particularities. For the transformation of the final energy into primary energy, the conversion factors proposed by the Romanian Methodology for calculating the energy performance of buildings (Mc001, 2022) were used. The formula for primary energy calculation is presented in Equation 1 below:

$$E_P = \sum_i (Q_{f,x,i} \cdot f_{Ptot,i}) - \sum_i (Q_{ex,i} \cdot f_{Ptot,ex,i}) [kWh/year] \quad (1)$$

where $Q_{f,i}$ = final energy consumption of type i, in kWh/year; $f_{P_{tot},i}$ = primary energy conversion factor for energy type i, values given at national level, presented in Table 2; $Q_{ex,i}$ = final energy of type i, produced at the building level and exported, in kWh/year; $f_{P_{tot},ex,i}$ = primary energy conversion factor for energy type i, produced at the building level and exported, values given at national level, presented in Table 2.

The specific primary energy is obtained by dividing the total primary energy consumption to the useful floor area.

Table 2. Primary energy and CO₂ equivalent emissions conversion factors to be used in Romania.

Energy source	Primary energy conversion factor			CO ₂ emissions conversion factors
	Non-renewable $f_{P_{ren}}$	Renewable $f_{P_{ren}}$	Total $f_{P_{tot}}$	
Natural gas	1,17	0,00	0,00	0,202
Thermal energy produced with solar panels	0,00	1,00	1,00	0,000
Environmental thermal energy	0,00	1,00	1,00	0,000
Electrical energy from the national grid	2,00	0,50	2,50	0,107
Electrical energy produced on-site or nearby and consumed directly by the building	0,00	1,00	1,00	0,00
Electrical energy produced on-site or nearby and exported to the national grid	2,00	0,50	2,50	0,202

The renewable energy share is to be determined as the ratio between renewable primary energy consumed by the building based on total primary energy consumption. The calculation of CO₂ emissions is carried out considering the conversion coefficients in Table 2 (Mc001, 2022).

2.2 Life cycle cost analysis

The life cycle cost analysis is based on the global cost calculation procedure in the European Standard 15459-1 (EN 15459-1, 2017). The global cost calculation includes the following types of costs, described as well in Equation 2: initial investment, sum of annual costs, residual value and disposal costs (if the case). The calculation can also be extended by adding the cost value for CO₂ emissions in the sense of the monetary quantification of the damage caused to the environment by CO₂ emissions released into the atmosphere. The different types of costs (initial investment costs, replacement costs, annual costs, and energy costs), as well as the final (residual) value are converted into present value global cost applying the appropriate discount factor.

$$CG = CO_{INIT} + \sum_j \left[\sum_{i=1}^{TC} (CO_{a(i)}(j)) * (1 + RAT_{xx(i)}(j)) + CO_{CO2(i)}(j) * D_{f(i)} + CO_{fm(TLS)}(j) \right] - VAL_{fm(TC)}(j) \quad (2)$$

where CG = global cost; CO_{INIT} = initial investment cost; $CO_{a(i)}(j)$ = annual costs in year i for component or service j; $RAT_{xx(i)}(j)$ = price increase rate in year i for component or service j; $CO_{CO2(i)}(j)$ = Cost for CO₂ emissions in year i for component or service j; $CO_{fm(TLS)}(j)$ = disposal costs; $VAL_{fm(TC)}(j)$ = residual value for component j.

3 CASE STUDY

3.1 Selected building description

The building chosen as the case study is a typical single-family house, located in Timisoara and built in 2017. The building has been designed and executed in such a way as to have an energy

performance above the minimum required according to the technical regulations in force at the time of design. Even though the building was constructed before the mandatory nZEB regulation was in force, the owner decided to use a higher level of thermal insulation than the minimum necessary for closing elements and highly energy performant windows (triple glazing windows). The architectural and geometrical description of the building can be seen in Figure 1.

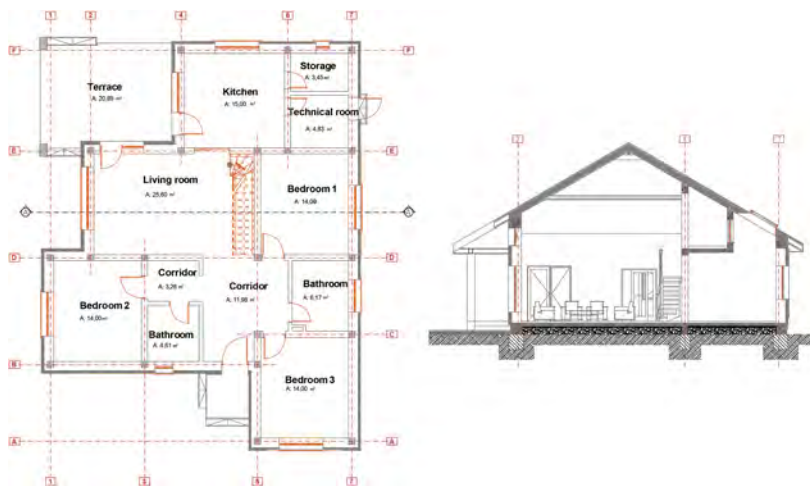

Figure 1. Architectural description of the case study building.

The height capacity of the building includes the ground floor where the main spaces of the house are and an attic which contains a guest's room, an office, and a bathroom. The total heated floor area is approximately 204,16 m², while the interior heated volume is about 584,14 m³. The building hosts a family of 4 persons. The building has a typical structural system for new single-family houses in Romania, consisting in confined masonry walls with reinforced concrete small columns and belts. The floor is made of reinforced concrete, while the pitched roof is made of wood covered with tiles. The foundation system is made of continuous reinforced concrete foundations under the structural walls. The external walls of the house are realized with masonry made clay bricks with hollows (380 mm) and thermal insulation of stone wool (150 mm). The ground floor is thermally insulated with extruded polystyrene (100 mm) placed under the reinforced concrete plate. The sloped roof (slope angle 30°C) is insulated with two layers, one of stone wool (200 mm) and one of mineral wool with aluminum vapor barrier (100 mm). The windows are triple glazing with low-E coating and PVC frame. The heating system of the building is composed by a radiant floor supplemented by radiators installed only in bathrooms. The heating radiant floor and the steel sheet radiators are supplied with heat agent (water) produced by the gas heating system located in the technical room. The domestic hot water is produced by the same gas heating system through a thermal boiler installed in the technical room. The domestic hot water production circuit is auto connected with priority to the hot water produced for heating. Cooling is only provided locally in the living room and bedroom 2 using a common air-conditioning unit and the building occupants claim this is enough to ensure comfortable indoor environment during the summer. The artificial lighting is made using LED lighting fixtures. The quality of indoor air is maintained through controlled natural ventilation (windows opening twice a day).

3.2 Energy assessment

The energy consumption of the existing buildings was firstly assessed using the electricity and natural gas invoices for a one-year period. In Table 3 are presented the total annual values for energy consumption for each type of energy carrier.

Table 3. Energy consumption of the building derived from one year period of energy invoices.

Energy source	Total annual energy consumption [kWh]	Total specific annual energy consumption [kWh/m ² .year]
Natural Gas (heating and DHW)	21524,14	105,43
Electricity (lighting, cooling, household appliances)	2860,36	14,01

Since the electricity and natural gas consumption retrieved from the invoices is not divided separately into consumption categories (heating, domestic hot water, cooling, lighting), the decision was taken to perform as well an energy consumption calculation following the monthly method described by the Romanian Methodology for Calculation the Energy Performance of Buildings (ref). A simplified calculation model was developed based on the input data summarized in Table 4. The energy consumption calculations are further presented in Table 5. It can be observed a relatively small difference between the calculated values and the ones derived from energy invoices.

Table 4. Input data related to building envelope and ventilation.

Characteristic	Description
Useful floor area	240,16 m ²
Thermal transfer characteristics	Element
	U-value [W/(m ² K)]
	Area [m ²]
	exterior walls
	0,218

	0,800
	33
Condensing gas boiler (for heating and domestic hot water)	useful power 8.4 – 24.6kW, efficiency 91.5%,
Natural ventilation air change rate n _a	0,5 h ⁻¹
Artificial lighting	LED lighting fixtures
	Total installed power 503,5 W
Interior temperature during the heating season	Actual temperature preferred by the users 23° C
Climate data	Building located in climatic zone II of Romania. Values provided in national regulations were used.

Table 5. Calculated energy consumption of the case study building.

Energy source	Heating [kWh]	Cooling [kWh]	DHW [kWh]	Lighting [kWh]	Specific total energy consumption [kWh/m ² .year]
Natural Gas	15981,90	0,00	6465,75	0,00	109,95
Electricity	0,00	775,5	0,00	1876,23	12,99

3.3 Solutions to increase energy performance

In the existing configuration, the building does not have any renewable energy system that could cover the energy demand of the building. To comply with the nZEB criteria as it is defined in Romania, several solutions for increasing the energy performance of the building were investigated. The focus was on solutions that could be easily implemented in the existing building without any major construction works. Thus, the proposed solutions consist in photovoltaic panels systems of different capacities for on-site electricity production and solar collectors for domestic hot water and are briefly presented in Table 6. The proposed number

of PV panels and solar collectors consider the available surface on the pitched roof on each orientation. The total primary energy is calculated using the formula presented in the methodology chapter, considering all the energy flows of the building, including solar thermal, electricity from photovoltaic panels, but also the excess energy that is delivered to the grid. The same principle is applied for calculating the CO₂ equivalent emissions. The renewable energy share is determined based on total primary energy consumption. The estimated energy performance indicators are listed in Table 7 and plotted in the graph in Figure 2 for each of the investigated scenarios.

Table 6. Description of energy efficiency solutions.

Individual solutions	Description	Estimated annual electrical energy production [kWh]	Estimated annual thermal energy production [kWh]
S1	8 kW on grid PV system 20 monocrystalline PV panels integrated on the roof (angle 30°C, East)	7737	0,00
S2	6.4 kW on grid PV system 16 monocrystalline PV panels integrated on the roof (angle 30°C, West)	6159	0,00
S3	3.2 kW on grid PV system 8 monocrystalline PV panels integrated on the roof (angle 30°C, South)	3800	0,00
S4	Solar collectors system for DHW 3 flat plane solar collectors integrated on the roof (angle 30°C, South)	0,00	3078
Packages of solutions			
P1	S1+S4	7737	3078
P2	S2+S4	6159	3078

Table 7. Estimated energy performance indicators for the investigated scenarios.

Case scenario	Total specific primary energy consumption [kWh/(m ² year)]	Renewable energy share [%]	Specific CO ₂ equivalent emissions [kgCO ₂ /(m ² year)]
Existing building (EB)	161,1	4%	29,46
S1	79,4	16%	19,32
S2	98,6	13%	21,39
S3	127,4	10%	24,47
S4	158,4	14%	25,63
P1	76,6	38%	15,49
P2	95,9	30%	17,56

Figure 2. Energy performance indicators for the investigated scenarios.

3.4 Life cycle cost analysis and payback period

The global cost calculations were performed for a period of analysis of 30 years and using a discount rate of 3%. The initial investment includes only the costs related to the proposed energy efficiency scenarios were considered. The annual maintenance costs were established as percentages of the initial investment of each component that requires maintenance (EN 15459-1, 2017). Considering the information available on the National Authority for Regulations in Energy field (2022), the price of natural gas was set to 0,061 €/kWh (including acquisition, transport, distribution, taxes and VAT) and an average price of electricity of 0,371 €/kWh was used, including taxes and VAT. The electricity exported to the grid was accounted with a price of 0,122 €/kWh. The payback assumed to be achieved in the year in which the discounted global cost of a scenario becomes less than the discounted global cost of the existing building. The global cost calculation results are presented in Table 8. As it can be noticed, the highest global cost is achieved by the existing building scenario followed by S4 which includes the implementation of 3 flat plane solar collectors integrated on the roof of building. The lowest global cost is achieved in case of scenario P1, which includes 20 monocrystalline PV panels integrated on the roof (angle 30°C, orientation East) and 3 flat plane solar collectors integrated on the roof of building. The payback period has similar values for scenarios S1, S2, S3, P1 and P2 and a significantly higher value for scenario S4.

Table 8. Global cost calculation results and payback period.

Scenario	Initial investment [€]	Global cost [€]	Payback period [years]
EB	0	72.921,86	0
S1	9800	42.414,40	5
S2	7800	44.045,92	4
S3	5500	47.963,33	4
S4	3000	72.145,51	16
P1	12800	41.638,05	6
P2	10800	43.269,56	5

3.5 Results and discussions

The graph in Figure 3 shows the investigated scenarios in terms of specific total primary energy consumption and specific global cost. The specific global cost and specific primary energy consumption have very close values for scenario P1 compared to S1 and for scenario P2 compared to S2. The least effective scenario is S4, which leads to a specific global cost and primary energy consumption very close to the one of the existing building. Moreover, this scenario does not comply with any of the energy performance indicators for single-family NZEB's in Romania.

Figure 3. Specific global cost and total primary energy consumption graph.

The degree of compliance with the nZEB criteria is presented in Table 9 for all the investigated scenarios. As it can be noticed, scenario P1 complies with all the 3 criteria.

The most difficult criteria to achieve is the one related to the CO₂ emissions limitation and the one related to the renewable energy share. The specific primary energy consumption criteria was

Table 9. nZEB criteria verification.

Case scenario	Criteria 1 – renewable energy share	Criteria 2 – specific total primary energy consumption	Criteria 3 – specific CO ₂ equivalent emissions
EB	✗	✗	✗
S1	✗	✓	✗
S2	✗	✓	✗
S3	✗	✓	✗
S4	✗	✗	✗
P1	✓	✓	✓
P2	✓	✓	✗

achieved for all scenarios except S4. However, it is worth mentioning that the low values of primary energy consumption are largely due to the quantification of the electrical energy produced in excess and delivered to the grid by subtracting it from the total value of primary energy.

4 CONCLUSIONS

This paper explored the possibilities of increasing the energy performance of a typical Romanian single-family house up to the nZEB standard. The proposed solutions considered the options that can be implemented easily, without causing discomfort to the occupants or additional works inside the building. Several scenarios were analyzed in terms of both energy use and life-cycle cost. Among the investigated scenarios, the one including 20 monocrystalline PV panels integrated on the roof (angle 30°C, orientation East) and 3 flat plane solar collectors led to compliance with all the criteria of the nZEB building as defined by the technical regulations in Romania. Moreover, the same scenario proved to be cost optimal as well because it leads to the lowest global cost on the considered period of analysis. The payback period this scenario is of approximately 6 years, compared to the existing building. The results of this study emphasize the fact that in a single-family house where that major consumption comes from natural gas, to achieve the nZEB standard, it is not enough to just implement a system of PV but also a solution that reduces the natural gas energy consumption.

End-of-life rule checking for transport infrastructure: The case of navigation locks

K.E. Bektas & I.E. Ozer
TNO, Delft, The Netherlands

ABSTRACT: Determining the end-of-life of infrastructures is an important decision in the Netherlands, where the large stock of assets currently reaches their design life. The Dutch Road Authority has set up a research program to address this on a national level. Currently, there are various documents describing the rules of aging. Yet information specifications are not defined. This forces the experts to focus on technical aging only and consider structures that are aged/too expensive to maintain in later stages. Since the scoping and budget assignment is based on the earlier prognosis, the process becomes suboptimal. There is a need for a holistic approach to identify ageing rules for the assessment of different object types. This paper presents an information model for navigation locks as a first step of such approach. It declares information needed to check rules automatically via case studies and proposes utilization of a technology as a future step.

1 INTRODUCTION

Public asset managers, particularly in the infrastructure domain, are challenged with renewing the large number of infrastructure due to physical ageing. Only in the Netherlands, there are 85,000 bridges and viaducts, 83,000 culverts, 2,400 km of quays and 7,800 pumping stations (Bleijenberg, 2021). A substantial amount of structures will reach the end of their service life in the coming decades given their design life time of 80 to 100 years (Klanker et al, 2016). For resources to be allocated on time, a long term prognosis of future renovation and replacement needs is required. In this context, the Dutch Road Authority (RWS) has set up a research program called Replacement and Renovation (V&R) to address the aging of infrastructures on a national and portfolio level. The first step of this program refers to an intake decision, where the ‘candidates’ are selected based on their end of service life and the budget prognosis is determined. This selection is important, since the objects in V&R are financed nationally and not by regular maintenance budgets of the regions at RWS. There are various documents established by different public entities for the selection process. They describe theoretic conditions categorized under technical, functional, and economic end-of-life (e.g. I&M (2013), VONK (2012)). There are also studies performed by RWS where the aging of structures is approached from a life cycle perspective and a metric (Economic End of Life Indicator -ELI) is established by Bakker et al (2016).

Currently, there are fundamental challenges in analyzing objects on portfolio level. Between various organizations, differences are observed in how they identify the theoretic end of life rules that are used as a eligibility to the V&R Program. Although these rules are explicitly defined and categorized as the technical, functional, and economic end-of-life in official documents, the rules are high-level, human-interpreted, do overlap and reside in various forms of documentation. Information specifications per rule are not always well defined and interrelations of shared issues are not set yet. This forces the experts to focus solely on technical ageing that they are the most familiar and exclude the other rules while assessing the end-of-life of an object. Another challenge is the large amount of available data that are collected by RWS and

also by the regional asset managers. The data from these two sources does not always match, has complex structures and takes cumbersome effort for the V&R expert to obtain a relevant dataset. This is challenging to do per object type and even more difficult to do on a large number of objects. In relation with the two challenges above, a categorization of objects is often done based on common issues and extrapolations: Objects that are prone to similar technical problems are grouped in relation with their theoretic life time and included in the intake. This was done based on characteristics rather than actual condition data of the objects.

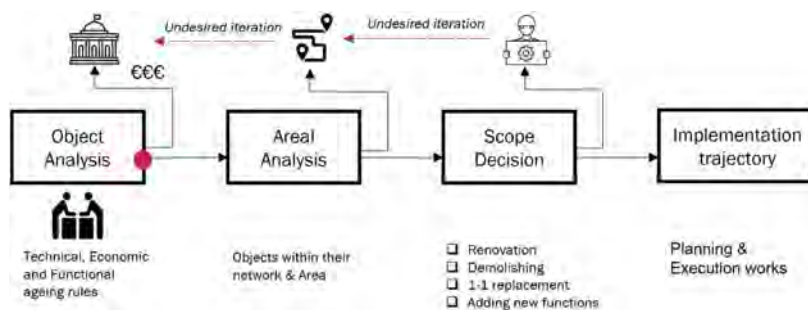

Figure 1. The V&R process and the intake decision moment as Step 1 (Bektas, 2021).

Considering this situation, the ultimate aim of this research is to develop an integral end-of-life model as an automated rule checking system that supports the V&R experts with more objective and accurate analysis leading to improved scope definition. This research proposes to (1) objectify aging rules under functional, economic and technical ageing, (2) specify information and data use per object type and (3) enable automatic checking of those rules which can optimize the intake decision making. This would lead to a more accurate scope and budget definitions and ease communications between involved parties.

Automated rule checking has been identified as a potential to provide significant value to the AEC (Architecture, Engineering and Construction) industry from both regulatory and industry perspectives. It is used to translate rules based on human language to computer interpretable rules, so that the object's compliance against the rules can be determined (e.g. building regulations compliance, safety regulation compliances). In this field, the key scholars are Eastman et al (2009), Solihin (2015), Solihin & Eastman (2015), Pauwels et al (2011); Pauwels et al (2017); Pauwels & Zhang (2015), Nawari (2012), Song et al (2018); Song et al (2020). The four stages of Eastman et al (2009) are: 1) Rule interpretation, 2) Model preparation, 3) Rule execution, 4) Rule reporting and visualization. This approach has been widely used in the building design domain particularly for objectifying human-language rules as building regulations, quality assurances and mostly on BIM (Building Information Model) data. Yet there is little evidences on the use of this approach for infrastructure domain, particularly on the aging of structures. Through such an approach, available technical information that is scattered across design documentation, inspections and planning are acquired, interpreted, and translated to the end-user. In that way, scattered data aims to be translated to decision information. This can provide a great insight into the identification of issues for the portfolio level of objects in an faster and explainable way.

In this paper, the focus is given on navigation locks and a multi-case study method is used. Four cases were selected as examples of navigation locks in the Netherlands, namely the complexes of Delden, Hengelo, Eefde and Volkerak. In Section 2, critical design characteristics that can have an influence on defining the end-of-life of these locks are listed. Later, the changed conditions over time (i.e. common issues) are identified and discussed under different aging categories. The ultimate result from the case studies become the main component of an automated rule checking system: Information Model for Locks that is presented in Section 3. This corresponds to the Stage 1 of Eastman et al (2009). Based on this, a proposed approach is selected for model preparation (Stage 2 of Eastman et al (2009)). This information model can be seen as

a kernel of the programming activities that will be conducted in the future to build the final rule checking engine that is explained in Section 4. Conclusions are given in Section 5.

2 CASE STUDY: END-OF-LIFE RULES FOR NAVIGATION LOCKS

2.1 *General information on the navigation locks*

The main purpose of a navigation lock is to overcome the water level differences between two water stretches for shipping, while maintaining the difference in water level. They are also used for water management purposes, e.g. to discharge a predefined amount of water within a certain period of time. A lock consists of a lock chamber, closed by different types of closing elements (e.g. gates) which are located in the lock heads. Below and adjacent to the structure, cut-off walls are usually used to prevent seepage and/or piping. Raising or lowering the water level in the chamber can be achieved by letting in/out the water through the gates or a by-pass pipe. Considering the operational aspects of a lock for shipping purposes, three main design requirements are defined. Firstly, lock dimensions must be sufficient enough to allow the normative ships to pass in the considered waterway. Secondly, the lock capacity (i.e. number of ships passing within a certain time interval) must be sufficient considering the present and future requirements (e.g. traffic intensity). Lastly, the time losses during a passage must be kept at a minimum (Molenaar & Voorendt, 2020).

In order to define the end-of-life aging rules, four navigation locks are analyzed, namely the complexes of Delden, Hengelo, Eefde and Volkerak. They are part of the main water network. A rich set of data is collected from inspection reports, FMECA analysis, 6-yearly inspection data, planning and measurement data as well as integral reports. The integral reports of the four locks, such as Arcadis (2012a; 2012b; 2014a; 2014b), become governing documents to identify potential V&R issues under aging rules. In the following sections, the critical design characteristics that can have an influence on defining the end-of-life are identified and also changed conditions over time are listed in Table 1. The differences and categorization became a conversation starter with the asset manager who decides whether large interventions are required and thus the objects become eligible to enter to the V&R Program of the RWS.

2.1.1 *Case Delden*

The Delden complex consists of a lock (1933), a pumping station, a fixed bridge over the lower head, several buildings, an emergency power plant and a channel leading to the pumping station. Due to the increase in shipping, ship sizes have reached its maximum value for this lock (CEMT class IV and limited Va) which minimizes the space between ships and chamber walls and the gate. This causes a higher risk of collision damage. The scaling up of the shipping class also means that there is an increase in engine power and the development of concentrated propeller jets creates a higher load on the bottom protection. This leads to damage on the bottom protection in the chamber and around the lock. Due to climate change, large flows have to be discharged more often. The composition of shiploads has changed significantly since construction, with an increase in the number of ships with dangerous cargo. This has possible consequences for safety on the lock itself, but also on the external environment safety around the complex.

2.1.2 *Case Hengelo*

The complex Hengelo also consists of a lock (1936), a pumping station, a fixed bridge over the lower head, a railway bridge and a channel leading to the pumping station. Similar to Delden complex, there is a higher risk of collision damage due to increase in shipping class. The consequences of a collision is expected to be greater due to the increased ship size. Large flows have to be discharged more often. Damage on the bottom protection in the chamber and around the lock is expected due to the increase in engine power which creates concentrated propeller jets.

2.1.3 *Case Eefde*

The complex Eefde consists of a lock (1933), a front lock (1952), pumping stations, drainage systems and various waiting locations and berths. Increase in ship size and engine power is

also a common issue for this lock. Due to heavier and larger ships, there is a restriction with regard to vertical clearance of the lifting doors. Changed safety factors for the loads and materials are more unfavorable than was considered during the design. As a result of the increased capacity of the drainage systems and pumping stations, greater flow velocities occur which affects the safety of shipping traffic. Due to heavier loads and modified standards, the assessment of fatigue is less favorable than at the time of design.

2.1.4 Case Volkerak

The Volkerak complex is the busiest and largest inland navigation lock complex in Europe. It consists of three adjacent locks (Locks 1 to 3) for commercial vessels and a yacht lock for recreational vessels. There are two bascule bridges across Lock 1, which allow an unlimited vertical clearance. Increase in ship size and engine power is also a common issue for this lock. Studies are currently being conducted to speed up the shedding process by increasing the lifting speed of the leveling gates. This can cause greater loads on the ships in the chamber and on the bottom protections. Arcadis (2014b) concludes that the loads on the ships are already too high and that the lifting speed must be reduced rather than increased. In the recent years, the number of ships has increased sharply. Despite the expansion of the third chamber ten years after the construction, it is expected that a fourth chamber is needed to keep waiting times within the accepted value.

Table 1. Critical characteristics of the complexes of Delden, Hengelo, Eefde and Volkerak.

Characteristics	Delden	Hengelo	Eefde	Volkerak (Lock 1)
Dimensions	Passage height: 6.20 m	Passage height: 5.30 m	Passage height: 6m	Passage height: unlimited
	Chamber length: 128 m	Chamber length: 119.7 m	Chamber length: 140 m	Chamber length: 308.9 m
	Chamber width: 12 m	Chamber width: 12 m	Chamber width: 12 m	Chamber width: 24.1 m
CEMT class	Suitable for class IV & limited suitable for class Va	Suitable for class IV & limited suitable for class Va	Suitable for class Va with draft limitation of 2.80 m	Suitable for class VIb
Built year	1933	1936	1933	1957-1977
National monument	Yes	Yes	Yes	No
Diff. in water level	6 m	9 m	6 m	
Function of the canal	Main waterway (Vw2)	Main waterway (Vw2)	Main waterway (Vw2)	Main waterway (Vw2)
Material of the chamber walls	Steel sheet piles	Concrete	Concrete	
Max discharge capacity	34.5 m ³ /s	-	100 m ³ /s	
Type of the gates/doors	Lifting gates	Upper head: lifting gates Lower head: two roller gates with lev- elling slides	Lifting gates	Electro- mechanically driven steel pointed gates
Vertical clearance	Limited	Limited	Limited	Unlimited
A flood defense?	No	No		
No. of ship per year	8400	1400	5650	
Average lock time	30 mins	30 mins	> 30 mins	

2.2 Identifying the aging rules

In order to define the object-specific aging rules, a database is constructed which includes the important key parameters of the locks that are investigated above. As a next step, a list of issues related to locks are analyzed to check whether there is a major problem regarding their structural safety or function. If the issues that cannot be solved by a regular maintenance and require a large intervention, they are then identified as a potential V&R issue. Later, the object-specific aging rules for locks are developed based on the theoretical aging rules that are found in the literature. These identified issues are then linked to the specific aging types by considering the rules that are given in Table 3. Lastly, the findings are enriched by inspection reports, external data and interviews with V&R experts. Some examples are given in Table 2.

One of the identified technical aging issue for a lock chamber is the corrosion of the sheet piles. If the chambers are made of steel sheet piles, major corrosion can lead to a thickness reduction of the walls. In this case, the stability and strength of the walls may not be ensured. Therefore, this issue is indicated as a technical end-of-life for a lock chamber wall. Another example of a technical aging issue is the critical components of the lock, such as gates, being obsolete. In this case, the lock cannot function properly until the related parts are changed. Since in this case the replacement is not possible, the gates reaches their technical end-of-life. Another common issue that is observed in all case studies is the CEMT classes being no longer suitable due to the increased ship size and relatively low gate heights (i.e. limited vertical clearance). This is an accurate example of the lock being reached to its functional end-of-life. When these issues are checked with the theoretical aging rules, they define more specific starting point of departures for V&R experts to analyze aging conditions for navigation locks. Table 3 presents this synthesis.

3 INFORMATION MODEL FOR NAVIGATION LOCKS

The information model synthesizes and declares all the parameters that are necessary to compute and check ageing rules. The scope of this information model is the rules defined in Table 1. Table 2 illustrates the main concepts modelled for navigation locks and end of life rules. The model has four realms. The first realm is *Network and Corridor Information*. Here the data concerning functional requirements number of ships passing, useful shipping dimensions, waiting time, width/length/depth of canal, maximum allowed ship classes as well as asset management district can be exemplified. The second realm is *Physical Decomposition Information*. The data here deals with specific objects forming the lock complexes, peak water discharge capacity, water level differences, lifting speed, chamber details, gate types and dimensions, network details and material of components. The decomposition is arranged based on the NEN 2667-4 standard. The third realm is *Condition of Navigation Locks*. Any red flags as aging rules use this information linked to the physical decomposition. It contains degradation mechanisms, damage assignment. The main source of the data is inspection results here. The fourth realm is *Risks and Measures for Navigation Locks*. The risk associated to the condition findings and planned measures are detailed here. Thus the information model contains data concerning functional requirements, decomposition, technical condition and cost of maintenance. It then becomes possible to use relevant data for selected functional, technical and economic ageing rules.

4 FOLLOW-UP TOOLING

The ultimate result of the case studies become the main component of an automated rule checking system: Information Model for Locks. This corresponds to the Stage 1 of Eastman (2009). Based on that a proposed approach is selected for model preparation (Stage 2 of Eastman (2009)). The information model is a kernel of the programming activities conducted in future to build the rule checking engine (to be presented in future as Stage 3 and 4). There are different approaches to build a rule checking model such as procedural or declarative programming. The follow-up of this project will follow declarative programming based on the benefits listed by Pauwels et al. (2011). The approach will particularly focus on a semantic model that declares domain concepts and properties to be able to control the data for rule checking. Semantic knowledge models aim to capture domain knowledge and can make it available for non-domain decision makers. The information model will be (automatically) translated to a semantic model by the help of open

Table 2. Critical V&R issues related to the locks that are assessed and linked to the specific aging type.

Aging Reason	Issue	Cause of the issue	Limit statement	V&R Measure	Mng. object (NEN 2767-4 lev.1)	Component (NEN 2767-4 lev.2)		Element (NEN 2767-4 lev.3)	Function	V&R Rules
						Chamber	Wall			
Technical	Reduction of thickness	Corrosion	x% of the wall thickness	Replacement of Sheet pile walls of the chamber.	Lock	Chamber	Wall		Shipping and water level management	[T1]
Functional	Increased load on the bottom protection	Scaling up the shipping class	x% increase in the average engine power	Replacement or Adding Bottom Construction.	Lock	Chamber	Bottom		Shipping	[F1]
Technical	Pits at the bottom construction	Erosion, Sedimentation, even Subsidence	x% material loss due to pits.x° inclination angle of the pits	Replacement or Adding Bottom Construction.	Lock	Chamber	Bottom		Shipping	[T1]
Functional	High risk of collision with a greater damage	Increase in ship size	Max dimensions for the relevant shipping class	Widening, deepening the chamber.	Lock	Chamber	Chamber dimensions		Shipping	[F1]
Functional	Larger flows have to be discharged more often	Climate change	Discharge capacity of the pump(s) + gate	Renovate whole pumping station/ Upgrade pumps.	Pumping station	Pump	Capacity		Water level management	[F1]
Functional	Collision with a greater risk	Increase in number of ships with dangerous cargo	Length of ships in relation to length of chamber /waiting area	Widening, deepening or renewing the chamber.	Lock	Chamber, Waiting Area	Chamber dimensions, Waiting Area dimensions		Shipping	[F1]
Technical	Cracks (with or without leakage)	Fatigue	Size of the cracks (mm)	If obsolete, replacement of gate (whole system).	Lock	Lock Head	Doors		Shipping & water level management	[T2]
Technical/Functional	High truss forces from the translation waves	Relatively high lifting speed of the top door during locking process	x% increase in the forces	-	Lock	Lock Head/ Gate	Doors		Shipping & water level management	-
Technical	Obsolescence of a critical component	(varies)	Special door types not produced anymore	Custom-made or replacement of the whole gate system.	Lock	Gate	Doors		Shipping	[T2]

Table 3. The overview of the theoretical and object-specific aging rules.

Theoretical aging rules	Object-specific aging rules (via the cases)
<p>Technical end-of-life</p> <p>[T1]When a structure has serious structural defects</p> <p>[T2]When a (critical) component is obsolete.</p>	<p>When the lock chamber is made by steel sheet piles, and there is a corrosion-led thickness reduction, and structural risk is registered</p> <p>When the lock doors of their chamber are not produced anymore (thus obsolete) and not in-stock.</p>
<p>Functional end-of-life</p> <p>[F1]When an asset no longer fulfils its designed function due to changing environment, requirements, demand.</p> <p>[F2] When there are new functions needed from the asset itself or the location where the asset is.</p>	<p>When the total discharge capacity of the pump(s) + gate is no anymore sufficient to handle peaks (m³/s), as larger flows need to be discharged</p> <p>When a lock (waiting area + chamber + lock-head) is limited to allow bigger ship sizes (CEMT classes Va vs V). And/or When the movable bridge is lifted bridge that has insufficient clear height.</p>
<p>Economic end-of-life</p> <p>[E1]When ELI indicator of Bakker et al (2016) comes closer to 1.</p> <p>[E2] When an asset is too expensive to maintain.</p>	<p>When EELI is > e.g. 0.8</p>

frameworks (i.e. Kehllo for Java). When the real life objects are defined according to these models, knowledge graphs are generated and inferencing and rule checking is done via the graphs. The open source tooling based on Apache Jena is foreseen as a follow-up since it is a free and open source Java framework composed of different APIs interacting together to process RDF

data and build Semantic Web and Linked Data applications. Figure 3 illustrates the main development steps for the tooling.

5 CONCLUSIONS

The end-of-life model with a rule driven approach aims to assist V&R experts and regional asset managers with clear, explainable, and justifiable assessments for the V&R intake. The information model is a kernel data model that clarifies links between data and concepts from network to component level. It is an outcome of in-depth case analysis in order to understand typical representative problems for each object type. Available yet scattered data and information (across RWS systems and accessible openly) has been utilized. The information model binds relevant data from an object perspective, i.e. decomposition, condition, planning, functional data with a holistic view. The model can also be used as a data acquisition template for a large number of navigation locks as a minimum-set of information and can provide a common agreement between third parties and RWS. In the future, the proposed model will systematically identify how characteristics of certain components contribute to the network performance of objects and how network characteristics influence the object performance. By this, a large number of objects (thousands) can be scanned quickly and efficiently in future for a more comprehensive prognosis.

ABSTRACT: In order to illustrate the relevance of sustainable concrete maintenance and repair, a case study of a concrete silo situated in an industrial area with corrosion damage is selected. The environmental and economic impact is determined through life cycle assessment (LCA) and life cycle cost analysis (LCCA) for six concrete repairs: (i) conventional repair, (ii) conventional repair with surface protection, (iii) galvanic cathodic protection with zinc foil, (iv) galvanic cathodic protection with zinc gauze, (v) impressed current cathodic protection with titanium gauze and (vi) impressed current cathodic protection with a conductive coating. Moreover, three different indented service life extensions are evaluated: 20, 40 and 50 years. In general, a repair with impressed current cathodic protection is indicated as the most sustainable for this case study. However, for other service life extensions (e.g. 15, 30 or 45 years) certain techniques could perform better regarding the environmental or economic impact.

1 INTRODUCTION

In the 1960s and 70s, the construction industry experienced a peak in the construction of reinforced concrete (RC) structures. Due to this fact, there is now and in the near future a high need for repair, because an increasing number of structures will or did already surpass their initial estimated technical life span. This is demonstrated by frequently occurring news articles of failing structures, sometimes even with deadly accidents (Vrt, 2022, Baker et al., 2021, Fumagalli, 2021).

More than 65% of the occurring damage at RC structures is related to reinforcement corrosion (Jones et al., 1997). This damage is caused by carbonation of the surrounding cementitious matrix, chloride ingress or a combination of the two. Corrosion affects the durability and safety of RC structures by (i) cracking and spalling of the concrete cover caused by the expansion of corrosion products around the reinforcement, and (ii) cross-section reduction of the rebars leading to a reduced bearing capacity of the element. Because the covering concrete layer is the main protective mechanism against the ingress of water, O₂, CO₂ and other aggressive compounds, accelerated deterioration of the RC structure will happen when this layer is damaged. In order to prevent and repair damage at RC structures, multiple interventions can be conducted with varying labor intensities and effects. This becomes even more important because climate change effects are expected to substantially impact corrosion acceleration and therefor the degradation of RC structures in the future (Pacheco-Torgal, 2018).

Instead of demolishing deteriorated concrete structures, their service life can still be extended by repair interventions. This is in most cases more environmentally and economically friendly than demolishing and rebuilding as their residual value is preserved (Renne et al., 2022). With the European transition towards a circular economy and the sustainable development goals in mind, it is

important to also consider the environmental impact along with the technical requirements and life cycle cost over the entire life cycle. The construction industry can even be considered one of the key actors in the global stage of sustainability (Maxineasa and Taranu, 2018). In order to fulfill this need, the quantitative assessment methods, life cycle assessment (LCA) and life cycle cost analysis (LCCA), can be used to determine, respectively, the environmental and economic impact of different strategies. In this manner, an optimization of the performance of products, processes and services over a life cycle perspective is possible.

A case study of a concrete silo situated in a Belgian industrial area and damaged due to reinforcement corrosion, selected for this study, illustrates the relevance of sustainable concrete interventions. A combination of carbonation and chloride ingress caused the damage. Moreover, six frequently used repair techniques for RC structures are analyzed: (i) conventional repair (CR), (ii) conventional repair with surface protection (CR-SP) and four electrochemical treatments to stop the corrosion process: (iii) galvanic cathodic protection with zinc foil (GCP-F), (iv) galvanic cathodic protection with zinc gauze (GCP-G), (v) impressed current cathodic protection with titanium gauze (ICCP-G) and (vi) impressed current cathodic protection with a conductive coating (ICCP-C). The service life extension of these interventions is estimated by the engineering office Sanacon which did an investigation about the state of the structure. They also provided reports with data (e.g. description case, quantities, prices, etc.) necessary to perform the LCA and LCCA. In this paper, three functional units (FU) are considered by assuming three service life extensions of 20, 40 and 50 years.

The amount of research about concrete repair and maintenance decision-making through LCCA and particularly LCA is rather limited (Renne et al., 2022). Additionally, the results of different cases are challenging to compare as they are strongly case-dependent. There is only one study comparing multiple repair strategies through LCA and LCCA of the ones that are considered in this paper (Wittcox et al., 2022). The study evaluates five interventions for revamping reinforced concrete balconies. For a service life extension of 20 and 40 years, ICCP is economical the most beneficial followed by CR and GCP. However, regarding the environmental impact, the order is the other way around. Only for 40 years, CR is less bad than GCP. In addition, two studies are found considering only the economic cost for more than one repair strategy selected in this paper. (Polder et al., 2016) report cathodic protection (CP) as less costly than CR for a service life extension of 35 years of a bridge. For an extension of 35 to 100 years, the order remains the same. However, these two repairs are the worst options of the five considered solutions. Secondly, for RC columns and a service life extension of 20 to 75 years CP with conductive coating should be less beneficial than CP with titanium mesh (Binder, 2013). Moreover, studies conducting only a LCA for the selected repairs were not found. So, the quantitative sustainability assessment of concrete repair is still in its infancy, which is a clear knowledge gap given its societal importance.

Therefore, this paper has the goal of estimating the environmental and economic impact of six repair technologies for a corrosion damaged RC silo, given that the deterioration diagnosis and damage assessment are already done adequately on beforehand. In this manner, the knowledge gap about the environmental and economic impact of RC repair strategies will be tackled. It can be determined which method is preferred above the other ones. This can be useful for repair selection in practice considering the necessary transition towards a sustainable economy.

2 RESEARCH METHODS

For this study a concrete silo situated in an industrial area in Belgium was selected, containing a silo 'block' with 23 round silos and a rectangular silo 'tower' attached to it. The silo was built in 1968 and has a height of approximately 35.3 m for the block and 47.1 m for the tower. The silo block has 11 cylinders on the outside with a diameter of 7.2 m, and are attached to each other in the middle with a concrete wall of ± 1.8 m wide. Furthermore, they are horizontally and vertically reinforced with ribbed rebars of respectively 14 and 10 mm with a spacing of 200 and 300 mm. Secondly, the beam shaped silo tower has a length of 18.2 m and a width of 6.6 m. Furthermore, the tower is reinforced horizontally and vertically with non-ribbed rebars of 10 mm with a spacing of 250 mm. An investigation was done by a Belgian engineering office which reported a really bad and dangerous condition of the construction. More particular, based on the carbonation depth and chloride content a residual life span of zero was

estimated for the silo block and on average 66 years for the silo tower. However, for some parts of the tower also a residual life span of zero was calculated. Based on this data, it can be concluded that a repair intervention is highly needed to achieve a safe state and a service life extension for the structure. A visualization of the particular silo can be seen in Figure 1. The total area of reinforced concrete subjected to the outside environment is 6690 m², containing approximately 50.4 tons of steel rebars. This data and other quantities and prices for further study are based on the reports of the engineering office.

Figure 1. 3D-model of case study silo.

For the analysis six repair methods are considered: CR, CR-SP, GCP-F, GCP-G, ICCP-G and ICCP-C for three functional units (FU 1, FU 2 and FU3). The multiple FU's are necessary due to the consideration of different intended service life extensions (i.e. 20, 40 and 50 y.). Therefore, the FU can be described as “the service life extension of a reinforced concrete silo, as specified in this paper, to an excellent condition for an additional lifetime extension of 20, 40 and 50 years”.

The potential of the repair methods to extend the service life is based on the experience of the engineering office which conducted the investigation of the structure. In addition, the included activities of the interventions with associated quantities are based on data provided by the same company. A schematical overview of the life cycle of each repair strategy is shown in Figure 2. Every time an intervention is needed, it is shown in the figure. In addition, the volume of concrete (in %) that is removed at each intervention and during maintenance is shown below the bar of each repair. It is assumed that the corrosion process has not yet corroded the reinforcing steel rebars to a degree in which the bearing capacity is no longer guaranteed.

Figure 2. Schematical overview life cycle repair methods for 2 FU's.

Moreover, a description of the included activities and the maintenance strategy of the different repairs, considered in both the LCA and LCCA, are shown in Table 1. The number of interventions shown in Figure 2 corresponds with the number displayed in the table.

Table 1. Overview activities of repair methods for each intervention during the life cycle.

Description activity	CR			CR-SP		GCP-F			GCP-G			ICCP-G		ICCP-C

2.1 Life cycle assessment

For the environmental evaluation of the different repair strategies, a LCA is conducted. In this LCA study, the changes to environmentally relevant flows are described as a response to possible decisions by using the consequential modeling approach. The two most important aspects here are the identification of marginal suppliers and the substitution of dependent co-products (Weidema et al., 2013). Moreover, the study includes the entire life of each repair scenario by following a cradle-to-cradle approach. This means that the following life cycle phases are taken into account: demolishing of the damaged or contaminated parts of the existing structure, reconstruction according to the procedure of the different repair strategies (see previous section), the operation phase and the end-of-life of each intervention. For the end-of-life, the recycling potential or system expansion approach is followed (Weidema et al., 2013). In addition, the impact of production is geographically delimited to Europe, while transportation to the construction site is approached in a Belgian context.

The ecoinvent database v3.8 was used to model background processes, applying the default principle of marginal supplier identification of ecoinvent. For materials or processes for which no ecoinvent records were available, an approximation is made based on expert judgements and literature values. For the impact assessment, the ReCiPe 2016 v1.07 method was used. It implements both midpoint (problem-oriented) and endpoint (damage-oriented) categories and uses a set of weighting factors to calculate a single score impact. However, only the single score is presented in this manuscript because a detailed analysis of the midpoints is beyond the scope. Full details of these midpoints can be found in the supplementary information. In the discussion section will still varying midpoint results compared with the endpoint results be highlighted.

2.2 Life cycle cost analysis

For the economic evaluation of the different repair strategies, a LCCA is performed. The processes considered in the previous assessment (i.e. LCA) are also considered here. The prices of these actions are based on data from the available reports provided by the particular engineering office. The Net Present Value (NPV) for the defined FU's is calculated according to Equation 1 (Jawad and Ozbay, 2006). In this manner, costs and revenues at different stages in time are compared, which is called discounting. It emphasizes the importance of present cash flows rather than future ones due to inflation and earning power (Moins et al., 2020).

$$NPV = I_0 + \sum_{i=1}^N \frac{CF_i}{(1+d)^i} \quad (1)$$

where I_0 = Initial investment; N = study period; i = year; CF_i = cashflow in year i ; d = real discount rate

The real discount rate can be calculated with Equation 2 (Jawad and Ozbay, 2006). In this study, d_n and r_{inf} are assumed to be 6.0 % and 2.0 % respectively to get a discount rate of 3.92 %, which is a reasonable value (Galle, 2016).

$$d = \frac{d_n - r_{inf}}{1 + r_{inf}} \quad (2)$$

where d = real discount rate; d_n = nominal discount rate; r_{inf} = inflation rate

3 RESULTS AND DISCUSSION

In this section, the results of both assessment methods are shown. First, the results from the LCA are discussed after which the LCCA results are discussed in turn. Subsequently, both groups of results are compared with each other.

3.1 Life cycle assessment

In Figure 3, the cumulative impact of the different scenarios is shown on a timeline which shows when an impact occurs as a result of an intervention. In general, ICCP is found to be the most environmentally friendly option. Certainly for FU1 and FU2, both ICCP alternatives (i.e. coating and titanium gauze) are the best out of six. ICCP-C has the lowest impact of 9.5 kPt closely followed by ICCP-G with an impact of 11.2 kPt for FU1. The other techniques have an impact of 1.7 to 3.3 times higher compared to this first strategy. The high impact of GCP-F is due to the need for zinc foil renewal already after 15 years. Secondly, for FU2, the impact of ICCP-C goes beyond this of ICCP-G to a total of 17.6 kPt compared to 12.1 kPt for ICCP-G. Furthermore, the difference between the repair with the lowest impact and the other techniques becomes just bigger with values which are 1.9 to 3.9 times higher. Lastly, for a service life extension of 50 years, ICCP-G remains the best option to pick with an impact of 12.5 kPt. However, ICCP-C becomes the third option with a value of 25.2 kPt closely followed by CR-SP with 26.2 kPt. The second most beneficial option is CR with an impact of 23.4 kPt. The GCP options have no good results, mainly due to the need for intensive intervention during the assumed service life extension. The impact of ICCP-G increases over the years slightly because only one repair intervention is needed. The increasing impact is due to the use of electricity by the system.

This study takes both endpoints and midpoints into account by the ReCiPe method. Similar trends are found for the midpoint indicators compared with the single score results. However, for several midpoints (e.g. global warming, ionizing radiation, fine particulate matter formation, ozone formation, terrestrial acidification, marine eutrophication, human carcinogenic toxicity, land use, mineral resource scarcity, water consumption) varying outcomes are achieved. Only the single score is presented in this manuscript because a detailed analysis of the midpoints is beyond the scope. Detailed information about the midpoints can be found in the supplementary materials.

Figure 3. Cumulative environmental impact (single score) for FU1, FU2 and FU3.

3.2 Life cycle cost analysis

The discounted cumulative cost during the life cycles of the six repair strategies is determined by calculating the NPV of each cost at every year and adding this to the total cost of previous years. For the different FUs, varying results are obtained, which can be seen in Figure 4. ICCP-C is found to have the lowest cost of m€ 2.20 for a service life extension of 20 years. The other strategies are quite more expensive for this FU with a cost of m€ 2.57 for GCP-F until m€ 3.35 for CR-SP. GCP-F is the second-best alternative, however, for a service life extension until 15 years, it is the cheapest option. In addition, this is also the case for an extension of 25 to 30 years. When FU2 is considered, ICCP-C remains the most beneficial option with a cost of m€ 2.64. The order of the other repairs is still the same, only ICCP-G became less expensive than GCP-F. They have respectively a cost of m€ 2.90 and m€ 2.93 for FU2. Moreover, GCP-G, CR-SP and CR have an economic cost really close to each other but on average 36 % higher than this of ICCP-C. Lastly, the same trends can be seen for FU3, only GCP-G became the worst option (m€ 3.76) instead of CR-SP and CR at FU1 and FU2 respectively. Besides, a change is present in the difference between ICCP-G and ICCP-C and GCP-F. More particular, the cost of ICCP-G and ICCP-C converted to each other resulting in a value of respectively m€ 2.91 and m€ 2.84. Furthermore, the difference between GCP-F and ICCP-G knows an increase to 7.5 % instead of 1.1 % at FU2. Therefore, for a service life extension of 50 years ICCP and more specifically ICCP-C is economically speaking the most beneficial option.

Figure 4. Discounted cumulative economic impact (NPV) for FU1, FU2 and FU3.

3.3 Comparison LCA vs. LCCA

The total environmental and economic life cycle cost for FU1, FU2 and FU3 are combined in Figure 5. In this manner, it can be seen if a strategy scores the best for both criteria or where certain repairs score better or worse than the others. A pareto front is not drawn due to the rather limited number of results to do this adequately. For FU1, it can be seen that ICCP-C scores the

best for both criteria. Therefore, this strategy should be conducted for an intended service life extension of 20 years. Regarding the other repairs, the results show that some score well for the economic cost (e.g. GCP-F) and others for the environmental impact (e.g. ICCP-G). Secondly, there is no consensus regarding the two criteria for FU2. Namely, ICCP-C has still the lowest economic cost but ICCP-G has the lowest environmental impact. However, the other four repairs don't score better than these two, so a good selection can still be made. Finally, the ICCP strategies are again the most sustainable for FU3. Only CR scores a little bit better (7.5 %) than ICCP-C for the environmental impact. In addition, regarding the LCCA, ICCP-C has a 2.5 % lower cost than ICCP-G. Overall, it can be concluded that ICCP is mostly the most suitable option.

Figure 5. LCA vs. LCCA for FU1, FU2 and FU3.

4 CONCLUSIONS

In order to improve the sustainability of existing reinforced concrete structures over their life cycle, a key factor is to reduce the environmental and economic impact of repair and maintenance interventions. These impacts can be determined by the quantitative assessment tools named LCA and LCCA by which a mutual comparison between the strategies can be done and sustainable decisions can be made. In this paper, a corrosion damaged concrete silo of 6690 m² exposed concrete surface situated in a Belgian industrial area is selected as case study. Six different frequently used repair strategies for addressing corrosion damage are evaluated through a life cycle assessment (LCA) and life cycle cost analysis (LCCA): (i) conventional repair (CR), (ii) conventional repair with surface protection (CR-SP), (iii) galvanic cathodic protection with zinc foil (GCP-F), (iv) galvanic cathodic protection with zinc gauze (GCP-G), (v) impressed current cathodic protection with titanium gauze (ICCP-G) and (vi) impressed current cathodic protection with a conductive coating (ICCP-C). So, the environmental and economic impact of these life extending repair actions with corresponding activities are evaluated over the entire life cycle of the concrete silo. This is done for three different intended service life extensions: 20, 40 and 50 years.

For a service life extension of 20 years, ICCP-C is the preferable option on the environmental and economic level. Furthermore, it is still economical the best option for a service life extension of 40 years. However, ICCP-G scores here better at the LCA. Thirdly, ICCP-G is found to have almost the lowest impact for both criteria at a service life extension of 50 years. Only, the economic cost of ICCP-C is 2.5 % lower. Therefore, the electro-chemical ICCP treatments are in general good options to conduct for this case study. This can be explained by the low initial cost/impact for ICCP-C and the low need for interventions after the first repair for ICCP-G.

Economically, the same trend was seen for FU1 and FU2 by (Wittcox et al., 2022) who reported ICCP as the most beneficial option for a service life extension of 20 to 40 years for balconies. Nevertheless, CR and GCP were environmentally speaking more sustainable than ICCP. For a bridge, (Polder et al., 2016) report CP in general as less costly than CR for a service life extension of 35 years. This is in line with the results of this study. Although, for an extension of 35 to 100 years these repairs should be the least beneficial of the five considered repairs. Moreover, CP with conductive coating should be more expensive than CP with titanium mesh for a service life extension of

20 to 75 years for RC columns according to (Binder, 2013). In contrast, the opposite result is seen in this case study. The comparison with other research shows the case-dependency of LCA and LCCA studies and the fact that results and conclusions cannot be generalized.

Finally, ICCP can still not be specified as the most sustainable option for every situation. When for example another service life extension is intended, other techniques can score better like GCP-F economically for an extension of 15 years. Therefore, we also want to highlight the importance of the assumed potential of the repairs to extend the service life as it can have a big impact on the results. Here, these values are determined based on expert judgement of the engineering office Sanacon. However, further research is needed about the service life extension of repairs by which the highest effect on the life cycle impact/cost is expected. Secondly, for some activities and products general prices and proxy LCA records are used. A more in-depth analysis of the necessary activities and materials with corresponding impacts and costs could improve the results.

ACKNOWLEDGMENTS

We thank the engineering office Sanacon for providing data and the Research Foundation Flanders (FWO-Vlaanderen) for supporting Matthias Buyle with a post-doctoral fellowship (Postdoctoral Fellow - junior; 1207520N).

Foundation for risk-based asset management for storm surge barriers

Y. Kharoubi, M. van den Boomen & M.J.C.M. Hertogh

Faculty of Civil Engineering and Geosciences, Delft University of Technology, Delft, The Netherlands

J. van den Bogaard

Rijkswaterstaat Ministry of Infrastructure and the Environment, Utrecht, The Netherlands

ABSTRACT: Due to climate change, the risk of flooding is increasing with potentially severe consequences on highly populated and economically developed coastal zones. Storm surge barriers protect against such events with the critical task of closing during extreme weather conditions to prohibit the propagation of water. This highlights the importance of maintaining the high reliability of these structures and the challenge to reach this goal for rarely operated and unique infrastructures. To deal with this challenge, the study creates a foundation to set an asset management approach for storm surge barriers or assets with similar characteristics. This is done by studying the case of The Netherlands with the aim to [1] describe the asset management approach, [2] identify key features of the approach, [3] investigate the connection between these features and the characteristics of the barriers, and [4] conclude the influence of the characteristics on the establishment of an asset management approach.

1 INTRODUCTION

The climate is changing with increasing global sea levels, surface temperatures, and precipitation among others. Despite the efforts to reduce emissions and global warming, the effects of climate change will continue to have an influence. The risk of flooding is unavoidable and measures to deal with it are crucial. Hard (infrastructures) and soft (nature-based) protective measures against sea level rise will support the continuity of coastal cities (Pörtner et al. 2022). However, the soft measures are not sufficient to reduce 2100 risks. Hard flood protection measures such as Storm Surge Barriers (SSBs) are required (Du et al. 2020).

SSBs are crucial for flood management especially in responding to climate change effects and complying with strict safety requirements (Jonkman et al. 2013). They are flood defences that are operated during extreme events to avoid catastrophic consequences. This requires high reliability of SSBs during extreme and rare events (Jordan et al. 2019). However, climate change challenges operation and maintenance (O&M) and imposes increasing expenses to sustain the current safety levels of protection measures (Pörtner et al. 2022). High sea level rise scenarios diminish the flood safety provided by SSBs and lead to more frequent closures of SSBs. Furthermore, SSBs deteriorate faster when design water levels are surpassed (Haasnoot et al. 2020). Therefore, O&M of SSBs are intrinsically challenged with strict requirements and are additionally confronted with climate change complications.

To preserve the safety levels provided by these structures, maintenance is performed based on intensive work and planning in systematic asset management (AM) approach (Jordan et al. 2019). AM supports organisations to perform O&M with limited budgets and under strict requirements in risky and uncertain conditions (Almeida et al. 2022). However, organisations face challenges such as ageing assets, changing operating conditions, limited resources, and loss of knowledge. AM tries to deal with these challenges through structured decision-making and balanced performance, risk, and resources (Shah et al. 2017). Despite its importance, the needed effort for AM is underrated, knowledge sharing among countries is disrupted, and research on the maintenance of flood defences in relation to their performance is limited

(Jordan et al. 2019). The latter can be supported with information on AM from other assets since AM as an approach is similar in many ways. However, it differs between assets due to the influence of special characteristics of an asset (Herder & Wijnia 2012). Furthermore, standards like the ISO 5500x cover AM requirements but do not cover “how” to fulfil the requirements and provide limited guidance for infrastructure assets. Models from practice can provide a better perspective while fulfilling the ISO requirements (Wijnia & Croon 2015). This is especially important for SSBs since they are relatively new structures, with the first SSB completed in 1958 (Mooyaart & Jonkman 2017), and the importance and complications of their AM is increasing. Therefore, the research aims to create the foundation for setting an AM approach for SSBs or similar assets by studying AM for SSBs from practice and analysing the approach relative to the characteristics of SSBs. This leads to the research question: How do the characteristics of SSBs influence the formation of the AM approach?

2 RESEARCH METHOD

In this paper, the AM for SSBs is investigated with a focus on the influence of SSBs’ characteristics on the AM approach. This is done based on literature and case study research. The characteristics of SSBs are derived from literature based on the following iterative process: articles were analysed such that different sections were associated with specific characteristics, the latter were compiled to reach more general characteristics with supporting content, then characteristics with limited evidence were further researched. For the study of the AM approach, the case of The Netherlands was investigated from papers addressing the AM approach, guidelines describing the approach, four interviews with experts who were involved in the development of the AM approach, and supporting documentation from the organisation managing the SSBs. The different sources supported the development of the overview of the AM approach such that general concepts were clarified from papers, detailed topics of the AM approach were explained from guidelines, and connections between topics into processes were concluded based on interviews and documentation from the organisation. Moreover, the data from the different sources were analysed by coding and categorising to identify the key features of the AM approach to reveal the core ideas based on which the overall approach is formed. These key features were then analysed relative to SSBs characteristics based on associations identified from the interviews with experts. Hereafter, the research question is answered and the influence of characteristics on shaping the AM approach is clarified.

3 STORM SURGE BARRIERS AND THEIR CHARACTERISTICS

This section introduces SSBs with clarification of characteristics (in italics) which in turn reveal general and unique properties of SSBs, their functionality, and their history.

A SSB is a *system within a system*. It is part of the flood defence system with the role of controlling water passage, reducing the flood risk, shortening the coastline without closing an estuary (Jonkman et al. 2013), and reducing the disruption of the landscape and environment (Walraven et al. 2022). Under normal conditions, SSBs remain open. They close to protect against flooding in case of storm surges. For SSBs to perform these functions, they consist of sub-systems (structural, mechanical, electrical, software). These sub-systems are studied to assess the sole failure of the SSB system (Mooyaart & Jonkman 2017) which is used for the overall assessment of the flood defence system.

Being part of a national flood defence system, SSBs are *public infrastructures* that are built and operated with national budgets to fulfil national safety requirements. In the USA, the United States Army Corps of Engineers (USACE) built and operated SSBs with different safety levels ranging between 100 and 500-year event (Morang 2016). In The Netherlands, the law specifies the acceptable failure probabilities for sections of the flood defence system with a range of 1:100 to 1:10⁶ (Jonkman et al. 2018). These safety levels are reached with *high investment costs* such as the Maeslant barrier with initial costs of \$940 million and O&M

expenses reaching \$17 million annually (Mendelsohn et al. 2022). Being public and expensive, SSBs are subject to *political processes* and *long-lead times until their construction*. Political reasons, such as funding processes, public support, assessments, and permits, contribute to long-lead times. The lead time for SSBs mentioned in Hill's study spanned between 14 and 37 years with construction time ranging between 8 and 10 years (Hill 2012).

These public structures protect against extreme flood events, thus SSBs are considered *critical infrastructures* as in The Netherlands (NCTV 2017) and the USA (CISA n.d). Critical infrastructures are systems or assets that are vital to a nation because any disturbance in their service can influence national security, economy, health, and safety (Alcaraz & Zeadally 2015). For the case of SSB, the loss in their service leads to flooding from extreme weather events, which in turn results in massive consequences. Such drastic events might occur because SSBs protect high-value economic and urban areas (Aerts 2018) in low-lying coastal zones with increasing populations and growing economies (Jonkman et al. 2013). Besides their primary role, SSBs are *multi-functional* with an impact on the economy, society, and ecology. SSBs reduce the risk of failure and costs of strengthening defences behind them (Nogueira & Walraven 2018) and enable less strict standards in the hinterland which then reduces disruption of the landscape and environment (Walraven et al. 2022). Moreover, SSBs allow navigation to resume especially for port cities and contribute to the economic development of delta regions (Meyer & Nijhuis 2013) SSBs' impact on ecology can be considered by allowing tidal and saltwater exchange (Mooyaart & Jonkman 2017). With these different functions, an *integrated approach* is required to account for the multiple functions of SSBs and their influences (Jonkman et al. 2013). In port cities such as Rotterdam and New Orleans, protection against flooding interacts with urban growth, economic development, and environmental issues (Meyer & Nijhuis 2013).

In practise, an integrated approach leads to *unique* structures that request innovative designs. SSBs are considered prototypes with a unique combination of the physical environment, requirements, and design (Walraven et al. 2022). The location of SSBs in estuaries and deltas with soft soils requires innovations in the design and construction of complicated foundations (Mooyaart & Jonkman 2017). Besides the geological complexity, being in water bodies in socio-economically important regions complicates the design and construction of SSBs. Innovations in science and technology were necessary to reach the design in the USA and The Netherlands (Meyer & Nijhuis 2013). After the challenges in design and construction, a *long life awaits SSBs*. They are designed for long periods such as the Eastern Scheldt barriers with 200 years of lifetime with consideration of 50 cm sea level rise (McRobie et al. 2005). Such design assumptions of the long-life structures might become incompatible as more knowledge is gained. For example, scenarios with accelerated sea level rise (beyond design assumptions) are probable (Haasnoot et al. 2020).

During this long life, SSBs' *operation is limited and dependent* on external conditions and intended use. The closure of SSBs is based on constant water level thresholds or constant annual exceedance probability that is used to update the triggering water level for closure with sea level rise (Chen et al. 2020). Generally, SSBs are designed for irregular storm surges whose occurrences are rare. Most of the barriers in the USA have not yet been operated at or near their peak design height (Morang 2016). In The Netherlands, the frequency of closure ranges from 1 every 10 years to a few times (1-8) a year (Nogueira & Walraven 2018). This dependency on the operation and the long life of SSBs lead to *dynamic operation*. For example, SSBs have to close more frequently and with longer closure duration due to sea-level rise that leads to more recurring water level exceedances (Chen et al. 2020).

4 ASSET MANAGEMENT FOR STORM SURGE BARRIERS: CASE OF THE NETHERLANDS

To investigate the AM for SSBs, the case of The Netherlands is studied based on data collected and analysed from various sources. The low-lying land has a long history of flood protection, strict safety standards, and frequent assessments. To comply with regulations, the so-called "ProBO: Probabilistic Operations and Maintenance" (now known as "Risk-based operations and maintenance") was set and followed by Rijkswaterstaat (Jorissen et al. 2016). ProBO enables demonstrating the fulfilment of performance requirements, provides constant

control of the system's performance level, sets O&M processes based on risks that affect performance, and triggers improvement. This is achieved with the different parts of ProBO shown in Figure 1 and elaborated in the following sections.

ProBO covers three main aspects technical, organisational, and contracting. Technical aspects focus on analyses to describe the system, assess risks, and determine performance levels. Organisational aspects cover operations, maintenance, and control and supporting processes. And contracting aspects focus on performance in relation to external parties performing maintenance activities. To sustain and optimise performance levels, the Deming cycle with Plan-Do-Check-Act phases is set as a framework (Bogaard & Akkeren 2011). Accordingly, ProBO is explained by distinguishing between the preparation of the three aspects of the PDCA cycle and the execution of the PDCA cycle.

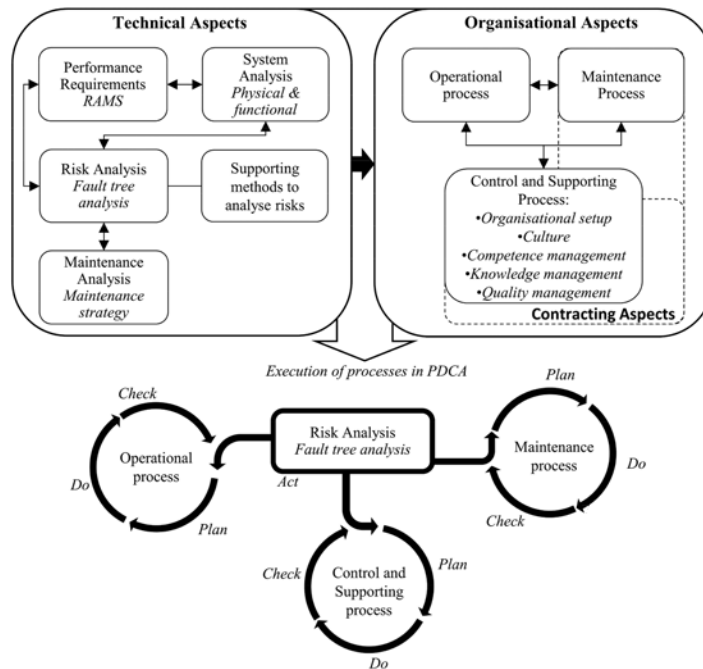

Figure 1. Illustration of ProBO – AM approach for SSBs.

4.1 Preparation

4.1.1 Technical aspect

The starting point of ProBO is the technical aspects. First, the performance requirements are derived from legislations and policies and translated in terms of quantitative reliability and availability requirements and other qualitative requirements of RAMS (Reliability, Availability, Maintainability, Safety). Afterward, the system is analysed and decomposed into physical and functional breakdown structures. A System Breakdown Structure (SBS) based on design information is performed and functions of elements and components and their interrelations to operate as a whole are determined and quantified in relation to performance requirements. These analyses are used for the risk analysis to reveal the risks that influence performance levels and guide towards actions that deal with these risks. Various methods are used and developed to support the risk analysis as shown in Figure 1. The results of the latter support the development of the fault tree that leads to quantifying the unreliability or unavailability and comparing them with requirements. The comparison leads to an iterative process as shown in Figure 1 with the double arrows. The iterative process aims to eventually meet performance requirements and

optimise when possible. Based on the risk analysis, the O&M is studied to sustain performance at acceptable levels and minimise lifecycle costs. The maintenance analysis looks into maintenance strategies using the concept of Reliability Centred Maintenance (RCM) and is based on information from the risk analysis. The aim is to select suitable maintenance to reduce the likelihood of a failure or its consequences. Then, maintenance and inspection activities are determined. The results of the maintenance analysis can be prioritised from a risk perspective such that components contributing most to the performance levels are given more attention in improving maintenance. Furthermore, the analysis can optimise the maintenance and minimise lifecycle costs as long as performance requirements are met (Bogaard & Akkeren 2011).

4.1.2 *Organisational aspects*

The results of the technical aspects are used to set up the organisational aspects of ProBO: operational, maintenance, and control and supporting processes. The operational process focuses on operating the system while ensuring functionality in accordance with performance requirements. So, operational scenarios, activities, procedures, instructions, preconditions, and resources are determined while considering performance requirements, human errors, and repair work during operations. Similarly, preparations for the maintenance process are performed based on the maintenance analysis previously described. The maintenance activities are derived from the analysis and described with the necessary procedures. These procedures are described while considering ways to facilitate repairs and reduce human errors and common cause failures. For both processes, the organisational setup, culture, and knowledge management are clarified with the help of the control and supporting process. Tasks, processes, responsibilities, and roles are linked to the activities to be performed in the O&M processes. The roles are specified in RASCI-method (Responsible, Accountable, Supportive, Consulted, and Informed) to clarify the distribution of roles and the communication between them. Furthermore, knowledge levels, competencies, and skills for the different positions within the department are identified along with development plans and training. To preserve the knowledge, ProBO includes Human Resource Management (HRM) plan. This plan clarifies the distribution of knowledge within the organisation and with external parties. The different features of control and supporting process are clarified in Figure 1 (Bogaard & Akkeren 2011).

4.1.3 *Contracting*

Since external parties are involved in the regular and major maintenance activities, contracting becomes an essential part that requires analysis and preparation in line with the objectives of ProBO. Accordingly, the decision to outsource and the degree of outsourcing are analysed by considering different stages of the PDCA of the maintenance process in relation to failure probabilities. Furthermore, the decision to outsource considers criteria in line with the objectives of ProBO such as: the organisation remains in control and meets performance requirements, risks are small or manageable, and the market situation permits outsourcing. To decide on the degree of outsourcing, the following are evaluated: integration of regular and major maintenance, combining disciplines, and responsibilities of the contractor. In the case of outsourcing, plans and processes are arranged to prepare contractors for applying ProBO. Furthermore, contracts clarify various points (such as contracted activities, performance requirements of the outsourced activities, maintenance mode, procedures, training levels, and documentation requirements) to ensure performance levels are met. In addition, the organisation has to prepare itself with the competencies and necessary knowledge to be able to control the processes and activities of the contractor (Bogaard & Akkeren 2011). Based on the above description, the contracting aspect can be seen in the maintenance process and control and supporting process.

4.2 *Execution of PDCA*

After the preparations are complete, continuous PDCA cycles are performed to preserve performance levels as required. The PDCA cycle is divided such that plan-do-check phases are applied to each of the three processes: operations, maintenance, control and support. Then, the information from the check phases of the processes is combined in a single act phase that evaluates the risk analysis to assess actual performance and compare it with the requirements.

The PDCA cycle starts with creating explicit plans for the processes by covering activities, methods for execution, organisation, and contracting. O&M activities covered in the previous analyses are scheduled and clustered to account for periods during which maintenance cannot be performed. The different details of the organisational and contracting aspects are planned such as work procedures to be followed are clarified, the tasks to be executed are set and allocated, staff training is scheduled, requirements for contracts are defined, and the quality system is set. Then, the plans are executed in the Do stage. The O&M activities are performed while complying with preparations done earlier. It is necessary to follow procedures in order to validate the risk analysis and demonstrate performance. During the do stage, the work is tracked with documentation on deviations, quality, and time. Furthermore, records are kept on actual data on processes, activities, detected anomalies, operational problems, and impractical work procedures among others. These records have to be linked to corresponding activities for assessments and future improvements. In the check phase, the processes are monitored and assessed based on collected data. For technical aspects, the data is used to identify trends and deviations in technical conditions and assumptions used in the risk analysis. For organisational and contracting aspects, the checks include: the quality of performed work of internal and external parties, deviations in the process and schedule, workability of procedures, and training level to further reduce errors. To support the act phase, the check phase also evaluates plans, the impact of proposed improvements, and unexpected behaviours. Accordingly, the check phase leads to a further understanding of all aspects, follow-up actions for improvements, and up-to-date data to be used in the risk analysis. At that time, the act phase proceeds to update the risk analysis and determine actual performance levels that are then compared to requirements. In case the requirements are not met, performance killers are identified and analyses are performed to suggest actions that improve performance to acceptable levels. The analyses look into the data and proposals from the Check phase in relation to performance, organisational maturity, and working methods. When the requirements are met, the influence of the follow-up actions is evaluated, changes to preconditions are analysed, improvement proposals are generated and approved, and clarifications on updates to plans are submitted. At the end of this phase, the input for the following PCDA cycles is set in a report including the new performance levels and follow-up actions. Finally, the plan stage restarts with information from the act stage (Bogaard & Akkeren 2011).

5 ANALYSIS AND DISCUSSION

By analysing the AM approach for SSBs followed in The Netherlands with coding collected data and categorising, the key features of the AM approach are identified as follows:

- Holistic Approach: Covers and connects technical, organisational, and contracting aspects via a risk analysis with the aim to meet performance requirements
- Comprehensive approach: Detailed preparation (analyses, procedures, instructions, process descriptions) and guidance for execution
- Strict approach: Requires following procedures and preparations to validate the risk analysis
- Risk-based: Risk analysis is the core based on which all three processes (Operation, Maintenance, Control and support) are set to manage risks that influence performance
- Quantitative approach: Provides evidence of compliance with performance requirements by assessing reliability and availability performance levels
- Execution that provides constant control: Constant control of the system's performance with regular assessment and checks with PDCA-based execution
- Continuous improvement: Continuous improvement at different levels (PDCA cycles, development plans and training for personnel, quality control, and audits)
- Connection between risks and people: Internal and external parties connected to risks by covering human errors, knowledge, competencies, and culture in relation to risks in the control and supporting process and linking the contracting aspect to the risk analysis

The key features noted above emerged during the development of ProBO which was initially designed for the Maeslant barrier to demonstrate the reliability of the barrier. Various requirements,

challenges, and drivers shaped ProBO into how it is now. The fact that the barrier is a public and critical infrastructure with strict safety requirements triggered the quantitative approach to demonstrate and control performance levels and improve maintenance to reach acceptable performance levels. A comprehensive, quantitative, and risk-based approach was needed to deal with the barrier's limited operation that hinders the direct understanding of performance. The limited operation challenged the maintenance of the components with information from suppliers that were assessed as insufficient due to operating conditions different from prescribed. This required an analysis (in this case fault tree) that is detailed to a level that can guide activities and support the calculation of performance from inspection and testing information. The fault tree analysis was inspired by [1] the design and construction phases that used this analysis to prove the requirements are met and [2] the nuclear power plants that have similar safety demands. This shows the influence of having strict requirements and being a critical infrastructure with safety-related regulations on the choice of approach. Furthermore, being a system within a system is another characteristic that had a role in choosing a quantitative and risk-based approach. The barrier protects the dike ring in the hinterland and supports the dikes in meeting their requirements, so the reliability of the barrier during O&M is needed to calculate the dike's probability to hold a certain water level.

As ProBO developed with more analyses, it became a holistic approach covering more than just maintenance. Initially, the design for operating the Maeslant barrier was fully automated to avoid human failure risks. However, human interaction was introduced to correct technical failures and improve the performance of the barrier. With the addition of human interaction, procedures, instructions, and training were added to reduce failure rates due to human errors. This is especially important for the closure of the barrier where the team follows strict procedures and instructions for certain failures or incidents that are analysed and detailed in the fault tree. Furthermore, human resource management was introduced to prepare the teams with the necessary knowledge and skills. Knowledge is managed since SSBs have a long life and are unique, so the learning possibilities from other similar assets are limited and it is necessary to learn from the specific asset.

Since the approach covers various details, its application is not unified for all SSBs. The details of the comprehensive approach are directly influenced by the uniqueness of SSBs, their multi-functionality, and their frequency of operation. For instance, the location and design of the SSB influence the O&M in different ways such as frequency, level of flexibility, and difficulty. Similarly, the multiple functions of SSBs (such as the discharge of rivers and navigation) influence the maintenance planning and the operation frequency controls the amount of asset information used in the analysis. Multi-functionality is also related to the risk-based and quantitative features of ProBO since they enable studying the influence on safety from other functions and demands of stakeholders. Safety remains the primary function of SSBs and other demands are considered after attaining the required safety levels with the risk analysis. Furthermore, the results of the risk analysis can be used to provide evidence of the performance level and the request for certain budgets for improvement from the government. Since the maintenance relies on budgets granted by the government, political processes can impact the ability to continuously improve and be in control of performance.

6 CONCLUSIONS

The current research investigated the unique characteristics of SSBs and how these shaped the AM approach for SSBs in the Netherlands. The derived characteristics provided background information on SSBs and helped in realising the challenges or requirements that certain characteristics create for the AM approach. This was further analysed in the case study that showed the development and implementation of an AM approach in practice. The results showed that certain characteristics of SSBs (such as limited operation and strict requirements) have a clear and direct connection to key features of the AM approach which has matured over time. Therefore, the study connects general characteristics, that apply to SSBs and other assets, to key features of an AM approach that can be considered for the AM of SSBs and assets with similar characteristics. Furthermore, future considerations for AM as noted by experts include [1] benefiting from advances in maintenance and data management, [2] starting

early with innovations and solutions for maintenance complications due to climate change, and [3] considering O&M in the design phase since the design might over-complicate the situation. These results are preliminary, and this case is part of a wider study on AM for SSBs.

Lessons learned from past earthquakes for horizontally curved bridges

E. Namlı

Emay International Engineering & Consultancy Inc., İstanbul, Turkey

T. Öztürk

Prof. Dr., İstanbul Technical University, İstanbul, Turkey

ABSTRACT: Transportation has an important and wide impact on the economy, social and cultural structure of countries. Highways and railways are part of the transportation system network where bridges and viaducts are the most critical structures of this system. Therefore, bridge damages not only result in direct losses, but also have social and economic impacts. Seismic behavior of bridges in curved alignment plane contain additional potential damages due to their complex geometries, although similar damages were observed for curved and straight bridges as examined in past earthquakes. In this study, the damages observed in horizontally curved bridges in the past earthquakes were investigated and the lessons to be learned according to the results obtained from past earthquakes on the curved bridges were examined.

1 INTRODUCTION

Transportation systems from past to present and the bridges that are a part of them have been one of the most important factors determining the level of civilization of the country as well as providing the transportation network in the countries. Damages in bridges after major earthquake ground movements not only affected transportation but also indirectly affected social-economic conditions of countries according to damage level. Therefore, it is of great importance to determine the seismic behavior of bridges and to design them according to that criteria. By examining the damage types occurred in the past earthquakes, a number of studies have been carried out in order to develop bridge designs in this aspect.

With the increasing population, the coincidence of urban and suburban roads has led to the need for different intersection solutions. Therefore, the use of horizontally curved bridges have become widespread for their aesthetic and economic advantages which exhibit geometric compatibility. On the other hand, due to their geometric irregularities, curved bridges are more sensitive to earthquake ground movements than straight bridges. Although similar damages were observed for both bridge types, more complex and destructive damage types were encountered due to the geometry of the curved bridges. For this reason, many studies have been carried out in order to understand the seismic behavior of horizontally curved bridges and to take necessary measures in the designs to be made.

Particularly as a result of the heavy damages in the bridges after the 1971 San Fernando earthquake, the behavior of these bridges under the influence of large ground movements became more remarkable. In the following years, the 1989 Loma prieta earthquake, the 1992 Petrolia Earthquake, the 1994 Northridge earthquake, the 2008 Wenchuan earthquakes brought more attention to the importance of the damage to the bridge in many horizontal curve alignments. The main damage types in bridges are; unseating of the superstructure, column shear collapse, foundation collapse, bearing collapse and insufficient column bending capacity. In this study, the damages observed in the bridges after the major earthquakes were mentioned and information was given about the determination of the seismic behavior of the horizontally curved bridges.

2 OBSERVED CURVED BRIDGE DAMAGES AND REASONS DURING PAST EARTHQUAKES

Transportation has an important and wide impact on the economy, social and cultural structure of the countries. Highways and railways are part of the transportation system network and bridges and viaducts are the most critical structures of this system. Therefore, bridge damages not only result in direct losses, but also social and economic impacts. Direct costs are defined as the state of post-earthquake functionality of the bridge, while repairing the bridge will restore its past function [1]. Indirect losses include the closure of traffic lanes, the decrease in traffic volume, or the complete closure of the bridge after damages in bridges and viaducts due to the earthquake ground motion. If the bridge is severely damaged, this road can be completely closed and if the process is long, it can have significant effects on the regional economy.

Some of the damage types that cause bridge closure are; unseating of the superstructure, column shear collapse, foundation collapse, bearing collapse and insufficient column bending capacity.

Seismic behaviour of bridges in the curve alignment includes additional potential damages, although similar damages were observed when the straight bridges and curved bridges were examined in the past earthquakes.

2.1 1971 San Fernando earthquake

2.1.1 1971 San Fernando earthquake features

San Fernando earthquake occurred at the northern part of the metropolitan Los Angeles which had a huge population of 8 million. The magnitude of the shock was 6.6 and it was generated by thrust faulting. San Fernando valley was thrusting under the Gabriel mountains and this earthquake rearrange these pressures. The relative motion across the fault plane was generated by the rock above moving upward along the fault and the rock beneath moving downward along the fault that was reverse thrust faulting.

2.1.2 1971 San Fernando earthquake bridge damages

According to the reports released after the earthquake 450 homes, 60 apartment buildings, 400 commercial buildings had severe damage; 600 homes, 200 apartment buildings and 450 commercial buildings had significant damage; and some 20000 structures had minor damage. Also 42 bridges had appreciable damage and 5 of the bridges had collapsed.

The major damage had occurred at the Golden State Freeway (Interstate 5)-Antelope Valley Freeway (California SR14 Interchange) Interchange. South Connector Overcrossing along this interchange, which was a curved nine-span reinforced concrete highway bridge with diaphragm abutment collapsed [3]. The bridge was completed at the time of San Fernando Earthquake. The bridge superstructure was divided into 5 separate segments by using 4 expansion joints. There were three tie bars used at each expansion joints in order to prevent the longitudinal deflection of the superstructure because of the creep and temperature effects (Figure 1).

According to the damage survey reports, as a result of the strong amplitude vibrations during earthquake the deck separation at expansion joint 2 initiated in the longitudinal direction. Therefore, it lead the tie bars at the expansion joints to be yielded and failed.

The failure of the restrainers caused the span four to fall of from its support because of unseating of the hinge locations the superstructure between expansion joints 1 and 2 (span 3 and 4) and the column 4 collapsed as seen in Figure 2.

The southbound SR14/I-5 Separation and Overhead structure was a 10-span curved concrete box-girder bridge with seat-type abutment and single column bent. The structure was constructed in five segments with four intermediate expansion joints. It was under construction at the time of the 1971 San Fernando earthquake. The damage of the superstructure occurred as a result of the settlement of the false work.

Golden State (I-5) and foothill freeway interchange (Interstate 210) interchange consisted many overcrossings and bridges.

Figure 1. The structural system of the SR14/I-5 South Connector Overcrossing (Tseng, Penzien 1975).

Figure 2. The collapsed sections of South Connector Overpassing after the San Fernando Earthquake (Shirazi 2015).

At the time of the earthquake many structures were completed but not open to traffic. Many collapses and failures occurred in the interchange.

2.1.3 Lessons learned from 1971 San Fernando earthquake

The main structural elements damaged after San Fernando Earthquake are can be listed as follows; Expansion joints, Columns, Column caps, Abutment walls & wing walls.

The bridges damaged or collapsed during the earthquake had commonly in span hinges with gaps and tie bars. Because of inadequate seat width of the deck at the expansion joints during the strong ground motion the displacement of the deck followed by falling of the spans. The reasons of the column damages were; inadequate ties both in size and spacing. For column caps

they were mainly poor of reinforcement for tying column bents to the deck/superstructure. Confinement reinforcements should be increased to prevent that type of the damage. In addition, column foundations had inadequate anchorage of main reinforcement bars that had caused the foundation failures. Also, behind the abutment the backfill should be improved in order to prevent the settlement during the shock. Thus, Abutment walls & wing walls need to be strengthened to better engage forces transmitted through backfill earth pressures

2.2 1994 Northridge earthquake

2.2.1 1994 northridge earthquake features

The Northridge earthquake M_w 6.7 occurred on January 17, 1994, beneath the San Fernando Valley. The mainshock hypocenter was at 19 km depth in the lower crust and it had a thrust faulting focal mechanism. After the mainshock, eight aftershocks of magnitude $M \geq 5.0$ and 48 aftershocks of magnitude $4 \leq M \leq 5$ occurred which form a diffuse spatial distribution around the mainshock rupture plane. The fault mechanism and the location of the Northridge Earthquake can be seen in Figure 3 [8]. San Fernando 1971 and 1994 Northridge Earthquakes differ mainly in the dip direction of the faults and the depth of faulting. The 1971 north-north-east trend of left-lateral faulting (Chatsworth trend) was not activated in 1994.

Figure 3. Map view of interpretation of fault planes (Carena, Suppe 2002).

2.2.2 1994 northridge bridge damages

During Northridge earthquake in 1994 ($M_w = 6.7$), seven major highway bridges collapsed and 157 bridges suffered from heavy damages [5]. Two out of collapsed bridges were horizontally curved in plane.

These curved bridges were the parts of Golden State Freeway (Interstate 5)-Antelope Valley Freeway (California SR14 Interchange) Interchange, called Southbound Separation and Overhead Ramp and North Connector Overcrossing Ramp (Figure 4).

These bridges had been designed before 1971 but constructed after 1971 after San Fernando Earthquake. Southbound Separation and Overhead bridge was a 10-span curved concrete box-girder bridge with seat-type abutment and single column bent. The structure was composed of five

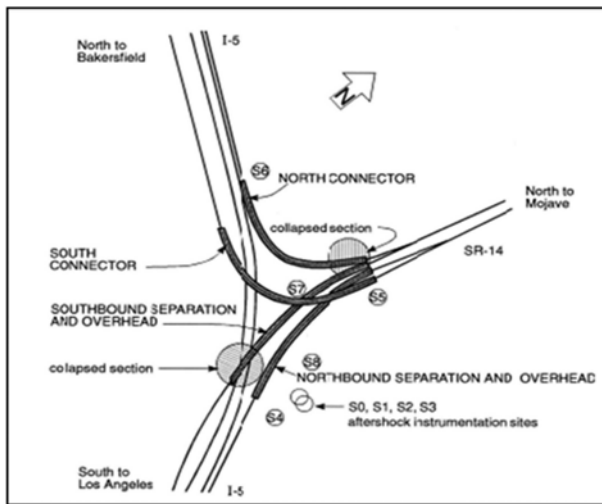

Figure 4. Plan view of SR14/I-5 Interchange and the observed damaged and collapsed regions of the bridges after earthquake (Shirazi 2015)

segments with four in-span expansion joints. Since the structure was under construction during 1971 San Fernando earthquake the damages were mostly settlement of the false work (Figure 5).

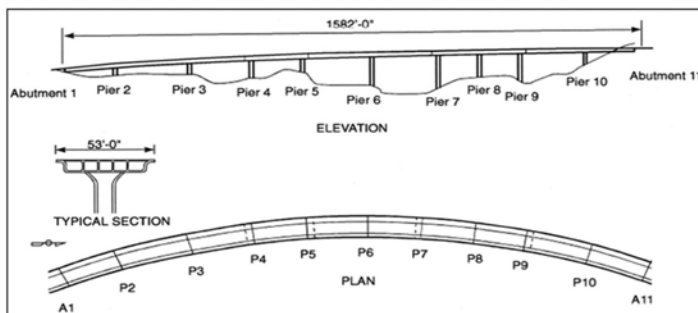

Figure 5. Plan and elevation view of southbound separation and overhead bridge (Moehle, Buckle 1994).

In the Northridge Earthquake the Pier 2 with a short and stiff column had failed and crushing of this pier followed with the collapse of the spans 1, 2 and 3 because of seat loss of the hinges. Pier 3 had also failed due to the collapse of the spans.

The other bridge collapsed during the Northridge earthquake was the North Connector Overcrossing. The structure had a curved concrete box-girder deck with 10 spans, seat-type abutment, and single column bent.

The bridge was composed of of five segments with four in-span hinges. In the Northridge earthquake, similar collapse mechanism had been observed like the Southbound Separation and Overhead bridge. Pier 2 was shorter and stiffer than the adjacent piers.

The collapse of the frame between abutment 1 and pier 3 had been initiated by the failure of Pier 2 because of its short height and consequently large stiffness. After the failure of Pier 2, the simply supported span between abutment 1 and the first hinge collapsed.

2.2.3 Lessons learned from 1994 northridge earthquake

The main structural elements damaged after Northridge are; Expansion joints, Columns, Column caps, superstructure. The bridges damaged or collapsed during the earthquake had commonly in span hinges with gaps and tie bars.

Because of inadequate seat width of the deck at the expansion joints during the strong ground motion the displacement of the deck followed by falling of the spans. The shorter but stiffer columns relatively to the adjacent pier columns generally failed and it was followed by other collapses. Columns inadequate ties both in size and spacing. For column caps they were mainly poor of reinforcement for tying column bents to the deck/superstructure. Confinement reinforcements should be increased to prevent that type of the damage.

2.3 2008 Wenchuan earthquake

2.3.1 2008 Wenchuan earthquake features

The Wenchuan earthquake with a magnitude of 8.0 according to CEA occurred in Sichuan Province, China on May 12, 2008. The earthquake killed 69,227 people and 17,923 people were still missing by October 8, 2008. The hypocenter of the earthquake was close to In Yinxiu Town. almost all buildings were destroyed and about 7,700 people, nearly 80% of the residents, were dead or missing.

The rupture of the Longmen Shan Fault induced the Wenchuan earthquake. Large scale thrusting of the Tibetan Plateau towards the east of the rigid block of Sichuan Basin resulted in the NE-SE dip-slip reverse fault. The fault zone extended from Yingxiu Town, Wenchuan County, to Mianzhu City, Beichuan County, and to Qingchuan County. The epicenter was located at Yingxiu Town. Extensive damage occurred in nearly 300 km long and 50 km wide regions along the fault.

2.3.2 2008 Wenchuan earthquake bridge damages

During the 2008 Wenchuan, many highway bridges damages were observed and reported China earthquake. The curved bridges, especially with high pier columns, exhibited complex dynamic behavior when they were subjected to vertical and horizontal ground motions simultaneously.

The reasons of this problem was defined as because of the mass eccentricity. It might have caused more complex behavior by generating additional bending moments and torsional effect. Baihua Bridge was one off the bridges that suffered from damage during the Wenchuan Earthquake. The bridge was an 18-span reinforced structure composed of straight and curved segments (Figure 6). The spans of the curved segment were supported by tall two-column bent and lateral beam that provided the lateral restraint between the columns. There were five intermediate expansion joints at the bents and two exterior joints at two seat-type abutments. At both ends of each segment, the bridge superstructure rested on the bent cap beam, while the intermediate piers did not have a cap beam.

Figure 6. Schematic of Baihua Bridge before the earthquake and column shear and flexural failure at bent (Moehle 1994).

During the earthquake, the four span continuous curved section had been collapsed completely. The first failure mechanism was stated that, as a consequence of transverse displacement of the bridge, lateral beam-column connections failed because of inadequate lateral confinement. Since the capacity at the connection of the column and lateral beam decreased in larger

drift the bridge collapsed. The dislocation of the girders from the seat in the longitudinal direction because of insufficient seat length and connection failure of the rubber pads supported the girders could be the other possible failure mechanism of the bridge. It is also stated that the curved alignment of the bridge could cause the complicated behaviour as seen in Figure 7.

Figure 7. Possible failure mechanism of Baihua Bridge and collapse of the bent 5 (Kawashima, Takahashi, Ge., Wu, Zhang 2009).

The other bridge damaged during Wenchuan Earthquake was the structures in the Huilan Interchange which consisted of a viaduct and four ramps. The ramps had circular reinforced concrete columns with low transverse volumetric ratio where some of them were fixed at their top to the box-girder and the others were connected to the superstructure via rubber bearings. During Wenchuan earthquake, flexural-shear failure in the circumferential direction of the short columns in the ramp bridge, including crushing of the concrete core, buckling of the longitudinal reinforcements, and rupturing of the transverse hoops, occurred at the top of the pier. The column failure led to fracture at the bottom of the box-girder. The low confinement of the column might be one of the major causes of damage to the columns, which were fixed at the top. The large uplift of the deck at the abutment resulted in damage to the rubber bearings under the box-girder and separation of the abutment and box-girder.

2.3.3 Lessons learned from 2008 Wenchuan earthquake

The main structural elements damaged after Wenchuan Earthquake the Northridge are can be listed as follows; Columns, Cap beams, Curved box girder superstructure. The dislocation of the girders from the seat in the longitudinal direction because of insufficient seat length and connection failure of the rubber pads supported the girders caused collapse of the bridges. In addition, the capacity at the connection of the column and lateral beam decreased in larger drift because of insufficient confinement.

3 CONCLUSIONS

In this study, the damages observed in horizontally curved bridges in the past earthquakes were investigated and the lessons to be learned according to the results obtained from past earthquakes on the curved bridges will be examined and summarized. In the scope of this study the destructive earthquakes; 1971 San Fernando, 1994 Northridge and 2008 Wenchuan were studied based on the damages and collapses occurred at the horizontally curved bridges. The major damage types that cause bridge closure are; unseating of the superstructure, column shear collapse, foundation collapse, bearing collapse and insufficient column bending capacity.

Researches have shown that although the similar damages had been observed for straight and curved bridges, the curved ones should be investigated precisely as they have potential risk because of the geometrical irregularities. The seismic response of the curved bridges should be studied regarding the earthquake direction effect. For seismic design of horizontally bridges performing time history analyses can be more beneficial instead of response spectrum analyses. Besides, in-span expansion joints on the superstructure of the curved bridges and the shorter but stiffer columns relatively to the adjacent pier columns should be avoided. The flexural and shear capacity of the piers should be investigated properly. Consequently, the seismic response of the curved bridges should be investigated in consideration of the lessons taken from past earthquakes and these effects should be taken into consideration at both design and construction stages of the horizontally curved bridges.

Using the USGS database to study parameter uncertainty when assessing pier scour using the HEC-18 framework

G. Gavriel, M. Pregnolato & P.J. Vardanega
University of Bristol, Bristol, UK

ABSTRACT: Bridges are important lifelines linking communities and their collapse due to flood events can result in severe social and economic impacts for communities. Estimation of maximum bridge scour depth is important for determining effective mitigation and adaptation procedures. HEC-18 is a well-established methodology to calculate scour depth. However, it is also often reported to yield conservative estimates of maximum scour depth in various publications. This paper presents a simple sensitivity study to assess the key inputs that affect the computation of maximum scour depth using the HEC-18 framework. The parameter ranges used in this analysis are sourced from an openly accessible database from the United States Geological Survey (USGS). In this study, HEC-18 is assessed against field measurements. The primary aim of this research is to study the impact of each key input parameter on HEC-18 estimates of maximum scour depth estimates.

1 INTRODUCTION

1.1 Background

Scour is the removal of material from the riverbed due to hydraulic actions. Bridges become unstable due to the presence of scour holes near the piers. This paper focuses on bridge pier scour, which is a type of local scour (see Maddison 2012 for a review of scour types). Improved understanding of bridge scour processes can assist with further development of probabilistic assessments (e.g. Maroni et al. 2022), and can also aid specification of scour monitoring systems (see Prendergast & Gavin 2014, Vardanega et al. 2021 for recent reviews of scour monitoring technologies). In this paper field data from the United States Geological Survey (USGS) scour database (Benedict & Caldwell 2014a, b, USGS 2004), hereafter referred to as the ‘USGS database’, are used along with the equations of HEC-18 to carry out a one-at-a-time sensitivity study to rank the effect of key parameters on computed maximum scour. The USGS database has been used in Gavriel et al. (2023) to examine the effect of different data sub-sets on the levels of conservatism from estimations of maximum scour depth using HEC-18 while this paper focusses on input parameter sensitivity.

The HEC-18 framework (e.g. FHWA 1993, Richardson & Davis 1995, Richardson & Davis 2001, Arneson et al. 2012) (along with other scour prediction frameworks) comprises a series of equations developed using laboratory flume tests (e.g. Richardson & Davis 1995, Richardson & Davis 2001, Zevenbergen 2010, Arneson et al. 2012, Briaud 2015a, b, Qi et al. 2016). Maximum scour depth of bridge piers is characterized by the following equation as given from Arneson et al. (2012):

$$\frac{y_s}{y_1} = 2.0K_1K_2K_3\left(\frac{a}{y_1}\right)^{0.65} F_r^{0.43} \quad (1)$$

the terms in Eq. 1 are defined in Table 1. An additional constant, named K_4 , was part of the HEC-18 equation in the previous version of HEC-18 (Richardson & Davis 2001). K_4 is used to correct for armouring of the piers caused by bed material. K_4 has been removed from the latest version of the framework (Arneson et al. 2012), it is therefore not included in Eq.1 and in this work. Further updates to the framework after the release of Arneson et al. (2012) are discussed in Shan et al. (2016) but these have not be incorporated into the analyses presented in this paper.

Many studies showed that HEC-18 framework gives conservative predictions when used to estimate field scour (Richardson & Davis 1995, Mueller & Wagner 2002, Zevenbergen 2010, Qi et al. 2016, Gavriel et al. 2022). Pizarro & Tubaldi (2019) compared the HEC-18 equations from Richardson & Davis (2001) to four other scour prediction methods using numerical data and concluded that all the studied methods produce conservative results. Yan (2013) and Rathod & Manakar (2020) also investigated the reliability of the HEC-18 equations compared to other scour methodologies concluding that the reliability of HEC-18 is predominately related to the model uncertainty. Figure 1 shows the results of the comparison between 19 flume test results from Kiraga et al. (2020) with estimated values from the HEC-18 equation for maximum bridge pier scour depth. In Figure 1, 14 out of the 19 scour depths are overestimated compared to the results from the flume tests.

Table 1. Definition of HEC-18 parameters (Arneson et al. 2012).

Parameter	Units	Notation	Definition
Pier Width	m	a	Width of the pier in the direction of flow
Pier Length	m	L	Length of the pier
Flow Depth	m	y_1	Flow depth directly upstream from the pier
Approach Velocity	m/s	V_1	Average flow velocity directly
Attack Angle	°	ϑ	Approach angle of the water in relation to the pier during a flood event
Scour Depth	m	y_s	Maximum depth of scour hole below the riverbed
Pier nose geometry correction factor	-	K_1	Correction factor based on the pier nose geometry
Bed condition correction factor	-	K_2	Correction factor based on the angle of attack of flow
Attack angle correction factor	-	K_3	Correction factor based on the bed conditions
Froude Number	-	F_r	Froude number

Figure 1. Comparison of scour depth measured in 19 flume tests by Kiraga et al. (2020) compared with the scour depth calculated using the HEC-18 framework (data from Kiraga et al. (2020)).

The full series of equations for the HEC-18 framework and detailed analysis on how to calculate scour depth can be found in Arneson et al. (2012). To calculate scour depth, the method

considers *bed material characteristics* (K_3), *flow characteristics* (V_1, y_1, ϑ), *fluid properties* (Fr_1) and the *geometry of the pier* (L, a) (Richardson & Davis 2001, Arneson et al. 2012). HEC-18 considers a round shaped pier as the base case scenario and thus K_1 corrects for the pier shape in the case it is either square (10% higher scour depth) or sharp (10% lower scour depth) (Richardson & Davis 2001, Arneson et al. 2012). K_2 corrects for the case where ϑ takes a value which is not zero (Richardson & Davis 2001, Arneson et al. 2012). K_3 takes the value of 1.1 except in the scenario of dunes which are higher than 3000 mm, where scour depth is considered to be 30% larger when compared to dunes which are less than 3000 mm high (Richardson & Davis 2001, Arneson et al. 2012). For more information on dune height, see Section 7.1 in Arneson et al. (2012). Out of the 936 datapoints, no value is higher than 1.1 for K_3 (Richardson & Davis 2001, Arneson et al. 2012). To rank the key parameters (from Table 1) that affect the HEC-18 computation and hence potentially contribute uncertainty in the results, a simple one-at-a-time sensitivity study was carried out using the HEC-18 equations and the USGS database.

1.2 Study aims

This research analyses the HEC-18 framework against 936 field datapoints to investigate its validity using real field data. The study aims to: (1) illustrate the conservatism of the HEC-18 approach by comparing maximum scour depth predictions to those from the USGS database and (2) perform an sensitivity analysis of the key HEC-18 parameters by using field data from the USGS database.

2 METHODOLOGY

2.1 USGS database

The USGS database includes data from 936 bridge piers from 31 out of the 50 states in the USA. The measurements of V_1, y_1 and ϑ are all taken during high flows. L and a were collected in times of low flow (Norman 1975, Jarrett & Boyle 1986, Butch 1991, Southard 1992, Mueller et al. 1994, Wilson 1995, Atkins & Hedgecock 1996, Hayes 1996, Hodgkins & Lombard 2002, Holnbeck 2011). For further details of the measurement of the scour depth hydraulic properties, soil properties and other information on HEC-18, the reader is directed to Benedict & Caldwell (2014a, b) and USGS (2004). Figure 2 shows that about 90% of the data is overestimated, confirming the results of past research (cf. Zevenbergen 2010, Arneson et al. 2012, Qi et al. 2016) that the method over-estimates the scour depth assessment.

Figure 2. Measured maximum scour depth against calculated maximum scour depth using HEC-18 using 936 datapoints from USGS database; 839 out of 936 points over-estimated (data from the USGS database).

2.2 Parameter distributions

Figure 3 shows the distributions of the parameters given in Table 1 from analysis of the USGS database used in this study. a , V_I , y_I and ϑ were compared against their frequencies to reveal approximately normal distributions (from a visual inspection of Figure 3). The histograms for a , y_I and V_I in Figure 3 reveal a distribution which can be approximated as normal. For the aforementioned inputs, there is a higher concentration of data near the mean and less data around one standard deviation above and below the mean. The assumption that ϑ is normally distributed is less reasonable and another distribution may potentially fit the data better. Analysis of the distribution of the parameters and the best-fit probability density functions will be undertaken in future work to refine the results presented in the present paper.

The data distribution for L is shown in Figure 3 but it should be noted that since 311 out of the 936 field datapoints were unavailable the unknown L inputs were calculated based on the 625 defined L values. 11.7 is the average of the L/a ratio of the defined a inputs therefore $L = 11.7a$. Also, K_1 , K_2 and K_3 input parameters are determined from primary data from the USGS database therefore their distributions are not shown on Figure 3. K_1 , K_2 and K_3 are studied in the following sensitivity study for completeness, however, any conclusions regarding their relative influence on the calculations should be made with caution.

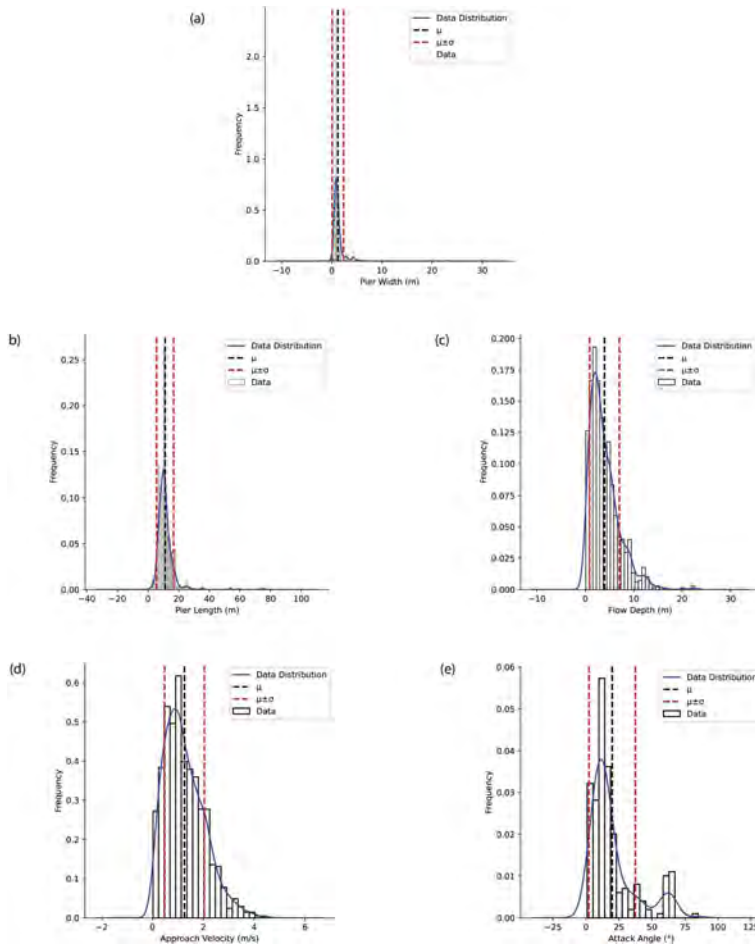

Figure 3. Histograms showing the distribution of the input data against the normal distribution; σ = standard deviation; μ = mean; (a) a ; (b) L ; (c) y_I ; (d) V_I ; (e) ϑ (data from the USGS database).

2.3 Sensitivity analysis

The following analysis assesses the impact each input parameter has on the pier scour estimation using the HEC-18 framework. For this analysis, the mean (μ), minimum, maximum and standard deviation (σ) were calculated for each input based on the 936 data from the USGS database (Table 2) (see Figure 3). Then, two base case scenarios are defined. For Base Case scenario 1 (BC1), all inputs are equal to their mean except ϑ which is equal to zero (this represents the case of zero bridge skew angle which occurs for about 80% of the records in the database). BC1 gives a value of scour depth equal to 2.04m. For Base Case scenario 2 (BC2), all inputs are equal to their mean. BC2 gives a scour depth value equal to 5.04m. Then, one input from each base case scenario is substituted on each iteration with the calculated minimum, maximum, $\mu \pm \sigma$ or $\mu \pm 0.5\sigma$. Each time an input changes, the result calculated from HEC-18 is recorded (Table 3). Table 3 shows all the scour depths calculated from substituting one input parameter at a time. To assess what impact each input has on the scour depth estimation, for each input a ratio of the computed answer against the base case scour depth is calculated. The difference between the maximum ratio and the minimum ratio for each input is shown by Table 3 as ‘maximum difference’. The difference in ratio between ‘ $\mu \pm 0.5\sigma$ ’ is also calculated. The difference in ratio is shown as ‘ $\pm 0.5\sigma$ difference’ in Table 3. The equation for calculating the spread for each iteration is shown by Eq. 2. Eq. 3 shows the calculation performed to determine the maximum difference between the iterations for each input parameter. A similar procedure was performed to calculate the ‘ $\pm 0.5\sigma$ difference’. Eqs.2 and 3 are as follows:

$$\gamma_s = \frac{y_c}{y_{bc}} \times 100 \quad (2)$$

where, γ_s = spread, y_c = calculated scour depth, y_{bc} = calculated scour depth from the base case scenario,

$$\gamma_{s(\Delta)} = \gamma_{s(max)} - \gamma_{s(min)} \quad (3)$$

where, $\gamma_{s(D)}$ = maximum difference in variation between calculated γ_s values for the input parameter considered, $\gamma_{s(max)}$ = maximum value from the calculated γ_s values for the input parameter considered, $\gamma_{s(min)}$ = minimum value from the calculated γ_s values for the input parameter considered.

The larger is the γ_s the higher the input factor influences the projected scour depth. The $\mu \pm 0.5\sigma$ is also calculated, in addition to $\mu \pm \sigma$ to test whether the rank changes when the inputs change. Values equal to zero have been eliminated from the computations for V_I and y_I because zero values give an error when scour is estimated (due to division by zero). Additionally, 81% of the USGS database consists of attack angles taken as zero. To better assess ϑ , two different base cases were considered to run the analysis as mentioned earlier. The parameter rank order changes for each base case scenario. For BC1, for which ϑ is considered to be zero, the rank remains unchanged for ‘maximum difference’ and ‘ $\mu \pm 0.5$ difference’. From BC1, a is ranked first indicating that it has the greatest impact on the scour depth estimation for HEC-18. V_I has the second highest difference, followed by y_I . For ‘ $\mu \pm 0.5\sigma$ difference’, V_I appears to be the most influential followed by ϑ .

For BC2 however, the rank changes between ‘maximum difference’ and ‘ $\mu \pm 0.5\sigma$ difference’. For ‘ $\mu \pm 0.5\sigma$ difference’ the results agree with Rathod & Manekar (2020) which found that ϑ is the most influential factor whereas the y_I was found to be the least influential. The rank for ‘maximum difference’ does not agree with Rathod & Manekar (2020). The inconsistency between the findings of this research paper and Rathod & Manekar (2020) may be because Rathod & Manekar (2020) performed a sensitivity analysis based on 19 laboratory based flume tests and random values produced from Monte Carlo analysis, whereas this research paper uses field data from the USGS database. In the instance of BC2, for which the attack angle is the mean of all

the non-zero θ angles, the difference is not the same for the ‘maximum difference’ and the ‘ $\mu \pm 0.5\sigma$ difference’. For the case of ‘maximum difference’, a appears to have the most impact on the scour depth estimation followed by V_I . K_I is listed as the least influential factor. Likewise, in the case of ‘ $\pm 0.5\sigma$ difference’, θ is again the most influential followed by a .

3 DISCUSSION

The difference in the ranking between the two base case scenarios shows that when θ takes a value which is not zero, θ impacts the scour depth estimation. In the case for which θ is zero, a is highly influential on the final scour depth, although its influence reduces when θ takes a value which is not zero. V_I has a high impact on the scour depth estimation, no matter the value of the attack angle. y_I appears to be of medium importance, since its rank ranges between places 3 to 5 (see Table 4).

Table 2. Parameter ranges from the USGS database.

Parameter*	μ	min.	max.	σ	$\mu+\sigma$	$\mu+0.5\sigma$	$\mu-\sigma$	$\mu-0.5\sigma$	c_v (%)
a (m)	1.23	0.29	22.86	1.14	2.37	1.80	0.09	0.66	93
L (m)	11.15	2.44	74.88	5.49	16.65	13.90	5.66	8.40	49
y_I (m)**	3.96	0.10	22.52	3.07	7.03	5.49	0.89	2.42	78
V_I (m/s)**	1.26	0.02	4.48	0.78	2.04	1.65	0.48	0.87	62
θ (°)**	19.91	1.00	85.00	17.55	37.46	28.69	2.36	12.14	88
K_I	1.00	0.90	1.10	0.06	1.06	1.03	0.93	0.96	6

*units given in brackets, if parameter is dimensionless no unit is shown. ** y_I calculations exclude values equal to zero (6 cases), V_I calculations exclude values equal to zero (13 cases) since $V_I = 0$ results in $y_s = 0$ which is unreasonable, θ calculations exclude values equal to zero (712 cases); c_v = Coefficient of Variation = σ/μ . $K_3 = 1.1$ for all cases considered in this paper.

Table 3. Results for trialed combinations for which the pier scour depth is calculated using HEC-18 by varying one parameter at a time; μ = mean; σ = standard deviation [K_I calculations not shown for brevity].

Parameter	a (m)		L (m)		y_I (m)		V_I (m/s)		θ (°)	
	BC1*	BC2**	BC1	BC2	BC1	BC2	BC1	BC2	BC1	BC2
μ	2.04	5.04	2.04	5.04	2.04	5.04	2.04	5.04	2.04	5.04
Min	0.80	2.27	2.04	2.79	1.24	3.06	0.35	0.87	-	2.25
Max	13.62	14.54	2.04	5.83	2.58	6.38	3.52	8.71	-	8.57
$\mu + \sigma$	3.13	5.73	2.04	5.83	2.21	5.45	2.51	6.21	-	6.57
$\mu + 0.5\sigma$	2.61	5.39	2.04	5.64	2.13	5.27	2.29	5.66	-	5.97
$\mu - \sigma$	0.38	1.08	2.04	3.71	1.67	4.12	1.35	3.33	-	2.51
$\mu - 0.5\sigma$	1.36	3.90	2.04	4.40	1.91	4.72	1.74	4.30	-	3.92
$\gamma_s(\Delta)$ [Eqs. 2 & 3]	648	266	0	60	66	66	155	155	-	125
$\gamma_s(\Delta)$ [Eqs. 2 & 3] for $\pm 0.5\sigma$	30	30	0	25	11	11	27	27	-	41

*Base Case 1 (BC1): μ of each input parameter from the USGS database except θ which equals to zero (accounts for 81% of the database for which $\theta = 0$). **Base Case 2 (BC2): μ of each input parameter from the USGS database.

Table 4. Ranking of the parameters showing the level of influence on estimation of pier scour depth using HEC-18 to calculate it for four different cases.

	$\pm \sigma$		$\pm 0.5\sigma$	
	Rank (BC1)	Rank (BC2)	Rank (BC1)	Rank (BC2)
a (m)	1	1	1	2
L (m)	5	5	5	4
y_I (m)	3	4	3	5
V_I (m/s)	2	2	2	3
θ (°)	-	3	-	1
K_I	4	6	4	6

4 CONCLUSIONS

This paper used 936 datapoints from the USGS database, to carry out a one-at-a-time sensitivity study for the HEC-18 framework. The analysis showed that the influence of the inputs change depending on whether the angle of attack takes a non-zero value. For BC1 the attack angle is zero; in this case, pier width is the most influential followed by the flow velocity. For BC2 the attack angle is a non-zero value and the attack angle and the pier width are highly influential. A more detailed analysis should consider additional distributions (other than the normal distribution) to better determine the most influential factor(s) affecting maximum scour depth predictions using the HEC-18 framework.

5 DATA AVAILABILITY

This study has not generated new experimental data.

ABSTRACT: Due to the long-term environmental exposure, steel bridge is threatened by loading capacity degradation caused by corrosion. Service life prediction is essential for steel bridges using time-variant reliability methods. This paper attempts to present a reliability-based methodology for the serviceability assessment of a steel girder subjected to corrosion. A corrosion growth model is adopted in this paper to evaluate the reliability of a corroded steel girder over time. A stochastic model of load effects is developed, and the first passage probability with a developed analytical solution is employed. To facilitate the practical application of the proposed methodology, a case study is presented. The method presented in this paper can serve as a rational tool for developing rehabilitation or maintenance strategies for steel bridges

1 INTRODUCTION

Corrosion-induced deterioration of steel almost certainly decreases the structural integrity. Many researchers (e.g., Li & Yang 2021, Wasim et al. 2020, Wang et al. 2018, Fernandez et al. 2015) indicated that corrosion not only reduces the cross-sections of structural components but also decreases the material properties. Accordingly, massive costs of repair and life disruption are induced. For example, the corrosion-induced annual losses in the building sector were approximately \$22.6 billion in the United States (Koch et al. 2001). Therefore, it is necessary to develop a cost-effective assessment method for corroded steel structures with an understanding the corrosion mechanism.

Corrosion on the steel surface is initialized by being exposed to oxygen and moisture and the corrosion growth can be accumulated by chloride chemicals (Gong & Frangopol 2020). For atmospheric corrosion, the progress is a combination of Oxygen reduction reaction and hydrogen evolution reaction (Revie 2008):

In Equation (2), H_2 can be stored in the micro-voids of steel to produce pressure, inducing the grain cracks that cause mechanical deterioration.

Field studies suggested that corrosion growth on steel is a random phenomenon, showing considerable variability (Gong & Frangopol 2020, Czarnecki & Nowak 2008). It is related to many factors such as environmental chloride level, moisture, and protection level. The deterministic approaches to predict the capacity of corroded steel structural components may not

be practical enough due to the random nature of corrosion growth and the inherent uncertainties of materials. As such, it is rational to probabilistically assess the service life and structural integrity of steel structures based on time-variant reliability theory.

This paper intends to present a time-variant reliability method for predicting the failure probability of corroded steel girder. The time-variant variables, such as the corrosion growth, are considered in the reliability analysis. A stochastic model of the load effect is developed. A worked example is presented to illustrate the proposed method. The significance of the proposed method in this paper is that it can predict failure time and be used for developing a time-dependent maintenance strategy.

2 TIME-VARIANT RELIABILITY

A failure criterion needs to be established to predict the probability of structural failure over its lifetime. In reliability theory, the failure criterion is expressed as follows (Melchers 1999):

$$G(t) = L(t) - R(t) \quad (3)$$

where $G(t)$ is the limit state function at time t , $L(t)$ is the load effect on the structures at time t , $R(t)$ is the acceptable limit (resistance) at time t .

The probability of failure can be determined as follows:

$$p_f(t) = P[G(t) \geq 0] = P[L(t) \geq R(t)] \quad (4)$$

where $P[\cdot]$ denotes the probability of an event. Equation (4) represents a typical upcrossing problem, as shown in Figure 1.

Figure 1. A schematic illustration of the first upcrossing.

The probability of upcrossing can be determined by the first passage probability as follows (Melchers 1999):

$$p_f(t) = 1 - [1 - p_f(t = 0)] \exp\left(-\int_0^t v dt\right) \quad (5)$$

where p_f denotes the probability of failure, and v denotes the mean upcrossing rate, which can be evaluated from the well-known Rice formula (Rice 1944) as follows:

$$v = v_R^+ = \int_{\dot{R}}^{\infty} (\dot{L} - \dot{R}) f_{L\dot{L}}(R, \dot{L}) d\dot{L} \quad (6)$$

where v_R^+ is the upcrossing rate of the load effect process $L(t)$ relative to the threshold $R(t)$, \dot{R} is the slope of $R(t)$ with respect to time, \dot{L} is the time derivative process of $L(t)$, $f_{L\dot{L}}$ is the joint probability density function for $L(t)$ and \dot{L} .

Li & Melchers (1993) derived an analytical solution to Equation (6) for non-stationary Gaussian process, which is expressed as follows:

$$v_R^+ = \frac{\sigma_{\dot{L}|L}}{\sigma_L} \phi\left(\frac{R - \mu_L}{\sigma_L}\right) \left[\phi\left(\frac{\dot{R} - \mu_{\dot{L}|L}}{\sigma_{\dot{L}|L}}\right) - \left(\frac{\dot{R} - \mu_{\dot{L}|L}}{\sigma_{\dot{L}|L}}\right) \Phi\left(-\frac{\dot{R} - \mu_{\dot{L}|L}}{\sigma_{\dot{L}|L}}\right) \right] \quad (7)$$

where μ and σ are the mean and standard deviation of random variables represented by subscripts L and \dot{L} , “|” denotes the condition, ϕ and Φ indicate the standard normal probability density function and cumulative distribution function, respectively.

For a given Gaussian stochastic process with a mean function $\mu_L(t)$ and auto-covariance function $C_{LL}(t_i, t_j)$, all terms in Equation (7) can be obtained as follows:

$$\mu_{\dot{L}|L} = E[\dot{L}|L = R] = \mu_{\dot{L}} + \rho_L \frac{\sigma_{\dot{L}}}{\sigma_L} (R - \mu_L) \quad (8)$$

$$\sigma_{\dot{L}|L} = [\sigma_{\dot{L}}^2 (1 - \rho_L^2)]^{\frac{1}{2}} \quad (9)$$

With

$$\mu_{\dot{L}} = \frac{d\mu_L(t)}{dt} \quad (10)$$

$$\sigma_{\dot{L}} = \left[\frac{\partial^2 C_{LL}(t_i, t_j)}{\partial t_i \partial t_j} \Big|_{i=j} \right]^{1/2} \quad (11)$$

$$\rho_L = \frac{C_{L\dot{L}}(t_i, t_j)}{[C_{LL}(t_i, t_j) \cdot C_{\dot{L}\dot{L}}(t_i, t_j)]^{1/2}} \quad (12)$$

$$C_{L\dot{L}}(t_i, t_j) = \frac{\partial C_{LL}(t_i, t_j)}{\partial t_j} \quad (13)$$

In time-variant reliability, it is justifiable to model the load effect $L(t)$ as a stochastic process. A generic model of stochastic process of the load effect $L(t)$ can be expressed as follows (Li & Melchers 2005):

$$L(t) = L_l(t) \cdot \zeta_L \quad (14)$$

Where $L_l(t)$ is a pure time function of load effect, ζ_L is a random variable accounting for all variability of basic random variables with unity mean, i.e., $E(\zeta_L) = 1$ and constant coefficient of variation (CoV).

The mean and auto-covariance function of $L(t)$ can be determined as follows (Li & Melchers 2005):

$$\mu_L(t) = E[L(t)] = L_l(t) \cdot E[\zeta_L] = L_l(t) \quad (15)$$

$$C_{LL}(t_i, t_j) = (CoV)^2 \rho_L L_l(t_i) L_l(t_j) \quad (16)$$

where $\mu_L(t)$ is the mean of load effect at time t , $C_{LL}(t_i, t_j)$ is the auto-covariance function of load effect between two points in time t_i and t_j , ρ_L is the auto-correlation coefficient for $L(t)$ between two points in time t_i and t_j .

As there are many random variables involved in the load effect, its mean and standard deviation function can be numerically obtained by using the Monte Carlo simulation (MCS) method. Since the load effect $L(t)$ is a function of many variables, such as the corrosion damage size, pipe geometry and loading, it is reasonable to be assumed as non-stationary Gaussian processes based on the central limit theorem.

3 WORKED EXAMPLE

To illustrate the application of the method, an example is adapted from Nie et al. (2020). In this case study, a simple supported H-steel girder ($150\text{mm} \times 150\text{mm} \times 8\text{mm} \times 8\text{mm}$) is selected, as shown in Figure 2.

The limit state function of the corroded steel girder can be established based on the maximum stiffness and bearing capacity as follows (Nie et al. 2020):

$$G(t) = \gamma_x W_x(t) f_y(t) - M_D - M_l \quad (17)$$

where γ_x is the plastic coefficient and $\gamma_x = 1.05$ for H-steel, $W_x(t)$ is the section modulus at time t , $f_y(t)$ is the nominal yield strength and it is assumed to be 287 MPa, M_D is the bending moment caused by the dead loads, M_l is the bending moment caused by live loads.

In Equation (17), the section modulus $W_x(t)$ can be calculated as follows:

$$W_x(t) = \frac{I_x(t)}{\frac{H}{2} - h(t)} \quad (18)$$

where $h(t)$ is the corrosion depth which can be expressed as a power-law model as follows:

$$h(t) = at^b \quad (19)$$

where $a=70.6$ and $b=0.789$ are the empirical fitted coefficients obtained from Kayser (1988).

$I_x(t)$ is the inertial moment of corroded steel girder that can be expressed as follows:

$$I_x(t) = \frac{(t_w - 2h(t))(H + 2h(t) - 2t_f)^3}{12} + \frac{2(B - 2h(t))(t_f - 2h(t))(H - t_f)^2}{4} + \frac{(B - 2h(t))(t_f - 2h(t))^3}{12} \quad (20)$$

where t_w is the web thickness and t_f is the flange thickness. The distribution types, mean and variation coefficient of the essential parameters are shown in Table 1.

Figure 2. Cross-section of the girder.

Table 1. Essential parameters in the example girder.

Parameters	Distribution	Mean	Variation coefficient
Dead load $D \left(\frac{kN}{m} \right)$	Normal distribution	6.80	0.07
Live load $l \left(\frac{kN}{m} \right)$	Gumbel distribution	0.88	0.23
Section width $B \text{ (mm)}$	Normal distribution	150	0.03
Section height $H \text{ (mm)}$	Normal distribution	150	0.03
Flange thickness $t_f \text{ (mm)}$	Normal distribution	8	0.03
Web thickness $t_w \text{ (mm)}$	Normal distribution	8	0.03

4 RESULTS

The load effect is calculated by Equations (14), (15) and (16). The mean of function and standard deviation can be calculated as a function of time using Monte Carlo simulation (MCS) together with the proposed model of corrosion depth. The up-crossing rate can be obtained

Figure 3. Probability of girder failure.

from Equation (7) for a given auto-correlation coefficient, and the probability of failure can be calculated by Equation (5).
