Limits of reuse of steel

P. Kamrath

Paul Kamrath Ingenieurrückbau GmbH, Germany

ABSTRACT: Demolition is the traditional technique, which handles the end-of-lifetime of any building, if refurbishing is not applicable anymore. Demolition is one of the biggest source of waste all over the world. The will to reduce waste leads to different recycling techniques. While waste of concrete can only go through a downcycling process and produces recycled gravel, steel and iron are used as source for new steel parts for decades. Old Steel will be generally separated and is used as a resource to produce new steel. Because steel is an expensive resource, the recycling quota of steel is above 90%. Nevertheless, the recycling of steel is energy hungry and produces a huge CO₂-footprint. Thus, the reuse of steel-elements can minimize this ecologic footprint. While for most C&D waste the focus lies on additional recycling options and the concept of urban mining is adapted, the future of steel-based buildings should be the reuse of steel-parts. The conceptual idea starts already when a building is planned by the application of a “design for deconstruction”. This paper discusses practical aspect of the reuse of steel-based parts and defines limits of reuse. Those limits are given by the steel quality as well as by aspects of contamination (tar, asbestos). Examples of succeeded recovering of steel parts are introduced.

1 INTRODUCTION

Demolition work in the modern building environment produces about 60% of the total waste occurring in Germany. One important key issue of demolition are strategies to prevent waste and therefore to reach high recycling quotes. For most objects to demolish, techniques are based only on a material-view as a waste. In other words: The building will become waste, which is first sorted and then it will be decided depending on the different materials of waste whether certain recycling techniques are useful. Thus, steel is sorted and is being put back into the cycle. Concrete may be downcycled to gravel. With these techniques and decisions the waste is going to be minimized. Such techniques are calls “urban mining”, which describes the view of something to demolish as a store of more or less usable materials.

A new view to the building to be demolishes does not focus on materials and their use as a recycled product but on parts of buildings as they are. Wouldn't it be good to keep columns and beams in-tact and to reuse them as already premanufactured used parts for a new building and to give them a new life? To precisely differentiate demolition with the intend of reusing parts from demolition intending the use of raw materials from now on deconstruction is used to describe the intend to keep parts or whole building intact and demolition is used only in the meaning of a total teardown with focusing on materials (see Figure 1).

2 DECONSTRUCTION VS. DEMOLITION

2.1 *Reuse, deconstruction and demolition*

Handling the end-of-lifetime of any building leads to three scenarios of renewing a building (Kamrath & Hechler, 2011b):

Deconstruction: A clearance could extend the lifetime and could be an alternative to demolition. During a building clearance, any non-load bearing parts of the building will be deconstructed. The rebuild process starts with the old skeleton.

Reuse of Structure: Deconstruction and reuse of the structure itself could be an alternative for some structures, especially those made of steel. This method helps to generate a second life for the load bearing structure e.g. for bridges or halls at another place.

Demolition: Complete demolition is the typical end-of-life scenario. To avoid waste and landfilling, reuse and recycling of materials should be considered.

The lowest impact on natural resources is achieved by reuse of whole structures or even a whole building. If a whole building can be deconstructed and rebuilt elsewhere, no waste is produced at all. If this possibility is considered prior to build, this is called “design for deconstruction”.

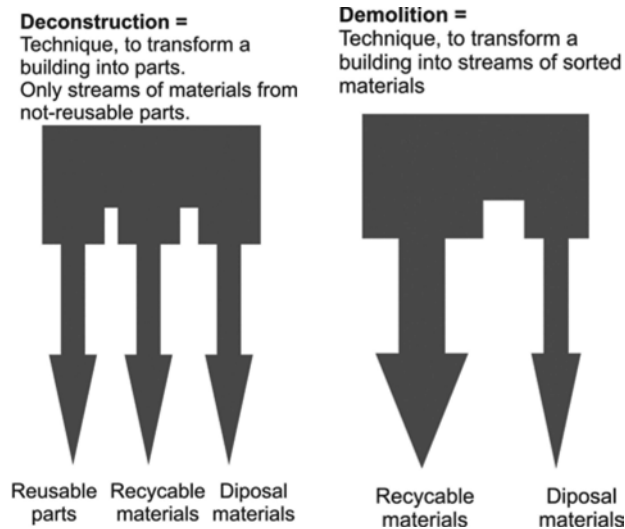

Figure 1. Waste streams occurring for general demolition work which is dividing the stream into recyclable materials and disposal materials only (e.g. hazardous). Comparison to a deconstruction waste streams, which handles reusable parts as a third stream.

2.2 Recycling

If whole structural elements cannot be reused or deconstruction is not applicable (e.g. structure failure), demolition and recycling of materials is the best choice. Recycling is divided into three stages, which are:

1st order recycling is the complete recycling of material with the focus of creating a new product with the resources of used materials. This is possible with all kinds of metals, plastics and glass. Steel is the world’s most recycled material. After melting the sorted materials, a new product of the same quality can be made.

2nd order recycling or downcycling can be done with all not-polluted mineral materials such as concrete, brick-stone and general masonry. Recycling of concrete is the process of producing gravel which can be used instead of natural gravel. Concrete however, unlike a 1st order material, while made from cement cannot be recreated into more or new cement. Once concrete has been made, there is no practical way to decompose it into the basic elements of sand, water, aggregate and cement that went into its formation. Nevertheless, processing waste concrete to produce recycled concrete aggregate (RCA) or recycled crushed concrete (RCC) has the potential to greatly reduce the quantity sent to landfill each year and complements the government’s sustainable development and waste minimization policies. The potential of RCC/RCA differs according to the local market. If natural gravel is cheap, the demand

for recycled concrete is low. If no natural resources exist (e.g. the Netherlands) the potential is high and the possibilities for recycling are high as well.

3rd order recycling concerns thermal use. Wooden materials and plastics with no possibility of 1st order recycling are possible sources of energy for power plants. If no thermal use is possible (e.g. due to pollution or contamination) landfilling is the only possibility.

2.3 *End-of-Life data for common parts*

Deconstruction is a special way of demolition with the goal, to keep as much from structures intact for a latter use as possible. The conceptual idea for matching deconstructing techniques is the “reverse building” technique (Hechler et al. 2011).

Demolition is focused on safety and materials while reverse building keeps elements intact. This technique is not applicable to any building. The lighter weighting the structures are, the better a reverse building concept is possible. Most of today buildings to deconstruct or demolish were not planned for a later use. Thus, the boundary conditions do not fit to perform a full reverse building deconstruction. There are a few examples of buildings, which apply to a “design for deconstruction”. That means, those buildings were already planned to deconstruct and reuse the whole on another site later (Dorsthorst & Kowalczyk 2002).

The life cycle of as structure consist of the production, fabrication, transport and erection of the construction materials, the use of the construction and finally the end-of-life of the construction.

Steel is here from the world’s most recycled material. The main conclusion from the diagram is, that it is mainly of interest to recycle materials which can be recycled cost-effectively and indefinitely, e.g. aluminum cans and glass bottles, can be reclaimed and recycled into more of the original product: new cans and bottles. The energy and material savings are substantial, and there are high consumer recycling rates in many countries.

The recycling of C&D Waste only partially addresses the problem, because it can lead to considerable consumption of resources in re-processing and transportation. Only a fraction of construction elements can be reclaimed and reused for their original purpose, and this is normally the best environmentally sustainable option at a local level. The average end-of-life scenario for construction materials is shown in Table 1 (SCI).

Recycling is hereby defined as the end-of-life recovery and reprocessing of a product (e.g. by re-melting of steel construction products to form new steel products) and Reuse is defined as the end-of-life recovery and reuse (e.g. of steel construction products as a product filling the same function with or without some reprocessing). The recycling rate (within a defined system) is defined as:

The tonnage of a product recycled/Tonnage of the product arising on demolition sites

The reuse rate is similar defined by replacing the word recycled with reuse (Hechler et al. 2011).

Confusion in existing in peoples’ minds about the nature of concrete recycling. Concrete, however, while made from cement, cannot be recycled into more cement. Once concrete has been made, there is no practical way to decompose it into the basic elements of sand, water, aggregate and cement that went into its formation. However, there are opportunities to crush and reuse concrete recovered from construction demolition. The recycled material can be substituted for fresh aggregate in some applications (World Business Council for Sustainable Development, 2008).

3 EXAMPLE: DECONSTRUCTION AND REUSE OF ROOFTOP MADE OF STEEL

3.1 *Overview*

The single storey hall was part of an old fabrication plant and located in Wuppertal, Germany. The production company has two fabrication sites. Due to growth over the years, this site was planned to be demolished and to be replaced by modern fabrication buildings afterwards.

Table 1. Average end-of-life scenario data.

Material	Recycling (%)	Reuse (%)	Landfill (%)
girder	88	11	1
Lintel	88	10	2
Road barrier	65	34	1
Post coated inner wall components	59	7	34
Doorframes	90	9	1
Insulated inner wall box	87	11	2
Metalstud wall	92	7	1
Services	87	11	2
Light gauge steel (housing)	87	11	2
Purlins and rails	87	1	2
Composite floor decking	81	15	4
Composite sandwich cladding panels	53	37	10
Roof plate (coated)	81	15	4
Profiled cladding and roofing panels	81	15	4
Heavy structural sections	87	11	2
Reinforcement [Steel Recycling Institute]	65	0	35

Total there existed 2 halls as well as an office building. While the office building and the greater part of the fabrication halls from the 1950s were planned to be demolished, the oldest hall was planned to keep for historical reasons. Unfortunately, modifications in the 1950s combined the bearing constructions of the office building with the historical hall. Because the fabrication started once in this hall, there was a deep interest, to keep as least the roof-structure and to integrate this as a remembrance to the beginning of the company.

3.2 Deconstruction

Demolition techniques are quite different from deconstruction. While demolition is fast because nothing needs to be kept intact, deconstruction or reverse building needs other machines as well as more care to the parts which should be deconstructed. It is evident to plan, when the technique has to be switched from demolition by excavators to techniques which keep parts intact (Figure 4 top).

The construction of the roof structure consists of steel-timbering. Up-on the bearing structure, the roof was build of wood with a regular sealing of old tar-based cardboard. Due to the filigree steal-structure preliminary cardboard and wood were deconstructed by man-power. Afterwards, all jointing's of the girders to columns were dismantled.

Figure 2. Overview of demolition and deconstruction. An office-building was demolished while the roof of an earlier fabrication hall was deconstructed and reused for the new building.

Figure 3. Deconstruction process: All not-bearing parts are removed. The steel-structure will be removed by crane.

Figure 4. Single storey hall after demolition of inner parts with intact roof. Steel-based roof structure after deconstruction.

Only the horizontal links retained for stability reasons. The links were dismantled just in time when the girders were removed.

To keep the steel timbering intact after the deconstruction, it was evident, to build a construction to store the elements. This construction was fabricated of steel (Figure 4 bottom).

In general, deconstruction is applicable. A general application needs to analyze costs and time for such techniques.

3.3 *Limitation of deconstruction for reuse*

Dismantling of structures for reuse issues is quite different from the regular demolition process. For regular demolition there is no need to keep anything intact. For demolition the boundary condition are safety of neighboring buildings and a focus on raw materials, while

the deconstruction focuses on the construction itself to be kept intact. Thus, there is an increase of hand-made work instead of the use of excavators.

In fact, both methods lead to the same rates of steel-reuse from the material view. If the costs are considered, the costs of deconstruction for reuse are much higher. Probably there are savings for the new building using the dismantled parts.

Nevertheless, deconstruction for reuse is possible even for single-storey-halls originally built the early 20th century. For this case, it was helpful, that the new use for the girder-structure is at the same site. Especially if only parts of structures are identified for reuse, it is evident to find a suitable building to integrate the used parts later. This building needs to fit the geometrical dimensions.

As long as the used structures are integrated on the same site, an additional benefit is the omission of any transports. Thus, there is a high saving of energy.

3.4 Deconstruction of modern SSH

The example was dealing with the architectural idea to keep the roof structure for later use as a remembrance of older times.

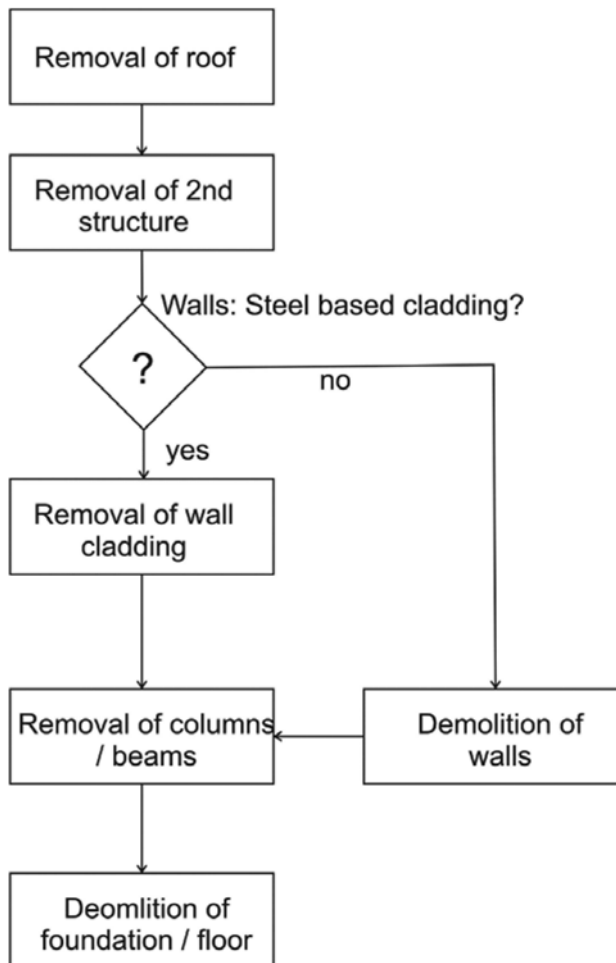

Figure 5. Demolition/deconstruction plan of a single storey hall. In general, there exist parts with a low interest to keep intact (roof cladding), the primary steel construction and the founding made of concrete, which can be downcycled in the end.

Mostly, deconstruction is interesting for SSH which were build in the last 20 years. It is assumed, that those halls meet nearly the same standards as we have today.

At first, all parts are sorted into parts to keep and parts not to keep. Thus, the waste streams as given in Figure 1 are identified. For demolition a precise division into parts is not necessary. As soon as parts are identified for deconstruction, the whole technique has to follow the needs of keeping the identified parts intact. Instead of a combined demolition of the roof including the primary structure, the cladding must be handled carefully for example (Figure 5).

For a general SSH the deconstruction plan should be as presented in Figure 5: Deconstruction becomes a mixture from reverse building (Roof, cladding removal), deconstruction of structure and demolition of concrete-based parts as funding and possibly walls.

The time consumption for reverse building is about 3 times higher than the time consumption for general, not parts-based demolition. Thus, costs and time for deconstruction are higher than for demolition. This may be worth the extra costs if the SSH can be sold to begin a new life on another place.

4 CONCLUSIONS

Reuse is limited by technical and economic issues. Technically mostly structures which are screwed are favored for deconstruction and reusing. The secondary structure may be welded and be renewed. The less parts are made of concrete such as walls, the better the reuse potential will be. For deconstruction the technique needs to be switched from excavator-work to crane based work. In fact, during a deconstruction, excavators are only needed for demolition of the foundation/ground-floor. If walls are made of concrete or masonry, an excavator needs to work parallel to cranes and lifts, which extends costs. Thus, the perfect reusing case are SSH (Single Storey Halls) with cladding on a screwed steel-based structure.

Besides technical issues, deconstruction possibilities are limited by economic issues. Deconstruction will take much more time than demolition on site. Today, the removal of buildings is mostly done as the begin of a new building. So, the removal goes ahead and is mainly performed as a preliminary clearance. The costs of removing steel-based structures are very low, because even regular recycling of the steel-based parts creates a high income and is described with urban mining. Thus, for the customer there is no need to put extra-effort or time into performing a deconstruction. His interest is mainly to have the new building/hall as fast as possible being built. Costs of regular demolition are about 5% of the building costs due to the high recycling potential of steel.

In western parts of Europe, the willing to use or reuse something is little as well. The intention to sale a complete SSH which is deconstructed cannot be a decision of the demolition contractor. Such an effort will not fit the time-planning of a building project. Thus, during the planning already a possible deconstruction needs to be taken into account. This must include a plan for storing the parts, the search for a new reconstruction place, planning for the reconstructed foundation and material tests. While demolition would be cheap, deconstruction will increase costs first.

Unfortunately, even the environmental effect is little. Especially steel is known as an up to 100% recyclable material. While construction made of concrete for example have small recycling potential and the former concrete can only be downcycled to gravel of concrete, steel-based parts can be remelted for unlimited times. Reusing may further lower the CO₂-footprint, but steel construction are already performing well.

Deconstruction for reusing today is a niche. Such projects are done for the great fairs such as the Bauma in Munich or the IAA in Frankfurt. Additional halls were planned as steel-based, light-weight constructions which are build such for the one-week lasting event and are deconstructed afterwards. The BAUMA for example is being held only every 4 years. Thus, the temporary hall is being rebuild on the same place for each fair again. The key for these temporary buildings is the possibility to rebuild them as additional place on exact the same place. Regular deconstruction with intended rebuilding needs the finding of a total new place.

The construction parts are intended to be sold. Selling complete halls as used parts need a market which does not exist today.

ACKNOWLEDGEMENTS

The research presented in this paper received funding from European Commission's Research Fund for Coal and Steel project under grant agreement No 747847.

The deconstruction of a steel based single story hall

P. Kamrath

Paul Kamrath Ingenieurrückbau GmbH, Germany

ABSTRACT: As part of the PROGRESS research project a steel-based single-story hall was deconstructed and the primary and secondary structure of the building was recovered. The structure was explored by UAV devices. The SSH is built of 7 different parts. From up to down the hall consists of the roof insulation build out of Styrofoam with a foil, the roof itself made of trapezoidal sheets, a secondary steel structure connected to the primary arcs. The steel-based construction is founded on a reinforced concrete plate. The plate and fundaments are located ca. 1,0m above the ground. The space in between is filled with sand or any other material suitable at the original building time. Exploring materials and even chemical tests of mineral waste is common and important due to the risk to contaminate the environment or risk health of people. To create drawings of buildings to demolish or dismantle is not worth the effort. Nevertheless, exact geometry knowledge is very helpful for the planning of a demolition project and was rebuild by the use of UAV devices. A technique was developed to perform the deconstruction for reuse of steel parts mainly by excavators. Thus, the recovering of usable parts and the demolition of the concrete based ground plate was performed by the same machines. This paper presents the results and discusses the possibilities of excavator-based deconstruction.

1 INTRODUCTION

Typically, single story halls are not built as temporary objects. Although costs for building are little compared to structures based on concrete, today's buildings are not intended for reuse. Nevertheless, a perfect SSH to test the reuse capabilities was found in Cologne, Germany. The owner had to remove a single-story hall from the area of the great market in Cologne. His intention was just the clearing of the area as he was committed by contracts with the operator of the market area. The building itself was about 25 years old, thus the structure had not reached the end of lifetime, which is at least 50 years.

For the practical work a compromise needed to be found between traditional demolition with the advantages such as little costs and high performance and new technologies which intend the reuse of the whole building.

So the goal was to explore a technology based on machines which are typical for demolition work and to perform a deconstruction with them. The use of the standard demolition machines is helpful because it opens the possibility to switch from deconstruction to demolition extremely fast. Even for projects not intended for deconstruction during planning this might open the possibility to optimize the project for reuse on a later stage. (see Figure 1).

2 OVERVIEW OF THE PROJECT

2.1 *General*

The great market of Cologne is an area, where different sellers of food and fruits store imported goods for reselling to companies, restaurants, and general food stores (Figure 1). The areal consists of many buildings and halls from all decades. The great market itself is not operating as seller itself. It generates the framework for other companies, which are selling the

goods. The idea is to have all the big players of imported fruits on one place. Most bigger cities in Germany have such markets for almost a century. Nevertheless, today there is little need for the idea of a centralized market. Thus, the market area in Cologne is closing during the next years and first companies are leaving the area today.

Especially the bigger companies were running out of space somewhere in the past and built additional storage halls. To extend their capabilities. Unfortunately, when leaving the area, they are contracted to remove “own” buildings.

The result is the need to remove even newer buildings which are perfectly reusable (Figure 2).

Figure 1. Area of the great market of Cologne with the object to deconstruct for reuse (left).

Figure 2. View through the market area with the single story hall to be deconstructed on the right (right).

2.2 Exploring the structure

In most cases for objects to remove there exists a lack of information. The original planning of a building does not exist anymore after some decades and the change of owners. In most cases there is no information about materials used, possible hazardous waste which in general was unknown to be hazardous in older times and no drawings of the formerly planned building.

Figure 3. Overview of the SSH on a UAV model: The hall consists of a visible over the ground structure which is made of steel with attached cladding (blue), a concrete structure which ends ca. 1m below the surface (red).

Exploring materials and even chemical tests of mineral waste is common and important due to the risk to contaminate the environment or risk health of people. To create drawings of buildings to demolish is not worth the effort. Nevertheless, exact geometry knowledge is very helpful for the planning of a demolition project.

During the planning, the steel-based part was identified as a possible reuse item while the concrete founding are to be demolished. For the crushed concrete there is a general possibility to downcycling and reuse the material as recycling-gravel. This is obviously the lowest form of recycling.

The concrete structure is mainly unknown. From general experience it can be assumed, that floor plate and walls were made of 20cm reinforced concrete. The space below the floor plate is assumed to be filled with sand or a similar filling. For calculation, a box with no holes and no empty spaces is assumed.

The steel-work is easier to explore. While the roof is made of trapezoidal sheets with insulation, the primary structure consists of 4 arcs made of 2 parts which are connected in the middle axis. The arcs are made of non-standard steel beams. The secondary structure is made of small beams. It was planned to deconstruct the primary and secondary structure. The trapezoidal sheets and the cladding are not recommended for reuse possibilities since a deconstruction of the light-weight parts is very time intensive (Figures 3 and 4).

Table 1 lists the main parts of the objects from the roof down to the fundamentals. In General, the concrete and filling are about 700m³/1.500to. The steel-base hall with cladding is approximately 50to only. Even if the structure is going to be reused, this causes that most materials of the building are still becoming waste.

The height of the hall is below 10m. That means, that the machines used for demolition may be used for deconstruction as well. This is important to switch during the work process between parts to deconstruct for reuse and concrete demolition work without changing the machines used. As a test case this opens up the possibility as well for projects not initially intended for reuse to deconstruct parts if it suits.

Table 1. Calculated masses and parts.

No.	Part	Size	Waste management
1	Roof	531 m ²	Recycling, disposal
2	Wall (steel)	414 m ²	Recycling, disposal
3	Ground plate	106,2 m ³	Recycling off-site
4	Fundaments (concrete)	55,2 m ³	Recycling off-site
5	Filling	630 m ³	Recycling
6	Reusable structure	20 to	Deconstruction reuse

2.3 Additional object information

Besides the exploration of a structure all known historical information were collected. Especially on industrial sites it is urgently important to collect data about bombings due to World War II. Close to the building a probably not-exploded bomb was detected. Also, exactly at the position of today's hall, a German gun emplacement was located. The bomb itself is not affecting the demolition of the hall – the distance will not become closer as 30m. Since the hall was built around the year 2000 the former gun emplacement was already known at times of building the hall. During earthwork at that time possible remains were already removed.

The result of the analysis of leftovers is, that there is no danger due to the found unexploded bomb as well as there is no need for further local investigations. Nevertheless, work below the ground-level should be done with care.

While the finding of a World War II leftover doesn't affect the deconstruction/demolition project itself, the possible bomb will be investigated by authorities soon.

Any building is connected to the sewage system in the ground as well as to electricity and other medias. It is evident that a building to remove needs to be cut from all the media systems before the demolition. The connection to the sewer system needs to be sealed to prevent pollution of the sewer system with ground material causing blockage of the sewage pipe.

The owner of the sewage system postulates a partly removal of the sewer system as well as sealing of the connections with concrete. The sewer system of the area is well documented.

3 DECONSTRUCTION OF SSH BY EXCAVATORS

3.1 Idea of excavator-based deconstruction

Generally, demolition is excavator based while deconstruction is based on lifting parts up. In easier words: Demolition is a technique to destroy a building or hall controlled and sort the masses into classes of materials. Deconstruction needs to survey the former elements. While

Figure 4. Steel structure: The primary structure is made of 4 arcs of steel. There is no visible connection plate on the ground. Obviously, the columns are poured into the concrete. (left).

Figure 5. Between each of the arcs smaller steel beams as a secondary structure are visible. The connections are screwed. (right).

during demolition connections of steel beams can be cutted with the help of the excavator (e.g. steel shear devices), a deconstruction project needs the connections to be unscrewed. Thus, an excavator seems not to be the right instrument for deconstruction.

On the other hand, after deconstruction of the steel parts an excavator is needed to remove the concrete basement parts. That means, that even a deconstruction of all reusable parts ends in traditional demolition of concrete-based parts. Today, the removal of halls or other buildings is mostly entitled as a demolition. Thus, the contract of the client only describes the total removal of a specific object but does not describe the technique. The contractor owes the removal of the object in a given time span. Mostly, the contract will not specify that the former object has to be destroyed and become waste. Thus, it is up to the contractor how he plans to remove the object. Deconstruction is only an alternative, if the deconstruction can be performed fast enough to follow the given time span for the demolition project. To minimize costs of the extra work for deconstruction it would be a good to use the same machines as for the demolition. Then, a deconstruction could be performed as an alternative with the later chance to sell the reusable parts.

The less additional machines are used, the better the deconstruction can perform against the demolition.

For the Cologne SSH the deconstruction by excavators was tested. As a first step, the different parts of the SSH were analyzed if deconstruction would be an alternative to demolition.

The SSH is built of 7 different parts. From up to down the hall consists of the roof insulation build out of styrofoam with a foil, the roof itself made of trapezoidal sheets, a secondary steel structure connected to the primary arcs. The steel-based construction is founded on a reinforced concrete plate. The plate and fundaments are located ca. 1,0m above the ground. The space in between is filled with sand or any other material suitable.

The deconstruction causes higher costs. Thus, it is important that parts are suitable for reuse after deconstruction. If they fail to be reused, those parts would be handled as waste/recycling materials only with the same effect as generally demolished parts. That means, that only those parts shall be deconstructed, which are not predisposed for deformation during the deconstruction process. Trapezoidal sheets are not deconstructable without deformation as well as sandwich elements could easily be damaged. Thus, it was chosen to deconstruct the primary and secondary structure while demolish the light-weight parts such as the cladding and the trapezoidal sheets.

Deconstruction of a SSH

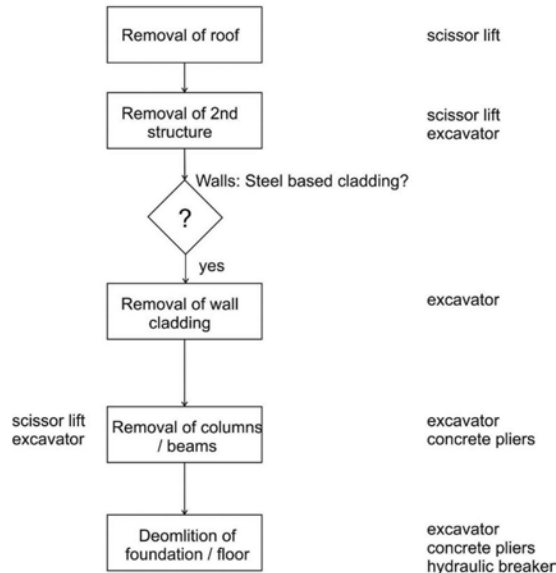

Figure 6. Deconstruction of the Cologne SSH by excavators. The primary and secondary structure is deconstructed for reuse. Cladding and light-weight materials are chosen for recycling only. Foundation is handled as regular demolition.

Table 2 lists the parts and the decision about the handling for the testcase. Figure 6 shows the deconstruction plan.

3.2 Dismantling of structure by excavator

For general demolition of an SSH the safe technique for demolition of the structure is given in Figure 7. The technique is based on flame cutting the adjacent girders and pulling the structure down. If the primary structure is poured in concrete, there exist cutting techniques to create a hinge that allows the needed movement.

Further in the project, it will be checked, if the connection can be uncovered so that flame cutting will become evident.

In fact, the technique is the same for deconstruction, except that no flame cutting is used. Instead the joints need to be unscrewed. The poured parts have to be dismantled by small excavators. It is evident not to release joints of the secondary structure before the anchoring in the ground. As well, deformation may become an issue. Thus, it is recommended to use two excavators for pulling the arcs to the ground.

Modern roof structures are insulated by a 30cm or more tick insulation of styrofoam. Removal by machines causes parts of the styrofoam to be destroyed and being blown away. To avoid the waste to be blown away it is recommended to remove the insulation by manual work. After the insulation removal, above the trapezoidal sheets all non-steel materials are deconstructed.

After the insulation of the roof the side walls were dismantled. During the dismantling by excavators with an attached gripper it was tested, whether the sandwich elements can be dismantled without damage. Thus, it was tested, if those elements were usable for reuse.

In fact, the gluing between the metal sheet and the insulation was weathered so much, that the connection was not stable anymore.

For separation the following technique was invented:

- 1) A Single element is laid down the ground.
- 2) The excavator grips one corner and pulls the metal sheet up. While pulling the sheet up the weight of the element is used to separate the metal sheet.

Table 2. List of parts of the SSH and decision of deconstruction vs. demolition.

Part	Description	Demolition	Deconstruction	Comment
Roof insulation	Foil with insulation of styrofoam		(x)	Recycling, disposal
Roof	Trapezoidal sheets	x		Recycling, disposal
Secondary structure	Steel beams, scerwed		x	Recycling off-site
Primary structure	Steel arcs, screwed but spilled into concrete		x	Recycling off-site
Side walls	Sandwich elements	x		Recycling
ground plate	reinforced concrete	x		Deconstruction reuse
Filling	Sand, earth or equal	(x)		

- 3) Two workers remove parts of insulation which adhere on the sheet.
- 4) The separated materials are sorted into metals and general waste.

Figure 8 shows the dismantling by excavator without deforming the sandwich elements. It was determined that separation of the different materials is best function, if the elements are not badly brought up but mostly in shape.

Thus, although in this example the sheets could not be reused, in general a dismantling technique open for reuse is recommended for the sheets. Even if reuse seems not practicable separating the materials will be easier if the elements are not deformed yet.

The main advantage of excavators in opposite to dismantling structures by hand is the better efficiency. Trapezoidal sheets are very light weight compared to the secondary or primary structure. If the sheets are not needed anymore the use of an excavator avoids unnecessary unscrewing of the sheets. In fact, screws will burst if the excavator grabs a sheet. Because the sheets are much thinner than any structure, no parts of the secondary or primary structure are affected. In fact, it seems that the excavator just pulls off the sheets without any resistance.

At this stage, most materials from the object became waste. All metals became part of the recycling process and are put back into the cycle for remelting. All insulation was used for energy recovery – in other words the styrofoam was burned and only used as energy source.

But, at this stage no parts were put back on the market as reusable parts. The reasons, why no parts were suiting the idea of reusing were:

- 1) Thickness of flat parts. Parts to be reused should be able to be handled without to much care. If parts tend to deform the chance is high that a certain percentage does not fit the claim of later reusing. If the parts are sold later for reusing but are not reusable due to deformation, they might be returned. The effort to deconstruct parts with zero deformation would be higher than the costs for generally new parts.
- 2) Especially the cladding on walls and roof are used during the first life for connecting certain building equipment parts to it. That causes changes in original colour, holes from connections and scratches to the sheets. While the bearing structure is mostly as on the first day of usage, the metal sheets look used. Reusing means that the whole SSH never will fit the definition of a new building.
- 3) It remains an open question, who will be responsible for deformations. If the former SSH was sold as one piece of reusable hall, each deformed part can cause claims by the buyer for a additional part which is free of deformation. Unfortunately, the risk is high to be responsible for the costs of those additional parts.
- 4) Even if just dismantled parts are sold, which may fit or not fit the needs for reusing, a price above the price of general scrap metal is only possible, if the percentage of not-deformed parts is at least 90%. To reach such a high percentage of intact parts, the efforts is becoming very high which may result in prices not inline with the market.

Generally, the deconstruction of parts is mainly done by cranes. For the test case it was chosen to use excavators. On the one hand, excavators are the typical machines for demolition and are multifunctional. Excavators can be used not only to lift things up but also with attached tools to remove concrete, to load materials and to separate waste.

Figure 7. Combined technique to dismantle the primary/secondary structure for demolition.

Figure 8. Removal of roof insulation and sealing; Left picture before removal.

Figure 9. Forces in dependence to the vertical distance of the crane. The smaller the distance becomes, the more horizontal forces arise. It may affect the connections so that other techniques are needed instead of classical up lifting by excavators.

If excavators are planned to be used, they are limited by height. If the object is larger than the height of the excavator, a deconstruction by excavator work will fail. The possible height of excavators already reaches 50m and more. Beside those special machines standard excavators reach ca. 15m in height. That matched most SSH.

Nevertheless, the higher the distance between the structure and the excavator, the little horizontal forces are (see. Figure 9). Especially if the arc is made of connected parts additional forces should be avoided. It was chosen to pull the arcs down by two parallel working excavators.

Figure 10 shows the solution: Lifting the whole arc up by one excavator would affect the connection point in the middle of the arc and is not recommended. Instead, two excavators

were used with grabbers to slightly pull down the arc. On the ground, all connections were released without the danger of collapse of parts of structure.

Before pulling the arc down, it was important to explore the connection of the steel-based arc to the concrete floor. From first explorations it was known that the steel arcs were not having plates on the concrete plate but were shed into the concrete.

3.3 Reusable parts

All parts identified for reuse needed to be checked afterwards. In general, all parts suited the quality needed. No parts were deformed. Some screw holes were damaged during flame cutting. Flame cutting was used, if unscrewing was not possible due to rust, mechanical errors, or impaired supply of the threaded rods.

Figure 12. Deconstructed parts of primary structure ready to be reused.

4 CONCLUSIONS

A SSH suitable to become a test case was found in Cologne. The hall was created in the beginning of the year 2000. It was important to test the possibilities to perform deconstruction with the same machines as the regular demolition is done.

The identification of parts which were deconstructed for reuse tried to estimate the risk of damage due to deformation. Thus, the primary and secondary structure was deconstructed while all light-weight parts were recycled only. During the deconstruction and demolition, it was realized, that the sandwich elements were aged so much over 20 years, that the glue failed at the connection of metal sheets and insulation was too bad for reuse. On the other hand, it was experimented, how separation of sheets could be possible on site.

Nevertheless, most waste masses are created by the demolition of concrete parts. The total masses only change little if reuse is applied.

On the other hand, if reuse is prepared with deconstruction techniques performed by excavators, the total costs are only little higher compared to general demolition. The additional time for deconstruction was only 20% higher than for a demolition without deconstructing parts. Thus, to increase the decision to deconstruct parts of modern SSH for later reuse, the later reuse has to be seen as an additional chance with low extra costs. This might help to start deconstruction as an idea performed even without having a special client or buyer. The risk of high costs is little. The chance to increase income of demolition of SSH due to selling reusable parts may justify more experiments.

From the practical view the deconstruction of light-weight parts seems the challenging thing in the future. Besides technical issues it is important to find a solution for the following question:

Who is responsible for parts which are not reusable after deconstruction due to deformation? What percentage of loss is acceptable? At the moment it seems difficult to put a hall on the market with only 75% of cladding. Additionally, sandwich profiles undergo an evolutionary process and may not be the same some years in future as today. That could result in a higher percentage of parts which are needed to be renewed. On the other hand: Deconstruction of light-weight parts is even competing against new parts if about 20% loss is included. Besides the technical problems the reuse of light-weight parts is a legal question of acceptable contract conditions.

The main result is the possibility to perform deconstruction by excavators instead of cranes. Deconstruction for reuse becomes so something, any demolition contractor could do or at least try.

Nevertheless, planning becomes important. A view to temporary situations as well as a higher risk of collapse follows the deconstruction idea.

On the development of regulations for the increased reuse of steel structures

H. Bartsch, F. Eyben, J. Voelkel & M. Feldmann

Institute of Steel Construction, RWTH Aachen University, Germany

ABSTRACT: When designing steel components, the industrial cycle is important to consider. At present, iron production in blast furnaces and the recycling of steel scrap predominate. However, there is great potential in the reuse of components instead of recycling. To date, only a small amount of structural steel is reused. Many steel constructions are, e.g. due to serviceability requirements, requirements without making use of the plastic material reserves and the usual over-strengths with large safety margins. Currently, components are recycled despite high quality and good condition, instead of being directly reused. So far, concrete regulations are missing.

This paper presents first approaches for the development of regulations for the increased reuse of steel structures. There are already initial drafts for design standards that address the reuse of structural steel. Research approaches are concerned with defining the suitability of different components for reuse. It needs the development of evaluation criteria, evaluation categories as well as conformity testing of existing components. Possible is the definition of different component quality groups or a designation according to the traffic light system. A special focus should be placed on the safety of reused components. Furthermore, approaches to determine the environmental and economic benefits of reuse help to show the great potential of reusing steel components.

Additionally, components subjected to fatigue loading can be designed efficiently by constructing connections obtaining high fatigue classes, e.g. the machined butt joint. Alternatively, post-treatments methods like mechanical treatments or heat-treatment methods provide important tools to create extremely fatigue strength structural elements.

In the future, structured and consistent recommendations should be made for safe reuse of steel, for which the paper presents proposals.

1 INTRODUCTION

With the “Green Deal”, the European Commission is pursuing the goal of counteracting the existential threats posed by climate change and environmental destruction. Future buildings must be designed and built to be as material-efficient, dismantling-friendly and recycling-friendly as possible, so that the reuse of components and the recycling of building materials can reduce waste, CO₂ emissions and energy requirements. The present paper presents approaches to design guidelines for an efficient reuse of steel structures and components, also including optimised fatigue loaded parts in the future. Therefore, the state of art focussing on the reuse of steel structures or components, as it is addressed in different historical and current standards and product declarations, is presented to give an overview on the existing regulations. A concept for designing a guideline for an economical reuse-procedure is then derived and extended to parts optimised for fatigue loading.

2 STATE OF THE ART REGARDING REUSE OF STEEL COMPONENTS

The reuse of steel structures or at least steel components is addressed in many outdated as well as present standards or guidelines. Nowadays, due to the need for sustainable solutions in the

construction-sector, reusing steel structures is becoming more increasingly important, which is also reflected in the fact that a lot of research is being carried out. Some approaches of outdated and current standards will be presented in the following. A historical approach for using “Old Steel” in Germany is given in the DIN 1050 Blatt 2 (DIN 1050 Blatt 2, 1947) of 1947. Old Steel is defined as steel which is extracted from destroyed components or buildings. It can be steel bars, shaped steel or plates. Due to the standard, old steel can be reused in new components or buildings under predominantly static load, but it has to be marked with a certain label. The marking, as exemplarily shown in Figure 1, contains information on the company, the supervising specialist engineer, who has to ensure the correct extraction and processing of the old steel, as well as the label for the old steel as defined in (DIN 1050 Blatt 2, 1947).

Figure 1. Example Marking for an Old Steel as defined in (DIN 1050 Blatt 2, 1947).

The label is defined referring to the production year of the steel as well as flange rusting. Steels with flange rusting, so reduced thickness due to rusting, smaller than 10 % are category I steels, while steels with a flange rusting between 10 and 25 % are category II. Steels, which were produced before 1900 gets an additional label “S”. Steels with more than 25 % thickness reduction due to flange rusting, are forbidden to be reused. For steels of category I, the allowed stresses according to DIN 1050 can be applied. For steels of category II, the cross-section resistances must be reduced to 80 %.

In current standards, Reuse of steel is for example addressed in the American standard ANSI/AISC 360-16 (ANSI/AISC 360-16, 2016), but more focused on applications outside the structural building. Especially for pipe supports and scaffolding, the usage of old steel is allowed. Annex 5 presents some testing procedures to check the material properties of steel to be reused. Here, mainly destructive testing methods, e.g. tensile tests with defined specimens at the defined spots of an old component, has to be done (ANSI/AISC 360-16, 2016) .

In the current development or revision of standards, the reuse-aspect is often discussed. In the current version of the revision of the prEN 1090-x (prEN 1090-x:2022, 2022) the reuse of steel structures or components is included. Rules for the deconstruction of steel structures as well as testing procedures for the materials are given. It is mainly valid for warm and cold-formed profiles. For connections and welded parts are no regulations defined. The standard is a supplement for the execution of steel structures in EXC1, EXC2 and probably EXC3 (with limits regarding fatigue) acc. to EN 1090-2 (EN 1090-2, 2015) with reused steel. An evaluation scheme, see Figure 2, to check the suitability of a steel/component to be reused is presented in (prEN 1090-x:2022, 2022). In a first step, all accessible information on the construction must be collected. In an early stage of the deconstruction, a visual inspection should be done to identify unsuitable components for reuse due to huge plastic deformations, cross-sectional weakening or corrosion. After that, components which are similar can be divided into groups (prEN 1090-x:2022, 2022). These groups or components are then assorted to one of the four defined evaluation procedures (A, B, C and D) based on the scheme in Figure 2.

The procedures contain regulations on material testing and checking the documentations. For procedure A for example, only non-destructive testing methods are required to validate the original documentations. Then the material properties can be assumed as listed in the documents. For procedure D, additional destructive tests have to be carried out, to determine the material properties, e.g. yield strength, tensile strength or chemical composition (prEN 1090-x:2022, 2022).

In addition to the standards, there are many guideline-documents focussing on reuse. The Steel Construction Centre Switzerland published a guideline-document (Technische

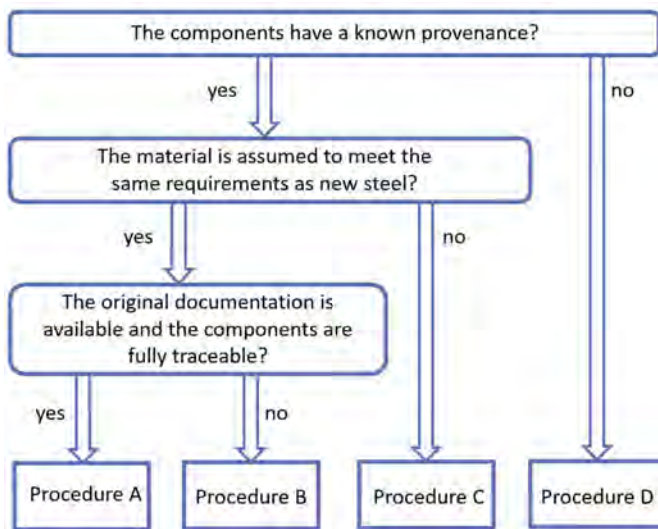

Figure 2. Evaluation scheme to check the suitability of components for reuse acc. to prEN 1090-x (prEN 1090-x:2022, 2022).

Kommission Stahlbau Zentrum Schweiz, 2022) on the reuse of steel components regarding structural analysis, surface protection and quality management. Here, recommendations regarding fatigue-loaded components are given to ensure the suitability for reuse (Technische Kommission Stahlbau Zentrum Schweiz, 2022) .

Product declarations for buying reused steel profiles are developed by the British Constructional Steelwork Association (The British Constructional Steelwork Association Ltd, 2022). Guidelines for the seller and buyer of reused steel, e.g. how to deal with tolerances in geometry or material properties, are given. In detail, also testing procedures, destructive and non-destructive, to determine material properties are listed (The British Constructional Steelwork Association Ltd, 2022).

Additional rules are implemented in (The British Constructional Steelwork Association Ltd, 2022), where sustainable requirements for steel structures are defined. In the field of steel products, there are constant changes, which influences different standards e.g. prEN 17662 prEN 17662, 2021(). In (prEN 17662, 2021), product declarations are increasingly supplemented with sustainable and reusable options. With this development, steel structures or components are seen within the whole live cycle and different scenarios of reuse in different stages of the live cycle are defined (prEN 17662, 2021).

Nowadays, reuse of steel, steel structures or components is also increasingly being investigated and promoted in the field of research. For example, as part of the railway project “i2030 – More rail for Berlin and Brandenburg”, a method was developed, to ensure the quality and steel grade of old steels from a disused existing bridge using non-destructive tests, see Figure 3 (IWT-AG, 2022).

The bridge is part of the Siemensbahn, was finished 1929 and closed down in the 80s. The bridge is under monument protection and should now be reused. In the project, the chemical composition was determined with an optical emission spectrometer (OES), which enables one to analyse many measuring points. The chemical composition was used to infer the steel grade of the different components (IWT-AG, 2022).

In the process of the revision of ONR 24008 (ONR 24008, 2014), an Austrian standard for assessing the load-bearing capacity of existing railway and road bridges, static and cyclic tests were carried out on riveted components from old bridges as part of a research project (Taras & Greiner, 2008). The static tests made it possible to determine the resilience of the riveted joint and the existing clamping forces. This allowed to compare the crack propagation in the fatigue tests with fracture mechanics models (Taras & Greiner, 2008).

Figure 3. Preparation and measurement of optical emission spectrometer to determine the steel grade (IWT-AG, 2022), © IWT-Solutions AG 2022, www.iwt-ag.de.

Furthermore, the reuse and further use of building components was investigated within the framework of a research project at the University of Applied Sciences in Constance; a building material lexicon with the evaluation of the reusability of various building materials was developed on the basis of a pilot project (John & Stark, 2021)

These partly very old regulations as well as the present approaches to reuse steel components must be bundled in a targeted manner to define innovative and practicable rules. Furthermore, the reuse of whole structures (e.g. entire hall frames or crane runway girders) including connection areas or cross-section changes are not addressed in detail in the current state of art. Also, the reuse of fatigue loaded components or to reuse the component for a fatigue loaded reuse-case, is not considered well.

3 PROPOSAL FOR A DEVELOPMENT OF GUIDELINES ON THE REUSE OF STEEL COMPONENTS

Against the background of the problematic situation described above with regard to the high CO₂ emissions in the steel construction industry and the major economic and ecological advantages of the reuse of steel components, the preparation of a recommendation for guideline on reuse, also consolidating the different approaches as shown in chapter 2, represents the first important step.

Since broad-based reuse in Germany is a new concept, the current possibilities for reusing steel products must first be analysed in detail. It must be clarified which products are already reused in which processes and how the potential for future reuse can be derived from this. Also, the current market of steel products and the adaptability of it has to be considered, whereby also the supply chain, with a view to the demolition sector and the current treatment of steel scrap in Germany, should be taken into account. The ecological benefits and economic potential should be displayed. In addition, the legal framework must be investigated to identify the possibilities and current limits of reuse. The determination whether and, if so, which legal obstacles must be overcome in the future is also related to this.

To determine the suitability of components for potential reuse, a subdivision of steel structures into typical component groups, e.g. according to the traffic light scale, can represent a simple designation system. In order to evaluate steel products already in use and to categorize them for reuse, a standardized concept must be developed. For this purpose, it is necessary to know the essential aspects that have a decisive influence on the reusability of components and that must be given special consideration. The history of the component and its documentation (production, coating, loading, etc.) as well as the results of possible material tests

(strength, ductility, toughness, chemistry) and the condition of the component are relevant. Based on this, it is possible to work out how the components can be classified on the basis of evaluation criteria for reuse.

The components should be assigned to different classes according to their suitability. The classes are graded from components that can be used adequately for new products to components that are no longer suitable as a construction product. The evaluation criteria can be divided into:

- A. Criteria on initially available information about a component (e.g. function) and
- B. Criteria for the evaluation of results from additionally required tests (e.g. characteristic yield strength).

Especially if no or little initial information is available, additional testing procedures are indispensable. For this purpose, test methods as well as specifications for sampling must be developed to determine the actual properties of the dismantled components. In addition to destructive testing, non-destructive testing methods are also particularly useful.

Optical laser measurement methods, such as handheld 3D scanners, cf. Figure 4, can be considered for recording the real geometry including imperfections. Further, e.g. hardness tests could be used to estimate the actual yield strength of the material. Such a testing concept requires detailed validation by means of a detailed test program.

Figure 4. Measurement of steel components using laser technology.

Provided that components can be classified; however, no statement can be made about the corresponding safety levels. To overcome this, a statistical evaluation must be developed in accordance with the semi-probabilistic safety concept according to DIN EN 1990 (EN 1990, 2020) and safety analysis in determining the actual prevailing properties of a component. Here, statistical distributions of the measured values from the previously defined test methods must be critically analysed and transferred to the safety concept of the Eurocode. The component resistances of reused components are subject to greater uncertainty with respect to geometry and material, so that the derivation of a partial safety factor, especially for reused components, must be realized.

After that, safe classifications for the reuse of steel components can be worked out. The classification should be based on the known information and additional test results. Here, components can also be classified individually area by area (i.e. areas with constant cross-sections or areas between discontinuities/defects). The overall class could, for example, be made analogous to the cross-section classification according to EN 1993-1-1 (EN 1993-1-1, 2005), considering the subclasses of the individual areas. Furthermore, the quality (also of areas) could be increased, e.g. on the basis of specifications for the post-treatment of individual areas or entire components, and thus an overall better class for reuse could be achieved. In order to verify the entire evaluation procedure, verification on the basis of different exemplary old building components is essential.

Finally, a guideline for the safe and efficient dismantling, testing and reinstallation of previously installed steel components and entire steel structures would be desirable. This guideline should represent a uniform procedure for the practical implementation of reuse on the basis of the normative specifications and further regulations to be developed. In this context, care should be taken to ensure that the instructions are as simple, clear and efficient as possible, e.g. in the form of tables or flow charts. In order to make reuse future-proof, design recommendations for the new construction of structures that are to be suitable for dismantling and reuse are also advisable.

These regulations should relate in particular to the steel materials to be used, the special design requirements and the structural design of the connections and connection details.

4 PROPOSAL FOR DESIGN OF FATIGUE-OPTIMISED STRUCTURAL DETAILS

When it comes to the reuse of steel components, fatigue-stressed structures are usually excluded from the outset. This is because for fatigue strength, the previous stress ranges on the component play a major role in its future service life – which in most cases are not precisely known. However, if we want to focus our approach to component design in the future more on long-term benefits, the reuse of fatigue-stressed structures is an option.

Since fatigue cracks initiate at notches the detailing of a steel connection is crucial for a long lifetime. The following three-level approach is suggested to design fatigue optimised details:

1. In order to be able to provide multi-variant recommendations for different structural details of a structure, a critical survey of the known fatigue standards is a necessary prerequisite to be carried out. Fatigue detail catalogues found in European and international standards (e.g. (EN 1993-1-9, 2010; Hobbacher, 2016) as well as regulations, e.g. in crane construction (EN 13001-3-1, 2019) list structural details in fatigue classes (FATs) depending on their execution. Here, design and execution options with particularly high FATs can be considered for various constructions. For the future, an adaptation of valid guidelines in the area of steel construction should be considered in this context as a first step.
2. At the Institute of Steel Construction, a detailed fatigue database has been developed together with the Karlsruhe Institute of Technology and the University of Stuttgart, in which more than 20.000 individual test results for various details of EN 1993-1-9 are documented (Bartsch, et al., 2020). This database (in 2024 to be published by the Deutscher Ausschuss für Stahlbau DASt e.V. online) has already proven to be a very valuable tool for deriving better detail categories and calculating more accurate fatigue strengths based on well-documented test results, see (Bartsch, et al., 2020; Bartsch, et al., 2021; Bartsch & Feldmann, 2021). Using the information of the data base, particularly favourable fatigue designs and executions that have achieved good results in the documented tests could be identified. This includes also post-treatment methods which lead to higher fatigue resistances and longer lifetimes for a possibly reused component, e.g. by grinding or remelting of the weld toe by TIG, peening, high frequency mechanical impact (HFMI), stress relieving, cf. (Drebenstedt, et al., 2021)
3. Finally, for very specific problems, finite element-based (FEM) numerical simulation techniques are also a useful tool, that allow assessment of stress concentrations resulting from different designs of typical details. Based on local fatigue concepts, the most favourable detailing of a structural part can be worked out.
4. For fatigue stressed-components to be reused, a specific prescription of the documentation of any information on applied stress ranges in terms of an accurate stress history and number of cycles is the basic requirement. Especially for components that are constantly exposed to the same repetitive stress ranges, e.g. certain crane runway girders, an exact documentation of the loads can be easily achieved.

5 CONCLUSIONS

To conclude, this paper presents first approaches for the development of guidelines to reuse steel structures and components. It was shown that the reuse of steel components was already used after the Second World War to counteract the shortage of materials, but due to economic growth did not become common afterwards. Nevertheless, several standards and guidelines have been developed since then to regulate or facilitate the reuse of steel components. Those different regulations in historical and present standards as well as ongoing and completed research projects were summarised and transferred to design recommendations for an approach to develop a guideline. The aim was to make the reuse of steel components as efficient, workable and user-friendly as possible. In a first step the suitability of a component for reuse must be checked by analysing the available information and the condition of the component itself. Depending on the results predefined additional tests must be carried out before a component can be classified. The extent to which a steel component can be reused depends on the class in which it is classified. To develop the classes for reuse, safety investigations acc. to the semi-probabilistic safety concept according to DIN EN 1990 (EN 1990, 2020) has to be made for all classification tools (e.g. 3D-scan, tensile tests etc.). The classification then can be done area by area for individual components resulting in an overall classification for the component with regards to the lowest classified area. The quality can be increased, e.g. on the basis of specifications for the post-treatment of individual areas or entire components. In addition to that, an approach to implement fatigue-loaded components in the reuse concept was presented. Fatigue detail catalogues and data bases should be used to seek out details with high FATs or favourable fatigue design and execution. Thus, numerical methods could be used to optimize typical details. Nevertheless, reuse of steel components with a history of fatigue loading is only possible if the stress ranges and load-cycles during service life are well documented.

In this paper it is shown that there already are standards, guidelines and research dealing with the reuse of steel. However, there is still a lack of guidance regards proper reuse on a daily basis. To exploit the economic and ecological potential of steel reuse a key factor will be a handy guideline making reuse easy to apply for those companies operating in the steel industry. Developing such a guideline still some research is needed specially to make the future investigation and classification of components as simple, clear and efficient as possible.

RFID-based traceability system for constructional steel reuse

P. Hradil & K. Jaakkola

VTT Technical Research Centre of Finland Ltd., Espoo, Finland

K. Tuominen

Purkupiha Group Oy, Lahti, Finland

ABSTRACT: This paper introduces a traceability system based on radio-frequency identification tags attached to the steel building components to provide a link to the cloud-based electronic material passport and 3D information model obtained by aerial scanning of the building before deconstruction. With such traceability system, the complete and accurate information about the building components, their quality and history can be readily available before the deconstruction of the building. This will allow more efficient reuse and better decision-making in deconstruction planning phase. For instance, it would be also possible to check actual demand for the particular component or the whole assembly. The technology was demonstrated on a real deconstruction and reuse of industrial steel hall in Tampere, Finland.

1 INTRODUCTION

Deconstruction of assembled steelwork is generally a straightforward task. However, facility owners and contractors are facing many challenges when trying to streamline the process into the successful reuse project when the recovered components are assembled again in a different place or configuration. It is important to understand the whole deconstruction process and its difference from the ordinary demolition already in the preliminary planning, allocation of time and resources, tendering and local approval procedures.

One of the barriers for successful reuse is lack of reliable and accurate information about the steel components, their age, material quality, coating or modifications made during their previous life. This paper introduces a traceability system based on radio-frequency identification (RFID) tags attached to the steel components to provide a link to the cloud-based electronic material passport and 3D information model obtained by aerial scanning of the building before deconstruction. VTT and Purkupiha are partners in Horizon 2020 project ICEBERG coordinated by Tecnalia, in which such technology has been demonstrated on a real deconstruction and reuse of industrial steel hall in Tampere, Finland.

Building information modelling is rather new in demolition and deconstruction business, but a lot of experience already exists in building design, construction and renovation works. The challenge related to the RFID technology is the selection of proper transponders that are cost-efficient but readable when attached to the steel surface, and can survive harsh treatment during deconstruction, storage, transport and repeated assembly. Contractors or facility owners can nowadays offer deconstructed building components for sale on various trading portals, but the information about their material and dimensions is typically produced after deconstruction. With our new traceability system, the information can be ready before deconstruction allowing more efficient reuse and better decision-making in deconstruction planning phase.

1.1 *Constructional steel reuse*

The reuse of building components is one of the international strategic spearheads in developing the circular economy in the construction sector. The need for more efficient building materials recovery is becoming more important for the contractors in building industry who will have to change their operations from the traditional demolition process to more difficult deconstruction in order to retain the value of the building elements. It is clear that among the existing buildings, only those connected by reversible connections (e.g. bolted) are ready to be disassembled and reused without large effort and damaging of the fabricated elements. Therefore, most of the constructional steel frames can be disassembled and we can see many good examples of their successful reuse, relocation, in-situ adaptive reuse, or further separation into reusable constituent products (Ungureanu et al. 2020). Constructional steel reuse is in many cases economically feasible solution (Kuhnhenne et al. 2018, Vares et al. 2019) and has very low environmental footprint (Ungureanu et al. 2019). We believe that the innovations in the reuse of constructional steel components can be directly projected into the reuse of other materials such as prefabricated concrete construction and engineered wood assemblies.

2 CONSTRUCTION PRODUCTS TRACEABILITY

2.1 *Digital Product Passport and Digital Building Logbook*

The proposal for new European Ecodesign for Sustainable Products Regulation (EU 2022b) strongly emphasizes digitalization of the products information and introduces ‘Digital Product Passport’ to electronically register, process and share product-related information amongst supply chain actors, authorities and end-users. Digital Product Passport means a set of data specific to a product and that is accessible via electronic means through a linear bar code symbol, a two-dimensional symbol or other automatic identification data capture medium (data carrier) that can be read by a device. Examples of the requirements for product-specific data defined in the regulation and its annexes are presented in Table 1.

Table 1. Digital Product Passport (EU 2022b), the most relevant data fields.

Data category	Examples of data fields
Administrative information	unique product identifier, data carrier, passport level, accessibility
Substances of concern	names, locations, concentrations, instructions for safe removal
Product performance	durability and reliability of the product or its components, ease of repair, maintenance, upgrading, re-use, remanufacturing, refurbishment and recycling, weight and volume, environmental or carbon footprint of the product, microplastic release, generated waste
Instructions and guidance	installation, maintenance, repair, disassembly, return and disposal Information for consumers, end-users and treatment facilities
Other relevant information	information under other Union law and so on

The proposal for new European Construction Products Regulation (EU 2022a) empowers the European Commission to establish Union construction products database or system that builds on the Digital Product Passport introduced by the proposed Regulation on ecodesign for sustainable products (EU 2022b). It also establishes the need for ‘Digital Building Logbook’. The logbook is specifically required in Article 12 of the Construction Products Regulation about used, remanufactured and surplus products, and therefore relevant for the reuse of construction products. The Construction Products Regulation refers for more details about the information requirements for the Digital Building Logbook to the EASME report (Volt & Toth 2020). Table 2 shows the outcome of the research conducted in their study in the form of the most relevant data categories and fields. Some of the information under ‘Product performance’ category can be readily available by the relevant certificates, such as Declaration of

Performance or Environmental Product Declaration. Therefore, it is important to standardize open data format for such declarations compatible with the other linked data such as various 3D information models.

Table 2. Digital Building Logbook (Volt & Toth 2020), the most relevant data fields.

Data category	Examples of data fields
Administrative information	unique building identifier, ownership, tenancy, maintenance, utilities, insurance and licenses
General information	year built, district heating access, solar potential, soil/terrain, climate, accessibility, safety manual
Building description/ characteristics	BIM, design documentation, technical systems and utilities, expected lifetime, fire evacuation plan, surroundings, historical context
Building operation and use	number of occupants, functions, energy/water consumption and production, behavioral insights
Building performance	EPC rating, envelope, total calculated energy consumption, renovation recommendations, climate resilience potential
Building material inventory	types, locations, volumes/weights, embodied carbon, life span, fire resistance classes, waste categories, chemical declarations, certificates, Global Trade Item Numbers
Smart readiness	SRI result, smart district potential, demand/response potential, charging infrastructure for e-mobility
Finance	Property value, tax, rent, maintenance cost, yield, valuation, other costs

It can be seen that most of the Digital Product Passport data fields from Table 1 may be allocated to the relevant category in the Digital Building Logbook in Table 2. Ideally, the former should be a subset of the latter.

2.2 ICEBERG solution

The goal of materials and products traceability system developed in the EU project ICEBERG is to collect and communicate all the relevant information to ensure better recovery, recycling and reuse of end-of-life building materials. The development, testing and implementation of the digital cloud platform and its relevant databases is still on-going, but the preliminary data fields relevant to reusable building components have been identified in its deliverable D1.4 “Functional Identification and Authentication Toolkit” (see Table 3).

Table 3. Data fields recommended for implementation in EU ICEBERG project.

Data category	Examples of data fields
Administrative information	unique product identifier, product type, etc.
Product operation and use	dates and geolocations of demolition, sorting, storage, transport, use within the current building
Product description/ characteristics	real properties observed or measured during inspections/testing such as range of sizes, lengths and thicknesses, total volume or mass, surface coating, impregnation or another treatment, classification (quality, decay rating, strength grading . . .), observed damage
Nominal properties and certification	Declaration of Performance, Environmental Product Declaration and other characteristics declared by the manufacturer/dealer
Other relevant information	photos

The information recommended for product reuse in Table 3 is partly overlapping with the requirements of Digital Product Passport (Table 1) and partly with the recommended information in the Digital Building Logbook (Table 2), but contains some additional data fields and categories. Therefore, more effort will be done in the development of the final version of the traceability platform to harmonize its data fields with the new European regulations.

3 RFID TECHNOLOGY FOR CONSTRUCTION PRODUCTS

3.1 Selection of RFID technology

Over the past years, NFC (Near Field Communication) reader has become a standard component of a modern smart phone, which has increased the popularity of the technology in general. However, the very limited read range of NFC, just a few centimeters at its practical maximum, is not enough considering the special requirements of the construction application (NFC Forum 2022). Fast readability of the tags in construction components while in place as well as when stored or transported requires a longer read range. Therefore, UHF RFID operating at 868 MHz, nowadays also commonly referred to as RAIN RFID, was selected as the RFID technology for this application (RAIN RFID alliance 2022). The maximum read range of several meters enables automated and fast reading of tagged items as well as reading of several, often also hidden tags at a time from one spot. In many cases, the exact position of the tag is not even known. Thanks to the passive, batteryless technology, the tags are practically ageless and due to their simplicity, still low-cost (Finkenzeller 2004). This enables individual tagging of even small construction parts and their life-cycle long traceability. The data structure and wireless interface of the selected system is based on EPC Gen2 and ISO 18 000 - 6C standards (EPCglobal 2013).

3.2 RFID components

The practical performance of a passive UHF RFID system depends a lot on the selection of the tag. There is a lot of misconception regarding the performance of UHF RFID systems, which is often based on using wrong types of tags that are not suitable for the intended use environment. The main categories of UHF RFID tags used here are label-type single-layer tags for dielectric objects and hard on-metal tags. Even within these main categories, it is important to find the right types according to the aimed read range, the physical limitations of the object, cost and e.g. durability aspects. As the tags are selected from the range of commercially available products, they are always somewhat of a compromise, but by proper selection, good performance can be achieved (Finkenzeller 2004, Nikitin & Rao 2006, Mercer et al. 2011).

Figure 1. UHF RFID Tags used for construction elements. SmarTrac Belt label tag (left) for wooden elements and Confidex Ironside (right) for large metallic parts.

For tagging the construction parts to be reused, three tag types were selected: SmarTrac Belt as a label for dielectric parts such as wooden beams (Avery Dennison 2021), Confidex Ironside for large metal objects (Confidex 2015) and Confidex Ironside Micro (Confidex 2021) for smaller or thinner metal parts. Figure 1 (left) shows Belt tag on a wooden beam, secured with two staples. Figure 1 (right) presents Ironside secured on a roof panel with

a cable tie. Figure 2 shows the assembly of Ironside Micro tag with a self-drilling screw and two tags assembled on door rails. Before assembly, the read range of the selected tags was verified by Tagformance Pro RFID measurement system (Voyantic 2022). Based on the measurements, Belt provides read range of 6 meters on wood, Ironside 6 meters on metal and Ironside Micro 4 meters on metal. Read range of Belt depends on the moisture of the tagged wood and that of the on-metal tags depends on the size of the metallic object, so the results are indicative. However, they confirm that the read ranges are adequate for remote and automatic reading of tags in the construction environment. The unit cost of the used transponders in large quantities is 0.08 € for Belt, 3 € for Ironside and 2 € for Ironside Micro.

Figure 2. Confidex Ironside Micro UHF RFID tag for small and thin metal objects and its assembly with a self-drilling screw (left and middle) and Nordic ID HH85 handheld UHF RFID reader (right).

The main RFID reader of the demonstrations is a handheld device, namely Nordic ID HH85 shown in Figure 2 right (Nordic ID 2022). The reader provides the maximum allowed power of 2 ERP for the both orthogonal polarizations, which enables the maximum read range of the tags also in the construction environment.

Of the coding schemes available within EPC Gen2 standard, SGTIN-96 was selected as a simple and efficient data format (EPCglobal 2013). In the demonstrator, the tags were preprogrammed using a data structure shown in Figure 3. The individual running number of the tag and its respective item was then associated with BIM. Another method of associating the data is to program the tags during the tagging process. However, operation range of programming is shorter than that of reading and the challenge of differentiating tags is greater due to the risk of unwanted programming, so preprogramming tags before installation is the preferable concept.

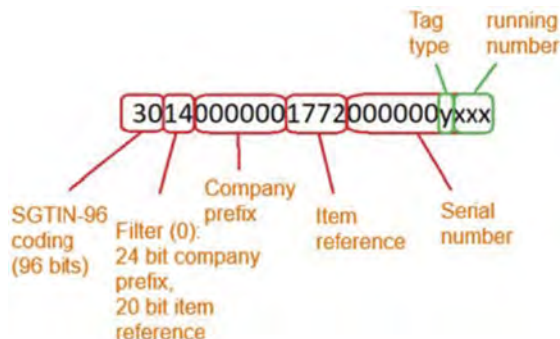

Figure 3. Data format used in the tags attached to the construction elements.

4 DECONSTRUCTION AND REUSE OF STEEL HALL IN TAMPERE, FINLAND

Purkupiha demolished 15 industrial properties on one jobsite during the year 2022 in Lamminpää Tampere. The demolition job was part of the area development actions. Buildings were demolished due to the area being transformed to accommodate residential blocks, commercial buildings and office buildings. Four buildings in the area were deconstructed, and the rest were demolished by using traditional methods. One of the deconstruction projects was an example of a case where the demolition contractor incorporates circular economy into the demolition job without the client's separate request. Purkupiha disassembled the steel hall and transported the reusable components to a new user (see Figure 4).

Figure 4. Manual deconstruction of the roof cladding (left) and the aerial view of the deconstruction site (right).

A 3D model of this building was generated for the purposes of deconstruction and reuse (see Figure 5). Tools and processes for creating an electronic material pass for buildings and building components were developed in the project ICEBERG. The goal of this study was the development of working methods for reuse, removal of suitable products from the structure in high quality, evaluation and traceability of building parts and development of documentation using digital information modeling to support planning of deconstruction and new installation of those parts. In the tests carried out in the project, the validity of the products and solutions was demonstrated in practice.

Figure 5. 3D scanning (left) and creating of building information model (right) of the steel hall.

Data collection and documentation of demolished buildings with the help of data modeling is completely new in Finland. It was shown in practice how digitization may promote reuse of construction parts and 3D data modeling is fully scalable in terms of technology. In this project its applicability and the added value was tested at the real demolition site. Purkupiha collaborated in this study with VTT Technical Research Centre of Finland Ltd. and Spanish Tecnalia, Research and technological development center. Additional information was produced for the design of new buildings and to the traceability of the original construction parts: RFID tags are linked to the cloud database and scanned to the data model directly from the site using a cloud service.

5 SUMMARY AND CONCLUSIONS

One of the largest barriers to reuse of building products is the lack of reliable information at its end of life and the complicated chain of contractors, material dealers and owners in the process. This results in expensive, and often repeated, testing and measurements of the material and product performance. Development of the digital traceability system will greatly improve this situation and has a potential to reduce costs and time needed for successful reuse project. Moreover, it may also improve the confidence of the potential buyers in the quality and performance of the second hand products. Many architects are afraid to use used parts because they don't know what condition they are in and where they have been used. In the future, they will have this data available in the cloud service. With the help of the database, designers can use a lot of accurate information they didn't have before. This will take reuse to a whole new level. RFID technology is promising solution because it is cheap, durable and reliable and the tags do not need dedicated power supply.

ACKNOWLEDGEMENTS

The research presented in this paper was supported by the EU project ICEBERG. This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 869336.

ABSTRACT: The paper presents a comparative environmental and economic analysis of several steel structures, starting from an optimal design case considering a new steel structure made with new materials, along with further design possibilities of the same steel building made using reclaimed elements. The analysis is based on a single-storey industrial hall, quantifying the savings achievable by reusing construction materials in a comparative life cycle assessment and life cycle cost assessment. The paper shows the environmental benefits together with the structural feasibility of a strategy based on the reuse approach in construction. The results show that the greatest gain is achieved in the production stage when the reuse approach is adopted rather than recycling. A 29-35% reduction in emissions is observed when the structure is built with reused steel, while the potential financial benefits are greater.

1 INTRODUCTION

Waste management policies in the EU aim to reduce waste generation and increase resource efficiency by using the potential of resources derived from waste to the utmost, reducing in this way the environmental impact of waste. The Waste Framework Directive 98/2008/EC (Directive 2008/98/EC of The European Parliament) promotes a waste conduct where prevention is first preferred, followed by reuse and recycling, having disposal as the last alternative. As construction and demolition waste (CDW) generates more than a third of all waste produced in the EU (Eurostat 2022), it has become a priority waste stream, challenging the sector for a higher amount of recycling, reusing, or other types of material recovery from CDW. A greater amount of CDW-recovered materials will not only promise a resource-efficient and competitive economy, but will also reduce high greenhouse gas (GHGs) emissions from the building sector.

There were several successful reuse projects in Europe (Coelho et al. 2020) demonstrating that structural steel reuse is possible and represents a viable solution in the construction sector, producing considerable benefits in terms of carbon emissions savings, time savings, or cost savings. Building with reclaimed elements requires additional engaging in deconstruction, reconditioning (e.g. sandblasting, coating steel elements) and transport, which may bring burdens in environmental impact but, at the same time, avoids the loads of the impact caused by the production of new structural elements which demand material sourcing and energy-intensive fabrication processes (Brütting et al. 2020).

The purpose of the analysis carried out in this work is to compare the environmental and economic impact of industrial steel structures (using indicators such as climate change in terms of GHG emissions, resource use, eutrophication and cost indicators). The assessment includes single-storey steel structures made of completely new materials, as well as structures made of reused elements for the entire structure, for components (elements of the primary structure), or just for some individual members of the structure. The study is based on a life cycle assessment (LCA) and a life cycle cost (LCC) of a single-storey industrial hall erected in Romania and for the cases where reclaimed steel elements were considered, it involved relocation from Germany to Romania.

2 ASSESSMENT SCENARIOS

Five scenarios were selected for the assessment.

Case 0: the study is built on a single-storey industrial hall located in Romania that has a total length of 30 m, with six identical frames at a spacing of 5 m. The span is 17.5 m and the height at the eaves is 6 m. The load bearing structure is made of hot-rolled steel sections (columns - HEA320, beams - IPE300, S355) and the envelope involves steel sandwich panels with mineral wool insulation (120 mm sandwich panels for the roof and 80 mm sandwich panels for the walls). All elements of the structure were designed as elements made from new materials. The total weight of steel consumption was 23682.8 kg + 2550.4 kg (hot-rolled steel profiles + cold-formed purlins).

Case 1: The structure originated in Germany and had (initial dimensions) a span of 17.5 m, a length of 35 m (7 bays of 5 m each), and a height of 6 m at the eaves. The columns were HEA300 and the beams were IPE 360 steel profiles with variable cross-sections at the beam-to-column connection. The steel grade is S355. To relocate to Romania, the structure had to withstand higher loadings than in Germany. To achieve this condition, it was concluded that only the portal frames of the structure can be reused either with a smaller bay than the initial one or by reinforcing the frames to be able to carry the new loads. Due to the high price of the second option, it was decided to build the structure with a bay of 0.5 m smaller than the original one. In the end, the structure to be rebuilt in Romania has a length of 31.5 m, seven bays of 4.5 m, and a width of 17.5 m. The existing roof, the wall bracing systems and the longitudinal beams were not strong enough to conform to the seismic requirements, which constrained their manufacture of new steel. In the end, the total weight of the steel structure is 24812.7 kg + 2695.1 kg (hot-rolled steel profiles + cold-formed purlins), from which 17907.1 kg represents reused steel. The existing envelope consisting of 80 mm steel sandwich panels with mineral wool insulation was reused for the structure erected in Romania, but to comply with the U-values existing in Case 0, an additional layer of 60 mm sandwich panels (new elements) was added to the entire envelope.

Case 2: Existing profiles (as individual members) for beams and columns have been identified in a stockyard in Germany derived from deconstructed buildings. The beams are IPE360 steel profiles and the columns are HEA400. The steel grade is S275. All other components represent new steel. As in Case 0, the structure has a total length of 30 m, with six frames at a 5 m spacing, a span of 17.5 m, and a height at the eaves of 6 m. The weight of the steel structure is 27716.3 kg + 2550.4 kg (hot-rolled steel profiles + cold-formed purlins), from which 16795.4 kg represents reused steel. The envelope has the same composition as in Case 1.

Case 3: Individual members of the steel profiles for beams and columns have been identified in a stockyard in Germany along with end plates for beams and columns. The beams are IPE360 steel profile, the columns are HEA400 and the end plates are 30 mm thick. The steel grade is S275. All other components of the steel structure represent new steel. The dimensions of the steel structure are the same as in Case 0 and Case 2. The total weight of the steel structure is 29112.1 kg + 2550.4 kg (hot-rolled steel profiles + cold-formed purlins), from which 19919.7 kg represents reused steel. The envelope has the same composition as in Case 1.

Case 4: The structure originated in Germany and has a total length of 30 m, with six identical frames at 5 m, a span of 17.5 m, and a height at the eaves of 6 m. The total weight of the steel structure is 27716.3 kg + 2550.4 kg (hot-rolled steel profiles + cold-formed purlins), from which all 27716.3 kg represent reused steel. Practically, the entire superstructure was relocated and reused in this scenario. The dimensions of the steel structure are the same as in Case 0 and Case 2. Only the purlins of the steel structure represent new steel in the superstructure. The same solution as in Case 1, was considered for the envelope.

The amount of steel consumption and the percentage of reused steel, for each case scenario, is presented in Table 1.

Table 1. Steel consumption (for the superstructure) - total steel vs. reused steel.

Case no.	Total weight [t]	Reused steel [t]	%	Purlins [t]
Case 0	23.7	-	-	2.55
Case 1	24.8	17.9	72.2	2.69
Case 2	27.7	16.8	60.6	2.55
Case 3	29.1	19.9	68.3	2.55
Case 4	27.7	27.7	100	2.55

3 SYSTEM BOUNDARIES

The case studies in the assessment considered the following system boundaries: (1) the main building components are the foundations and the ground floor slab (concrete and steel rebars), the steel load-bearing structure (hot-rolled and cold-formed steel elements), sandwich panels (steel sandwich panels with mineral wool insulation), triple glazed windows and sectional sliding gates; (2) other materials and components considered in addition to steel: (a) concrete foundations and concrete floor: 185 m³; (b) triple glazed windows: 22.5 m²; (c) sectional sliding gates: 48 m²; (3) the steel rebars were counted as new material, with an input of 73% steel scrap in the manufacturing process and an end-of-life scenario with 95% recycling potential and 5% landfilling or loss of material after sorting (Celsa Steel 2020); (4) for all scenarios, the same U-values/components were considered in the assessment, i.e. for the external walls, roof elements, ground floor slab, windows and entrance door; (5) the heated floor area of the industrial hall is 525 m²; (6) the operational lifetime of the building is 25 years.

4 ENVIRONMENTAL ASSESSMENT

Using the LCA, the environmental impact of secondary products can be evaluated when recycling or reuse is involved. It demands the allocation of environmental impact over different uses, and there are various approaches to reporting this in LCA, which may characterise the process as upstream (Allacker et al. 2017). The approach to accounting for recycling and reuse in LCA, in this paper, was evaluated using the modular approach, based on the principles of European standards (EN 15643:2021, EN 15804:2012).

Production stage: Modules A₁-A₃. This assessment considers the manufacture of the load-bearing structure, foundations, floor slab, envelope, windows, and industrial sectional doors. The LCA results are calculated for each case scenario considering a “new structure with new materials” and “reused elements” in which different amounts of reused steel were evaluated from the deconstructed industrial building halls. The product stage for the reused elements includes blasting and coating (where required) (JSC Litana ir Ko 2021).

Construction stage: Modules A₄-A₅. In these modules, the assessment includes the transportation of all construction materials from the manufacturer to the building site, the transportation of equipment, and the construction of the structure. As the location of the building site was considered close to the site, all the distances from the manufacturers to the building site are between 10 and 70 km.

For the reused steel structure (Case 1) and elements (Cases 2, 3 and 4) the distance considered for the transport of reused steel and sandwich panels was 1200 km. Euro 5 articulated

truck transport (27 t payload capacity) and Euro 4 concrete mixer transport (12-14 t) were assigned to the transport of construction materials from the GaBi database (Sphera Solutions 2021) and 65-80% of the payload was considered in the evaluation; also a return journey of empty trucks was taken into account in the evaluation.

Building construction included excavation of soil for the foundation and floor slab, concreting and assembly of steel structure and envelope using a 10 t auto-crane, forklifts, man-lifts, wheel loader, bulldozer, excavator, concrete pump and packaging waste processing (Sphera Solutions 2021), (European Association for Panels and Profiles 2018), (JSC Ameko Konstrukcijos 2018).

Use stage: Modules B₁-B₇. The use stage refers to the lifetime of the building, which starts from the completion of building construction, and ends when the building is deconstructed or demolished. As the industrial hall life expectancy in each case study in this evaluation is 25 years, maintenance, repair, replacement of elements, or refurbishment was not considered during this lifetime. The evaluation of operational energy consumption was based on the energy demand for a distribution warehouse (Konrad et al. 2021) and includes energy consumption for space heating, cooling, lighting, IT, security, computers, and other systems. In the assessment, neither heat recovery nor mechanical cooling were considered. The use stage was identical for each case scenario. Therefore, both new and reused buildings have the same environmental impact during the use stage.

End-of-life: Modules C₁-C₄. In this assessment, the end-of-life scenario for each one of the five cases studies involved an instance for “demolition and recycling” and another one for “deconstruction and reuse” (Module C1). The deconstruction included the dismantling of steel structure and envelope using a 10 t auto-crane, forklifts, man-lifts, hydraulic breaker excavator, and wheel loader (Vares et al. 2019), while demolition included working with a 10 t auto-crane, bulldozer, hydraulic breaker excavator, hydraulic scrap shear and wheel loader. The energy demand for the demolition of the steel load-bearing structure was assumed to be 0.239 MJ/kg of steel product if the product is recycled and 0.432 MJ/kg of steel product if the product is to be reused (Gordon Engineering 1997). For cold-formed steel elements, the impacts of deconstruction were modelled based on data from the literature on energy use in demolition, accounting for 0.085 kWh of diesel-powered machinery work per kg of deconstructed steel (Europrofil AB 2020). For concrete, the environmental impact included the use of diesel in the demolition process (Interbeton 2021), while for reinforcement, it included the consumption of diesel for the recovery of reinforcement from crushed concrete (Celsa Steel 2020). The deconstruction process of the steel structure follows the reverse assembling process, to which additional effort is added to preserve the integrity of the deconstructed components for reuse (EN 15804:2012). Where no other data were available, the supplementary effort was generated in the study as a 1.5 workload multiplier for the amount of reused elements at the end-of-life (Coelho et al. 2020).

Benefits and loads beyond the system boundary: Module D. Recovered materials, recovered structures or elements of the structure, steel scrap recycling can result in benefits in the form of CO₂ (or other impacts) savings. In this paper, the data for Module D are based on scenarios that consider current practises and current rates of materials recycling. The calculation model used for the assessment of Module D - Climate Change-total [kg CO₂eq] is based on an innovative calculation model (Hradil et al. 2019), compatible with the methodology of the standard EN 15804:2012. The calculated impact involving potential environmental credits or burdens generated by future lifecycles is based on the impacts of reuse and recycling of the materials jointly operated. The calculation is based on the inputs and outputs of recycled and reused materials, the impact of virgin material production, and the impact of theoretical pure recycling. The yield of the recycling process was considered 0.916 t of recycled steel per 1 t of steel scrap (as specified by the World Steel Association 2017) and the information about Modules A1-3 was based on Environmental Product Declarations (EPDs) by Ruukki Construction (2020).

4.1 Assessed scenarios for the environmental impact

Each of the five cases studied covered a scenario for “demolition and recycling” and one for “deconstruction and reuse” in the end-of-life module. It was assumed in the assessment that

when it comes to the reuse of construction materials, both steel and envelopes are reused materials, as described in the following scenarios.

- *New steel - demolition and recycling (Case 0)*: in the assessment it was considered that the external input of steel scrap includes 20% from manufacturing processing (both the blast furnace and the electric arc furnace are used in the fabrication processing) (Sphera Solutions 2021) and that 90% of the steel is recycled at the structure's end-of-life;
- *New steel - deconstruction and reuse (Case 0)*: in the assessment it was considered that the external steel scrap input includes 20% from manufacturing processing, 90% of the steel is reused at the end-of-life of the structure and 90% of the remaining steel is recovered for recycling. Furthermore, 90% of the envelope was considered reused and from the remaining sandwich panels 90% of the steel sheets were recovered for recycling (3.45% of the total mass of the sandwich panels);
- *Reused steel structure - demolition and recycling (Case 1)*: 65.1% of the total steel weight in the superstructure (incl. purlins) represented reused steel and the remaining new steel has an external scrap input of 20%. At the end-of-life of the structure, 90% of the steel is recycled (including 90% of the steel sheets from the sandwich panels);
- *Reused steel structure - deconstruction and reuse (Case 1)*: 65.1% of the total steel weight of the structure (incl. purlins) represented reused steel and the remaining new steel has an external scrap input of 20% from manufacturing processing. At the end-of-life of the structure, 72% of the steel load-bearing structure (representing steel frames only) is reused and 90% of the remaining steel is recovered for recycling (25% of the total steel mass). Also, it was considered that 90% of the envelope is reused and 90% of the steel sheets are recovered from the remaining sandwich panels for recycling (3.45% of the total mass of the sandwich panels);
- *Reused steel elements - demolition and recycling (Case 2)*: 55.49% of the total steel weight in the superstructure (incl. purlins) represented reused steel and the remaining new steel has an external scrap input of 20%. At the end-of-life of the structure, 90% of the steel is recycled (including 90% of the steel sheets in the sandwich panels);
- *Reused steel elements - deconstruction and reuse (Case 2)*: 55.49% of the total steel weight of the structure (incl. purlins) represented reused steel and the remaining new steel has an external scrap input of 20%. At the end-of-life of the structure, 55.49% of the steel load-bearing structure (representing only columns and beams only) is reused and 90% of the remaining steel is recovered for recycling (40.06% of the total steel mass of the superstructure). Also, it was considered that 90% of the envelope is reused and 90% of the remaining sandwich panels are recovered for recycling;
- *Reused steel elements - demolition and recycling (Case 3)*: 62.91% of the total steel weight of the structure (incl. purlins) represented reused steel and the remaining new steel has an external scrap input of 20%. At the end-of-life of the structure, it is assumed that 90% of the steel is recycled (including 90% of the steel sheets in sandwich panels);
- *Reused steel elements - deconstruction and reuse (Case 3)*: 62.91% of the total steel weight of the structure represents reused steel and the remaining new steel has an external scrap input of 20%. At the end-of-life of the structure, 62.91% of the steel load-bearing structure (representing columns and beams only) is reused and 90% of the remaining steel is recovered for recycling. Also, 90% of the envelope was considered reused and from the remaining sandwich panels 90% of the steel sheets were recovered for recycling;
- *Reused structure - demolition and recycling (Case 4)*: 100% of the total steel weight in the superstructure (incl. purlins) represented reused steel, only the rebars in the foundations were considered new steel, with an input scrap of 20%. At the end-of-life of the structure, 100% of the steel is recycled (including 100% of the steel sheets in the sandwich panels);
- *Reused structure - deconstruction and reuse (Case 4)*: 100% of the total steel weight in the superstructure (incl. purlins) represented reused steel. At the end-of-life of the structure, all the steel in the load-bearing structure is reused.

The percentage of steel used in the description below refers to the steel used in the superstructure (main and secondary structure) only (see Table 2).

Table 2. Assessed scenarios for steel in the superstructure - Input and output flow of the material.

End-of-life scenario for steel: Recycle scenario	In			Out		
	New material	Reused material	Recycled material (scrap)	Waste	Material for reuse	Material for recycling
Case 0	80%	0%	20%	10%	0%	90%
Case 1	27.92%	65.10%	6.98%	10%	0%	90%
Case 2	35.61%	55.49%	8.90%	10%	0%	90%
Case 3	29.67%	62.91%	7.42%	10%	0%	90%
Case 4	0%	100%	0%	0%	0%	100%

End-of-life scenario for steel: Recycle scenario	In			Out		
	New material	Reused material	Recycled material (scrap)	Waste	Material for reuse	Material for recycling
Case 0	80%	0%	20%	1%	90%	9%
Case 1	27.92%	65.10%	6.98%	3%	72%	25%
Case 2	35.61%	55.49%	8.90%	4.45%	55.49%	40.06%
Case 3	29.67%	62.91%	7.42%	3.71%	62.91%	33.40%
Case 4	0%	100%	0%	0%	100%	100%

5 LIFE CYCLE ASSESSMENT RESULTS

The assessment of the environmental impact was expressed using Total Climate Change as a pointer following the rules described in EN 15804 (2012). Table 3 presents the greenhouse gas (GHG) emissions for each case study. As the results show, in the production stage (A1-A3), the savings are between 25-26% when reclaimed steel is used in construction compared with the case using new materials only. Relocating the entire superstructure of the industrial hall and reusing it as it involves a decrease in the emissions in the production stage of up to 33%. In the end-of-life stage (C1-C4), when the deconstruction process requires additional effort to preserve the integrity of the deconstructed components for reuse, the savings are acquired by the recycling scenarios.

Table 3. LCA results of the assumed scenarios.

Scenario	Demolition and recycle [tCO ₂ e]				
	Case 0	Case 1	Case 2	Case 3	Case 4
Environmental impacts (A-C)	1230.14	1193.99	1195.22	1195.81	1185.32
Production stage (A1-3)	143.97	104.94	106.43	106.76	96.45
Construction stage (A4-5)	22.46	25.00	24.79	24.97	24.93
Use stage (B)	1048.83	1048.83	1048.83	1048.83	1048.83
Dem./Dec. stage (C1-4)	14.88	15.23	15.16	15.22	15.22
Loads and benefits (D)	-58.39	43.12	31.37	42.63	58.10

Scenario	Demolition and recycle [tCO ₂ e]				
	Case 0	Case 1	Case 2	Case 3	Case 4
Environmental impacts (A-C)	1242.93	1207.42	1207.42	1209.00	1209.99
Production stage (A1-3)	143.97	143.97	104.94	106.43	106.76
Construction stage (A4-5)	22.46	25.00	24.79	24.79	24.97
Use stage (B)	1048.83	1048.83	1048.83	1048.83	1048.83
Dem./Dec. stage (C1-4)	27.68	27.68	28.95	28.95	29.40
Loads and benefits (D)	-128.44	-45.75	-46.18	-43.72	26.88

According to the results, the highest environmental impact is shown in the case where structures erected with new elements are deconstructed for the next reuse case ($2.35 \text{ t CO}_2 \text{ e/m}^2$ – Case 0), while the lowest emission rate is registered when structures are built with reused portal frames and at the end-of-life of the structure, steel is recovered for recycling ($2.25 \text{ t CO}_2 \text{ e/m}^2$ – Case 4).

LCA savings are reflected as negative values, while positive values define the burdens of material utilisation. Benefits and loads beyond the system boundary are not aggregated with the life cycle impacts (Modules A to C). In scenarios where the structures are built with reused elements and the end-of-life steel is recovered for recycling, a burden is recorded in the assessment. The highest potential savings ($0.244\text{-}0.269 \text{ t CO}_2 \text{ e/m}^2$) appear in the scenario in which the industrial hall was erected with new elements, which are deconstructed for the next reuse case at the end-of-life. Figure 1 presents the total LCA results of the scenarios assessed in the industrial hall.

Figure 1. Total LCA results of the scenarios including loads and benefits beyond the system boundary.

6 ECONOMIC ASSESSMENT

The calculation of economic indicators is based on the same scenarios and modules as in the LCA analysis, referring to new steel and reused steel structures, which were associated with time and financial costs. The assessment of the economic performance of the cases studied follows the rules described in EN 16627 (2015). Potential cost savings include revenues for recycled steel (earnings from sold steel scrap), revenues from the sold steel elements or sold structure, and revenues from the sold sandwich panels. The returns considered in the case of recycling were 193 euro/ton of sold steel scrap (the value represents the price of auctioned steel scrap in Romania at the time of the assessment) while the gains from the sold recovered structure (without refurbishment) were calculated at a value of 639 euro/ton of steel. Additional costs for expertise, redesign, testing, sandblasting, and repainting were counted in cases where reused steel was involved.

The results of the life cycle cost assessment show that the economic impact in the production stage (Modules A1-A3) is represented by a 1-8% decrease in the cost when construction materials are reused. When the entire superstructure is relocated and reused, the economic impact in the production stage is less than the economic impact of structures built with new materials with more than 13%. The higher economic impact of the scenarios that involve reused materials is maintained also in the assessment of the total life cycle when the costs increase by 6 to 45 euro/m² compared to the scenarios that relate only to new materials. Total life cycle cost also considers the costs of demolition, deconstruction, and transportation of dismantled materials, which is why the savings gained in the production stage related to the reuse of the construction materials are counterbalanced by the costs of the deconstruction of the structure in the end-of-life stage. The life cycle cost results of the assessment for all stages of the life cycle, including potential savings, are given in Table 4 (potential savings are reflected as negative values). According to the results, the highest LCC (modules A-C) is shown in the cases where the structures erected with reclaimed elements are deconstructed for the next reuse case (911 €/m^2) and the lowest LCC in the case where the construction uses new steel structures and after demolition recovered steel is sold for recycling (858 €/m^2).

Table 4. LCC results of the assumed scenarios.

Scenario	Demolition and recycle [k€]				
	Case 0	Case 1	Case 2	Case 3	Case 4
Environmental impacts (A-C)	454.60	456.53	459.73	459.36	450.53
Production stage (A1-3)	112.66	104.71	108.19	107.28	97.70
Construction stage (A4-5)	36.13	44.61	44.25	44.67	45.55
Use stage (B)	294.90	294.90	294.90	294.90	294.90
Dem./Dec. stage (C1-4)	10.91	12.31	12.39	12.51	12.39
Loads and benefits (D)	-6.55	-7.37	-7.82	-8.05	-7.82

Scenario	Demolition and recycle [k€]				
	Case 0	Case 1	Case 2	Case 3	Case 4
Environmental impacts (A-C)	469.65	474.27	478.17	478.31	468.98
Production stage (A1-3)	112.66	104.71	108.19	107.28	97.70
Construction stage (A4-5)	36.13	44.61	44.25	44.67	45.55
Use stage (B)	294.90	294.90	294.90	294.90	294.90
Dem./Dec. stage (C1-4)	25.96	30.05	30.83	31.46	30.83
Loads and benefits (D)	18.71	-16.83	-18.22	-18.93	-18.22

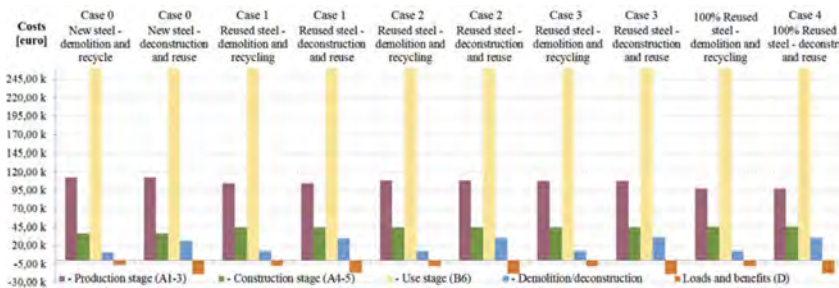

Figure 2. LCC results of the scenarios, including loads and benefits beyond the system boundary.

Figure 2 presents the total LCC results of the assessed scenarios, where the savings are reflected as negative values. When considering the loads and benefits from Module D only, the highest savings (32.50 euro/m² – 36.66 euro/m²) come when the structure is deconstructed for future reuse at the end-of-life, but when the total life cycle is considered, the costs of the structure built with reused construction materials (Cases 1, 2, 3 and 4) exceed the costs of the structure designed with elements from new materials (Case 0).

7 CONCLUSIONS

The end-of-life quality of construction products plays an important role in considering the circular economy, as buildings have a long-intended life span and require a significant amount of material resources. To maintain circularity, these resources have to be kept in service through reuse, reclaim or recycling. The present assessment considered five different case studies, where the building is constructed from new or reused components, and in which the components will be reused or recycled in the future. The results of the environmental assessment showed that reuse is a strategy that offers superior environmental benefits to recycling (modules A-C), the greatest gain being visible in the production stage (A1-3), where the GHG emissions are between 25-33% lower when the structure is built with reused steel (183.71 kg CO₂ e/m² for structures built with reused steel compared to 274.22 kg CO₂ e/m² for structures built

with new steel). According to the results, when it comes to the economic potential of the reuse stages in various reuse and recycle scenarios, the scenario with reused steel elements resulted in higher potential savings (between 32.50 €/m² and 36.66 €/m²) compared to the recycling scenario (between 12.47 €/m² and 15.33€/m²). However, due to the large variety of materials and building practises, it is recommended to perform LCA and LCC calculations on a case-by-case basis, as the results could differ significantly from the present study.

Optimal strengthening of masonry arch bridges with externally bonded reinforcing layers

M. Bruggi & A. Taliercio

Department of Civil and Environmental Engineering, Politecnico di Milano, Milan, Italy

ABSTRACT: Strengthening is a natural step following a failed bridge assessment. Referring to masonry bridges, a numerical tool is presented to find the optimal distribution of reinforcement to be externally bonded to two-dimensional elastic no-tension structural elements, with the aim of maximizing their overall stiffness. Notwithstanding the non-linearity of the adopted material model, no incremental procedure is needed to prescribe equilibrium of the strengthened element. Indeed, the same minimization procedure handles both the energy-based solution of the no-tension elastic body and the topology optimization problem that distributes the optimal reinforcement. A few numerical simulations are presented to assess the capabilities of the proposed procedure in defining the optimal reinforcement layouts for masonry arches and arch bridges, subjected to gravity loads and resting on fixed or elastic foundations. Designers can exploit the tool to sketch a preliminary layout of the FRP strengthening, which should be subsequently detailed according to technical codes.

1 INTRODUCTION

Externally bonded Fiber Reinforced Polymers (FRPs) are nowadays widely used to strengthen, upgrade, or retrofit deteriorated masonry structural elements (Foraboschi 2001, Grande et al. 2008). FRPs have several positive properties, including resistance to wear and corrosion, flexibility, high strength-to-weight ratio, etc. Unlike other materials (e.g., reinforced concrete and steel) that were widely used in the past to strengthen existing buildings, FRPs do not significantly increase the weight of the of the building and, as such, are extremely appropriate in seismic regions (Shrive 2006). FRPs compensate the limited tensile strength of masonry, and increase the load-carrying capacity and ductility of the repaired structural element, as experimentally and numerically shown by several authors (see e.g. Caporale & Luciano 2012).

Drawbacks related to the use of FRPs as retrofitting materials for masonry structures are the possibility of debonding, which can nullify the effectiveness of the reinforcement (see e.g. Capozucca 2010, 2011), or worsening in crack diffusion in the unreinforced regions (Angelillo et al. 2014). Debonding can be avoided by appropriate surface treatments, using fasteners, or applying carbon FRP plates at the intrados of masonry arches, rather than strips or sheets, as suggested by Borri et al. (2011).

According to these remarks, the interest in obtaining methodologies suitable to identify effective reinforcing layouts for masonry constructions under given load conditions is apparent. Some authors basically propose to arrange the reinforcement according to a strut-and-tie scheme, either in such a way as to heal the cracks formed in the unreinforced element (Li et al. 2013), or using optimization procedures (Krevaikas & Triantafillou 2005). A simple strut-and-tie scheme, however, might not be the most appropriate one to retrofit elements of complex geometry, or subjected to nontrivial load conditions. Accordingly, Bruggi & Taliercio (2013) and Bruggi et al. (2013) proposed a general approach based on Topology Optimization (TO - see e.g. Bendsoe & Kikuchi 1988) for 2D, in-plane loaded structural elements, to obtain reinforcing layouts that

minimize a suitable maximum equivalent stress for a prescribed amount of reinforcement. A similar approach was later proposed by Cunha & Chaves (2014) and Bruggi & Taliercio (2015a) for transversely loaded 2D structural elements. In these papers, the optimal reinforcing layout maximizes the elastic stiffness of the reinforced element for a given amount of fiber reinforcement; in the latter paper, the anisotropic and unsymmetric behavior in tension and compression of the reinforcing layers is also taken into account.

Recently, Bruggi & Taliercio (2017) proposed an approach to define the optimal fiber-reinforcement of 2D structural elements made of no-tension materials (e.g. plain concrete or masonry). Here, this approach is specialized to masonry arches and arch bridges that have to be retrofitted by externally bonded FRP strips. The reinforcement is supposed to be unable to carry compressive stresses. A TO formulation is presented to distribute a prescribed amount of fiber-reinforcement at either the intrados or the extrados of the arch, or at both sides, to maximize the overall elastic stiffness of the strengthened element. Unlike the papers quoted above, where the structural elements to be reinforced are linearly elastic, a no-tension model is used to account for the negligible tensile strength of the material. The stress analysis of the no-tension element is itself reduced to a TO problem, according to the approach recently proposed by Bruggi (2014). Indeed, following Del Piero (1989), masonry is supposed to be a hyperelastic, no-tension material. The possible anisotropy associated with the brickwork bond is neglected, and masonry behaves isotropically if all the principal stresses are strictly negative (compressive). The occurrence of positive (tensile) principal stresses is prevented by replacing the isotropic material by an equivalent, orthotropic material whose elastic constants depend on the principal stresses and on the orientation of the principal stress directions. Hyperelasticity allows the equilibrium of the body to be enforced by solving a topology optimization problem, i.e. finding the distribution of the equivalent orthotropic material that minimizes the overall strain energy of the no-tension body.

The main advantage of the approach proposed here is that both the analysis of the no-tension solid and the definition of the layout of the optimal no-compression reinforcement are embedded within the same minimization procedure.

Following Amir & Sigmund (2013) and Gaynor et al. (2013), a combined truss-continuum approach is adopted to model the strengthened element.

2 EQUILIBRIUM OF NO-TENSION BODIES AS A TOPOLOGY OPTIMIZATION PROBLEM

Consider a 2D no-tension isotropic solid, occupying a volume Ω . Typically, the solid can be made of plain concrete or masonry: in the latter case, the macroscopic anisotropy of the material is neglected, as the tensile strength of masonry is actually negligible only perpendicularly to the joints. Mathematical formulations aimed at analyzing no-tension materials were proposed by several authors since the '80s of last century (see e.g. Giaquinta & Giusti 1985, Del Piero 1989, Cuomo & Ventura 2000). More recently, Angelillo et al. (2010) proposed to analyze no-tension solids by replacing the real material by an 'equivalent' orthotropic material that exhibits negligible stiffness in any direction along which the principal stresses in the real medium are non-negative. This idea was later exploited by Bruggi (2014) to re-formulate the analysis of 2D no-tension solids as a TO problem: the distribution of the equivalent material is obtained by minimizing the strain energy of the solid. This non-incremental approach provides the solution under given loads through a one-shot energy-based optimization procedure, provided that the applied loads are compatible with the no-tension constraint. The collapse load of no-tension 2D solids can also be determined by an algorithm based on the approach outlined above (Bruggi & Taliercio 2015b).

The problem formulation is only briefly recalled hereafter; further details can be found in the papers referred above. Let \mathbf{t}_0 denote tractions prescribed over the free boundary of the solid, Γ_t , whereas \mathbf{u}_0 denote displacements prescribed over the constrained boundary, Γ_u . Also, let (z_1, z_2) be the symmetry axes of the equivalent orthotropic material. These axes are assumed to be locally aligned with the directions (z_I, z_{II}) of the principal stresses (σ_I, σ_{II}) at any point of the real

solid, to maximize the material stiffness (Pedersen 1989). Let θ denote the angle between (z_I, z_{II}) and the axes of a given Cartesian reference system. In weak form, the problem solution can be sought as follows:

$$\left\{ \begin{array}{l} \min_{\rho_1, \rho_2} \quad \frac{1}{2} \int_{\Omega} \mathbf{D}(\rho_1, \rho_2, \theta) : \varepsilon(\mathbf{u}) : \varepsilon(\mathbf{u}) d\Omega \\ \text{s.t.} \quad \int_{\Omega} \mathbf{D}(\rho_1, \rho_2, \theta) : \varepsilon(\mathbf{u}) : \varepsilon(\mathbf{v}) d\Omega = \int_{\Gamma_t} \mathbf{t}_0 \cdot \mathbf{v} d\Gamma \quad \forall \mathbf{v}, \\ \mathbf{u}|_{\Gamma_u} = \mathbf{u}_0, \\ \theta \text{ s.t. } z_1 = z_I \text{ and } z_2 = z_{II}, \\ \rho_1, \rho_2 \text{ such that } \sigma_I \leq 0 \text{ and } \sigma_{II} \leq 0, \\ 0 < \rho_{min} \leq \rho_1, \rho_2 \leq 1, \end{array} \right. \quad (1)$$

where \mathbf{u} denotes the (infinitesimal) displacement field, $\varepsilon(\mathbf{u})$ is the (infinitesimal) strain tensor, \mathbf{D} is the fourth-order elasticity tensor of the equivalent orthotropic material, and ρ_1, ρ_2 are nondimensional parameters defined hereafter. In plane stress conditions, and using Voigt's notation, the matrix of the elastic stiffness constants in the material reference frame (z_1, z_2) can be expressed as

$$[D] = \frac{1}{1 - \nu_m^2} \begin{bmatrix} \tilde{E}_1 & \tilde{\nu}_{12} \tilde{E}_2 & 0 \\ \tilde{\nu}_{21} \tilde{E}_1 & \tilde{E}_2 & 0 \\ 0 & 0 & \tilde{G}_{12} (1 - \nu_m^2) \end{bmatrix}, \quad (2)$$

where \tilde{E}_i ($i = 1, 2$) are the Young's moduli of the orthotropic equivalent material, \tilde{G}_{12} its shear modulus, $\tilde{\nu}_{12}, \tilde{\nu}_{21}$ its Poisson's ratios (with $\tilde{\nu}_{12}/\tilde{E}_2 = \tilde{\nu}_{21}/\tilde{E}_1$). To prevent the principal stresses from being positive in the equivalent solid, the stiffness of the orthotropic material is prescribed to vanish along the direction(s) of the tensile principal stress(es) in the real solid. To avoid numerical instabilities, the elastic constants of the equivalent material are related to those (E_m, ν_m) of the real isotropic material according to a generalization of the so-called SIMP model (Bendsøe & Sigmund, 1999), which reads

$$\tilde{E}_i = \rho_i^p E_m, \quad \tilde{\nu}_{ij} = \sqrt{\frac{\rho_i^p}{\rho_j^p}} \nu_m, \quad \tilde{G}_{12} = \sqrt{\rho_1^p \rho_2^p} \frac{E_m}{2(1 + \nu_m)} \quad (3)$$

for $i, j = 1, 2$. The parameters ρ_i ($i = 1, 2$) range from a strictly positive value ρ_{min} to 1 (see Eq. (1)), the extreme values corresponding to a negligible stiffness or a non-penalized stiffness along z_i , respectively, depending on the sign of the relevant principal stress; these parameters can be interpreted as 'nondimensional material densities' along the symmetry axes of the orthotropic solid. A strictly positive lower bound is prescribed, to avoid singularity of the stiffness matrix in a finite-element formulation. p is a penalization parameter, usually taken equal to 3 (Bendsøe & Sigmund, 1999).

The expressions of the equivalent constants in Eq. (3) are similar to those proposed by Cordebois & Sidoroff (1982) for anisotropic damaged materials, thus considering the penalization of the elastic constants as a form of tensile damage.

3 OPTIMAL FIBER-REINFORCEMENT OF 2D NO-TENSION BODIES

Assume now that the no-tension solid has to be retrofitted by unidirectional FRP layers. These layers are assumed to withstand only tensile stresses along the fibers. A given amount of reinforcement, V_f , normalized to the maximum amount that can be bonded over the entire free boundary of the body, is prescribed. A minimization problem is formulated to find the optimal distribution of reinforcement that maximizes the stiffness of the strengthened body. The no-compression constraint is enforced using a SIMP-type approach similarly to Eq. (3).

The solution of the nonlinear equilibrium problem for the reinforced body is sought by embedding the minimization procedure within the energy-based approach presented in the previous Section: the discretized FE form of the procedure is presented hereafter. A mesh made of N truss elements for the reinforcement layers, and M four-node plane elements for the underlying no-tension solid, is used. The non-dimensional densities used to enforce the no-tension constraint in the original solid and the no-compression constraint in the reinforcement are assumed to be element-wise constant. In the j -th truss-like element the density of the reinforcement is denoted by x_j , whereas in the i -th plane element the densities that govern the stiffness of the ‘equivalent material’ along its symmetry axes are denoted by x_{1i}, x_{2i} . The orientation of the material symmetry axes of the i -th FE with respect to the global Cartesian reference frame is denoted by θ_i .

The stiffness matrix of the j -th truss element can be expressed as $x_j^p \mathbf{K}_{0j}$, where \mathbf{K}_{0j} is the stiffness matrix if the element undergoes tensile stresses (so that $x_j = 1$). The stiffness matrix of the i -th plane element will be denoted by $\mathbf{K}_i(x_{1i}, x_{2i}, \theta_i)$. The implemented discrete form of the problem formulated above reads:

$$\left\{ \begin{array}{l} \min_{x_j, x_{1i}, x_{2i}} C = \\ \text{s.t.} \quad \sum_{i=1}^M \mathbf{U}_i^T \mathbf{K}_i(x_{1i}, x_{2i}, \theta_i) \mathbf{U}_i + \sum_{j=1}^N \mathbf{U}_j^T x_j^p \mathbf{K}_{0j} \mathbf{U}_j \\ \sum_{i=1}^M \mathbf{K}_i(x_{1i}, x_{2i}, \theta_i) \mathbf{U}_i + \sum_{j=1}^N x_j^p \mathbf{K}_{0j} \mathbf{U}_j = \mathbf{F}, \\ \theta_i \text{ such that } z_1 = z_I \text{ and } z_2 = z_{II}, \\ x_{1i}, x_{2i} \text{ such that } \sigma_{i,I} \leq 0 \text{ and } \sigma_{i,II} \leq 0, \\ 0 < \rho_{min} \leq x_{1i}, x_{2i} \leq 1, i = 1 \dots M \\ x_j \text{ such that } \sigma_j \geq 0, \\ 0 \leq x_j \leq 1, j = 1 \dots N \\ \frac{\sum_{j=1}^N x_j A_j}{\sum_{j=1}^N A_j} \leq V_f, \end{array} \right. \quad (4)$$

where $\mathbf{U}_i, \mathbf{U}_j$ are the arrays of the d.o.f.s of the 2D and the truss-like finite elements, respectively; \mathbf{F} is the array of the equivalent nodal loads.

In Eq. (4), the objective function is the structural compliance C , i.e. the work of the external loads at equilibrium. The overall strain energy (half of the structural compliance C) is the sum of that stored in the underlying no-tension material and in the fiber-reinforcement to be optimized. Note that the adopted objective function is the same suggested by building codes (EN 1992-1-1, 2004) to derive optimal reinforcement layouts for r.c. members.

In Eq. (4), the constraints in Eq. (1) are reported in discretized form. Additionally, the third last constraint avoids the presence of any strengthening material carrying compressive stresses. The second-last constraint concerns the reinforcement density in any truss element, which is allowed to vanish if the element undergoes compressive stresses. Finally, the last constraint enforces an upper bound on the volume of reinforcement, depending on the area of each truss element, A_j , and the relevant density.

The constrained minimum compliance problem stated in Eq. (4) can be numerically solved by the so-called Method of Moving Asymptotes (MMA – see e.g. Svanberg, 1987). This gradient-based method uses sequential convex programming and the analytical computation of the sensitivities of the objective function. At each iteration, the MMA solves a sequence of simpler approximate sub-problems, which are separable, convex and constructed according to the sensitivity information at the current step, as well as to the iteration history. This approach has been found to be effective in solving large-scale TO problems, giving results in agreement with those achieved through optimality criteria, see e.g. Bendsøe & Sigmund (2003).

The stress constraints in Eq. (4) are enforced by implementing the penalization approach proposed by Ananiev (2005), with the main aim of reducing the computational effort related to the implementation of clusters of local stress constraints. Whenever a principal stress is found to be positive in any element i of the no-tension material, or the stress is found to be

negative in any element j of the reinforcing layer, the corresponding design variables are penalized, and a modified compliance \widehat{C} is computed. The penalized densities are defined as

$$\begin{aligned}\widehat{x}_{1i} &= kx_{1i}, \widehat{x}_{2i} = kx_{2i}, i = 1 \dots M, \\ \widehat{x}_j &= kx_j, j = 1 \dots N,\end{aligned}\tag{5}$$

where $k < 1$ is a penalization factor (herein $k = 0.5$). This heuristic approach was shown to be effective in the treatment of stress constraints (Ananiev, 2005).

Figure 1. Optimal fiber-reinforcement of a single arch made of linear elastic NT material: the principal compressive stresses in the strengthened element are also shown.

Figure 2. Optimal fiber-reinforcement of a three-span arch bridge made of linear elastic NT material resting on rigid supports: the principal compressive stresses in the strengthened element are also shown.

Providing the MMA with the reduced objective function \widehat{C} and the relevant sensitivities, the gradient-based minimizer updates the design variables x_{1i} , x_{2i} ($i = 1 \dots M$) and x_j ($j = 1 \dots N$), and prevents any stiff material to exist along the weak direction(s) of the no-tension body, as well as any compressed reinforcement element. Computing the sensitivities of the reduced objective function \widehat{C} with respect to the minimization unknowns is straightforward (see Bruggi & Taliercio, 2017).

4 NUMERICAL APPLICATIONS

In the numerical applications shown hereafter, attention is focused on the reinforcement of arch-like structural elements. The elastic properties of the no-tension isotropic material are $E_m = 4,500$ MPa

and $\nu_m = 0.2$. The thickness of the FRP layer is $t_{fr} = 1.40$ mm, whereas the elastic modulus of the reinforcement is $E_r = 205,000$ MPa.

Figure 3. Optimal fiber-reinforcement of a three-span arch bridge made of linear elastic NT material assuming the pier to rest on an elastic support: the principal compressive stresses in the strengthened element are also shown.

First of all, a single semi-circular arch, with an external radius of $R_{em} = 4.75$ m, an internal radius of $R_{im} = 4.00$ m, and an out-of-plane thickness of $t_{hm} = 1$ m, is considered. The arch undergoes its self-weight, being $\gamma_m = 18$ kN/m³ the unit weight, and the weight of an infill up to the top of the extrados of the arch, being $\gamma_i = \gamma_m$ the unit weight of the added material.

The optimal layout of two tension-only reinforcing layers, which can be located along the intrados and/or the extrados of the arch, is sought. To make the fiber-reinforcement at the intrados effective, tension-resistant fasteners must be provided to connect the reinforcement to the inner (compressed) part of the body. Otherwise, radial tensile stresses would occur and nullify adhesion. A maximum volume fraction of reinforcement $V_f = 0.5$ is prescribed.

Figure 1 shows the optimal reinforcement, along with the principal compressive stresses in the strengthened specimen. The FRP layers are located at the crown, where a cracked area is found, at the intrados of the abutments, and at the extrados of the haunches. Note the presence of fasteners around the crown, to fulfil equilibrium of the reinforcing curved layer. Fasteners also help the flow of the compressive stresses deviate towards the bulk of the no-tension body, as shown by the orientation of the principal stresses at the abutments. It must be noticed that the overall amount of distributed reinforcement is less than V_f . The need to consider a volume fraction stems from the use of a topology optimization formulation, having the aim of limiting the amount of reinforcement to be used. In this example and those that follow, the no-compression requirement for the FRP layers prevents the optimizer from exploiting any compressive reinforcement to improve the overall stiffness. Hence, the upper bound becomes active depending on the values of V_f .

Then, a three-span arch bridge is considered, assuming that each span has the same geometry as the arch investigated above and that the same loads (gravity and fill) are applied. Symmetry is exploited, and only the left part of the bridge (including an arch, half of the central span, and the supporting pier) is analyzed. In Figure 2 the layout of the optimal fiber-reinforcement and the principal compressive stresses in the strengthened element are shown, assuming the supports to be fixed. The optimal reinforcement of the central arch is quite similar to that of the single arch, see Figure 1. However, both the location and the extension of the reinforcing layers of the outer arch are remarkably different. Thus, modeling the entire bridge is an essential task to achieve an effective strengthening.

As a peculiar feature of the adopted linear elastic no-tension model, elastic supports may be straightforwardly introduced in the numerical simulations. In Figure 3, the optimal layout of the fiber-reinforcement in the same three-span arch is presented, along with the principal compressive stresses in the strengthened element, assuming now the base of the pier to rest on an elastic foundation, with a modulus of subgrade reaction $k_p = 0.1 \text{ N/mm}^3$. This accounts for the deformability of the supporting foundation and the underlying soil. Compared to the case of fixed support shown in Figure 2, a more homogeneous stress distribution is found at the base of the pier. Concerning the optimal layout of the reinforcing layers, minor modifications are found in the outer arch, whereas a larger amount of reinforcement is used in the central one.

5 CONCLUSIONS

A theoretical formulation based on Topology Optimization has been proposed to define the optimal layout of a given amount of reinforcement to be applied on 2D masonry arch-like structural elements to maximize their stiffness. Assuming masonry to be an elastic, isotropic, no-tension material and FRPs to resist only tensile stresses, the formulation simultaneously avoids principal tensile stresses in the arch and compressive stresses in the reinforcement.

The main advantage of the proposed approach is that no incremental procedure is needed to compute the objective function, notwithstanding the inherent non-linearity of the adopted material model. The same minimization procedure deals with both the energy-based analysis of the no-tension elastic body, and the topology optimization problem that distributes the optimal reinforcement.

The examples presented in Section 4 show that when FRP strips are used to retrofit no-tension arches, fasteners are required at the intrados: otherwise, any reinforcement would be simply blown out, owing to the inability of the material to withstand radial tensile stresses. In all the applications, smooth convergence of the objective function was found in a reasonable number of iterations. Also, soil deformability was found to affect the optimal reinforcing layout (compare Figures 2 and 3).

The implementation described in this contribution considers a single load case, meaning that it is directly applicable to long span masonry arch bridges, where live loads are small in comparison to dead loads. When small and medium-span bridges are addressed, multiple load cases must be considered. This may be done by optimizing separately for each one of the relevant load cases and, then, looking at the envelope of the achieved solutions as the effective reinforcement to be used. However, this procedure does not guarantee that the amount of reinforcement is less than the prescribed volume fraction. To overcome this issue, a single optimization procedure may be implemented adopting as objective function a weighted sum of the strain energy for each one of the load cases, while taking into full account the volume constraint.

In the continuation of the research, an extension of the formulation to 3D no-tension solids is planned. The aim is to propose optimal reinforcing layouts for masonry vaults of any geometry, typically groin, rib, and domical vaults, possibly including lunettes. Refined finite element meshes, or higher-order finite elements, are expected to be required to obtain meaningful solutions, with a dramatic increase in computational cost compared to 2D problems. On the other hand, the possibility of avoiding incremental solutions is expected to make the proposed numerical approach more robust and less expensive than ‘classical’ optimization procedures for nonlinear bodies.

Static and seismic assessment of Ponte delle Capre, a masonry arch bridge

F. Casarin, S. Bellin & M. Mocellini

R-Struct Engineering srl, Padova, Italy

R. Fabris

Public Works Office Director, Municipality of Torrebelticino, Torrebelticino (VI), Italy

ABSTRACT: Ponte delle Capre (Goats Bridge) is a masonry arch bridge located in Torrebelticino (Vicenza, Italy) above the Leogra creek. Its origins are not documented, but it is supposed to date back to XIV century. The bridge is 25 m long and 4.30 m wide; it has one arch: its span is 21 m and the rise 8.50m. The structure is composed of stone masonry and lime mortar. The structure is currently subject to the transit of heavy vehicles, as it is the only access route to a nearby steel carpentry factory. The present study describes the assessment of the structural behavior of the existing bridge, considering static (traffic) and seismic actions, in order to evaluate the safety level and define retrofitting interventions.

The bridge has been analysed through Finite Element Model: a 3D model of the bridge has been built with solid elements (bricks), using MIDAS FEA NX software, starting from the 3D physical layout acquired with laser-scanner methodology and managed using Autodesk Recap Pro software. A deep on-site investigation campaign has been performed to calibrate morphological features and mechanical characteristics of structural materials.

Linear analysis has been initially used for static assessment and dynamic frequencies evaluation; static and seismic nonlinear analysis (pushover) has been then performed, considering the total strain crack model for structural materials.

In conclusion, a proposal for the structural retrofitting of the existing bridge is presented, with the aim of combining structural performance and cultural heritage preservation, by using compatible materials and maintaining the original function of the existing arch.

1 INTRODUCTION

In the framework of the Italian Recovery and Resilience Plan (Next generation EU), the European Union financed interventions for the protection of land and water resources, including the restoration and structural retrofitting of Ponte delle Capre (Goat Bridge), an existing arch bridge located in Torrebelticino, a small town near Vicenza, on the Vicentine Prealps.

Ponte delle Capre is an ancient masonry bridge dated back to XIV century, built above the Leogra creek, a water course that flow from mount Pasubio to Vicenza.

This paper describes structural analysis carried out for the static and seismic assessment of the existing bridge and then for the design of the retrofitting intervention. The engineering challenge was constituted by the heavy loads to which the bridge is exposed: it is the only access route to a nearby steel carpentry factory, which entails a daily crossing of the bridge with heavy vehicles. The intervention had to combine the cultural heritage preservation and the static and seismic retrofitting to the current national standards.

The combination of traffic loads, safety factor and actions has been defined following the new Italian guidelines for risk classification and management, safety assessment and monitoring of existing bridges, published by Italian Ministry of Transportation in July 2022, considering

the Operativity Condition, that means 30 years reference time and reduced safety factors, but traffic loads as prescribed by the current national standard.

Figure 1. View of the bridge.

2 DESCRIPTION OF THE BRIDGE

2.1 *Historical context*

Ponte delle Capre is a masonry arch bridge with a humpback shape. Its origins are not documented, but it is supposed to date back at least to the XIV century, since it is mentioned in a document dated 1332 A.D. The shape of the arch recalls the type of masonry arch bridge often defined in Europe with the name “devil’s bridge”, originally considering the structure so complex and daring that its construction could only be considered possible by means of an artifice of the devil: a similar legend occurs also for this bridge.

An important historical document, dated 1590, attests the reconstruction of the bridge, damaged by the flood of the Leogra creek in 1572. The extent of the works carried out is not known, but probably the different masonry composition between basal and central part is connected to these interventions, as well as the insertion of the tie-rods visible on the arch (Snichelotto & Pretto 2022).

Other restoration interventions date back to 1791 and 1891.

The original pavement was raised around 1960, reducing the original shape, substituting the stone finishing with asphalt. The raising of the filling caused the out-of-plane overturning of the spandrel walls, which was restored in 2010, with the realization of a reinforced concrete slab 40cm thick on the lateral quarters of the arch, anchored to the walls by steel ties and rounded anchor plates, still visible on the spandrel walls.

Currently the structures of the bridge show signs of degradation and deterioration: on the arch intrados widespread efflorescence and biological patina are visible, together with severe mortar degradation on joints, mostly caused by the infiltration of water, due to the absence of extrados waterproofing. Moreover, some cracks are visible, especially located at the base of the arch and at the middle span, as shown on the crack pattern survey of the bridge’s intrados, shown in Figure 2; this mechanical distress can be related to the material deterioration (i.e. mortar washout due to water leakage) but also to the high traffic loads passing on the bridge today, surely not previewed in the original design of the bridge; indeed the structural assessment analysis highlighted as most stressed areas the abutments and the middle span, where main cracks have been detected.

Figure 2. Intrados plan view of the bridge, current state and crack pattern survey.

2.2 Geometrical and structural description

The bridge has a length of about 25m, a height of approximately 21m and a width of 4.30m. It is composed by a single arch: its span is 21 m and the rise 8.50m. The thickness of the arch is 65 cm in the central part, while increase to 120cm near the supports. The stone arch is laid directly on the rocky bank of the river, with a reduction of the thickness, as seen during investigations.

The road path is composed of a single lane carriageway (3.70m wide) limited by the masonry parapets that act also as road barrier; parapets have a variable height from 65cm to 100cm, due to the rise of the slope of the pavement. On Figures 3-4 the survey of the bridge is shown.

Figure 3. Transversal sections, at keystone on left, at quarter on right, current state.

Figure 4. Axonometric view of the bridge, current state.

From the structural point of view, the bridge is composed of stone masonry, but different typologies are present. The basement of the arch is of regular squared stones, while the rest of

the vault is built with rounded local stone (named “lardaro”, a quartz phyllade), such as spandrel walls and parapets. Lateral arches present a more regular texture, made with squared stones interspersed with bricks as regularization elements. Masonry joints are made with lime mortar, even if there is a widespread surface with cement mortar repointing.

The filling of the arch consists of a mixture of soil, gravel and stones; a reinforced concrete slab 40cm thick is present above the filling on the lateral quarters, while in central part the asphalt pavement (6-10cm thick) is directly laid above the structural arch. R.c. slab is anchored to the spandrel walls by means of steel bars and external rounded plates, visible on the two spandrel walls. Steel tie-rods (6 elements) have been inserted through the arch during previous consolidation interventions, probably in the XVI century (Snichelotto & Pretto 2022).

3 STRUCTURAL INVESTIGATIONS

3.1 *On site investigation campaign*

A thorough structural investigation campaign was conceived and executed to achieve an adequate knowledge level for the design of the interventions. Considering the needs of preservation of the existing structures, as requested by the Cultural Heritage Authority, non-destructive and slightly destructive tests have been used: single and double flat jack tests to obtain information on the local state of stress and the mechanical characteristics of masonry, carried out in the regular stone masonry and in the irregular one; micro-core drillings with video-endoscopic inspection, for the evaluation of the internal composition of the arch and of the filling; collection of mortar samples for characterization and mineralogical-petrographic study, performed on samples extracted from the flat jack tests or core drillings; georadar on the pavement surface in order to identify the extension of the reinforced concrete slab. Soil investigations (DPSH, Dynamic Probing Super Heavy) and geophysics tests (MASW) completed the on-site campaign.

3.2 *Obtained results*

The endoscope investigations allowed to obtain the morphology of the bridge, identifying the thickness of the arch (65cm in the central part, 120cm at the springers), of the filling layer and of the r.c. slab below the asphalt. The abutments area was also inspected, noting that the arch thrust is directly transferred to a stone substrate.

Single flat jack tests highlighted a high compression stress on the arch near the support, 2.80 MPa on the West side, 3.59 MPa on the East side; this difference between the two sides of the arch may be due to local stress concentration, considering that the East flat jack was made on the regular stone masonry with very thin mortar layer.

Despite the high compression stress, the double flat jack registered a very good masonry mechanical properties, both in terms of stiffness and of resistance; the comparison between the obtained results and the Italian Standards recommended values for the considered masonry typologies shows much higher values for the masonry of the arch. In Table 1 flat jack test results are reported, together with the comparison to the National Standard recommended values (NTC18).

Table 1. On site tests on masonry (flat jack).

Test ID	Location	Local stress N/mm ²	Max stress N/mm ²	Elastic mod. N/mm ²	fc (NTC18) N/mm ²	E (NTC18) N/mm ²
MD.01	West support Irregular stones	2.80	5.56	7435	1.80	1260
MD.02	East support Squared stones	3.59	7.08	23788	7.00	2850

Flat jack tests usually do not allow a suitable determination of the compression resistance, however in this case curves of the flat jack tests were almost straight and registered an almost complete recovery in the unloading phase, sign that the inelastic phase was not reached. Maximum compression stress reached in the tests can safely be considered as compression resistance of the masonry. Additional tests would have been useful to confirm these results, but for preservation reasons were not authorised.

Mortar samples tests shown two main mortar types: recent cementitious mortar and original/ancient lime mortar, which registered an average compression resistance of 7,25 MPa (punch test), highlighting a very good composition.

3.3 Material properties

Considering the structural survey and the on-site investigation tests results, two main masonry typologies have been considered: regular squared stone masonry (for basement and lateral arches) and irregular stone masonry (for the central part of the vault); corresponding mechanical properties are shown in Table 2. For the filling a density of 24 kN/m³ and deformability modulus E=50 MPa have been considered.

Table 2. Mechanical properties of the two masonry typologies.

Type ID	Masonry typology	f_c N/mm ²	$\tau_0 - f_v0$ N/mm ²	E N/mm ²	G N/mm ²	γ kN/m ³
01	Irregular stone masonry	5.00	0.074	7435	2974	24
02	Squared regular stones masonry	7.00	0.230	23788	9515	24

For non-linear analysis a Total Strain Crack model has been used (Rots, 1988, Lourenço, 1996), that allows to consider an equivalent homogeneous material with elastic-plastic behavior (with softening curve) in compression, and elastic-fragile (with behavior controlled by the fracture energy) in traction.

Non-linear properties of materials have been defined based on results of flat jack tests (for compression resistance and elastic modulus) and on National Standards parameters (for tensile resistance); fracture energy values have been initially defined based on literature parameters: a sensitivity analysis has been performed for the final value definition, comparing the nonlinear behavior with cinematic and linear analysis results (i.e. hinge positions, maximum stressed zones, etc.). In Table 3 considered non-linear material properties are shown.

Table 3. Non-linear properties of the two considered materials.

Type ID	Masonry typology	f_t N/mm ²	G _{f,t} N/mm	h mm	f_c N/mm ²	G _{f,c} N/mm	h mm
01	Irregular stone masonry	0.11	0.07	400	5.00	5.00	400
02	Squared regular stones masonry	0.23	0.15	400	7.00	10.00	400

4 NUMERICAL MODEL

A three-dimensional model of the bridge is constituted using MIDAS FEA NX finite element software. The finite element model of the bridge is generated using brick elements with 6 or 8 nodes and 3 degrees of freedom for each node. The mesh is generated automatically by the software and counts 20007 nodes and 19472 brick elements.

The model creation started from the 3D laser-scanner survey, which provided the physical model of the bridge. Point cloud has been managed and simplified using Autodesk Recap Pro and Revit software; geometry has hence been imported in Midas FEA NX software, by which the mesh has been automatically generated. Considering the bridge directly laid on the rock, fixed external constraints have been applied.

Self-weight analysis has been performed for the model calibration, comparing the compression stress with single flat jack tests result: a good match is noted with the MD01 test (West support), while a slight discrepancy is present on the MD02 (east support), probably due to local stress concentration.

Dynamic modal analysis has also been done to evaluate the natural frequencies of the bridge, briefly reported in Figure 5.

Figure 5. Natural frequencies and mode shapes of the bridge.

5 PRESENT STATE STRUCTURAL ANALYSIS

The assessment of the structural capacity of the existing bridge has initially been done using simplified kinematic analysis (Heyman, 1982), considering the traffic loads in different positions and combinations (Figure 6b).

Linear static analysis has been performed using the described FE model, considering permanent and live loads (wind, snow, and traffic) as prescribed by National Standards. Principal stresses have been compared with resistance values, properly reduced considering safety factor and knowledge factor. In order to consider a no-tension masonry capacity even in the context of the linear analysis, a redistribution of the tensile stresses in the verification section was considered, partializing its thickness (Figure 6a).

Kinematic and linear static analysis highlighted that the existing bridge does not meet the requirements of National Standards for static loads. Considering the peculiarity of the bridge case-study, dated back to 1300, Italian guidelines for risk classification and management, safety assessment and monitoring of existing bridges (D.M. 01/07/2022) has been used to define the traffic loads: “Operating” and the “Transitability” conditions have been considered. The first one provides for the transit of all vehicular traffic categories, but considering lower load combination factors, calculated considering 30 years as reference time. Such verifications are not satisfied in the current state analysis, both in case of tandem traffic load 300 kN (in two axis) considered in the center position of the arch or in the asymmetric position (at the thirds of the arch). In particular, in the first case the most stressed section is the key of the arch, while in the latter the most stressed sections are the thirds of the arch and the abutments. This behaviour is consistent with the influence line of the arch structures. In the current state, the minimum static safety coefficient calculated is 0,67 in the middle section.

Therefore, the analysis has been performed considering the “Transitability” condition, that means a 5 years reference time, and two different load cases: 75 kN distributed in two axis and 180 kN distributed in three axes. These traffic categories, together with only light vehicles case, have been selected considering the real traffic conditions, connected to the nearby steel carpentry factory. In both cases the most stressed section is in the abutment when the tandem load is in the asymmetric position at the thirds of the arch. The safety coefficient in the “Transitability” condition is equal to 1,02, giving the positive verification results in every section.

Comparing the performed analysis, the unsatisfactory static situation of the structure has been proven, identifying the most stressed sections in every loading scheme; most stressed area in the elastic FEM model match with the crack pattern survey, confirmed also by the kinematic analysis and by the position of the plastic-hinges highlighted in the non-linear analysis.

Considering the presented results, a traffic limitation to the bridge has been imposed, allowing the transit only to intermediate heavy vehicles (180kN, three axes), until the design interventions execution.

Nonlinear analysis has also been performed for seismic assessment, highlighting a seismic safety level around 40% of the design action.

Intervention design has been thus developed to guarantee the “Operating” condition, in order to remove the traffic limitation, but also considering the Culture Heritage Authority prescriptions.

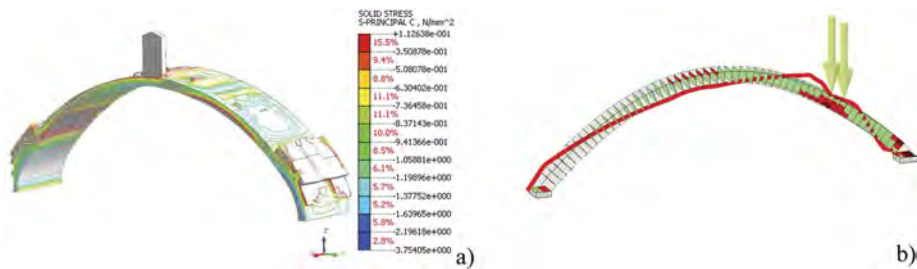

Figure 6. Linear static analysis result from F.E. Model (a) and kinematic analysis results (b) with the thrust line in the most unfavorable tandem load condition.

6 RETROFITTING INTERVENTIONS AND DESIGN ANALYSIS

The challenge of the design activity consisted of combining the cultural heritage preservation and the retrofitting of the structure to the design traffic loads, considering that the transit to heavy vehicles had to be maintained, at least until the realization of a new bridge for the access to the steel carpentry factory. Present state analysis highlighted the main vulnerabilities of the bridge, connected to excessive tensile stresses on the arch section in case of eccentric traffic load.

The design planned to increase the resistance section of the arch and insert tensile resistance elements, by means of a new r.c. slab above the existing masonry arch. To maximize the material compatibility, the new slab - 10cm thick - will be realized using lime concrete (C12/15) and stainless steel rebars. Confining of the arch for containment of pressure curve is granted by masonry walls at arch extrados (masonry stiffeners), made with clay bricks and lime mortar, reinforced by stainless steel rebars inserted on joints. The filling of the vault is designed with lightweight material, with an upper lime concrete slab for point loads distribution. The retention of the spandrel walls is provided by slab connection and by the insertion of stainless-steel tie-rods with external anchors, to avoid out-of-plane overturning. The intervention is completed by the restoration of the masonry walls and arch, by the means of traditional technique such as grouting and repointing.

The structural function of the arch has been maintained, improving its behavior and capacity by inserting confining devices and tensile resistance elements, applying the structural honesty concept (than means maintain original function, reinforcing only critical aspects). To do this, verification procedure has been deepened considering values of material strength linked directly to the on-site tests and less conservative than those one required by the Technical Standard.

Seismic design level has been checked considering non-linear pushover analysis, which was performed applying a monotonically increasing pattern of transversal forces, calculated from the linear dynamic spectral analysis, so proportional to the vibration modes of the structure. Both directions have been considered.

Pushover analysis was performed in two main steps: first static vertical loads have been applied, then the incremental horizontal forces were added. The seismic capacity of the structure is defined by the curve of the base shear force versus the horizontal displacement (considered in the middle of the arch) which has been converted in the response of an equivalent nonlinear

Figure 7. Design FEM numerical model - 3D views.

single degree of freedom system, for its comparison with the design spectrum (Fajfar 2000, 2002). In the design state the displacement capacity results higher than the seismic demand.

Figure 8. Pushover curves (on left) and pushover analysis results in terms of plasticized elements in the design state (on right): pink= partially open -loading; blue= partially open -unloading.

7 CONCLUSIONS

In this paper an intervention proposal for the structural retrofitting of Ponte delle Capre is presented. The design approach sought the structural consolidation with improvement of the static and seismic behavior adhering to the concept of *structural honesty*, this implying the respect of the structural function of the original resistant elements of the bridge. At the same time, the use of new structural reinforcement systems is based on the selection of new materials that respect as much as possible the principles of conservation also imposed by the Cultural Heritage Authority, aiming however to return to the community an infrastructure that is called to resist project actions required for newly built structures, considering the particular need to maintain transit for heavy vehicles. Designers called to intervene on Cultural Heritage need a greater project sensitivity than for new buildings design. Considering that the risk linked to the design choices is higher, the use of more refined calculation as nonlinear analysis is required, to minimize over-design that can cause the loss of historical values. The professional risk is also linked to the interpretation of the Technical Standards which are appropriate for newly built structures but often have technical limits if dogmatically applied to cultural heritage. The Guidelines for existing bridges, as well as the ISO 13822 Standards and the ISCARSAH Directives help in the appropriate assumption of more suitable calculation hypotheses.

Damage accumulation in the structural life and assessment of masonry bridges

T.E. Boothby

The Pennsylvania State University, University Park, PA, USA

D. Coronelli

Politecnico di Milano, Milan, Italy

ABSTRACT: Structural conditions along the life of masonry bridges show changes in geometry caused by load effects, settlements, environmental actions and material deterioration, with accumulation of damage in time. Particular attention should be paid to transverse load effects on spandrel walls, together with the consequences of water ingress in the structure. The paper first analyses the approaches in the Italian CNR DT213 and the British CIRIA C800 to consider damage accumulation in the assessment. The effects of water ingress are then shown through a review of case studies. Example of limit analysis accounting for damage due to cracking and water seepage is proposed. The conclusions address the needed research developments

1 INTRODUCTION

Failure mechanisms that actually occur in masonry arch bridges are characterized by the progressive development of cracks in various positions (Harvey, 2012). The design and maintenance codes for masonry bridges and for masonry-earthwork structures in general pay scant attention to the transverse load effects that can be observed in masonry bridges. This is contrary to the authors' experience that the effects of lateral loads on the spandrel walls precipitate the majority of the failures of such bridges. These effects include the following: bulging of spandrel walls; sliding of spandrel walls with respect to the arch barrel; overturning of spandrel walls; longitudinal cracking in the arch barrel.

Whether one of these effects appears, or which one of these effects appear, is a function of the relative strength of the spandrel wall and the arch barrel. Each of the failure modes listed above is a function of some weakness in the load path for lateral loads. Overturning of the spandrel wall generally indicates a slender wall, while sliding indicates a more stocky wall. Bulging seems to indicate some lateral restraint, as provided by a bond beam or a concrete parapet. Cracking of the arch barrel indicates that the wall is sufficiently proportioned to resist failure of the wall itself, or that the bonding within the arch barrel is insufficient to resist the lateral forces in direct tension. A further effect, which will be modelled later in this article, is that transverse bending in the arch barrel due to heavy concentrated wheel loads induces longitudinal cracking adjacent to the inside of the spandrel wall, as the spandrel wall stiffens the arch barrel in both directions: longitudinally and transversely. Similar cracks can form in ribbed bridges.

These effects have been described by a few authors, most often in a qualitative manner. Harvey (2012) describes qualitatively the evolution of damage in the arch barrel that may result from the stiffening influence of the spandrel wall. Sokolovich et al. (2021) attribute the longitudinal cracking to the shear stresses induced in the arch barrel by the passage of trucks relatively close to the spandrel wall. Polatsu et al. (2019) simulate the separation of a spandrel wall by discrete elements, which incorporates three different effects described above: the failure initiated by a separation of the spandrel wall from the arch ring, then sliding of the spandrel wall, and finally an overturning failure of the spandrel wall. They identify this failure as

occurring at a lower load than the global failure of the arch ring—it is probable that the former would be considered as a failure of a real bridge.

A careful study of the causes of these phenomena includes lateral loads on the spandrel walls, vehicle impact, transverse bending of the arch barrel and water entry into the fill. The last item is a significant cause of the appearance of transverse damage, or may exacerbate transverse damage due to another cause.

This article will focus primarily on the changes in material properties and assemblies induced by entry of water into the bridge structure and possible means of assessing the damage that results from this factor.

2 ASSESSMENT GUIDELINES

The assessment approaches in the Italian CNR DT213 (2015) and the British CIRIA C800 (Gilbert et al., 2022) are considered. Two ways of accounting for damage accumulation are highlighted. The Italian guidelines define a factor of confidence related to knowledge of geometry, cracking, texture and material properties. CIRIA C800 defines the permissible limit state analysis, i.e. the point beyond which progressive load-induced degradation occurs in the bridge life, using a model including actual geometry and damage.

2.1 *Italian CNR DT 213*

2.1.1 *Damage in limit state verifications*

The “Instructions for the evaluation of structural safety of masonry road bridges” (CNR, 2015) define a factor of confidence on the basis of the knowledge of material properties and the structural damage. The factor is used to multiply the partial safety factor, dividing in turn resistance in limit state verification.

The knowledge is built by the survey of the geometry, the crack pattern and interpretation of their causes, analysis of the deterioration; exam of the masonry texture and structural details; determination of the material strength and physical properties, through testing or based on the literature. The factor of confidence is quantified in the range 1.0-1.35 as a function of the knowledge level, with the highest value corresponding to limited knowledge.

An additional factor of non-conformity measures the difference between the bridge proportions and the state of the art proportion rule. The range is 0.85-1.15, corresponding to the best and worse level respectively. Also this factor multiplies the partial safety factor.

A coefficient for material deterioration (section 6.5.4) is defined in the range 1.0-1.20 based on the type of deterioration observed and its extension. This is multiplied by the partial safety factor to divide the material strength in verifications.

The document indicates that knowledge on cracking is essential for structural analysis and repair and strengthening interventions. Cracking is defined physiological if it does not alter the use of the carriageway and displacements do not alter in a significant way the geometry.

The document defines serviceability limit states, with the structure bearing stresses limited within allowable stresses and physiological cracking. Formulations for crack width calculation are proposed. The ultimate limit states are defined for the activation of collapse scenarios.

The values of partial safety factors in the Italian code are in a range 2.0-30.0 according to masonry units and mortar quality.

2.1.2 *Transverse load effects*

Section 3.10.1 and 3.10.2 prescribe the verification of the load bearing capacity of the fill and the spandrel walls, under lateral pressure given by the fill material, with the most critical position of the live loads. For the former the document reports the methods of the Italian national code. This in turn considers the possibility to use an observational method (NTC2018 6.2.5), by monitoring relevant displacements or crack widths with respect to limits determined for safety reasons.

2.2 CIRIA C800

2.2.1 Damage

The CIRIA C800 Guidelines (Gilbert et al., 2022) define a Permissible Limit State (PLS), to determine the point beyond which progressive load-induced degradation occurs in the bridge life. This is analysed using a model including actual geometry and damage in the material strength properties.

The document underlines the need to model defects directly rather than applying global condition factors. Mortar loss should be modelled by a loss of cross-section. In a similar way, fine transverse cracks in a PLS assessment (because of the deterioration effect of opening and closing of joints over time) and large transverse cracks (>1mm) in an ULS assessment should be modelled as cross-section loss.

Alternatively it is possible to assess the PLS via monitoring, checking the stability of cracks and displacements.

2.2.2 Transverse load effects and spandrel walls

The Guidelines highlight the effect of stiff elements attracting high stresses such as those generated at the interface of a barrel bearing on a stiff spandrel, with flexible soil fill, showing that this may result in a common defect of longitudinal cracks detaching the wall (Section 3.6 “Common defects”). The document underlines that the principal load bearing action depends on the masonry thickness and the weight of the masonry and superimposed fill, considering horizontal mobilized pressures and attached spandrel walls as secondary, as they may become detached. Nevertheless the guidelines indicate the need to assess the principal as well as the secondary elements, and concerns over their safety may lead to an “assessment failure”.

Amongst the preliminary assessment operations a survey of the voids in the internal areas adjacent to spandrels is indicated (section 5.2.3).

Building the model of the bridge, spandrel walls should be considered in 3D models, defined as level 3. Spandrel walls should not be considered in more simple 2D models, because of their possible detachment. This last event leads to an increase of flexibility and can be captured by monitoring displacements, and modelled considering a reduced effective width.

The verification of bridges in flood conditions should consider modelling of water pressure and effective stresses if seepage conditions are anticipated. Stability of spandrels under flooding with rapid drawdown should consider the effect of saturated fill with no supporting hydrostatic pressure (section 7.2.4).

3 WATER INGRESS AND BRIDGE FAILURE

The entry of large amounts of rainwater into the fill of the bridge has been documented as a cause of failure or incipient failure in several arch bridges. Many of these collapses were initiated or exacerbated by the entry of water into the fill adjacent to the spandrel wall. This was the clear cause of the simultaneous loss of both spandrel walls of the Blaine viaduct in Eastern Ohio (Figure 1). The bridge was in poor condition generally and endured a collapse of both spandrel walls due to the combined effect of heavy rains and floodwater (USGS, 1999).

The Wyebrook Bridge, Chester County, PA also underwent a spandrel wall collapse as a result of poor drainage facilities and heavy rains (Boothby and Craig, 1996). A spandrel wall collapse of Rockville Bridge, PA, (Froio, 2012) precipitated a train derailment. Although this failure does not appear to be described in refereed literature, newspaper and other popular articles (Guida, 2010; Stonearchbridges.com, 2019; Explore Pennsylvania History, 2022), attribute this failure variously to water intrusion, freeze-thaw and settlement.

A similar issue is present on a large population of bridges of the former Pennsylvania Railroad (built between 1899 and 1910) especially the bridges that consist of ‘ribbed arches’ (Figure 2). This is a system for overcoming a skew crossing by approximately one meter wide arches offset from each other. The joint between the arches is susceptible to opening, water intrusion, and ballast leakage. The bridges noted had pre-existing issues with the spandrel

Figure 1. Collapse of Blaine, OH viaduct 1999 (viewed from above).

walls including longitudinal cracking of the arch barrel and leaning of the spandrel walls. It is not entirely clear that these collapses were due to the entry of rainwater, but the accumulating damage was most probably due in part to the entry of water, weakening of the fill and erosion of the fill.

These effects are primarily due to earth pressures on the spandrel walls, although they are usually exacerbated by the flow of water through the fill. Often, as a result of the structural effects described here, a path is opened for this flow of water that potentially causes an acceleration of the adverse effects.

Figure 2. Photogrammetric reconstruction of crack in a ribbed skew railway arch bridge 2022 (viewed from below).

4 MODELLING OF DAMAGE RELATED TO WATER INGRESS

A limit analysis model (Coronelli and Giangregorio, 2023) for vaults is here extended to simulate the effects of water ingress. The kinematic model divides the system with discontinuities joining nodes on a regular square mesh. The kinematics include three relative rotations and three displacements, and compatibility is enforced at each node. The flow rule considers no-tension, infinite compression strength for axial force and bending, friction and cohesion for shear and torsion.

As a first example of analysis, the bridge geometry considers a span of 3m, the barrel with a 0.2m thickness and spandrel walls with a 1m depth, 0.6m thick, flush with the barrel at the intrados. A live load is applied at 3/4 of the span, along a line parallel to the support, with a length of 1.8m.

Two analyses are carried out (Figure 3). The first considering the same strength properties for the interfaces in all discontinuities: friction angle 35 degrees and cohesion 0.2 N/mm². The second analysis considers the damage caused by water flowing at a crack formed at the interface of one spandrel wall and the barrel, reducing to zero friction and cohesion.

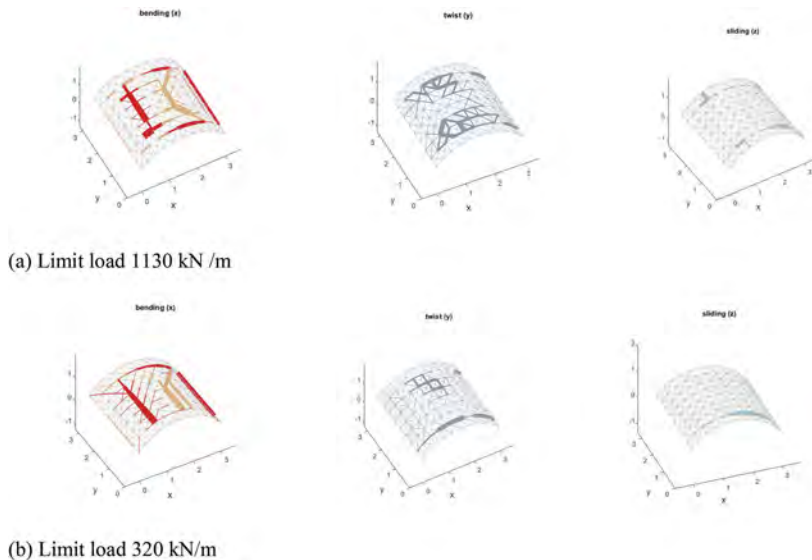

Figure 3. Failure mechanism change and limit load reduction related to water flow damage: (a) sound bridge; (b) cracking along spandrel-vault interface.

The effect of the material degradation is a significant reduction in the limit load with a change in the failure mechanism. The first analysis shows a symmetric mechanism in the barrel between the spandrels, with four line hinges as well as torsion and sliding. In the latter case the mechanism is non-symmetric, with the barrel sliding relative to the spandrel and twist occurring without torsion damage on one side.

As a second example, a bridge barrel is considered, with a span of 3m and a 45° skew in plan (Figure 4a). A construction with unskewed masonry is considered, with a bonding pattern parallel to the abutments. Damage is considered to occur in correspondence of transverse cracks opening at 1/4 of the span; here the friction and cohesion for shear stresses are reduced to 10%.

The mechanism without damage (Figure 4b) shows four line hinges. The mechanism with damage (Figure 4c) shows twist and sliding under the load, and a more complicated flexural hinge pattern. The failure load is reduced by 14%.

Figure 4. Effects of water ingress at transverse crack location: (a) geometry. Yield lines at failure load: (b) no damage from water ingress; (c) damage at transverse sagging crack at $\frac{1}{4}$ span, corresponding to live load location. Legend: red=sagging; yellow= hogging; grey=twist.

5 CONCLUSIONS

Two relevant National guidelines have been analysed, for the consideration of existing damage in assessment of masonry arch bridges. The Italian CNR DT213 defines a factor of confidence including evaluation of the damage conditions of the structure. The factor is used in ultimate limit state verifications, reducing the factored resistance for higher damage levels; hence the value can be adjusted to consider local conditions of sections considered in verifications. CIRIA C800 indicates methods for direct modelling of damage, and defines a performance limit state (PLS) to verify that stress levels do not overcome a reference level. Both documents suggest the use of monitoring for safety verification as an alternative to analytical methods and limit state verifications.

Amongst the causes of damage, the paper highlights the importance of considering transverse effects of loads on masonry arch bridges. These cause different types of cracking, that can be connected to water ingress causing further damage. Spandrel wall collapse has been shown to be related to water ingress in many cases of real bridge failure.

The effects of water ingress have been shown to affect the failure mechanisms and resistance of masonry arch bridges, using a 3D limit analysis model to study the failure of bridge barrel vaults.

The research developments will address the study of existing bridges with the development of models for the structure including fill, spandrel and abutment walls.

ACKNOWLEDGEMENTS

The Authors are grateful to Mohammed Rakeh and Joe Kallas for completing the photogrammetric study and providing the image in Figure 2.

Three-dimensional limit analysis of barrel arch bridges

D. Coronelli

Politecnico di Milano, Milan, Italy

M.C. Giangregorio

Milan Order of Architects, Milan, Italy

ABSTRACT: A model based on the kinematic approach of limit analysis is here described and applied to analyze barrel arch bridges up to collapse. The approach extends concepts of the Discontinuity Layout Optimization (DLO), formulated by Smith and Gilbert (2007), applied for two-dimensional geotechnical, slabs and arch bridges to the three dimensional geometry and structural response of a cylindrical shell. This is done by describing the barrel structure with nodes connected to each other by the possible fracture lines and imposing compatibility and associated flow rules for rotation, sliding and twist. The simplified model of a bridge is formulated according to the component structural analysis proposed by the Italian CNR DT213/215. Experiments on masonry barrels up to collapse are considered as benchmark for the application of the model, including straight and skew barrels.

1 INTRODUCTION

The response to failure of masonry arch bridges is understood as a three-dimensional structure (Royles and Hendry, 1991). Limit analysis is one of the most commonly used tools to study the failure mechanism and predict the limit load. An upper bound approach is formulated here, allowing the calculation of the collapse multiplier and relative mechanism for the barrel vault of a bridge. Such simplified model of the bridge is formulated according to the component structural analysis, one of the approaches proposed by the Italian CNR DT213/215, as a first step to a more comprehensive three dimensional analysis including the fill, spandrel walls and abutments.

The discontinuity layout optimization (DLO) was proposed by Smith and Gilbert (2007) for plane plasticity geotechnical problems, then extended to slabs with arbitrary geometry (He, 2014) and to masonry arch bridges (Gilbert et al., 2010). Given a set of nodes in the structure geometry, the procedure allows the determination of the collapse mechanism and associated upper bound limit load, through the identification of the subset of inter-node discontinuities which are present in the critical failure mechanism.

A step to extend the general formulation of DLO to three-dimensional shell problems is proposed here. The structure geometry is described with nodes connected to each other by the possible segmental fracture lines and imposing compatibility and associated flow rules for rotation, sliding and twist.

Experiments on masonry barrel vaults tested up to collapse (Vermeltfoort, 2001) are considered as benchmarks for the application of the kinematic algorithm.

2 MODEL

2.1 *Geometry and kinematics*

It is possible to describe the geometry of the vault as an arch with a translation in the orthogonal direction to the plane where it is drawn. In Figure 1 the arch is positioned in the plane

x-z and the direction of the translation is the y axis. The origin of the global axis (x-y-z) is at one corner of the vault. The thickness of the shell is considered directed in an orthogonal direction respect to the middle surface.

On the middle surface a grid of nodes is defined. The nodes are connected to each other by fracture lines. Smith and Gilbert (2007) study 2D problems with segmental fracture lines connecting each node with all other nodes. In the formulation proposed here for barrel vaults each fracture line connects one node to the adjacent.

Compared to a rigid block analysis, obtained dividing the shell along circumferential and longitudinal planes, a more general set of possible fracture lines is considered. The two-dimensional Discontinuity Layout Optimization method in the literature consider all fracture lines obtained connecting each node to all others in the mesh. As a first step for the extension to three-dimensional geometry in shells, the formulation proposed here considers fracture lines connecting each node to the adjacent nodes in the mesh, thus limiting the length of fracture lines i.e. only a subset of fracture lines are considered.

Figure 1. Division of the surface in a grid with nodes.

The formulation is three-dimensional. Two different reference systems are considered: global (x, y, z), and local (x', y', z'); the latter is different for every fracture line (YL). The local reference system chosen has the direction of the axis x' from the first node to the second node of the fracture line; axis z' is the normal to the shell surface; y' is obtained by the right-hand rule.

2.2 Formulation

The general discretized “Discontinuity Layout Optimization” (DLO) problem stated as kinematic formulation is (Smith and Gilbert, 2007):

$$\min \lambda f_L^T d = -f_D^T d + g^T p \quad (1a)$$

$$Bd = 0 \quad (1b)$$

$$N_{flow} p - d = 0 \quad (1c)$$

$$f_L^T d = 1 \quad (1d)$$

where λ is a dimensionless load factor that is found by the solution of the problem; f_D is the vector of dead load and f_L is the vector of live load; p and g are vectors of plastic multipliers and their corresponding work equation coefficients, and d contains the relative displacements and rotations along the discontinuities in the local reference system. The equation of the principle of virtual work is imposed; minimizing the collapse multiplier for the live loads, leads to Equation (1a). Considering the kinematic problem formulation for shells, a given fracture-line i contributes to the global compatibility constraint Equation (1b). B is the compatibility matrix that resolves all discontinuity displacement in global (x,y,z) components at each node; d is the vector of relative displacements and rotations in the local reference system (x', y', z'). Equation (1b) imposes that the sum of the displacements and rotations at all nodes must be zero, in the global reference system. N_{flow} is a flow matrix where the yield functions are considered (see the

following section), with positive plastic multipliers p . In this kinematic formulation the discontinuity displacements d and the plastic multipliers p are the variables solved by a linear programming algorithm, to obtain the minimum value of the multiplier of the live loads representing the collapse load, λ . The constraint in Equation (1d) allows to obtain the value of the load multiplier with the minimization on the right hand side of Equation (1a).

The vectors f_D and f_L (Figure 2) represent the forces to calculate the work of the dead load with the self-weight and the live load (Equation 1a) on the part of the structure above the fracture line.

Figure 2. Load on a generic fracture line.

2.3 Plastic flow and dissipation.

Given the resistance criteria, the plastic flow components are given by the product of the N_{flow} matrix by the plastic multipliers, expressed with positive and negative parts.

The flexural rotation ϑ_x , the twist ϑ_y , the in plane rotation ϑ_z , and the three displacements sliding δ_x δ_z and the positive only δ_y for tension are allowed. Rotations and sliding displacements are coupled with normal displacements (Figures 3 and 4). If the line represents a free boundary, all the rotations and displacements are allowed, and there is no coupling between the different displacements.

$$Np - d = \begin{bmatrix} 1 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & -1 & 0 & 0 & 0 \\ t/2 & t/2 & \tan \phi \cdot cT & \tan \phi \cdot cT & l/2 & l/2 & \tan \phi & \tan \phi & 1 & 0 & \tan \phi & \tan \phi \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & -1 \end{bmatrix} \begin{bmatrix} p_{1i}^+ \\ p_{1i}^- \\ p_{2i}^+ \\ p_{2i}^- \\ p_{3i}^+ \\ p_{3i}^- \\ p_{4i}^+ \\ p_{4i}^- \\ p_{5i}^+ \\ p_{5i}^- \\ p_{6i}^+ \\ p_{6i}^- \end{bmatrix} - \begin{bmatrix} \vartheta_{ni} \\ \vartheta_{zi} \\ \delta_{x'i} \\ \delta_{y'i} \\ \delta_{z'i} \end{bmatrix} = \mathbf{0}$$

Linear relations are used to define the yield functions, and normality is assumed for the fracture line representing a constrained boundary or an internal discontinuity. The length of the segment connecting two adjacent nodes is indicated as l . The flexural yield function is based on infinite compression and no tension, with the section rotating around the intrados or extrados edge for ϑ_{ni} and around the discontinuity ends for ϑ_{zi} . The flow is formulated with friction angle ϕ and non-zero cohesion for shear and torsion. The torsion moment cT on the cross section is calculated following Portioli et al. (2014).

The analysis of skew bridge vaults requires considering the shear and torsion stresses acting together with normal stress, in relation to the masonry texture used (CNR, 2015; Sarhosis et al., 2014). Lourenço (2000) studied the out-of-plane response of masonry panels and shells,

Figure 3. a) Yield function with shear and normal force and b) sliding.

Figure 4. a) Yield function with torsion and axial forces and b) twist c) displacement.

showing that the flexural resistance in the plane orthogonal to the courses can be the double of that parallel to the masonry bed joints. Tassios and Avramidou (1988) discussed the variability of friction angle, considering failures in directions equal to or different from the bed joints plane.

To consider the effect of the masonry texture, in the formulation used here values of the friction coefficient and cohesion based on tests are considered for the discontinuities parallel to the joint planes, and the one for the other directions which was 50% greater.

3 RESULTS

The case of a square barrel vault tested by Vermeltoort (2001) is shown (Figure 4). The span is 3m, and the width 1.25m, with a vault thickness of 0.1m. The masonry texture has courses parallel to the support lines. Load lines were spaced 0.6m in plan. Three constant loads of 5KN were applied at the first, third and fourth transverse lines, while the live load was in the second position from the left support (see Figure 5).

A coefficient of friction $\tan(30^\circ)$ and cohesion 0.1MPa are considered for the discontinuities parallel to the joint planes, and 50% greater for the other directions.

Figure 5. Test results (Specimen R1, Vermeltoort, 2001): cracking close to failure.

Figure 6. Analysis results, flexural fracture lines (red sagging, yellow hogging).

Figure 6 shows the collapse mechanism analysis results, with four flexural hinge lines, sagging under the load and right support, hogging on the left near to support and at the right of the live load. The limit load prediction was 37.5kN, while the test result was 40.7kN.

The case of a skew bridge vault tested by Vermeltoort (2001) is shown (Figure 7). The span of the bridge is 3m, and the width 1.25m, with a vault thickness of 0.1m. The skew is obtained by translating in plan one support over a distance equal to the bridge width. The masonry texture has courses parallel to the support lines. Three constant loads of 5kN were applied at the first, third and fourth transverse lines (see Figure 5), in the direction perpendicular to the inclined edge. A variable load at the second line was increased to failure, reaching a limit load of 26kN, with the mechanism showing the hinging described in Figure 7.

Figure 7. Test results (specimen S2, Vermeltoort 2001): cracking at failure.

The results (Figure 8) show flexural hinging at location corresponding to those observed experimentally, together with twist, in particular along the hinging directions. The limit load predicted is 36.75 kN.

The model was developed focusing on obtaining a mechanism comparable to the test results. The overestimation of the experimental result can be explained by the absence of the interaction of shear and torsion in the formulation, and the associated flow used. In addition, the fixed position of discontinuities can contribute to this result of an upper bound discrete approach.

4 CONCLUSIONS AND DEVELOPMENTS

A kinematic limit analysis model is proposed to consider the 3D collapse mechanism and failure load of arch bridge vaults. Three relative displacements and three rotations are considered at the interface between portions of the structure. Infinite compression strength and no-tension are considered for normal stresses; constant friction with non-zero cohesion are considered for shear stresses. The masonry orthotropy is modelled assuming higher friction and cohesion along the directions different from the masonry bed-joints.

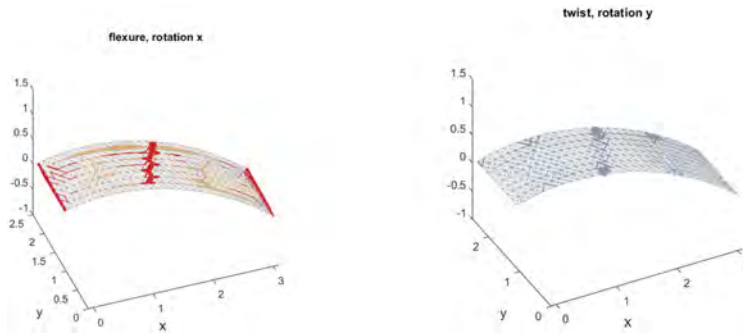

Figure 8. Analysis results: (a) flexural rotations (red sagging, yellow hogging); (b) twist.

As a first step for the extension of Discontinuity Layout Optimization to three-dimensional geometry in shells, the formulation proposed here considers fracture lines connecting each node to the adjacent nodes in the mesh. The developments should consider all possible fracture lines, extending the formulation proposed.

Results for square and skew arch bridge vaults show fair agreement with test results. The model setup considers only the barrel vault; further research will include other parts of the bridge structure.

The collapse mechanism prediction provides indications for the assessment, with the possibility to compare the crack pattern in a survey to the analytical results, and supports the choice of the position of monitoring locations.

ACKNOWLEDGEMENTS

The authors acknowledge the collaboration with prof. Matthew Gilbert, during a visiting PhD period at the University of Sheffield in 2019. The authors are grateful to Prof. A.T. Vermeltoort for the personal communications and the photographic material on the test results.

The Reinforced Arch Method for the life of the ancient bridge of Omegna

L. Jurina & E.O. Radaelli

JURINA e RADAELLI Studio Associato, Milan, Italy

D. Coronelli

Politecnico di Milano, Milan, Italy

ABSTRACT: Extending the life of historic masonry bridges frequently requires strengthening of arches showing damage or limited load bearing capacity. The “Reinforced Arch Method” (RAM) uses a cable on the extrados and/or the intrados, prestressing the blocks. A recent application is the xv century bridge (Ponte Antico) in Omegna (Verbania, IT) along a route of an historic quarrying district. Originally formed of two stone arches, today a damaged structure with one arch remains after a 20th century collapse. The structure is modelled numerically and assessed in the present condition and with the strengthening by four extrados cables, comparing the results of a linear elastic finite element model and limit state verifications, and static limit analyses with optimization of the thrust line and limit load. The strengthening and the intervention proposed for the collapsed arch are discussed, in relation to their new life as a footbridge on a touristic route.

1 INTRODUCTION

The necessity of interventions on arch structures is frequent in the field of the strengthening of historic masonry bridges showing damage conditions or limited load bearing capacity for live loads. The damage is generally related to the limited tensile and flexural strength of masonry, particularly in the presence of non-symmetrical gravity loading, horizontal seismic actions or, as in the case considered in this paper the effects of water pressure during a flood.

Historic bridges suffer from the environmental actions along centuries of life, and the lack of maintenance. Climate change causes flooding and extreme flow conditions causing increasing threats for these systems (Drdacky and Slizkova, 2012).

A strengthening technique denominated “Reinforced Arch Method” (RAM) has been proposed by the first author (Jurina, 2012). The method consists in the laying of a tension cable on the extrados and/or the intrados of the arch, in order to prestress the blocks thus providing flexural strengthening. The cable tension brings the system in action by applying a set of radial forces on the arch, leading to a reduction of the thrust-line eccentricity, thus avoiding or anyway delaying the formation of flexural hinges. The over 500 experimental tests carried out on scale models have demonstrated the validity of this method, using arches with different geometries: roman, pointed and segmental arches.

A recent application of the RAM method, with ongoing worksite activities, has been the historic bridge on the Strona torrent in Omegna (Verbania, IT). This construction which dates back to the xv century was originally formed of two stone arches, each measuring 13.30 metres, along a route of an historic quarrying district. Today a damaged system with only one arch remains after a collapse at the start of the 20th century. Restoration and strengthening activities have been undertaken. Within the structural assessment and design, the structure has been

modelled numerically both in the present condition and with the strengthening by way of four extrados cables, pre-tensioned by 30KN each. The paper shows the assessment results obtained by a linear elastic finite element method, and limit analyses with a static approach to calculate the collapse load multiplier, using a recently developed calculation model.

The intervention proposed for the masonry arch of the bridge that collapsed is discussed, in relation to its compatibility with the surviving structure and its new life as a footbridge on a touristic route.

2 BRIDGE DESCRIPTION AND CONDITIONS

The bridge over the Strona torrent is located in the municipality of Omegna (VB). The construction dates back to the 15th century, by the will of Duke Gian Galeazzo Sforza, and consisted of two stone arches. The eastern bank humped back arch collapsed at the beginning of the 20th century.

Figure 1. Life of the bridge (a) in the early 20th century (left); (b) in 1952 after the collapse (right) of the eastern span; (c) conditions prior to the restoration works; (d) rendering of the restoration project.

The arch span is 13.6m, the cross section thickness 0.4m and width 2.1m. The standing Western wing walls extend 6m on the bank. The central support is on rock elevating above the water flow. The collapsed span to the East corresponded to a lower elevation above water flow; the collapse was related to erosion of the foundation on this bank side with the torrent in full spate. Figure 1a shows the conditions prior to the collapse. Figure 1 b-c show the conditions in recent times, after the collapse and prior to the start of restoration works. Further damage of the walls and parapet above the standing arch is visible. Figure 1d shows a rendering of the restoration project described in the next section.

3 INTERVENTION AND RECONSTRUCTION

The intervention (Figure 2) includes foundation strengthening by piles reaching rock at 4.5m depth, strengthening of the stone arch (RAM), spandrel and wing walls ties, reinforced concrete arch construction and a reinforced concrete slab for the whole length of the bridge roadway. The missing span is replaced with a reinforced concrete arch structure faced with stone. This choice, approved by the Ministry of Cultural Heritage, was the fruit of the comparison of different alternative solutions (see Section 6).

Figure 2. Structural restoration with cable layout and anchoring, and new bridge span.

4 THE REINFORCED ARCH METHOD (RAM)

The main purpose of the “RAM – Reinforced Arch Method” is to modify the distribution of loads, acting on the arch, vault or dome so that the combination of the old loads plus the new loads can be the “right one” for the given and known geometry of the masonry structure. It’s worth to mention that cables can be applied with similar effects either on the extrados or the intrados of the arch, obtaining the same consolidation results. In the first case (i.e. at the extrados) cables can be simply laid down on the masonry or, if needed, a thin layer of fiber reinforced mortar can be interposed to regularize the surface. In the second case (i.e. at the intrados) some connection devices are needed to transfer the loads between cables and masonry.

Experimental and numerical results showed a linear relationship between the load multiplier factor μ and the tension force N applied to the cables.

The Reinforced Arch Method, in its several variations, is an innovative solution that adjusts many different geometries, with acceptable aesthetic results and other important advantages, such as: necessity, lightweight, minimally invasive, removability.

Figure 3. Radial forces applied on the arch by means of RAM (extrados and intrados).

The extrados solution was chosen for the Omega bridge because the conditions of the structure easily allowed the removal of the remaining part of the construction on top of the arch, to install the system.

5 MODELS FOR ASSESSMENT AND DESIGN

5.1 Materials

The arches, spandrels and abutments are made of roughly cut stone masonry. The fill is made of rubble with an estimated unit weight of 10 KN/m^3 . Material properties were determined with the Italian Code NTC2018. The characteristic compression strength is 3.2 MPa and the factored strength for ultimate limit state verifications is 0.95 MPa . For shear the friction coefficient is equal to 0.4 and the characteristic cohesive bond strength 0.065 MPa (factored 0.02 MPa). The strengthening ties are made of stainless steel INOX AISI 316, diameter $\Phi 16 \text{ mm}$ with 222 wires, grade 1470 MPa .

5.2 Finite element analysis and verifications

The design and verifications were carried out based on the Italian code NTC 2018. Four linear elastic FEM models were set up using SAP2000 (CSI, 2019) – see Figure 4:

- 1) 3D model with plane shell elements for the existing arch and spandrel and wing walls, for static loading; this corresponds to the as built configuration prior to the intervention.
- 2) 3D model with the addition of brick elements for the fill; this corresponds to the strengthened existing stone masonry structure;
- 3) 2D model with one-dimensional frame elements for the new RC arch span, for static loading;
- 4) 3D model of the whole bridge for seismic verifications.

Figure 4. Finite element model: (a) the western span (model n.2); (b) the barrel and reference sections.

Flexural resistance verifications were based on the eccentricity e calculation, from the calculated axial force and moment in the arch cross-section; cracking occurs for $e > t/6$ and loss of resistance for $e > t/2$ (t = cross-section depth).

The strengthening effect is considered by an increase of the axial force in each cross section, equal to the tension in the cables.

The load conditions were the gravity loading ultimate limit state and the seismic actions; the latter are low in relation to the seismicity of the site and are not discussed in the following.

5.3 Limit analysis

A 2D limit analysis model has been developed. The arch is divided into rigid blocks separated by interfaces where flexural and sliding verifications are carried out. No-tension interfaces are used. Finite compression strength is considered, limiting the thrust line position within a band interior to the block depth. For the shear interface a constant friction coefficient equal to 0.4 is used. A linear program is solved obtaining the maximum static multiplier, corresponding to the limit load and the optimized thrust line position.

The effect of the RAM strengthening is modelled as resultant radial forces on each block, calculated as components of the tie tension forces along the extrados with a circular shape.

The model is set up with 20 blocks for the arch; the remaining parts are modelled as loads:

- Case 1: arch weight (20 KN/m³), fill weight (10 KN/m³), spandrel walls (18 KN/m³) and live load.
- Case 2: the same as Case 1, with the addition of radial forces transferred by RAM ties.

(*) calculated with no tension assumption, linear stress distribution

Figure 5 shows the comparison of design moments in combination 2 and cross-section resistance for the non-reinforced and reinforced configurations; in addition the moment distribution for the limit load is shown. Figure 6 shows the increase of the limit load relative to the design load, for increasing tension of the reinforcement. The masonry strength increase given by bed-joint repointing and injections is considered as well, in the passage from non strengthened (tension = 0) to strengthened cases.

5.4 Comparison of results

The project allows the comparison of different analysis and verification methods. Elastic finite element analysis sets up a model with geometrical features closely related to the survey results for

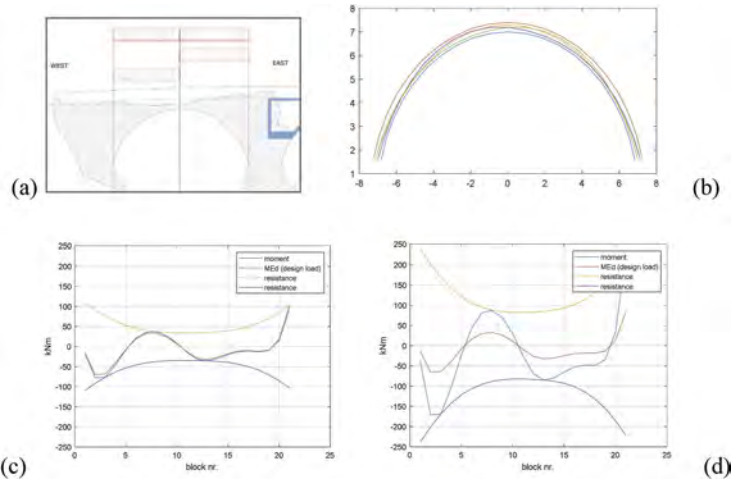

Figure 5. (a) Variable load distributions and (b) strengthened arch lines of thrust for limit loads. Comparison of moment load effects for arch (c) without strengthening (combination 1, limit multiplier = 1.1) and (d) with RAM strengthening (combination 1, limit multiplier = 2.64).

Figure 6. Increase of the limit load relative to design load as a function of RAM reinforcement tension.

arch vault, spandrel walls and fill. With a choice of elastic material properties the model furnishes an equilibrium solution for selected load distributions. This can be used for the structural verifications prescribed by codes, such as the Italian national specifications, under the assumptions of no-tension and limited compression and shear strength. The assumed elastic behavior highlights critical structural conditions by elevated eccentricity of the normal force in the arch sections, resulting in very high compression stress or even eccentricity beyond the section limits.

Limit analysis model considers only the arch as load bearing element. The cross section limit moments are calculated with finite compression and no tension strength, without the possibility of exceeding the cross-section resistance with a model closer to the masonry arch mechanical response.

Figure 7 shows the comparison of the ratio of maximum compression stresses and strength in the FEM based design (Section 5.2) with the ratio of the design moments to the resistance for the limit analysis (Section 5.3). The design moments are obtained dividing the limit moments by the maximum load multiplier obtained. The two models are based on different assumptions. The limit state verifications are carried out for the maximum compression and shear stresses compared to the corresponding strength. The stress distribution is linear in the compression zone. This leads to determine more critical conditions, particularly for the non-reinforced arch (see Table 1) and for the reinforced arch as well.

Figure 7. Comparison of assessment results for the resistance of the RAM reinforced arch, full load combination 1 (a) ratio of design stress and strength (from elastic analysis); (b) ratio of design load moments to moment resistance (limit analysis).

6 DISCUSSION

The life of the bridge started in the XV century in relation to mining and quarrying activities of the Strona valley. The intervention was urgent because of the risk of collapse of the remaining span, damaged by the flow of the Strona torrent. A new phase will start with the restoration and strengthening of the bridge, aiming at providing a path for pedestrians within a cultural and touristic project.

Figure 8. Study of alternative solutions: examples of projects: a) medieval bridge in Su Ponti Ecciu - Allai (Oristano) b) Pont Trencat (Catalunya); c) Roman bridge in Sogliano al Rubicone (www.jurina.it).

The solution chosen for the span that collapsed was the result of a multidisciplinary work in collaboration with the Ministry of Cultural Heritage. The structural and the architectural designers, evaluated multiple solutions relating to the method of reconstruction of the collapsed span; examples of projects in the practice were taken into consideration (Figure 8). In fact, different structural materials were considered, including masonry, steel and concrete, analyzing their advantages and disadvantages in terms of ease of execution, durability, maintenance and, last but not least, costs. The final choice was the use of reinforced concrete, finished with roughly cut stones.

7 CONCLUSIONS

The following conclusions can be drawn, based on the case study shown, concerning the RAM strengthening system, analytical methods for verification and design solutions to extend the life of the historic bridge in Omega.

The strengthening system provides an increase in resistance proved by two different verification methods, maintaining the features of the original construction where this was still standing. The project allows the comparison of different analysis and verification methods. Finite element analysis provides a good geometric model with relative ease, using available commercial packages. The elastic solution with equilibrium, though different from the real behavior

of a masonry structure, gives indications for design based on a lower bound approach. These can be integrated with a limit analysis lower bound model, with a more simple geometry but assumptions closer to masonry response. Thrust line analysis with limits for eccentricity can be easily set up e.g. using a spread sheet, predicting the limit load. Developments considering limited compression strength and shear sliding within an optimization solution have been shown in the paper.

The solution chosen to reconstruct the part that collapsed was the result of a comparative study considering different configuration and materials. The elements in favor of a reinforced concrete system with a stone facing were the structural stability and cost of this solution.

Numerical investigation of 3D response characteristics of masonry bridges by detailed mesoscale masonry models

M.S. El Ashri, S. Grosman, L. Macorini & B.A. Izzuddin
Imperial College London, London, UK

ABSTRACT: This paper adopts a detailed 3D mesoscale modelling strategy to tackle the pressing challenge of assessment for masonry arch bridges. Most of these structures have undergone severe deterioration during their service-life under both increasing traffic loads and environmental actions. However, they still represent a major portion of existing infrastructure for roadway and railway traffic in Europe. The development of reliable assessment methods for such structures is urgently required. However, this is clearly hindered by their complex behaviour. In the adopted modelling strategy, the heterogeneous nature of masonry arch bridges is addressed by adopting a discrete mesoscale modelling for masonry components in conjunction with a continuous modelling for backfill. In addition, the interaction between the different bridge parts is accounted for using nonlinear interface elements at the physical interfaces, where a mesh tying approach is employed to connect non-conforming meshes. The computational effort associated with such detailed models is efficiently optimised using a domain partitioning technique, where the bridge is subdivided into smaller partitions allowing for an efficient parallel computation. This modelling strategy aims at capturing the overall behaviour of masonry arch bridges, which is dominantly three-dimensional mainly due to the asymmetry of typical traffic loads and the complex geometry in the case of skew bridges. In the paper, the response of realistic 3D bridge samples with various loading and geometric configurations is investigated leading to an improved understanding of their typical 3D behaviour to collapse.

1 INTRODUCTION

To identify the main behavioural characteristics of masonry arch bridges, both experimental and analytical investigations have been carried out over the past few decades. The experimental tests carried out by Transport Research Laboratory (TRL) (Page, 1995), as well as Melbourne and his collaborators (Melbourne & Gilbert, 1995, Hodgson, 1996) have demonstrated a 3D behaviour associated with masonry arch bridges. Such 3D behaviour can be fully captured only by using 3D assessment methods, a need which has been recently addressed by several researchers. Milani & Lourenco (2012) developed a macro-scale FE homogenised strategy to investigate the 3D behaviour of masonry arch bridges. Thereafter, Papa et al. (2021) put forward a 3D adaptive limit analysis procedure, which can be used to predict the ultimate behaviour of skew arches interacting with backfill. Discrete Element Method (DEM) has been lately used by Forgács et al. (2018) and Pulatsu et al. (2019) to develop 3D models for masonry arch bridges taking into account the contribution of both backfill and spandrel walls.

The 3D mesoscale modelling approach adopted in this paper has been previously utilised to analyse both single span (Zhang et al., 2018) and multi-span masonry arch bridges (Tubaldi et al., 2018). In these previous studies, a simplified continuum approach was adopted for modelling spandrel walls, where they were considered as a lateral extension for the backfill but with different material parameters. Recently, a mesoscale description for spandrel walls that allows for the actual masonry bond has been developed, and it has been adopted for the

analysis of single span square arch bridges (Grosman et al., 2021). In this paper, this full mesoscale description is further extended to analyse single span skew arch bridges, as outlined in the following sections.

2 METHODOLOGY

To develop an improved understanding for the complex 3D behaviour of masonry arch bridges, a 3D modelling strategy that can capture cracks and plastic deformations within the structure up to collapse is adopted in this paper. This strategy accounts for the nonlinear behaviour of different bridge components, as well as their mutual interaction. This is achieved by using the discrete 3D mesoscale modelling approach developed by Macorini & Izzuddin (2011) to model the masonry components in the bridge, allowing for the actual masonry bond within the arch barrel and spandrel walls. This approach utilises 3D elastic solid elements to model masonry units and 2D zero-thickness nonlinear interface elements to model both mortar joints and potential fracture planes within bricks. Each brick unit is modelled using two solid elements with an interface element in the middle of the brick to allow for cracking within the brick itself due to tension or shear. The material nonlinearity in masonry is lumped within the interfaces using the cohesive-frictional material model developed by Minga et al. (2018a), whereas geometric nonlinearity is considered using a co-rotational approach for interface elements and using Green's strains for solid elements. This is complemented with a continuous elastoplastic modelling approach for backfill, where the backfill domain is discretised using 3D solid elements. The plastic response for backfill is defined by a modified Drucker-Prager yield criterion as described by Zhang et al. (2018).

In addition, the interaction between the different parts of the bridge is considered using nonlinear interface elements at the physical interfaces between the different domains, where the same material model used for the interface elements within the mesoscale representation of masonry is adopted. Having matching interfaces between the different components could be impractical. Therefore, a mesh tying method, which has been developed by Minga et al. (2018b) based on the mortar method, is adopted to allow for the connectivity between non-conforming meshes between the arch barrel, backfill, and spandrel walls.

Such detailed models are associated with a significant computational cost which is efficiently reduced using a domain partitioning technique (Jokhio & Izzuddin, 2015), where the bridge is subdivided into smaller partitions. These partitions are linked together using a parent structure allowing for an efficient parallel computation, where each partition is analysed using an independent processor. This whole proposed methodology is implemented in the nonlinear finite element program ADAPTIC (Izzuddin, 1991).

3 NUMERICAL SIMULATIONS

3.1 *Validation*

To demonstrate the capability of the adopted mesoscale modelling strategy to simulate the response of masonry arch bridges, two experimental tests are used for validating the proposed numerical models. The first test is on the square arch bridge "Square Bridge 3-3" tested at Bolton Institute (Melbourne & Gilbert, 1995), while the second test is on the skew arch bridge "Skew Bridge 3-3" tested by Hodgson (1996). The two bridges have similar dimensions with a span of 3m, a rise of 0.75m and a width along the abutments of about 3.5m. Also, the arch barrel for both bridges is composed of 2 rings following the stretcher bond with a total thickness of 0.215m. The spandrel walls are built according to the English bond on top of the arch barrel at each face to confine a crushed limestone backfill. The two bridges are tested up to failure under a line load applied at quarter-span parallel to the abutments. It should be noted that the skew bridge is constructed according to the helicoidal method with a 45° skew angle.

Since the two bridges have been tested within the same experimental programme, the properties for the construction materials of the two bridges are comparable as indicated in (Melbourne & Gilbert, 1995) and (Hodgson, 1996). The material parameters for the mesoscale models are calibrated based on the material tests performed within the experimental programme. These properties include the compressive strength, Young’s modulus and Poisson’s ratio for brickwork. Also, the properties for the backfill are provided based on the material tests performed within the experimental programme, where the friction angle is 60° and the cohesion is almost negligible. However, the provided properties do not cover all the parameters required for the numerical models. Therefore, the remaining parameters are calibrated based on previous research by Zhang et al. (2018) and Grosman et al. (2021) to validate the square arch bridges “Bridge 3-1” and “Bridge 3-3” tested at Bolton Institute (Melbourne & Gilbert, 1995). The main material parameters used for the validation of the numerical model are provided in Table 1.

Table 1. Material parameters for interface elements.

		Mortar joints	Backfill-Arch	Spandrel wall-Arch
Normal stiffness (k_n)	N/mm ³	100	40	100
Tangential stiffness (k_t)	N/mm ³	50	20	50
Tensile strength (f_{ti})	MPa	0.20	0.002	0.10
Compressive strength (f_{ci})	MPa	26	26	26
Cohesion (c)	MPa	0.25	0.003	0.15
Fracture energy in tension (G_{ti})	N/mm	0.01	1E5	0.01
Fracture energy in shear (G_{si})	N/mm	0.05	1E5	0.05
Internal friction angle (ϕ_i)	Rad	0.464	0.54	0.464
Dilatancy angle (ψ_i)	Rad	0.00	0.00	0.00

The numerical load-displacement curves for both square and skew bridges provide a good approximation to the experimental response as shown in Figures 1(a) and (b). The numerical response in both cases slightly overestimates the peak load by about 10%, and slightly underestimates the experimental initial stiffness. The deformed shapes at failure for both square and skew bridges, as outlined in Figures 2-4, agree in having a four-hinge failure mechanism for the arch barrel, where the hinges form below the load, around three-quarter span, and at the two springings. However, the failure mode in the case of square bridge is purely two-dimensional under the effect of the line load. This is not the case for the skew bridge which fails under a three-dimensional four-hinge mechanism, where the formed hinges are not parallel to the abutments. Moreover, the hinges take a saw-toothed pattern due to the helicoidal construction method for skew arches. In addition to the four-hinge mechanism, a notable sliding between the two rings of the arch barrel is predicted for both bridges, which agrees with the experimental observations (Melbourne & Gilbert, 1995, Hodgson, 1996). The numerical

deformed shapes clearly exhibit out-of-plane deformations for the two spandrel walls close to the loading beam. The crack pattern for spandrel walls at failure includes two main vertical cracks close to the loading beam and at three-quarter span due to the deformations of the arch barrel. These two cracks are accompanied by a horizontal crack at the base of the spandrel/wing wall away from the load. Although this crack pattern applies to the two spandrel walls in the square bridge, it only applies to the Eastern spandrel wall in the skew bridge due to the three-dimensional response associated with asymmetric skew geometry.

3.2 Parametric study on masonry arch bridges

The validated numerical models for both the square and skew arch bridges are considered as control specimens for the development of a parametric study on masonry arch bridges. This parametric study aims at developing a more profound understanding for the complex behaviour of masonry arch bridges under various loading conditions.

3.2.1 Line load parallel to abutments

First, a line load parallel to the abutments is applied at mid, third, quarter, and eighth span. For the case of square bridges, the load capacities under line loads at third, quarter and eighth of the span are almost identical, where the load at the third span is the most critical. Conversely, the line load at the mid-span exhibits the highest load capacity compared to the other locations, as depicted in Figure 5(a). The load-displacement response for the case of skew bridges, as shown in Figure 5(b), indicates that line load at quarter span is the most critical, followed by the loads at third, eighth, and mid span respectively. For both the square and skew bridges, the initial stiffness for the bridge under line loads declines as the load is applied further from the abutments as indicated in both Figures 5(a) and (b).

Figure 5. Numerical load-displacement curves for the vertical displacement below line load on the intrados of (a) square bridge; (b) skew bridge, showing the influence of line load at different locations.

For square bridges, the line loads at third and eighth span produce the same two-dimensional four-hinge mechanism as in the case of load at quarter span. The only difference is the location of the hinge below the load, which shifts in each case. In contrast, the line load at mid span results in a two-dimensional five-hinge mechanism, where the hinges form below load, around quarter and three-quarter span and at the two springings, as displayed in Figure 6. This is reflected in Figure 5(a) with the high load capacity associated with the mid span case in the load-displacement curve. These observations for square bridges also apply for the skew bridges. However, the mechanisms convert from being two-dimensional into three-dimensional, where the hinges take a saw-toothed shape, as well as being not parallel to the abutments. Regarding spandrel walls, the same crack pattern of the quarter-span case is observed in all the other cases for the square bridge. Again, this pattern is only applicable to

Figure 6. Numerical deformed shape at failure for square bridge under line load at (a) eighth span (b) third span (c) mid span.

Figure 7. Numerical deformed shape at failure for skew bridge (showing the Eastern spandrel wall) under line load at (a) eighth span (b) third span (c) mid span.

the Eastern spandrel wall in the case of skew bridges, whereas the Western wall undergoes a more complex cracking pattern which varies based on the load location.

3.2.2 Patch load

In this section, both concentric and eccentric patch loads of size (500mm×600mm) are applied at quarter and mid span. The load-displacement curves for square bridges, shown in Figure 8 (a), indicate that patch loads at mid span exhibit a higher load capacity compared to those at quarter span. This observation is consistent with that in the case of line loads. In terms of load eccentricity, concentric patch loads applied at mid-width generally tends to provide a higher capacity compared to eccentric loads applied at quarter width. However, the effect of eccentricity on load capacity is more significant at quarter span than at mid span. In reference to the initial stiffness, square bridges provide a higher stiffness under patch loads at quarter span than at mid span, which is compatible with the behaviour under line loads. In case of skew bridges, patch loads at three-quarter width are also considered due to their asymmetric geometry. Most of the observations for square bridges also apply to skew bridges except for the effect of eccentricity on load capacity, which is less significant in the skew bridges.

Figure 8. Numerical load-displacement curves for the vertical displacement below patch load on the intrados of (a) square bridge; (b) skew bridge, showing the influence of patch load at different locations.

The deformed shapes at failure for square bridges under patch load at various locations outline the complex cracking behaviour within the arch barrel, as outlined in Figure 9. This complex behaviour is expressed in the form of diagonal cracks extending from below the patch load to the faces of the arch barrel. It is also obvious that the previous hinge mechanisms associated with line loads are no longer observed, where more complex three-dimensional failure mechanisms develop within the arch barrels. For spandrel walls, the crack pattern is almost identical to that observed for the case of line loads. However, the severity of the cracks is dependent on the proximity level for the patch load with respect to the spandrel wall.

Figure 9. Numerical deformed shape at failure for square bridge under patch load at (a) mid-span mid-width; (b) mid-span quarter-width; (c) quarter-span mid-width; (d) quarter-span quarter-width.

Unlike square bridges, hinges along the whole width of the arch barrel form below the patch load in the case of skew bridges. The formed hinges are saw-toothed due to the helicoidal construction method, but in this case, they are diffused over a larger area below the applied load. This can be due to the characteristics of the patch loads which tend to trigger 3D effects compared to the line loads. These observations are supported by the failure mechanisms predicted for the different cases, as shown in Figure 10. It can be noted that patch loads at quarter span result in a four-hinge mechanism, whereas loads at mid span lead to a five-hinge mechanism, which is compatible with the failure modes under line loads. These observations agree with the load-displacement curves in Figure 8 which shows that load eccentricity is less significant in the case of skew bridges. This is further indicated here by the fact that patch loads do not significantly alter the failure mode for skew bridges compared to the case of line loads. Regarding spandrel walls, the Eastern spandrel wall maintains the same crack pattern composed of two vertical cracks and one horizontal crack in most of the cases. On the other hand, the Western spandrel wall undergoes more complex cracking based on the load location along both the span and width of the bridge.

Figure 10. Numerical deformed shape at failure for skew bridge (showing the Eastern spandrel wall) under patch load at (a) mid-span mid-width; (b) mid-span quarter-width; (c) mid-span three quarter-width (d) quarter-span mid-width; (e) quarter-span quarter-width; (f) quarter-span three quarter-width.

4 CONCLUSIONS

This paper explores the main characteristics of the 3D response for masonry arch bridges using detailed 3D mesoscale models, considering the actual masonry bond in all the masonry components. Both square and skew single-span multi-ring masonry arch bridges are investigated in this paper to develop an improved understanding of the complex behaviour of these structures. The validated numerical models have demonstrated the capability of 3D mesoscale models to simulate the behaviour of masonry arch bridges, representing the experimental behaviour in terms of both the load-displacement response and the failure mechanisms. These validated models are used afterwards in a parametric study on both square and skew masonry arch bridges. This study led to the development of a better understanding for the 3D behaviour of these structures, summarised in the following main findings:

- The most common failure mechanism for both square and skew masonry arch bridges is a four-hinge mechanism. The four hinges form normally at the load location, away from the load (three-quarter span), and at the two springings.
- The previous observation takes place mainly when line load is applied at quarter, third, or eighth of the bridge span. When the load is applied at mid-span, this failure mechanism converts into a five-hinge mechanism, where the hinges form below the load, at quarter and three-quarter span, and at the two springings.
- In the case of square bridge, the failure mechanism under line loads is mostly two-dimensional. However, it is different in the case of skew bridges, where the hinge mechanism becomes three-dimensional with the hinges non-parallel to the abutments, also exhibiting a saw-tooth shape due to the nature of the helicoidal construction method.
- Under the effect of patch loads, the behaviour of both square and skew bridges becomes dominantly three-dimensional. For square bridges, failure mechanisms with diagonal cracks take place regardless of the location for patch load, whereas mechanisms with diffused hinges form in the case of skew bridges.

- It was found that the least critical load position for both square and skew bridges is at mid-span, whereas the most critical position is at third span for square bridges and at quarter span for skew bridges.
- The initial stiffness for both square and skew bridges tends to decrease as the load is applied further away from the abutments.
- The effect of eccentricity for patch loads on the load capacity is more significant at quarter-span than at mid-span in the case of square bridges. For skew bridges, the effect of eccentricity is less significant.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge support from EPSRC grant EP/T001607/1 (Project title: Exploiting the resilience of masonry arch bridge infrastructure: a 3D multi-level modelling framework). Additionally, the authors would like to thank Prof. Matthew Gilbert for the data he has provided on the experimental tests performed at Bolton Institute.

Experimental investigation of the effect of masonry infill on the performance of masonry arch bridges

S. Amodio, M. Gilbert & C.C. Smith
The University of Sheffield, UK

ABSTRACT: Numerical modelling forms a fundamental part of most masonry arch bridge assessments. However, the numerical models employed need to be validated against full-scale bridge tests, or, alternatively, against tests on scale models. This contribution describes a programme of tests carried out on medium-scale masonry arch bridges to explore the effects of internal spandrel walls and masonry backing on structural performance, since the effects of these elements appear to have been little investigated previously. The tests have provided high quality benchmark results that have been used to validate numerical models developed using the discontinuity layout optimization (DLO) limit analysis method. It has been found, both experimentally and numerically, that internal spandrels and backing can contribute significantly to bridge load-carrying capacity.

1 INTRODUCTION

Masonry arch bridges continue to form an essential part of the transport systems of many countries around the world. However, many aspects of their behaviour remain quite poorly understood. For example, although the behaviour of masonry arch bridges containing soil backfill has been extensively investigated over the last few decades (Page 1993, Melbourne & Gilbert 1995, Boothby et al. 2004, Augustus-Nelson & Swift 2020), significantly fewer studies have examined the effects of other infill materials, such as backing and internal spandrel walls, which are common in long span bridges and viaducts. Harvey & Harvey (2017) and Gilbert et al. (2022) have observed that the presence of backing can potentially trigger different modes of response, by moving the effective arch springing locations. Also, experimental evidence has suggested that external spandrel walls may have a significant stiffening effect on the arch barrel (Royles & Hendry 1991, Melbourne et al. 1997). However, due to a lack of research, internal spandrel walls are in practice often modelled using a fictitious soil fill material, with the unit weight adjusted to take account of internal voids (Network Rail 2006); this approach appears likely to lead to inaccurate predictions of load carrying capacity.

In order to improve our understanding of the modes of response of bridges containing masonry backing and internal spandrel walls, a programme of quasi-static load tests to failure on laboratory bridges has recently been conducted at the University of Sheffield, with the aim of quantifying their contributions to bridge load-carrying capacity. Medium-scale models have been employed as these have the advantage of allowing rapid test turnaround and also reducing costs. The main aim of the research was to provide high quality test data that could be used to validate numerical models. In the present study, test results are compared with predictions from numerical limit analyses conducted via discontinuity layout optimization method (DLO). Preliminary outcomes from the study are presented herein.

2 EXPERIMENTAL INVESTIGATION

2.1 General test arrangement and design

An experimental test campaign was developed that included single and multi-span bridges incorporating either masonry backing, internal spandrels or sand backfill, with the principal aim of comparing their respective contributions to load carrying capacity and influence on failure modes. The multi-span models only included two spans as this was considered sufficient to investigate the primary failure modes likely to be encountered in full-scale multi-span bridges, which typically involve two adjacent spans (Melbourne et al. 1997).

The models had segmental arch barrels composed of voussoir blocks extending across the full width of the bridge (198mm) and were built without external spandrel walls to represent approximately plane strain conditions. This aided interpretation of the test data and also allowed direct comparison with 2D numerical models.

The bridges were constructed with sandstone blocks, cut using precise CNC manufacturing process to obtain high geometrical accuracy, with thin joints used to achieve closely fitting arch barrels; this was designed to increase repeatability of the tests. For convenience, masonry joints were filled with fast setting 'liquid magnesium' (or 'liquid chalk'), a commercially available product, composed of isopropyl alcohol, magnesium carbonate hydroxide and resin.

Both backing and internal spandrels were built with a typical stretcher bonding pattern. However, a number of bridges with spandrels were constructed with an alternative bonding pattern to emulate the presence of cracks in correspondence of the load and to allow investigation of the effect of different load distributions on load carrying capacity. The main bridge dimensions are shown in Figure 1.

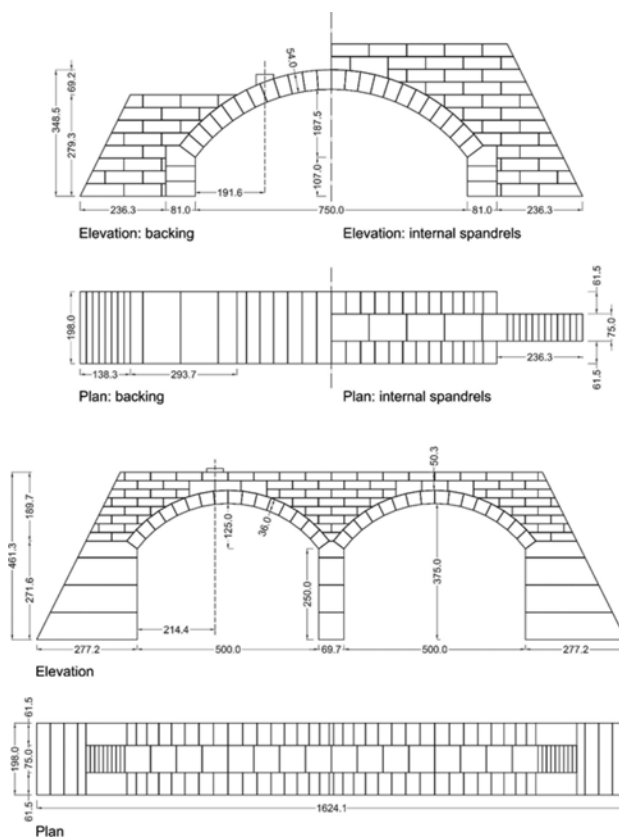

Figure 1. Main dimensions of single and multi-span bridge models tested, with backing and internal spandrel masonry shown (all dimensions in mm).

The tests were performed in a purpose-made test rig apparatus (described in Pytlos 2015) that features a stiff and transparent test chamber and an automated sand filling process via pluviation to ensure uniform and consistent backfill density, in the case of the soil filled bridges. The loading system included an electric actuator operated in displacement control mode while bridge displacements were measured using five LVDT transducers positioned perpendicular to the arch intrados.

2.2 *Single span bridge tests*

All the single span models were tested to failure by alternately applying the load at the $\frac{1}{4}$ span and $\frac{3}{4}$ span points, except in the case of the sand backfilled models, which were tested only at the $\frac{1}{4}$ span point.

A first series of tests on bare arch models indicated that the chalk material used in the joints provided a small bond strength that was lost once cracks in the joints were formed. Also, when a given arch was first tested, it exhibited a slightly stiffer response and higher load-carrying capacity compared to subsequent repeat tests. However, the chalk material appeared to foster good test repeatability; for the three benchmark bare arches tested, each loaded four times, the average failure load was 191.1N and the coefficient of variation was 3.8%.

Tests on models with backing included three nominally identical bridges (named B1, B2, B3), though in B1 and B2 the abutments were left free to move (albeit movement of these was observed only in the case of B2), while B3 had fixed abutments. The backing had the same width as the arch barrel and covered $\frac{2}{3}$ of the arch height on each side; it provided an increase in load-carrying capacity of approximately 40% in the case of the bridge with free abutments and 77% (on average) in the case of the bridges where abutments were fixed (or were not observed to move). However, the failure load was observed to be particularly sensitive to the form of the crack pattern that developed in the masonry infill far from the load, following deformation of the arch. Here sliding and/or rocking failure were observed to occur, though the extent of these mechanisms appeared to be influenced by the variable nature of the masonry bond strength and/or by slight differences in the construction. As a consequence, variability in the results was observed to be higher (approximately 8%). These differences in load-carrying capacity can be observed by comparing the load-displacement responses of bridges B1 and B3 when tested at $\frac{1}{4}$ and $\frac{3}{4}$ span (see Figure 2). Finally, in the case of bridge B2 the abutment far from the load rotated outwards, pushing into the backing, which also rotated rigidly. This failure mechanism led to a reduced capacity and less smooth load-displacement response, as also shown in Figure 2.

Similar considerations and differences in failure loads were observed for the models with internal spandrels. These bridges contained a single longitudinal wall of 75mm width, over-arching the barrel along its centreline. Failure was via formation of hinged mechanisms, dividing the spandrel walls into three main sections, with major cracks forming close to the $\frac{1}{4}$ and $\frac{3}{4}$ span hinges. Additionally, more diffused, cracks were observed in the wall section far from the load, where combined hinging and sliding failure occurred. Also in this case, the wall failure modes were likely influenced by the variable masonry bond strength and possible small differences in wall construction. The substantial strengthening effect of the spandrels provided an increase in load-carrying capacity of approximately 4.3 times compared to that of a bare arch, with an average failure load of 828N.

Furthermore, some of the models incorporated non-interlocking wall blocks in the region close to the load to emulate the presence of cracks, effectively directing the applied load onto the arch. This reduced bridge load carrying capacity to an average load of 472.2N, that is 57% of the failure load obtained from other models with a regular masonry bond.

Tests on two bridges with sand backfill exhibited very similar failure loads (average = 862.1N) and mechanisms to those observed in bridges with internal spandrels. However, the main difference is that the spandrel walls occupied only 38% of the bridge width; therefore, these provided a greater stiffening effect per unit width, i.e. 11N/mm versus 4.4N/mm of the sand.

Finally, tests were carried out on bridges containing both backing and internal spandrels. These bridges performed similarly to models that included spandrels only, though the presence of backing provided an increase in load-carrying capacity of approximately 12%. Results from all single span bridge tests are summarized in Table 1.

Figure 2. Load displacement responses of single span bridges with backing when loaded at $\frac{1}{4}$ span (left) and $\frac{3}{4}$ span (right). Note that in bridges B1 and B2 the abutments were left free to slide (though abutment movement were only observed in the latter model), while in B3 these were fixed.

Table 1. Experimental and numerical results of single and multi-span bridge models.

Bridge series	Backfill type	No. of models	No. of tests	Average experimental load (N)	Numerical load (N)	Numerical/Experimental
Single span	Bare arch	7	28	191.1	200.2	1.05
	Backing (free abutments)	1	4	268.1	238.4	0.89
	Backing	2*	8	338.1	317	0.94
	Spandrels ('cracked' wall)	3	5	472.4	508.9	1.08
	Spandrels	2	8	828	827.6	1
	Backing + Spandrels (free abutments)		8	474	439.9	0.93
	Backing + Spandrels	2**	8	926.8	928.5	1
Multi-span	Sand backfill	2	2	862.1	763.6	0.86
	Bare arches	2	8	66	70.6	1.07
	Spandrels	2	8	234.6	261.2	1.11
	Sand backfill	2	2	306.7	316.5	1.03

*One of the models (B1) had free abutments, though these were not observed to move during the tests.

**The same two models were first tested with fixed abutments and then with free abutments.

2.3 Multi-span bridge tests

The multi-span bridges tested comprised bare arch models and models with either internal spandrels or sand backfill. Preliminary numerical investigations were conducted to find the critical load position for these bridges, and it was found to be near the arch crown (as also found by Melbourne et al. 1997). Thus, the bridges were loaded near the crown of each of the two arches in turn. All the models failed via formation of a typical 7 hinge mechanism involving both spans and rotation of the intermediate pier. Results from the bare arch tests had a variability of just 3%.

The internal spandrel walls provided an increase in bridge load-carrying capacity of approximately 3.5 times compared to the bare arches. At failure, major cracks developed close to the hinges that formed at the crown of each arch, dividing the wall into three main sections, that rotated rigidly as the arches pushed sideways. Also, further cracks developed in the wall section furthest from the load. After the first test, the deformed geometry and the loss of masonry bonding strength affected the load-displacement response observed in subsequent repeat tests, with the peak load also reducing by approximately 13%.

Bridges with sand backfill failed in similar hinged mechanisms, though these exhibited a significantly increased load-carrying capacity (+31%). Nonetheless, the spandrels still provided higher strength per unit width than the sand fill (3N/mm vs. 1.55N/mm respectively). Results from all multi-span bridge tests are summarized in Table 1.

3 NUMERICAL MODELLING

3.1 Model details

Numerical analyses were carried out employing the discontinuity layout optimization (DLO) limit analysis method (Smith & Gilbert 2007). This has been developed for both 3D and 2D problems, though the latter has been adopted here since the bridge models exhibited 2-dimensional failure modes. The analyses were conducted using the LimitState:GEO software (2021), which implements the DLO technique.

A key advantage of this method is that both masonry and soil elements can be modelled directly. However, the mathematical formulation assumes that the friction behaves in an associative manner, which can potentially lead to overestimations of load-carrying capacity.

The masonry is represented as an assemblage of discrete rigid blocks, with sliding and crushing failure permitted at the interfaces between blocks. The soil is modelled as a Mohr-Coulomb material, with a mobilized strength assumed in the region of soil remote from the load to take account of the fact that deformations at peak load are not sufficient to mobilize the full strength of the soil in the passive region (Smith et al. 2004). However, defining appropriate mobilization factors is not straightforward (Gilbert et al. 2010, Callaway et al. 2012).

Here it has been assumed that full soil strength is mobilized on the active side of the bridge, while a factor of 0.5 has been applied to the soil internal angle of friction and cohesion on the passive side. Also, a strength multiplier of 0.5 has been applied to the soil-arch interface. These values enabled reasonable correlation to be obtained between the numerical model and experimental results.

The material properties adopted in the models are provided in Table 2. The sand internal angle of friction was measured via shear box tests and found to be 37 degrees. Pilot wrench tests were also carried out on masonry samples to determine the joint bending resistance, with regression analyses performed to characterize the masonry in compression. These regression analyses appeared to suggest that the very edges of the joints were very weak but very much stronger elsewhere. Although this two-crushing strength model was adopted in the DLO models involving sand fill material, more experiments are required to investigate this further; in all the other models a low compressive strength (of 0.25N/mm²), applied to the whole joint, was adopted. The masonry joint friction angle was measured via tilt table tests and was found to be 37 degrees; however, to take account of the non-conservatism arising from the assumption of associative friction, a reduced angle of friction of 33 degrees was used in the models. Finally, a reduced unit weight was assigned to the spandrel walls to take account of the reduced width relative to the barrel.

Table 2. Material properties adopted in the numerical models. A mobilization factor of 0.5 was applied to the soil strength parameters in the passive region of the bridge.

Material properties					
Masonry			Sand		
Arch/Backing unit weight (kN/m ³)	Spandrels unit weight (kN/m ³)	Compressive strength (kN/m ²)	Joints' friction angle (deg)	Unit weight (kN/m ³)	ϕ (c') [deg (kN/m ²)]
23.618	8.946	250*	33	17.554	37 (0)

*Assumed value, adopted in all models except the ones with sand backfill.

3.2 DLO validation

Using the aforementioned assumptions led to reasonable computed DLO failure loads being obtained (all within 15% of the experimental values, see Table 1), together with failure mechanisms that are representative of those observed during the experiments in most cases (e.g. see Figure 3 and 4).

As discussed in Section 2.2, the load-carrying capacity of the single span bridges appeared quite sensitive to the failure modes that occurred in the infill masonry remote from the load.

Figure 3. Failure mechanism of single span bridge with internal spandrels and superimposed hinges (top image) and failure mechanism predicted by DLO (bottom image).

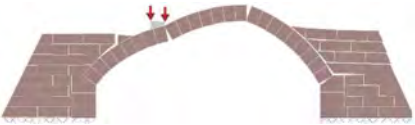

Figure 4. Failure mechanism of single span bridge with sand backfill and superimposed hinges (top image) and failure mechanism predicted by DLO (bottom image).

These involved a combination of sliding and hinging modes, which led to various crack patterns and thus differences in failure loads of over 10% in some cases.

Although in the DLO models primarily sliding modes in the backing and spandrels were predicted, in some of the experiments, rotation of a large portion of masonry was observed. This can be modelled by preventing sliding in relevant joints to ensure that rotation becomes the critical failure mode. An example is shown in Table 3, in which similar differences in peak loads are also predicted by DLO if the same failure modes observed in the experiments are induced.

Table 3. Predicted mechanisms of a bridge with backing, modified to replicate the failure modes observed in specific tests.

Bridge test	Failure mechanism	Experimental load (N)	Numerical load (N)	Numerical/Experimental
B 1-1		309.3	336.8	1.09
B 1-2		349	366.3	1.05

3.3 Commentary

In addition to the results presented in the previous sections a series of parametric studies have been performed. These indicate that the numerical models are relatively sensitive to the soil properties and to the chosen masonry crushing strength and angle of friction. In relation to the latter, it is also known (e.g. see Valentino et al. 2023) that the assumption of associative friction can lead to quite significant over-predictions of capacity when relatively few masonry blocks are involved, as is the case here.

Furthermore, in the DLO analyses of bridges containing soil backfill, as this is modelled directly, a mobilization factor needs to be applied to the passive side soil strength. However, determining an appropriate mobilization factor and identifying the extent of passive region is not always straightforward.

Nevertheless, a major benefit of DLO is that results can be obtained rapidly and directly, with relatively few input parameters and without the need to perform a time-consuming and often unreliable incremental analysis.

4 CONCLUSIONS

A programme of quasi-static load tests to failure on laboratory bridges has been carried out to investigate the effect of masonry backing and internal spandrels on bridge load carrying capacity. The tests have confirmed the significant strengthening effect of these two infill materials. It was found that bridge models containing internal spandrels and sand backfill performed similarly, with failure via hinged mechanisms in both cases, though the internal spandrels provided a greater stiffening effect per unit width. Masonry backing also measurably increased load carrying capacity.

The discontinuity layout optimization (DLO) numerical procedure has been found to provide results that are in reasonably close agreement with experimental failure loads (within 15% in most cases), using input parameters common across bridge models. Experimentally observed failure modes could be reliably modelled in most cases. However, additional masonry joint characterization tests are required to improve confidence in the results obtained.

Multi-fidelity modelling of masonry arch bridges under traffic loading

S. Grosman, Q. Fang, L. Macorini & B.A. Izzuddin

Imperial College London, London, UK

ABSTRACT: Masonry arch bridges are part of the historical heritage from the Industrial Age in the UK and Europe. To preserve this infrastructure, robust assessment methodologies are required to adequately account for the effects of evolving loading and material degradation. This work presents 3D multi-fidelity modelling strategies for masonry viaducts which can be used for accurate assessment. The masonry components of the bridge structure are modelled using high-fidelity mesoscale models or efficient macroscale models. Filling materials are represented using elasto-plastic models considering their cohesive and frictional nature. The interaction between the different parts is taken into account by adopting non-linear interface elements allowing for sliding and separation. The results of numerical investigations on a realistic viaduct under traffic loading, which were conducted by performing nonlinear simulations under transient loading, showcase the potential of accurate 3D modelling comparing the results from mesoscale and macroscale models.

1 INTRODUCTION

The pressing need to predict the structural performance of a massive amount of masonry arch bridges in the UK and around the world has prompted the development of assessment methods for these complex structural systems. Various numerical modelling strategies have been developed over the past few decades, and they generally entail nonlinear analysis capabilities and numerical solution procedures of various degrees of sophistication. The paradigm of numerical simulation of masonry bridges at different loading levels up to collapse is mainly based on the Finite Element (FE) or Discrete Element methods. Accurate predictions under different loading conditions require the use of 3D models providing a complete geometric description of masonry bridges and viaducts. In particular, the 3D representation is the only way to accurately represent such complex phenomena as complex arch cracking patterns observed in real masonry bridges or the frequently reported outward movement (walking) of spandrel walls (Ozaeta García-Catalán & Martín-Caro Alamo, 2020).

Conventionally, 3D continuum-based methods rely on a macroscale description of the different masonry constituents (Fanning & Boothby, 2001, Caddemi et al., 2019). That is, masonry is considered a single homogeneous and isotropic continuum where nonlinear effects are captured in a ‘smeared’ fashion. Although this offers computational efficiency, it simplifies the real heterogeneity arising from the combination of brick/stone units and mortar. The main limitation of such a macroscale strategy is associated with substantial difficulty when determining reliable material parameters.

The mesoscale description, in contrast, comprises separate representations of the two distinct constituents of masonry: the brick/stone unit as solid elements and the mortar layers as zero-thickness interface elements (Macorini & Izzuddin, 2011). This strategy has been recently applied to investigate the response of masonry arches (Zhang et al., 2016) and bridges (Zhang et al., 2018, Tubaldi et al., 2020, Grosman et al., 2021). The mesoscale description facilitates the explicit consideration of masonry bonds as well as the modelling of complex arch

geometries such as a skew arch. It also enables the capturing of radial cracking, ring separation and more complex 3D cracks in masonry bridges.

While the 3D mesoscale models generally provide more realistic predictions, they are also associated with substantial difficulties in mesh generation and significant computational costs, which can hinder their use for the practical assessment of large structures. In the following section, multi-fidelity modelling strategies, based on meso- and macroscale masonry models, with a parametric mesh generator tool developed at Imperial College London for accurate 3D simulations of masonry viaducts are presented and used to investigate the response of a realistic brick-masonry railway viaduct under traffic loading.

2 MULTI-FIDELITY MODELLING STRATEGY

This section introduces the detailed modelling strategy developed to investigate masonry viaducts which has been implemented in ADAPTIC (Izzuddin, 1991), a finite element code for advanced nonlinear analysis of structures. Macroscale and mesoscale masonry models are used to simulate material nonlinearity in the masonry components of the analysed structure. The two strategies can be also combined leading to mixed meso- macroscale models (Grosman et al., 2023). As specified before, in the macroscale modelling strategy, the masonry components are modelled using 3D continuum elements, sized independently from the dimensions of bricks and mortar joints (Figure 1a). The material described in this case is based on a constitutive model combining the concepts of plasticity and damage (Lee & Fenves, 1998, Chisari et al., 2020). It is worth noting that appropriate interpretation is needed to relate the results obtained with such models to real material behaviour. On the other hand, in the mesoscale description (Figure 1b), the masonry material is modelled based on separate representations for units and joints. More specifically, as elaborated in Macorini and Izzuddin (2011), elastic solid elements are used to describe units and nonlinear interface elements to represent mortar joints and potential failure surfaces within bricks. The material description for nonlinear interfaces employs a cohesive-frictional constitutive model (Minga et al., 2018), providing computationally robust solutions to the local nonlinear problem. The latter approach can capture the propagation of local damage, but it is associated with significant computational costs. Mixed meso- macroscale models employ detailed mesoscale descriptions only for critical spans or segments and more efficient macroscale representations for the remaining parts of the analysed viaduct (Figure 1c). This combination improves computational efficiency while allowing for capturing the local damage phenomena.

Figure 1. Modelling strategies for masonry viaducts: (a) macroscale, (b) mesoscale and (c) mixed meso-macroscale models.

To facilitate extensive numerical analysis of masonry viaducts featuring diverse geometries, materials, and loading characteristics, a novel parametric design tool has been recently developed by the authors (Grosman et al., 2023) as an add-on component within the Rhino & Grasshopper environment (McNeel & Associates, 2010). The developed tool provides a comprehensive parametric description for each distinct structural component of the bridge (arch barrel, backing/backfill, spandrel wall, pier etc.) and allows for a robust way of joining these components together to form the masonry bridge as depicted in Figure 2. Each component can support both meso- and macroscale definition and is fully parametric. Connectivity

between distinct adjacent components is established via a set of nonlinear interfaces. 3D modelling of large and complex structural systems, such as realistic masonry viaducts, bears a high computational cost, even when using the more computationally efficient macroscale models. Thus, to improve computational efficiency further, the advantage is taken of the domain decomposition approach earlier developed at Imperial to parallelise the solution procedure between multiple processor cores (Jokhio & Izzuddin, 2015, Izzuddin & Jokhio, 2017). To accurately represent transient railway loading for nonlinear dynamic simulations, the developed tool integrates capabilities for the automatic generation of traffic loading according to the vehicle axle profile and speed. In comparison to static analysis with incremental application of train loading, dynamic analysis with transient loading is capable of capturing more realistic propagation of the damage in the brickwork.

Figure 2. The modular approach to bridge assembly.

According to the developed modelling strategy for accurate simulations of masonry viaducts under train loading, model material parameters for masonry, backfill and backing should be obtained from material tests on masonry specimens taken out from the analysed structure. More specifically, physical tests on masonry cores can provide stiffness and strength properties of units and mortar joints, which can be used directly in mesoscale masonry models. Subsequently, calibrated mesoscale models can be employed within a multi-level computational strategy (Chisari et al., 2020) to determine suitable material properties for more efficient macroscale models. Of course, where results from material tests are not available, a range of material properties for masonry can be assumed from the literature. In this case, the results of the numerical simulations with assumed material properties provide performance limits for the analysed structure.

3 NUMERICAL EXAMPLES

In this work a realistic multi-span multi-ring masonry viaduct with a backing layer above the masonry piers, which contain concrete infill, is analysed under traffic loading. Figure 3 depicts the main geometrical characteristics of the bridge structure. In the numerical simulations, only four spans are represented, where the investigation is focused on the response of the two internal spans. Two alternative strategies are compared by modelling the two internal spans using a detailed mesoscale model, Model 1 in Figure 4a, or an efficient macroscale model, Model 2 in Figure 4b, to represent material nonlinearity in the masonry components of the viaduct segment. On the other hand, the external spans, which are modelled with the same macroscale mesh for the internal spans of Model 2 but assuming elastic behaviour for the masonry parts, are included in the viaduct model mainly to provide appropriate boundary conditions for the investigated internal spans. The two alternative models for the analysed 4-span viaduct segment, Model 1 with a mixed meso- macroscale mesh and Model 2 with a macroscale mesh, are shown in Figure 1c, a. Table 1 and Table 2 provide the material parameters used in Model 1 and Model 2 for solid elements and interface elements, respectively. The material parameters include Young's modulus (E), Poisson ratio (ν), compressive strength (f_c), tensile strength (f_t), tensile fracture energy (G_t), shear fracture energy (G_s), compressive fracture energy (G_c), cohesion (c), friction angle (ϕ), dilatancy angle (ψ), normal stiffness (k_n) and tangential stiffness (k_t). In the macroscale model, masonry compressive strength,

tensile strength, and tensile fracture energy are set to the same values as those used for the mortar interface in the mesoscale model. The masonry Young's modulus used in the macroscale model is calculated via simple homogenisation along the circumferential direction of the masonry arches, which represent the main masonry components of the analysed bridge structure, based on the brick unit Young's modulus and the normal stiffness of the mesoscale mortar interface adopted in the mesoscale model.

The response of the structure under traffic loading has been investigated by performing nonlinear dynamic analyses representing a ballast-laying train travelling over the viaduct. More specifically, the ballast-laying train is composed of one locomotive and five coaches with standard axle configurations, as indicated in Figure 5. The viaduct has 2 separate tracks,

4 RESULTS

4.1 Viaduct behaviour under standard axle loading

The predictions provided by Model 1 and Model 2 are compared focusing on the 3D displacement components at locations T1 and T2 under Track 1 and Track 2 at the arch crown intrados in the right middle span (Figure 6). The time-history displacement curves are compared in Figure 7, where a very good agreement is found between detailed mesoscale and simplified macroscale models. This confirms the accuracy and potential of the macroscale model, even with unsophisticated calibration of model parameters for the masonry material, to predict the serviceability response of a complex masonry viaduct.

Figure 6. Locations where the displacement components are analysed under train loading.

It is also of interest to examine the damage pattern in the brickwork of the masonry component of the viaduct. The damage pattern is obtained when the train travelling through the viaduct, at the position shown in Figure 8, where the first bogie of the locomotive just passes through the middle pier. Figure 9 depicts the damage patterns in the middle span resulting from the mixed-meso- macroscale model (Model 1) and the macroscale model (Model 2). In order to visualise the deformed shape of the viaduct under traffic loading, the traffic-induced displacements are scaled up by 1000 in Figure 9a.

Figure 9a shows bed joint separations at the top of the spandrel wall above each pier. It is worth noting that the predicted damage in this location is due mainly to the application of the

Figure 7. Displacement of the nodes under Track 1 (left) and Track 2 (right) in both mixed-scale and macroscale models.

bridge self-weight prior to the passage of the train. A medium level damage is observed also at the bed joint at the soffit of the arch barrel at the right intermediate span, where 5 train axles pass through. Longitudinal and transverse cracks have not yet appeared in the arch barrel under the assumed train loading, as suggested by the undamaged transverse mortar interfaces and longitudinal brick-brick interfaces.

Figure 9b confirms that the macroscale model (Model 2) can provide a realistic prediction of damaged regions in the spandrel walls and arch barrel, based on comparison against the reference Model 1. Although the progression of the crack in the brickwork cannot be accurately captured by the macroscale model, considering its much-improved computational efficiency, it can be utilised to study displacement time-histories and damage patterns of realistic viaducts under serviceability train loading.

Figure 8. Position of the train when damage patterns are studied.

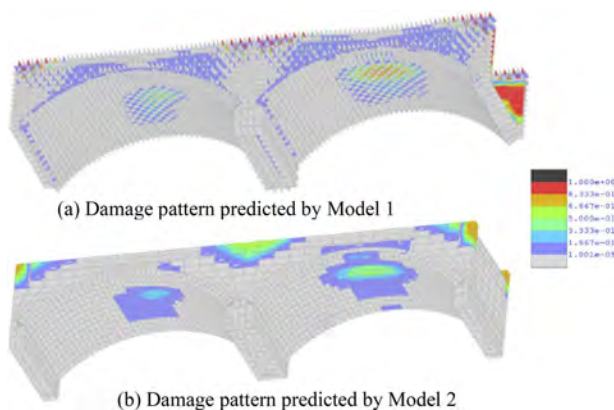

Figure 9. Damage pattern of the middle spans when the ballast-laying with typical axle load passing.

4.2 Viaduct behaviour under increased axle loading

To further investigate the nonlinear behaviour of the masonry viaduct under increased loading scenarios, a three times heavier train is applied to the viaduct. More specifically, a ballast-

laying train with the same speed and axle arrangement, but with triple axel loading, is applied on Track 1 of the viaduct. Both models with different levels of fidelity are generated. The damage patterns of the viaduct when the train passes through the viaduct at the position shown in Figure 8 are studied.

Figure 10a shows the damage pattern in the middle spans predicted by the mesoscale model. As indicated by Figure 9b, the separation of the brick head joints at the top of the spandrel wall above the pier - initially induced by self-weight - propagates radially, culminating in a step-crack damage pattern at this location. Figure 10c depicts the damage pattern in the arch barrel, where a substantial portion of the mortar joints is entirely open in the transverse direction resulting in transverse fractures at the intrados of the arch.

In addition to the progression of cracks that appear under standard service loading, triple service loading causes damage in further locations. Figure 10d shows shear sliding between the spandrel wall and the arch and the onset of ring separation, and Figure 10e shows some evolving head joint separation at the spandrel wall and bed joint separation at the soffit of the arch barrel.

Figure 11 shows the damage pattern predicted by the macroscale models, which provides a satisfactory indication of the location and degree of damage in the spandrel walls and arch barrels.

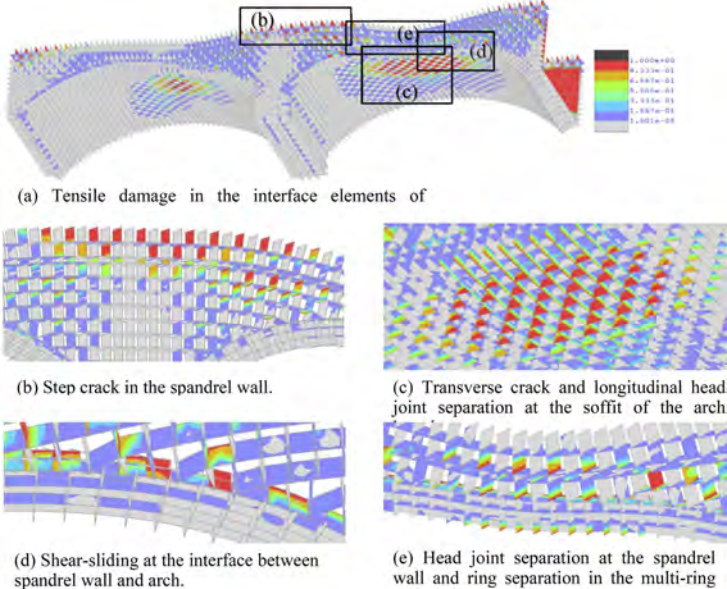

Figure 10. Damage pattern in the middle spans predicted by the mixed meso- macroscale model (Model 1) when a train under the passage of a train with triple axle load.

Figure 11. Damage pattern of middle spans predicted by macroscale model when a train with triple axle load passing.

5 CONCLUSION

This work showcases the potential of using 3D models with different degrees of complexity for predicting the response of a realistic multi-span viaduct segment under train loading. A mixed meso- macroscale model, representing specific viaduct segments with detailed numerical descriptions explicitly modelling masonry bond, was developed and used as a baseline model to assess the ability of a more efficient macroscale model to predict the response under serviceability and increased traffic loading. The results obtained indicate that the simpler macroscale model, including a straightforward calibration of the model material parameters for the masonry components, enables an accurate prediction of the viaduct displacements and the location of damage. On the other hand, the detailed mesoscale model offers an improved description of cracking in the brickwork of the analysed structure and enables a practical incorporation of a wide range of defects as found in real masonry viaducts, but at the expense of an increased computational cost. In future research, the developed multi-fidelity modelling strategies will be validated against monitoring data and used to investigate the response of realistic masonry viaducts under different loading conditions.

Analysis of masonry arch bridges using multi-scale discontinuity layout optimization

Linwei He, Nicola Grillanda, John Valentino, Matthew Gilbert & Colin C. Smith
Department of Civil and Structural Engineering, University of Sheffield, Sheffield, UK

ABSTRACT: Masonry arch bridges are still in active usage in many countries across the globe. However, the analysis tools that generally underpin the assessment process for these structures have traditionally been 2D, which means that 3D modes of response cannot be captured. This contribution introduces a multi-scale limit analysis method for 3D masonry arch bridges using discontinuity layout optimization (DLO), which is a highly efficient limit analysis technique that automatically identifies the collapse load and associated failure mechanism of a solid or structure. Using this approach, a macroscopic shell continuum is assumed, using a homogenized material that is obtained by analysing the microscopic behaviour of a representative pattern of masonry units in the structure. Therefore, potential 3D failure modes for masonry arch bridges can be revealed. The basic model assumes rigid masonry units, and takes into account key engineering features such as aspect ratio of masonry units. Simple examples are used to validate the proposed method; then simple square and skew masonry arch bridges are analysed to demonstrate the efficacy of the proposed method.

1 INTRODUCTION

Masonry arch bridges are long-lived structures that are still in widespread usage across western Europe and other parts of the world. Modern techniques for the structural analysis of masonry arch bridges can be traced back to works by Kooharian (1953) and Heyman (1966), where masonry was assumed to possess infinite stiffness, infinite crushing strength and sliding resistance and to have joints with zero tensile strength. Under these assumptions, an arch will collapse via the opening of a sufficient number of hinges, with the stability of the structure depending only on its geometry (Heyman 1969).

Many numerical tools have been developed to analyse the 2D behaviour of masonry arch bridges. For example, Livesley (1978) introduced a computational limit analysis tool to model the collapse behaviour of assemblies of rigid blocks, using linear programming (LP) to obtain solutions. Other computational methods based on the static or kinematic theorems of plastic analysis, have also been proposed since. Practical software tools have also been developed to analyse masonry arch bridges for industrial users, e.g., LimitState:RING (Gilbert 2001) and ArchNURBS (Chiozzi et al. 2016). Furthermore, strategies have been proposed to allow masonry crushing and sliding phenomena to be modelled (the latter with both associated and non-associated flow behaviour); see Gilbert (2007).

However, the main focus of previous work has been on the development of 2D modelling tools, which are clearly not capable of modelling the 3D behaviour of masonry arch bridges, which can be important in some cases (e.g. when skew bridges are involved). Whilst it is in principle straightforward to extend 2D methods to 3D if all constituent masonry units are explicitly modelled, and potential hinge locations coincide with the locations of mortar joints (e.g. see Portioli et al. (2014) and Grillanda et al. (2022)), this requires detailed geometrical information about the locations of all voussoirs in the bridge. Such information may not be readily available, and collecting it may involve laborious processes. Alternatively, a multi-scale (or homogenized) approach can be utilized, where the model is represented by a continuous material characterized by a suitable (homogenized) yield domain. de Buhan and

Figure 1. Steps in general DLO procedure (a) problem specification (square slab under out-of-plane UDL); (b) node discretization; (c) interconnection of nodes with all potential discontinuities; (d) identification of critical subset of potential discontinuities using optimization; (e) corresponding collapse kinematics.

de Felice (1997) and Sab (2003) respectively introduced homogenization methods for in-plane and out-of-plane masonry structures. Their work has attracted significant interest, and several strategies have been presented to deduce the homogenized properties depending on the initial assumptions, and various numerical approaches have been developed; see Milani et al. (2006a,b, 2008).

Discontinuity layout optimization (DLO) is a highly efficient numerical method that can be used to automatically identify the collapse load and the associated failure mechanism of a solid or structure. DLO directly models the potential discontinuities that can occur at failure, and utilizes efficient mathematical programming solution methods to obtain solutions. DLO has been applied to a broad range of applications, including geotechnical engineering problems (e.g., Smith and Gilbert 2007) and slab yield-line analysis problems (e.g., Gilbert et al. 2014). Although DLO can be used to directly analyse masonry structures by modelling joints as discontinuities, following a ‘heterogeneous’ approach (e.g., Gilbert et al. 2010), the full potential of DLO becomes apparent when used in conjunction with a multi-scale representation of the constituent masonry, since it obviates the need to model all constituent masonry units explicitly. Initial work in this area was recently carried out by Valentino et al. (2023), who introduced a multi-scale DLO method for in-plane masonry problems. In the present work the approach is extended to model 3D shell problems such as masonry arch bridges, where a macroscopic shell continuum is assumed and where a homogenized material obtained by analysing the microscopic in- and out-of-plane behaviour of a representative pattern of masonry units in the structure is employed. The paper is organized as follows: firstly, the standard DLO method is introduced; secondly, the proposed multi-scale approach is developed and relevant mathematical expressions are given; thirdly, several numerical examples are used to demonstrate the efficacy of the method; finally, conclusions are drawn.

2 GENERAL DLO FORMULATION

The main steps in DLO are illustrated in Figure 1. Firstly, the geometry of the problem, together with boundary and load conditions are specified (Figure 1a). Secondly, the problem domain is discretized using nodes (Figure 1b). Thirdly, potential discontinuities are created by interconnecting nodes (Figure 1c). For a shell structure, each discontinuity involves 6 kinematic variables, as shown in Figure 2, including in-plane shear displacement d_t , in-plane normal displacement d_n , out-of-plane shear displacement d_z , bending rotation r_t , twisting rotation r_n and in-plane rotation r_z . Finally, the most critical failure mechanism is identified (Figure 1d) by solving the following optimization problem (after Smith and Gilbert 2007):

$$\text{minimize } -\mathbf{f}_D^T \mathbf{d} + \mathbf{g}^T \mathbf{p} \quad (1a)$$

$$\text{subject to } \mathbf{Bd} = 0 \quad (1b)$$

$$\mathbf{f}_L^T \mathbf{d} = 1 \quad (1c)$$

$$\mathbf{Np} - \mathbf{d} = 0 \quad (1d)$$

$$\mathbf{p} \geq 0, \quad (1e)$$

Figure 2. Kinematic variables in a discontinuity AB : (a) coordinate system; (b-g): in-plane shear displacement d_t , in-plane normal displacement d_n , out-of-plane shear displacement d_z , bending rotation r_t , twisting rotation r_n and in-plane rotation r_z .

Figure 3. Multi-scale approach: modelling a periodic masonry structure using a microscopic model defined via a RVE and a macroscopic model solvable via DLO.

where \mathbf{f}_D and \mathbf{f}_L are vectors containing respectively specified dead and live loads, \mathbf{d} and \mathbf{p} are, respectively, vectors containing all kinematic variables shown in Figure 2 and their associated non-negative plastic multipliers. Also \mathbf{g} is a work coefficient vector, so that $\mathbf{g}^T \mathbf{p}$ describes the internal energy dissipation along discontinuities. \mathbf{B} is a compatibility matrix, used to ensure all kinematic variables are compatible at nodes. Finally, \mathbf{N} is a flow rule matrix describing the failure criteria with respect to kinematic variables. With respect to variables \mathbf{d} and \mathbf{p} , optimization problem (1) is a LP problem, so that a globally optimal solution can be identified. In addition, a post-processing step can be carried out to visualize the failure mechanism; see Figure 1e. Note that the steps in Figure 1 will create a large number of potential discontinuities (e.g., see Figure 1c), so a vast number of potential failure modes can be replicated. This means that DLO is capable of obtaining highly accurate solutions.

3 MULTI-SCALE APPROACH

As mentioned previously, DLO can readily be applied to masonry structures simply by only modelling joints as potential discontinuities (e.g., the heterogeneous model in Figure 3). However, this approach does not take full advantage of DLO, since the numbers of potential discontinuities involved is limited, such that a full ‘layout optimization’ is not required.

However, DLO becomes more valuable when a multi-scale approach is adopted, and the locations of discontinuities are not known *a priori*. As shown in Figure 3, the multi-scale approach first defines a representative volume element (RVE), which captures the microscopic behaviour of a periodic masonry structure, including interlocking effects and the failure criteria at joints. Then a macroscopic model is created, assuming a continuum problem solvable via well-developed limit analysis methods, though which now involves the use of a homogeneous material model derived by analysing the heterogeneous behaviour of the RVE. To develop a multi-scale DLO method, the RVE, microscopic and macroscopic models are now examined.

Figure 4. RVE and the corresponding macroscopic strain rate tensor: (a) geometry of the RVE, comprising four rigid bodies (*A*, *B*, *C* and *D*) and five joints (1,2,...,5); (b) in-plane macroscopic strain rate tensor; (c) macroscopic curvature tensor.

3.1 RVE

For sake of simplicity, the RVE in de Buhan and de Felice (1997) is used here (Figure 4a). The kinematic properties of the RVE are defined by a macroscopic strain rate tensor \mathbf{E} , following the Love-Kirchhoff plate model (after Cecchi and Sab 2002):

$$\mathbf{E} = \begin{bmatrix} E_{11} & E_{12} & X_{11}y_1 + X_{12}y_2 \\ E_{21} & E_{22} & X_{12}y_1 + X_{22}y_2 \\ -\frac{X_{11}y_1 + X_{12}y_2}{2} & -\frac{X_{12}y_1 + X_{22}y_2}{2} & 0 \end{bmatrix}, \quad (2)$$

where E_{11} , E_{22} and E_{12} are components of the in-plane strain rate tensor; also X_{11} , X_{22} and X_{12} are components of the curvature tensor and y_1 and y_2 are the position coordinates in the RVE, as shown in Figure 4. Taking into account the periodicity conditions (see e.g. Cecchi and Sab 2002 for detailed derivations), the displacements and rotations of the four vertices $ABCD$ can be written with respect to variables in \mathbf{E} :

$$\mathbf{u}_A = \begin{bmatrix} E_{11}b/2 \\ E_{12}b/2 \\ a^2X_{22}/4 - b^2X_{11}/16 \end{bmatrix} + \mathbf{u}_c, \quad \mathbf{\Omega}_A = \begin{bmatrix} -0.5bX_{12} \\ 0.5bX_{11} \\ 0 \end{bmatrix} + \mathbf{\Omega}_c \quad (3a)$$

$$\mathbf{u}_B = \begin{bmatrix} E_{12}a \\ E_{22}a \\ -a^2X_{22}/4 + b^2X_{11}/16 \end{bmatrix} + \mathbf{u}_c, \quad \mathbf{\Omega}_B = \begin{bmatrix} -aX_{22} \\ aX_{12} \\ 0 \end{bmatrix} + \mathbf{\Omega}_c \quad (3b)$$

$$\mathbf{u}_C = \begin{bmatrix} -E_{11}b/2 \\ -E_{12}b/2 \\ a^2X_{22}/4 - b^2X_{11}/16 \end{bmatrix} + \mathbf{u}_c, \quad \mathbf{\Omega}_C = \begin{bmatrix} 0.5bX_{12} \\ -0.5bX_{11} \\ 0 \end{bmatrix} + \mathbf{\Omega}_c \quad (3c)$$

$$\mathbf{u}_D = \begin{bmatrix} -E_{12}a \\ -E_{22}a \\ -a^2X_{22}/4 + b^2X_{11}/16 \end{bmatrix} + \mathbf{u}_c, \quad \mathbf{\Omega}_D = \begin{bmatrix} aX_{22} \\ -aX_{12} \\ 0 \end{bmatrix} + \mathbf{\Omega}_c. \quad (3d)$$

where \mathbf{u}_A , \mathbf{u}_B , \mathbf{u}_C and \mathbf{u}_D are the displacement vectors of the four vertices respectively; also $\mathbf{\Omega}_A$, $\mathbf{\Omega}_B$, $\mathbf{\Omega}_C$ and $\mathbf{\Omega}_D$ are the rotation vectors and \mathbf{u}_c and $\mathbf{\Omega}_c$ are constant displacement and rotation vectors of the RVE, respectively. Figure 5 shows the relative displacements and rotations of the RVE with respect to the variables in \mathbf{E} .

Figure 5. Associated displacements and rotations of the RVE (showing kinematics without reference to applicable flow rules).

3.2 Microscopic model

Since the displacement and rotation vectors at the four vertices of the RVE are given in (3), the relative displacements at the five joints in Figure 4a can be calculated using:

$$[\mathbf{u}]_{\alpha\beta} = \mathbf{u}_\alpha + \boldsymbol{\Omega}_\alpha \times (\mathbf{y}_d - \mathbf{y}_\alpha) - \mathbf{u}_\beta - \boldsymbol{\Omega}_\beta \times (\mathbf{y}_d - \mathbf{y}_\beta), \quad \text{for } \alpha, \beta \in \{A, B, C, D\} \quad (4)$$

where $[\mathbf{u}]_{\alpha\beta}$ is the relative displacement vector (or ‘displacement jump’) between masonry blocks α and β . Also \mathbf{y}_d is a vector containing coordinates of a point at the joint. Note that for each joint, $[\mathbf{u}]_{\alpha\beta}$ comprises the normal displacement $[u_n]$, in-plane shear displacement $[u_i]$ and out-of-plane shear displacement $[u_z]$.

Given the relative displacements at joints, flow rules can now be written. Here Mohr-Coulomb failure criteria is assumed:

$$[u_n]_j \geq \mu \sqrt{[u_i]_j^2 + [u_z]_j^2}, \quad \text{for } j \in \{1, 2, 3, 4, 5\}, \quad (5)$$

where μ is the coefficient of friction, $[u_n]_j$, $[u_i]_j$ and $[u_z]_j$ are the relative displacements of joint j shown in Figure 4, calculated by substituting (3) in (4). The average energy dissipation within the RVE can be derived as:

$$\Pi = \frac{1}{ab} \sum_{j=1}^5 \int_0^{l_j} \int_{-\frac{t}{2}}^{\frac{t}{2}} \frac{[u_n]_j c}{\mu} dt dl = \frac{ct(E_{11} + E_{22})}{\mu}, \quad (6)$$

where Π is the average energy dissipation within the RVE, c is the cohesion, l_j is the length of joint j in Figure 4a, and t is the thickness of masonry blocks. The inequality constraints in (5) and the equation in (6) define the microscopic behaviour of the RVE.

3.3 Macroscopic model

The macroscopic model assumes a continuum problem solvable via the standard DLO approach shown in Figure 1. Variables of the macroscopic strain rate tensor \mathbf{E} can be derived as:

$$\mathbf{E} = \mathbf{T}\mathbf{d} \quad (7)$$

where \mathbf{T} is a transformation matrix, readers interested in its derivations are referred to Valentino et al. (2023). Also $\mathbf{E} = [E_{11}, E_{22}, E_{12}, X_{11}, X_{22}, X_{12}]^T$ is a vector containing components of macroscopic strain rate tensor in Equation (2) and $\mathbf{d} = [d_t, d_n, dz, r_t, r_n, r_z]^T$ is a vector of kinematic variables in DLO.

3.4 Multi-scale DLO formulation

Given both microscopic and macroscopic models, the full DLO formulation can be written as:

$$\text{minimize } -\mathbf{f}_D^T \mathbf{d} + \sum_{i=1}^m l_i \Pi_i \quad (8a)$$

$$\text{subject to } \mathbf{B}\mathbf{d} = 0 \quad (8b)$$

$$\mathbf{f}_L^T \mathbf{d} = 1 \quad (8c)$$

$$\left. \begin{array}{l} \mathbf{E}_i = \mathbf{T}\mathbf{d}_i \\ \mathbf{N}(\mathbf{E}_i) \leq 0 \end{array} \right\} \text{ for } i = 1, 2, \dots, m \quad (8d)$$

where \mathbf{d}_i and \mathbf{E}_i are, respectively, vectors containing DLO kinematic variables and macroscopic strain rate tensors for discontinuity i and m is the number of discontinuities. Also Π_i is the averaged energy dissipation in the RVE, obtained in Equation (6), such that $\sum_{i=1}^m l_i \Pi_i$ is the

total internal energy dissipation within the structure. \mathbf{B} is a compatibility matrix, \mathbf{f}_L and \mathbf{f}_D are load effect vectors, as shown in Problem (1). Finally, $\mathbf{N}(\cdot)$ is the microscopic flow rule defined in Constraint (5). Since in (5) the constraints are quadratic cones, Problem (8) is a conic programming problem, which can be solved efficiently via modern convex optimization solvers such as MOSEK (MOSEK ApS 2022).

4 NUMERICAL EXAMPLES

4.1 Simple validation example: L-shaped wall

This example is a L-shaped wall previously studied by Portioli et al. (2014). The geometry of the wall is shown in Figure 6a. The masonry blocks have a dimension of $0.8 \text{ m} \times 0.03 \text{ m}$ and a thickness of 0.04 m . Cohesion c and the coefficient of friction μ are set to 0 and 0.7, respectively. The wall is subject to a horizontal body force $w = \lambda G$, where G is the self-weight of the structure, and λ is the load factor. Solutions obtained using rigid block and DLO methods are shown in Figure 6b-d, with the resulting failure mechanisms being quite similar. The load factor obtained using rigid block analysis was 0.195 (identical to that found by Portioli et al. 2014), while the result obtained by multi-scale DLO is 0.155, which is lower than the former. This is because that the multi-scale approach effectively assumes that the constituent masonry blocks are infinitely small, and block interlocking effects in this case become less significant than when blocks are larger; see Valentino et al. (2023) for more details.

Figure 6. L-shaped wall: (a) geometry; (b) rigid-block analysis using a heterogeneous approach via standard DLO, $\lambda = 0.195$; (c) multi-scale DLO, $\lambda = 0.155$; (d) failure mechanism of (c).

4.2 Square masonry arch bridge

The second example involves a square masonry arch bridge subject to a centreline point load $F = 1 \text{ kN}$ applied at quarter span. The geometry of the bridge is shown in Figure 7a, where the bridge span is $L = 0.75 \text{ m}$, width is $L/2$, and thickness is $t = 0.054 \text{ m}$, and the unit weight is set to 23.6 kN/m^3 . Cohesion c and the coefficient of friction μ are set to 0 and 0.75, respectively. In the rigid block model, a total of 24 voussoirs with an aspect ratio of 2.318 (full block measured at the mid-surface) are used, and the resulting failure mechanism is shown in Figure 7(b). On the other hand, using multi-scale DLO, the curved geometry is approximated via piecewise-linear surfaces; see solution obtained using a coarse (150 node) numerical discretization in Figure 7(c). Note that discontinuities (e.g., hinges) can now occur within a given arch segment, so the computed load factor is lower than that obtained via rigid block methods, where hinges can only occur at joints. Also, two intersecting discontinuities are observed to form under the point load applied on the arch centreline.

4.3 Skew bridge

In the third example two skew bridges are considered, using the same base configuration as in the previous example. In this case the arch geometries are obtained by ‘shearing’ the arch by 15 and 45 degrees (i.e., the skew angle). In addition, voussoirs are configured using the helicoidal method (see Forgács et al. 2017), which can be taken into account in DLO by rotating the local coordinate system in each piecewise-linear surface. Figure 8a and b show the results obtained using a skew angle of 15°; the load factor is 0.488, which is 57% higher than that obtained for the square bridge. This is due to interlocking effects arising from the helicoidal voussoir configuration, leading to rotated hinge lines. If the skew angle is increased to 45°, the

Figure 7. Square bridge: (a) geometry; (b) rigid-block analysis (with 24 voussoirs), $\lambda = 0.327$; (c) multi-scale DLO, $\lambda = 0.311$; (d) failure mechanism of (c).

Figure 8. Skew bridge: (a) and (b), skew angle 15° , $\lambda = 0.488$; (c) and (d), skew angle 45° , $\lambda = 0.774$.

load factor increases further, with the failure mode clearly showing rotated hinge lines and twisting failure near the right abutment.

5 CONCLUSIONS

In this paper the powerful and highly efficient discontinuity layout optimization (DLO) procedure is applied to the analysis of masonry arch bridge structures. Here DLO is used in conjunction with a multi-scale representation of the constituent masonry, obviating the need to model individual masonry units explicitly. In the multi-scale approach, a macroscopic shell continuum is assumed, using a homogenized material model that is obtained by analysing the microscopic behaviour of the representative volume element (RVE) of masonry units in the structure. Several numerical examples, including those involving square and skew arch bridges, are used to demonstrate that 3D responses of masonry arch structures can be captured via the proposed approach. Bridges with complex geometries and spandrel walls can directly be modelled using the homogenized shell DLO method, though further developments are required to ensure soil-structure interaction in soil-filled masonry bridges.

The role of history in the structural assessment of a multi-span masonry arch bridge

G. Zani, P. Martinelli, G. Cardani & M. di Prisco

Department of Civil and Environmental Engineering, Politecnico di Milano, Milan, Italy

ABSTRACT: The long history of an important multi-span masonry arch bridge built in 1336 in Lecco, Italy, across the Adda River and still in use today is presented here. The study was one of the preliminary stages of an extensive structural investigation project that led to prescriptions on the current use and management of this bridge. The objective is to describe the historical-constructive evolution of the Azzone Visconti Bridge, named after its creator and Lord of Milan; because of its complex and long history, the bridge appears today as the structural assemblage of several substructures. The intent is to present a comparison of different structural modeling approaches, already adopted in the safety assessment of the bridge. Finally, the possibility of implementing the valuable information recovered from the historical study (e.g., existing material heterogeneities, cracking patterns, and past interventions) into alternative analytical models is discussed.

1 INTRODUCTION

Historical bridges are an important part of a country's cultural heritage because their evolution has accompanied the history of a civilization, ready to overcome natural obstacles and facilitate exchanges with neighboring populations. However, in times of battle they were often subject to attack, demolition and reconstruction. For this reason, many of them are registered as protected architectural heritage. Some of them have survived many centuries of use through constant maintenance but have undergone numerous transformations to better adapt to the new demands of the 20th century. Not only external agents, but also increased vehicular traffic, as well as increased maximum allowable accidental loads, represent possible damage factors for the structure. To ensure safe working conditions, the load-bearing capacity of these bridges must be evaluated and demand levels carefully assigned.

The long history of an important multi-span masonry arch bridge built in 1336 in Lecco, Italy, across the Adda River and still in use today is presented here. The study was one of the preliminary stages of an extensive structural investigation project that led to prescriptions on the current use and management of this bridge. As part of an institutional collaboration between the Politecnico di Milano (Lecco Campus) and the Municipality of Lecco, extensive research activity involving different disciplines and research groups was initiated in 2014, with the aim of investigating the load-bearing capacity of the bridge, under the scientific coordination of the last author.

This paper focuses attention on the Azzone Visconti Bridge, a masonry arch bridge that was for centuries (until 1955) the only road connection between the two banks of the Adda River, the only outlet of Lake Como, and is still an important access route to the city of Lecco (northern Italy). The bridge had several abutments and drawbridges and, after later enlargement, now has 11 spans of different sizes. The bridge is considered to be the most important medieval evidence in the city, and is one of the most impressive masonry works in the entire region.

The bridge has been profoundly modified in the 20th century. Because of its complex and long history, it now evidences the structural assemblage of several substructures and has thus lost its homogeneity, becoming more vulnerable.

The intent is to present here a comparison of different structural modeling approaches, of varying degrees of sophistication, that have already been adopted in bridge safety assessment. Finally discussing the possibility of implementing the valuable information recovered from the historical study (e.g., existing material heterogeneities, cracking patterns, and past interventions) into alternative analytical models.

2 THE HISTORIC-CONSTRUCTIVE EVOLUTION OF THE BRIDGE

The Azzone Visconti Bridge (also known as *Ponte Vecchio*) is a historic masonry arch bridge built in the 14th century, consisting of ten piers, eleven arches and two abutments, one on the east side of Lecco and one on the west side of Malgrate of the Adda River. It has an overall length of about 133 m and an average deck width of about 6.2 m. Although the bridge appears today to be very different from the original construction, it remains one of the most important examples of military engineering from the Middle Ages.

2.1 From the origin in the 14th century to the 17th century

The bridge was built at the behest of the Lord of Milan, Azzone Visconti, between 1336 and 1338, connecting for the first time in the territory the two banks of the Adda River, which until then had belonged to the Duchy of Milan and the Republic of Venice. The bridge was equipped with a stronghold, a central tower and a larger one towards Lecco, while the two heads were equipped with a ravelin (Figure 1a,b). The bridge was also defended by three drawbridges, placed at the fortifications, and was armed with bombs and thrusters. In the 17th century, those who wanted to cross had to pay a toll managed by a consortium composed of several co-owners, nobles from Lecco and Milan, as well as of a monastery.

Figure 1. Azzone Visconti Bridge: a) model of the 1st phase, mid 14th century (bridge as a fortress with only 8 spans, adapted from di Prisco et al. 2019) and b) detail of the fresco depicting the Battle of Lecco and the bridge with the fortress, in the Medici castle in Melegnano (MI); dating of the painting estimated between 1544 and 1555 (adapted from Comandù et al. 2005).

Figure 2. The bridge after 1533, when the great tower was destroyed and already with 11 spans (courtesy of Ambrosiana Library of Milan).

The Azzone Visconti Bridge was originally built with eight arches. The bridge was later expanded in two phases (1350 and 1434) to 11 arches to widen the cross section of the river, favoring faster water flow and reducing flooding in the Como area. The bridge has undergone continual modifications over time due to wars and the water level of Lake Como. In fact, the Adda River is the only emissary of the lake, and the bridge piers constitute an obstacle to the water flow. For this reason, due to repeated flooding of Como at the far end of the other closed branch of the lake, the riverbed was lowered even in the last century and the piers were consequently consolidated.

After the wars fought by Gian Giacomo Medici, known as the Medeghino in 1531, the bridge was severely damaged (Figure 2) (Belloni et al. 1992) and, in the early 17th century (1600-1608), it was renovated on behalf of the Spanish Governor.

2.2 The 18th and 19th century

Its strategic and economic importance would last for centuries (Figure 3a,b), until the last battle won by the Austrian-Russians of the Holy Alliance against the French and Cisalpine troops between April 25 and 27, 1799. On that occasion, the French blew up an archway to slow down the enemy's passage and flight, and this damage would not be repaired until after the end of Napoleonic rule (Figure 4). As a sign of gratitude for the victory, a small chapel was erected in the center of the bridge (Figure 4b), but which is no longer present. In the 19th century, the abolition of the military stronghold of Lecco gave the start to many changes made with the intention of facilitating transit. The lateral towers were demolished to facilitate the passage of carriages (Figure 4).

Figure 3. Azzone Visconti bridge: a) 2nd phase model, end of 18th century (11-span bridge with towers and drawbridge, adapted from di Prisco et al. 2019); b) view of the bridge, 1760-1771, etching of G.C. Bianchi (Giulini 1760).

Figure 4. Azzone Visconti bridge: a) in 1806 (water-colour by P. Birmann) with two demolished towers and two arches destroyed after the Napoleonic damages and b) with reconstructed arches and a small chapel visible in the center of the bridge in the early 20th century (extracted from Resegoneonline.it 2014).

2.3 The 20th century

In 1909-1910 the existing bridge deck was enlarged by means of cantilever steel beams to host a tramway and to cope with the increasing traffic. Additional engaged piers were added on both sides to support the cantilevers (visible in Figure 5b). In 1949-1950, a radical intervention was carried out by Prof. Eng. A. Danusso: a) to facilitate the outflow of the river, the riverbed was lowered by about 2 m; b) to protect the bridge piers, the foundations of 7 piers were strengthened; c) the foundation of each pier was reinforced by introducing a large diameter

steel encasing ring, about 5 m deep, filled with concrete and constrained at the top by an additional reinforced concrete (RC) outer ring (Figure 6); d) to widen the roadway, the deck was completely removed (Figure 5) and a continuous RC caisson was inserted between the two masonry spandrel walls and filled with coarse granular material (mix of pebbles and mortar). The caisson was made square or U-shaped, depending on the varying height between the extrados of the arches and the deck. e) In addition, the engaged piers (or pilasters) added around 40 years earlier above the cutwaters, were removed.

Three arches damaged by the out-of-plumb of the piers were strengthened. External pedestrian footbridges were also added using cantilever steel beams and RC slabs resting on the aforementioned beams. Over the next 70 years, after this invasive intervention, no further work was carried out other than routine maintenance. Figure 7 shows a view of the bridge as it appears today.

Figure 5. Azzone Visconti bridge: a) model of the bridge with the most significant strengthening intervention depicted in blue: removal of the original deck and infill, insertion of a continuous concrete caisson and enlargement of the foundations. b) photo before the strengthening when the deck was removed in 1949-1950 and grafted piers were still present. 3 REMARKS ON THE HISTORICAL ANALYSIS FOR STRUCTURAL EVALUATION

The bridge has a very irregular geometry, as evidenced by an accurate laser scanner survey (Barazzetti et al. 2016), and has piers with different rotations and very different arch spans, as confirmed by the historical-constructive evolution described above.

Different masonry textures are observed in the spandrels (Figure 8b), from river pebbles arranged in a herringbone pattern in the original arches to roughly cut stones in the modified and/or repaired parts, to more rectangular stones and slabs for the added parts; discontinuities are clearly visible.

Masonry repairs can be observed at the ends of the fortress demolished during the 16th century war (occupying three spans: n. 6, 7 and 8 as in Figure 1). Metallic anchorages placed approximately at the haunches of the arches and arranged in such a way as to have the iron tie-rods in a transverse rather than longitudinal direction are visible (Figure 8b); there is no date of insertion.

The crack pattern, after the last intervention, shows small vertical cracks in the 3 oldest buttresses to the east of the former fortress, where the out-of-plumb of the 5th bay (from the east) already repaired in the 1950s is evident and of about 50 cm (Figure 8a).

Figure 8. a) Out-of-plumb of the 5th bay southwards and b) photogrammetric view of two piers (south side) at the barrels of arch 5 with the crack pattern survey highlighted in red.

The historical research provided crucial information for future investigations, such as the strong heterogeneity of the bridge structure, modified over the centuries with different constructive techniques. The classification of masonry textures and the crack pattern survey also confirmed the sequence of construction phases showing the discontinuities in the structure highlighted by the historical research (Figure 9), resulting in a refined identification of structural heterogeneities (di Prisco et al. 2019) and helping to better understand the current state of conservation of the bridge. The historical occurrence of damage and cracking, in fact, identifies critical areas that have suffered over time from exceeding the elastic limits of the materials or from the interaction with the river.

At least six different substructures highlighted in different colors were recognized in Figure 9: i) the central portion highlighted in gray, which corresponds to the original construction; ii) the first extension (green) toward the Lecco shore, built about ten years later; iii) the last pier

Figure 9. Azzone Visconti bridge: configuration of the historical construction evolution (view of the North side of the bridge, adapted from di Prisco et al. 2019).

finished around one century later (red); iv) the arch built to replace a drawbridge (magenta) at the end of the 18th century; v) the last two arches toward Malgrate (yellow) destroyed in 1799, and rebuilt 7 years later and, finally, vi) the consolidation of the pier foundations in the middle of the last century.

Although in similar cases greater accuracy must be used in modelling the discontinuities and different properties of the masonry must be taken into account, in this precise case, the massive intervention carried out in the 1950s achieved such a stiffening of the deck that it dominated over the underlying inhomogeneities and discontinuities, at least with respect to gravitational forces. Therefore, it can be assumed that the homogeneous models adopted up to now and presented in Martinelli et al. 2018, Zani et al. 2019, 2020 succeed in representing well the actual behavior of the structure.

4 MODELLING APPROACHES FOR HISTORICAL MASONRY BRIDGES

To analyze the response of the Azzone Visconti bridge subjected to a specific load configuration imposed during an acceptance load test, several interpretation models were set up during the investigation (Figure 10). Specifically, limit analysis models using the RING software (RING 2021) and two-dimensional (2D) finite element (FE) analyses implemented in Abaqus (Dassault Systèmes 2016) were developed for the central arches 6-8; additional three-dimensional (3D) FE models, also implemented in Abaqus, were employed to simulate the response of the entire bridge.

RING (Figure 10a) is a simplified and user-friendly analysis tool based on the rigid block limit analysis technique and designed to quickly check the adequacy of masonry arch bridges against the most recurrent failure modes. The 2D FE model depicted in Figure 10b is made with beam-type and plane stress elements combined with translational springs simulating the soil and the infill materials. The full 3D FE model (Figure 10c) is made of solid elements combined with rotational and translational non-linear springs representing the soil. In the 2D FE model the nonlinearity was partially accounted for assuming the tensile strength of the arches equal to zero and assuming a rigid-plastic generalized constitutive relationship with strain hardening and non-associated flow rule for the soil (Nova & Montrasio 1991). The 3D FE model accounted for the material nonlinearity in most of the bridge components by means of the concrete damaged plasticity model (Lubliner et al. 1989; Lee & Fenves 1998). A detailed description of the 2D and 3D FE models is herein omitted but can be found in Martinelli et al. (2018) and Zani et al. (2020), respectively.

Table 1 reports the potentials and limitations of each modelling approach observed in their practical application. The following factors/effects have been considered: (1) role of spandrel walls (if present), (2) role of infill material, (3) transverse behavior, (4) reproduction of existing cracking patterns and local damage, (5) reproduction of material heterogeneities, (6) reproduction of strengthening intervention(s), (7) soil-structure-interaction beneath the foundations, (8) rapid prediction of the ultimate bearing capacity and (9) ease in creating the model and extracting the results.

Table 1. Potential of the modelling approaches described in Section 4 (Y: yes; P: partly; N: no).

Factors/effects	RING model			2D FE model			3D FE model		
	Y	P	N	Y	P	N	Y	P	N
Spandrel walls			•		•			•	
Infill material	•				•			•	
Transverse behavior			•			•		•	
Cracking patterns and local damages		•			•				•
Material heterogeneities	•			•				•	
Strengthening intervention(s)		•			•			•	
Soil-structure-interaction beneath the foundations			•		•			•	
Rapid prediction of the ultimate bearing capacity	•				•				•
Ease in creating the model and extracting the results	•			•					•

Figure 10. Representation of (a) limit analysis model (arches 6-8), (b) 2D FE model (arches 6-8) and (c) full three-dimensional FE model (adapted from Zani et al. 2020).

Regarding the RING model, the main limitations are due to the difficulty in correctly reproducing reinforcement interventions (such as the presence of a complex RC caisson) and simulating the nonlinear soil-structure interaction beneath the foundations. On the other hand, one of the main advantages – aside from the ease of model creation and results extraction – is the rapid assessment of the ultimate capacity of the bridge with regard to masonry components.

As for the 2D FE model, the main limitations include the difficulty in reproducing the transverse behavior and the partial reproduction of the infill and spandrel walls. The ease in creating the model and extracting the results is one of the main merits.

Concerning the 3D FE model, the main limitation is the computational burden combined with significant effort in model creation and result extraction. Strengthening interventions and transverse behavior can be captured correctly. The 3D FE model also allows reliable reproduction of the nonlinear soil-structure interaction. According to the authors, both the 2D and 3D nonlinear FE models risk providing a less reliable estimate of ultimate capacity than that provided by limit analysis, as the increased sophistication of the simulations could lead to a reduced control over unpredicted numerical phenomena.

5 CONCLUSIONS

The paper presents the historical-constructive evolution of an important multi-span masonry arch bridge (named Azzone Visconti Bridge) built in 1336 in Lecco. The bridge has undergone several transformations over the centuries, growing from the original eight arches to the current eleven. The bridge was also profoundly modified in the 20th century with strengthening works aimed at adapting it to the new requirements of vehicular traffic, but distorting its homogeneity.

A comparison of three different structural modeling approaches with varying degrees of sophistication, namely limit analysis, 2D nonlinear FE analysis, and 3D nonlinear FE analysis, is presented. The potentials and limitations of each approach are highlighted using the Azzone Visconti Bridge as a case study. The strengthening interventions, which played a key role in correctly reproducing the structural behavior of the Azzone Visconti bridge, are difficult to reproduce with limit analysis models and require the use of advanced 3D FE analysis. Correct reproduction of the bridge transverse behavior and soil-structure interaction also requires the use of 3D FE analysis. Limit analysis provides a rapid assessment of the ultimate bearing capacity of ordinary multi-span masonry arch bridges, whereas 2D and 3D FE analyses, given their increasing level of sophistication, require more effort to provide reliable predictions.

Finally, the work also highlights the importance of uncovering and interpreting historical information related to the bridge. For example, the past presence of towers later destroyed may play a decisive role in the over-consolidation of the soil beneath the foundations and can provide useful information about the significant loads sustained by the structure over time.

ABSTRACT: Masonry arch bridges form an integral part of our infrastructure network, and their safety is important for the functioning of our society. Now, assessing the structural performance of ageing masonry infrastructure is a complex task. Existing ageing masonry arch bridges are characterized by inherent variability and may have stochastic material properties even in the same bridge. Hence, a realistic methodology for structural assessment of masonry arch bridges is crucial to protect the ageing masonry bridges and utilize these resources efficiently. In this study, stochastic-based assessment on the load-carrying capacity of masonry arch bridges has been performed, which introduces material variabilities into a two-dimensional structural analysis model based on the Discrete Element Method (DEM). Over 100 probabilistic analyses have been developed to assess the ultimate load that a bridge can carry when subjected to monotonic loading at a quarter span. The bond properties of mortar joints, including cohesion, tensile strength, and friction angle, were considered as stochastic variables following a normal distribution. The computational results were compared against the experimental results obtained from the literature. From the results analysis, it was shown that the computational model considering the random variability of bond strength properties can better predict the load-carrying capacity of the masonry arch bridge than the deterministic one. The bond strength at the unit-to-mortar interface significantly affected the ultimate strength of the masonry arch bridge.

1 INTRODUCTION

Masonry arch bridges form a significant part of the UK and European infrastructure network. It is estimated that there are approximately 200,000 masonry arch bridges and culverts in Europe and 40,000 masonry arch bridges in the UK. Most of these bridges were constructed between the 17th and 19th centuries and are still in service today (Forgács et al. 2021). After being used for over a hundred years, the significant structural deterioration caused by several environmental impacts may result in a reduction in the durability and load-bearing capacity of the bridges. On the other hand, most of these old masonry arch bridges support traffic loads much higher than those originally designed to carry, which can pose a serious threat to the safety of the bridges. Thus, there is an urgent need to assess the in-service behavior and predict the load-bearing capacity of masonry arch bridges to inform their repair, maintenance, and rehabilitation strategies.

Assessing the structural performance of ageing masonry arch bridges is challenging due to the inherent variability in their material properties. So far, several computational approaches, ranging from simple to high-fidelity, have been developed to predict the ultimate load-carrying capacity of

masonry arch bridges (D’Altri et al. 2019). Within these numerical methods, a large number of input parameters are required to describe the mechanical behavior of materials and define the interactions between different elements. These parameters need to be carefully selected so that the model can accurately reproduce the behavior of real structures (Sarhosis & Sheng 2014).

Now, in order to assess the influence of material variability on the ultimate load-carrying capacity of masonry structures, high fidelity numerical modelling approaches coupling with Monte-Carlo simulations have been used (Li et al. 2014, Muhit et al. 2022). For example, Sarhosis et al. (2019) proposed a methodology which considers the spatial variability of masonry materials. The proposed method was integrated into a two-dimensional (2D) discrete element modelling approach to predict the stochastic strength of masonry walls containing openings. The study also carried out a series of sensitivity analyses to determine the factors affecting the load-carrying capacity of masonry walls. Later, the approach was adopted and incorporated within the three-dimensional (3D) Discrete Element Method (DEM) software for assessing the mechanical behavior of other masonry structures (Pulatsu et al. 2022, Gonen et al. 2022).

Following the research carried out by Sarhosis et al. (2019), this paper presents a stochastic-based assessment of the load-carrying capacity of masonry arch bridges subjected to static load. More than 100 realizations were carried out on a masonry arch bridge model developed based on the 2D DEM. Computational results were compared against the experimental findings obtained from the literature. The stochastic parameters considered in the current study included the friction angle, tensile strength, and cohesion at the unit-to-mortar interface, representing the bond properties of mortar joints. Moreover, sensitivity analysis was carried out to investigate the influence of these mortar bond properties on the load-carrying capacity of the masonry arch bridge.

2 METHODOLOGY

The heterogeneity and inherent variability in material properties are the most remarkable characteristics of ageing masonry arch bridges, which considerably affect the structural behavior and load-carrying capacity of the bridge. However, most of the computational models in previous research have failed to consider material variabilities. In other words, the same (uniform) material parameters were usually assigned throughout the masonry domain by engineers/researchers (Sarhosis et al. 2019). This study has adopted a probabilistic approach to investigate the influence of random material properties on the mechanical behavior of masonry arch bridges. The framework of the methodology adopted in this study is summarized in Figure 1.

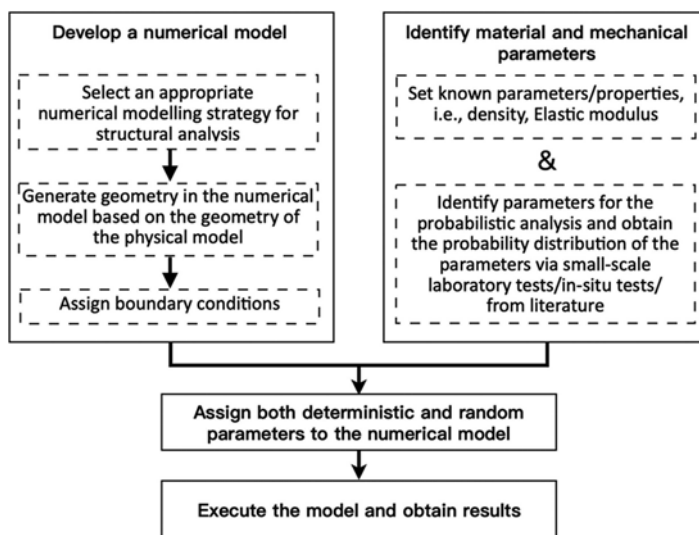

Figure 1. Framework for introducing material variabilities in computational models.

Overall, the methodology involved introducing material variabilities into the computational model. As the first step, the critical parameters for the probabilistic analysis need to be identified, and the mean values and probability distributions of these parameters can be obtained from either small-scale laboratory/in-situ tests or the literature. Having assigned deterministic and stochastic parameters to the computational model, simulations and sensitivity analyses can then be executed. It is worth noting that the parameters used for the probabilistic analysis should be selected based on the characteristics of the structure. For example, as the low bond strength of mortar joints has been found to be one of the dominant factors affecting the mechanical behavior of historical masonry arch bridges (Sarhosis et al. 2019), the bond properties of the unit-to-mortar interface, including friction angle, tensile strength, and cohesion, have been selected as random variables for probabilistic analysis in the study.

3 EXPERIMENTAL TESTING OF A MASONRY ARCH WITH BACKFILL

Full-scale static tests on brickwork masonry arch bridges were carried out by Augustus-Nelson et al. (2018, 2020) at the University of Salford. Figure 2 shows the experimental setup and dimensions for the test chamber and the bridge model. The test was carried out under plain-strain conditions with two stiff walled chambers to restrict any out-of-plane movement of the fill and arch barrel. Class A Engineering bricks and a lime mortar with a mix ratio of 1:2:9 (cement:lime:sand) were used to construct the bridge model to produce the low bond strength characteristic found in real masonry arch bridges.

The experimental model mainly contained an arch barrel constructed with a header bond configuration. The span and thickness of the arch barrel were equal to 3 m and 0.215 m, respectively, and the span-to-rise ratio of the arch was 4:1. The cohesionless MOT type I limestone was selected as the backfill material, which was placed into the test chamber and compacted layer by layer until it reached the 0.3 m over the crown of the arch. During the test, a monotonic load was applied by a hydraulic actuator via a load-spreading beam to the level surface of the backfill above the quarter of the arch barrel.

Figure 2. Masonry arch bridge model tested in the laboratory (Augustus-Nelson et al. 2018).

4 DISCRETE ELEMENT MODELLING AND THE COMPUTATIONAL MODEL

Past experience has demonstrated that cracking in masonry arch bridges occurs at the unit-to-mortar interfaces due to the low tensile and shear resistance of the mortar joints. This characteristic makes the discontinuum modelling approach more appropriate compared with other approaches (e.g., homogeneous ones) in simulating the cracking behavior and failure mechanism of masonry arch bridges. In this study, the 2D commercial software, Universal Distinct Element Code (UDEC), based on the DEM, was used to develop the numerical model (Itasca 2011).

Developing a model in UDEC starts with creating a single block covering the domain to be analyzed. Then, the original block generated is discretized into several small blocks in accordance with the geometry feature of the target structures. In the numerical model shown in Figure 3, the arch barrel was assembled by several individual bricks, which were represented by independent deformable blocks with a linear elastic behavior. Mortar joints were

represented by zero-thickness interface elements between blocks as shown in Figure 4a. The mechanical behavior of joints in the normal and shear directions (see Figure 4b and c) are subjected to the following equations:

$$\Delta\sigma_n = -K_n\Delta u_n \quad (1)$$

$$\Delta\tau_s = -K_s\Delta u_s \quad (2)$$

where $\Delta\sigma_n$ and $\Delta\tau_s$ are the change in normal and shear stress, respectively; K_n and K_s stand for the stiffness in the normal and shear directions, respectively; and Δu_n and Δu_s are the change of displacement in the normal and shear directions, respectively.

The numerical model developed in the present work had the same geometry and dimensions as the large-scale bridge tested in the laboratory. Table 1 lists the material and mechanical properties of masonry units, backfill, and backfill-to-arch ring interfaces in the numerical model. These parameters were kept constant (deterministic) throughout the stochastic analysis. On the other hand, material properties of mortar joints, including the tensile strength (J_{ten}), cohesion (J_{coh}), and friction angle (J_{fric}) were considered stochastic to isolate the influence of remaining parameters (i.e., backfill properties and backfill-to-arch ring interface properties) on the load-carrying capacity of the masonry arch bridge and highlight the effect of bond properties with inherent variability found in most real masonry arch bridges. The mean and coefficient of variations (COV) of the stochastic parameters are listed in Table 2 which were obtained from material characterization tests in the laboratory. J_{coh} and J_{fric} were assumed to be normally distributed (Gaussian distribution) while J_{ten} was assumed fully correlated to J_{coh} according to the following equation (Milani & Lourenco 2013):

$$J_{ten} = J_{coh} / 1.4 \quad (3)$$

In terms of loading and boundary conditions of the computational model, the blocks representing the tank walls, basement, and abutments were considered fixed. A monotonic load was applied by controlling a block with the same width as the load-spreading beam to move downwards at a constant velocity. It is worth noting that adaptive damping was assigned to the model to obtain a convergent static solution. In this way, the large displacement of blocks was allowed with the sequential contact detection and update.

Figure 3. 2D numerical model of the masonry arch bridge based on the DEM showing meshing at the backfill and arch barrel.

5 RESULTS AND DISCUSSION

Figure 5a shows a typical failure mechanism of the masonry arch bridge obtained from the computational model. From all simulations, the same four-hinge failure mechanism was observed, with high compressive stresses concentrated at the hinge locations, which was consistent with the experimental observation (see Figure 5b). In particular, with the downward movement of the load platen, a tensile crack initiated at the intrados of the arch underneath the load platen, forming one hinge at the quarter of the arch. The other three hinges occurred

Figure 4. (a) Contacts between blocks; Mechanical behavior of the zero-thickness interface at the (b) normal and (c) shear direction.

Table 1. Material and mechanical properties of masonry units, backfill and backfill-to-arch interfaces adopted in the numerical model (assumed).

Material	Unit weight	Young's modulus	Poisson's ratio	Friction angle	Tensile strength	Cohesion

Table 2. Statistics of the bond properties of unit-to-mortar interfaces.

Property	Symbol	Mean value	COV	Distribution
Unit-to-mortar interface friction angle	J_{fric}	35 degrees	0.06	Normal
Cohesion at the unit-to-mortar interface	J_{coh}	0.02 MPa	0.2	Normal
Tensile strength at the unit-to-mortar interface	J_{ten}	$J_{ten} = J_{coh}/1.4$	-	-

at approximately the two edges and three-quarters of the arch barrel. Furthermore, the independence of the failure mechanism from the unit-to-mortar bond characteristics suggested that the failure mechanism of the masonry arch bridge was governed by the boundary conditions and bond configurations of the arch barrel, rather than by the material properties of mortar joints.

Figure 5. Failure mechanism and deformation of the masonry arch bridge obtained from the (a) computational (magnitude factor is 5) and (b) experimental model.

Figure 6 compares the numerical results against the experimental load-displacement relationships of the masonry arch bridge. The mean values for J_{fric} and J_{coh} were equal to 35 degrees and 0.02 MPa, respectively, and the respective COV of these two parameters were equal to 6% and 20%. As the load platen moved downwards, the load carried by the bridge increased until it reached a peak. The fluctuations and reductions observed in the load-displacement curves were related to the crack initiation and propagation process, as well as

the stiffness degradation of the bridge under loading. The results also illustrated the influence of the stochastic bond strength properties on the load-carrying capacity of the masonry arch bridge. In principle, a relatively large range of ultimate loads, from 124.33 kN to 273.65 kN, was obtained from the computational model with stochastic bond strength properties. The experimental model had an ultimate load of 142.7 kN, which fell within the range obtained from the computational model and was closer to the lower limit of the range.

Figure 7 shows the sensitivity analysis results of the ultimate load on the bond strength of the mortar joint. In numerical simulations, the mean values of J_{coh} varied from 0.015 MPa to 0.04 MPa with a COV of 20%. The values of tensile strength and cohesion were fully correlated according to Equation 3. For all the simulations, the mean value and COV for J_{fric} remained at 35 degrees and 6%, respectively. In Figure 7, the red lines are trend curves for the maximum, average, and minimum loads obtained from the simulations. It was calculated that the standard deviations for the results of four groups with different mean values of bond strength were all equal to approximately 40%, which highlighted the influence of stochastic bond properties of the unit-to-mortar interface on the ultimate load of the masonry arch bridge. With the stochastic properties of mortar joints, a range of peak loads was obtained from the computational model with different mean values of cohesion and tensile strength. Nevertheless, a significant positive correlation between the bond strength and ultimate loads was observed. With the increase in the mean bond strength, the average load-carrying capacity of the bridge increased, suggesting that the bonding strength of the mortar joints is one of the dominant factors affecting the overall strength of the masonry arch bridge.

Figure 6. Experimental (red line) against numerical (grey lines) load-displacement curves.

Figure 7. Sensitivity of the ultimate load on the bond strength of mortar joints (the mean value of J_{coh} at the unit-to-mortar interface varied from 0.015 MPa to 0.04 MPa, with COV remaining at 20%).

6 CONCLUSION

Ageing masonry arch bridges are characterized by inherent variability and may have stochastic material properties even in the same bridge. Such random properties could result in a considerable variation in the strength and stiffness of the masonry arch bridge. However, most of the previous studies have ignored this variation in material properties and instead assigned the same (uniform) parameters through the masonry structure for simplicity, which can lead to an inaccurate evaluation of the ultimate strength of a real masonry arch bridge.

This paper presents a stochastic-based assessment of the ultimate strength and mechanical behavior of masonry arch bridges to address this issue. Stochastic bond properties of unit-to-mortar interfaces were assigned to a 2D computational model developed based on the DEM, and over 100 simulations were executed to predict the load-carrying capacity of the masonry arch bridge. From the analyses of the results, it is shown that the computational model with stochastic material properties can better predict the load-carrying capacity of a real masonry arch bridge with inherent material variabilities. Moreover, the random bond properties did not affect the failure mechanism of the masonry arch bridge investigated and all computational models had a four-hinged behavior. However, with the stochastic bond strength of unit-to-mortar interfaces, the predicted ultimate loads of the bridge had a variation with a COV of approximately 40%, which is expected as the mean value of bond strength increased, the load-carrying capacity of the bridge increased significantly.

The study reported herein is the preliminary findings of the more sophisticated computational model being developed. Hence, such finding assumes and considers the simplest case, while more complicated scenarios like spatially variable bond strength properties of masonry, the correlation between unit-to-mortar interfaces in the same course and different courses, complicated statistical relationships between strength properties, more sophisticated considerations of the backfill materials, etc. can be considered in future studies.

ACKNOWLEDGEMENT

This work was funded by the EPSRC project “Exploiting the resilience of masonry arch bridge infrastructure: a 3D multi-level modelling framework” (ref. EP/T001348/1). The financial contribution is very much appreciated.

New UK guidance for the assessment of masonry arch bridges

Matthew Gilbert, Colin C. Smith & Serena Amodio

Department of Civil and Structural Engineering, University of Sheffield, Sheffield, UK

ABSTRACT: Masonry arch bridges are long-lived structures that continue to form a vital part of our transport infrastructure. However, they are facing a number of challenges associated with their extended period in service and the changing requirements of modern transport systems. CIRIA C800 provides new, freely available, guidance for the assessment of masonry arch bridges, building on recent research findings and advice already available in existing CIRIA guidance and in UK highway and railway assessment codes. Most significantly, the new guidance promotes the use of the Permissible Limit State (PLS), the point beyond which progressive load-induced degradation occurs under service loads during the intended life of a bridge. This is designed to allow engineers to more reliably identify the bridges that are likely to be most susceptible to the damaging effects of repeated cyclic loading. Background information on the new guidance is presented in the paper, including details of a simplified PLS calculation method and an example that demonstrates how it can be applied in practice.

1 INTRODUCTION

Approximately one million masonry arch bridges are currently in use worldwide, the majority of which are over 100 years old, and which are handling traffic that is very different to that which their builders originally intended. These bridges include one or more masonry arches serving as the primary means of supporting the applied loads, though incorporate a wide range of construction details. Given the large numbers of such bridges currently in service, it is important that bridge owners have access to information that can inform their efficient management, ensuring that limited maintenance budgets are focused appropriately. Central to this is having access to useful information garnered from periodic bridge assessments.

In the middle of the last century the well-known MEXE method of assessment was developed for masonry arch bridges (National Highways, 2022). This sought to determine the level of service load that could be carried and includes both ‘analysis’ and ‘observational’ elements. However, since the ‘analysis’ element of the method has known flaws (Wang & Melbourne, 2010), the observational element of the method is arguably more useful, albeit this does not provide a predictive capability. These flaws have led to reduced usage of the MEXE method in recent years, with the current UK assessment code for highway bridges (National Highways, 2022) indicating that the MEXE method cannot be applied to bridges with spans of less than 5m or greater than 18m. Instead limit analysis methods (after Heyman, 1982) have increasingly been used in recent years. These are used to determine the Ultimate Limit State (ULS) load, with a fixed factor of safety then applied to determine the Serviceability Limit State (SLS) load. This is because no widely accepted SLS criteria for masonry arch bridges have been developed to date.

Of course, bridge assessment requires the availability of competent assessment engineers, who also need to have access to effective tools. Unfortunately, two issues have been found to adversely affect the quality of these assessments:

- many assessment engineers are unfamiliar with masonry arch bridges, and how they carry applied loading, in part because they are typically not treated on university syllabi;

- current generation assessment approaches are often unable to discriminate between bridges that have the capacity to carry additional loading, and those that do not.

A new guidance document, CIRIA C800 (Gilbert et al., 2022), has therefore been prepared to address both the above issues, addressing the first by providing educational material and the second by presenting a new, more discriminating, assessment approach. In the latter case the approach presented involves supplementing existing ULS calculations with independent Permissible Limit State (PLS) calculations, where the PLS is defined as the point beyond which progressive load induced degradation occurs under service loads during the intended life of the bridge. Significantly, the simplified PLS calculations presented involve the use of the same limit analysis methods used for ULS analysis, though use different inputs.

The paper is structured as follows: section 2 presents an overview of the new CIRIA C800 guidance; section 3 describes key aspects of the new limit state assessment approach presented in CIRIA C800; in section 4 these calculations are applied to a railway masonry arch bridge; finally, in section 5 conclusions are drawn.

2 NEW UK GUIDANCE: CIRIA C800

CIRIA C800, ‘Guidance on the assessment of masonry arch bridges’ (Gilbert et al, 2022), is a new document designed to provide practical guidance to practitioners involved in the assessment of bridge constructions that include masonry arch elements. It is free to download from the CIRIA website (<https://www.ciria.org>) and was designed to expand and bring up to date the sections on assessment in an existing CIRIA guidance document, CIRIA C656 (McKibbins et al, 2006), taking advantage of recent research findings as appropriate. CIRIA C800 comprises eight chapters and nine appendices, with the majority of these comprising useful background information for assessment engineers with a range of backgrounds, from those who are new to the assessment of masonry arch bridges, to experienced engineers who wish to refresh or update their knowledge in the area. Since masonry arch bridges are not covered on most university syllabi, little prior knowledge is assumed.

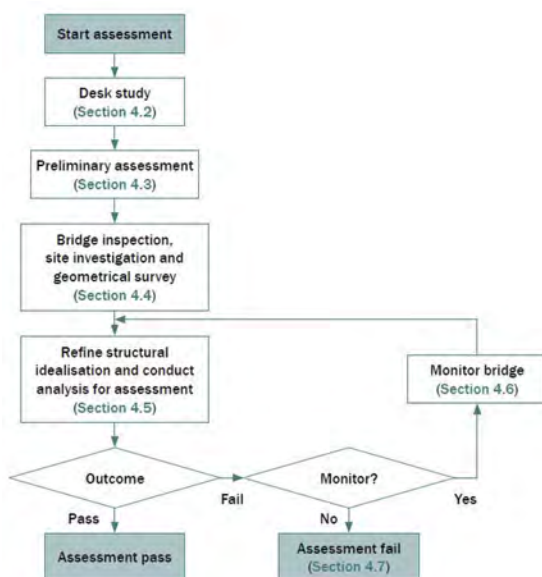

Figure 1. Steps in the bridge assessment process (from CIRIA C800, Gilbert et. al. 2022).

Steps in a typical bridge assessment process are outlined in Figure 1; this assumes that the assessment will require calculations to be performed, with monitoring of a bridge carried out only if the bridge cannot be demonstrated to have the required capacity.

It is evident from the process depicted in Figure 1 that it involves many steps that can only be carried out effectively by a competent assessment engineer, who is familiar both with masonry arch bridge constructions, and with the calculation methods that are used to analyse them. In this respect, clearly a good level of understanding is important; without it, appropriate data will likely not be gathered, or inappropriate models and/or model inputs may be used, leading to inaccurate assessment. Thus, CIRIA C800 contains numerous figures and tables designed to ensure readers are familiar with key principles; an excerpt is reproduced in Figure 2.

Observation	Notes	Illustrative examples
1. The pattern of loading in relation to the shape of a masonry gravity structure governs overall stability.	This means that it is important to accurately measure the shape of the arch barrel, piers etc when undertaking an assessment, and to use patterns of loadings that are representative of those that will be applied in practice in assessment calculations.	<p>Shallow arch: low profile where a low mid-span point load W is required to cause failure via formation of hinges (a), and pointed arch profile where a high load is required to cause failure via formation of hinges (b).</p>
2. Masonry gravity structures resist applied actions through their inherent self-weight and thickness.	Self-weight is often beneficial, so scenarios where it is not factored up should be included in assessment calculations. Also, the thickness of all masonry elements (arch barrels and piers) should be carefully measured before assessment.	<p>Force P required to cause overturning failure of a stack of blocks (a), required force reduces if blocks have lower unit weight (b), and required force reduces if blocks are thicker (c).</p>

Figure 2. Sample observations to explain fundamental behaviour (from CIRIA C800, Gilbert et. al. 2022).

In the excerpt shown in Figure 2 the aim is to emphasize the importance of arch shape, and the fact that masonry gravity structures derive their resistance from the thickness and self-weight of the masonry. It is also noted that as self-weight is often beneficial, an assessment should include calculations where this is not increased via application of partial factors – something that may be unfamiliar to engineers who are used to assessing steel or concrete structures.

In addition to providing general background information, a key element of CIRIA C800 is a chapter describing a new assessment approach that involves use of both ULS and Permissible Limit State (PLS) calculations, where the PLS is defined as the point beyond which progressive load induced degradation occurs under service loads during the intended life of the bridge; how this fits in a limit state assessment of a bridge is outlined in the next section.

3 LIMIT STATE ASSESSMENT

3.1 Ultimate Limit State (ULS) assessment calculations

A ULS assessment of a masonry arch bridge typically makes use of analysis calculations that draw upon the theorems of plastic limit analysis, firmly established in the middle of the last century, and shortly afterwards interpreted in the context of masonry arch bridges by workers such as Kooharian (1953), Heyman (1982) and Harvey (1988). Considering the lower bound (or ‘safe’) theorem of plastic analysis, this states that the structure can be deemed to be safe providing an equilibrium state can be identified and applicable ‘yield’ criteria are not violated. In the case of a masonry arch bridge, it is usual to neglect the tensile strength of the masonry, such that bending resistance is provided by the normal force, much of it arising from gravity loads, and the thickness of the masonry cross-section (Figure 2). It can be shown that the main applicable equilibrium and ‘yield’ criteria are satisfied if the thrust line (or, when masonry compressive strength is included, ‘thrust zone’) lies entirely within the thickness of the masonry. Other yield criteria can be accounted for in a similar way; for example, the line/zone of thrust should cross voussoirs at a sufficiently steep an angle to ensure that applicable shear (sliding) failure criteria are not violated. In a normal ULS analysis masonry materials are not generally considered in detail – though in reality their properties will generally degrade

over time, either due to environmental effects, long term loading (creep) or due to repeated application of loads (fatigue).

Most masonry arch bridges also contain soil backfill, which significantly increases load carrying capacity, by: (i) applying significant vertical dead weight (to effectively ‘pre-stress’ the masonry); (ii) dispersing the loads from vehicle axles (so as to be less concentrated); and (iii) providing horizontal ‘passive’ restraint to sway of the arch into the surrounding fill material; see Figure 3. In his proposed analysis method for masonry arch bridges Heyman (1982) took account of (i) and (ii), but ignored (iii). This apparent shortcoming was addressed by others in the years that followed (e.g. Harvey 1988). However, horizontal soil pressures generally require large displacements of the constituent masonry elements to be mobilized. Thus, whilst it is justifiable to include these pressures in a ULS model, it is much less so when normal vehicle load levels are involved, since the resulting deformations are likely to allow opening and closing of joints, that in turn are likely to lead to progressive degradation of the structure over time.

Figure 3. Soil-arch interaction (after Smith et al. 2004).

3.2 Permissible Limit State (PLS) assessment calculations

3.2.1 Background

When a masonry arch bridge is overloaded for a prolonged period, warning signs will normally become clearly evident (e.g. flexibility under live load, cracks that grow with time, increasing distortion, etc). However, once the bridge reaches this stage, the damage can be extensive and costly to repair, or in some cases, may be beyond repair. Therefore, it is important to have a way to forewarn engineers that a particular loading condition is likely to lead to distress.

Instead of trying to predict when individual cracks might form (which would require sophisticated analysis tools and extensive knowledge of the structure), it is much more practical to examine the underlying cause of why deflections under load begin to increase. In a typical bridge with soil backfill, increased deflection under load is associated with mobilization of passive soil pressures. Though these can contribute greatly to ultimate load carrying capacity, large structural movements are needed to mobilize these. (N.B. If spandrel walls are attached then, prior to large passive soil pressures being mobilized, the spandrel walls will be engaged. In this case the stiffness mismatch between the walls and surrounding backfill will be large at this point, hence often leading to cracks/detachment; the likelihood of this can be reduced if the level of load is kept below the PLS load level.) Similarly, comparatively large deformations (strains) are required in order to fully mobilize masonry strength in compression, due to the inherently inelastic, non-linear, behaviour of masonry. These observations open up the possibility of developing a first order analysis method to establish approximately when damage is likely to occur, coinciding with the point at which deflections start to grow.

3.2.2 Simple PLS assessment method

Given the background described above, CIRIA C800 describes a simple PLS assessment method for masonry arch bridges that is undertaken by performing a conventional limit analysis, though with:

- unfactored service loads;
- limited lateral soil pressures (lateral soil pressure coefficient, $K = 1$);
- reduced compressive strength (e.g., taking partial factor on the material strength, $\gamma_m = 2.0$ corresponds to a cyclic loading endurance limit for compressive loading of 0.5, after Casas (2009));
- transverse cracks modelled, if present;
- due account taken of the flexibility of other elements (e.g. near surface elements, which may increase load distribution much more at the ULS than at the PLS).

3.2.3 Commentary

A potentially useful way of conceptualizing the PLS is to consider that bridges manifesting load-induced deterioration have exhausted their primary modes of resistance, and have started to engage less reliable secondary modes of resistance, such as soil passive pressures and/or spandrel wall resistance. The resulting simple PLS assessment method described above can thus be undertaken using the same limit analysis tools traditionally used to determine ULS capacity, though now neglecting passive resistance. Also, a reduced value of masonry compressive strength is used. Since primary modes of resistance are being relied upon, the degree of modelling uncertainty is lower than when ULS calculations are being performed, which can be reflected in the partial factors used.

3.2.4 Underpinning research

A number of bridges were cyclically load tested in the laboratory to explore to provide supporting data (Augustus Nelson et al, 2018a, 2018b, Augustus-Nelson & Swift 2020); e.g. Figure 4 shows views of sections of the arch barrels of two bridges cyclically load tested to failure.

Figure 4. Observed cyclic loading induced damage in two laboratory bridges: (a) clay filled bridge; (b) crushed limestone filled bridge (from CIRIA C800, Gilbert et. al. 2022).

Due to time and cost constraints only a relatively small number of bridges could be subjected to cyclic loading regimes. Therefore quasi-static load tests undertaken on bridges from the literature were also studied to estimate the level of load required to mobilize increasing displacements, likely to correspond to the point at which passive pressures start to be mobilized and hence also to the PLS load. This is indicated by a break in the load-displacement response; best-fit bilinear and trilinear representations of load-displacement plots were extracted and used to identify experimental PLS load envelopes - a sample is shown in Figure 5.

Figure 5 also shows predicted ULS and PLS analysis results obtained using the LimitState: RING software (LimitState Ltd 2020), in the latter case using simple PLS assessment method assumptions. In this case although the predicted PLS load lies slightly below the experimental PLS load envelope derived from a load-displacement plot, it falls within the PLS load envelope obtained when a nominally identical bridge was cyclically loaded to failure (the damage shown in Figure 4b occurred when the cyclic load level was increased from 70kN to 80kN).

3.3 Assessment process

The approach presented in CIRIA C800 is, as far as possible, consistent with that used in the Eurocodes and with CS 454 (National Highways, 2022), which adopts a similar approach to the Eurocodes. Figure 6 shows an extract from CIRIA C800 that summarises the applicable inputs, including partial factors, to be applied in ULS and PLS assessments.

Figure 5. Sample load-deflection plot derived from test on crushed limestone filled laboratory bridge, also showing experimentally derived and predicted ULS and PLS loads (from CIRIA C800, Gilbert et. al. 2022).

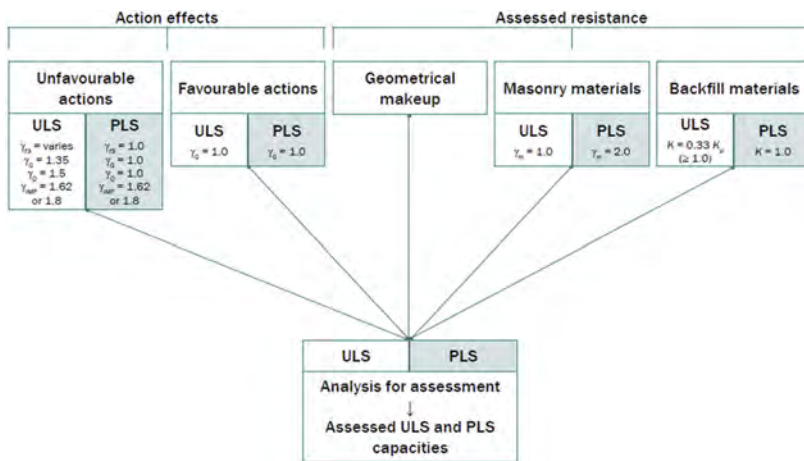

Figure 6. Key ULS and PLS analysis for assessment inputs (from CIRIA C800, Gilbert et. al. 2022).

Since primary modes of resistance are being relied upon in the PLS, the degree of modelling uncertainty is lower than when ULS calculations are being performed; this is taken account of by adopting a loads effect factor γ_{f3} of 1.0 in the former case, and above 1.0 in the latter case (except when a detailed ‘Level 3’ assessment is being carried out).

4 EXAMPLE ASSESSMENT: SINGLE-SPAN RAILWAY BRIDGE

For comparative purposes a single-span railway bridge, Whiley Hill Bridge, is here assessed using both NR GN/CE/C/025 (Network Rail, 2006) and CIRIA C800.

The bridge is a single-span masonry arch bridge located in County Durham on George Stephenson’s original Stockton to Darlington railway. The bridge comprises an approx. 3.3m span semicircular stone voussoir arch span resting on abutment walls; see Figure 7 (see CIRIA C800 for geometrical details). According to archive documents the structure was constructed in

1824 and as such is one of the oldest railway bridges still in service in the world. The bridge supports a single track carrying both freight and passenger traffic. Long term monitoring of crown deflections found these to be beyond acceptable limits, with the overall trend showing slowly increasing deflections with time, suggesting progressive load induced deterioration. Freight trains consisting of wagons laden with coal hauled by a class 66 locomotive were the most onerous traffic routinely using the bridge at the time of the original assessment. The wagons were consequently down-rated, with loading reduced to 23 tonnes per axle. Also, the track was realigned to place it nearer the centre of the structure, and crown displacements of the bridge were monitored periodically to allow deterioration of the bridge to be tracked.

Figure 7. Whiley Hill bridge: (a) elevation, (b) traffic surface (from CIRIA C800, Gilbert et. al. 2022).

A survey indicated that the abutments have a thickness similar to that of the arch and no evidence of backing was found. Monitoring of arch crown deflections revealed that live loading was causing progressive damage. A survey carried out in 2011 reported that a longitudinal crack had formed in the arch barrel and through both abutments, together with other more recent longitudinal cracks. Also, localised fractures and dropped stones were observed in the arch.

The bridge was reported to have black gravelly sand backfill with coal fragments. Tests on soil samples indicated an internal angle of friction of 40 degrees and a relatively high cohesion of 33 kN/m². However, the latter may be due to suction pressures since the soil was partially saturated and cannot be relied upon. Therefore, it was taken as zero in the analysis. The masonry unit weight and coefficient of friction were not made available, while values for the crushing strength and ballast unit weight were tNR/GN/CIV/025. The load model adopted in this study is a type RA1 (short lengths) with 23 tonnes axle loads, which correspond to the maximum live loading on the bridge. The bridge effective width is generally taken as the distance between longitudinal cracks; considering the numerous cracks present in the barrel, a conservative effective width of 1.8m has been adopted. Also, given that the bridge incorporates slender abutments, it was deemed appropriate to model two scenarios in which the abutments were either assumed to be rigid or modelled explicitly to allow these to also fail.

Results from the resulting CIRIA C800 and NR/GN/CIV/025 assessments are presented in Table 1. Note that an 'adequacy factor' above 1.0 indicates that the factored applied loading can be safely carried; below 1.0 means that this is not the case. The LimitState:RING software (LimitState 2020) was used to perform all assessment calculations.

It can be seen from Table 1 that, according to NR/GN/CIV/025, irrespective of the scenario considered, the bridge has sufficient load carrying-capacity. In contrast, the PLS capacity calculated according to the method described in CIRIA C800 results in a PLS adequacy factor of less than 1.0 in both scenarios. Given that the bridge has been showing signs of progressive load-induced deterioration, the CIRIA C800 assessment clearly appears to be much more realistic.

Table 1. Whiley Hill Bridge: summary of assessment results (from CIRIA C800, Gilbert et. al. 2022).

Scenario	Document	Limit state	γ_e (γ_{fe} for vehicle loads)	Impact factor	γ_{fs}	Analysis adequacy factor
A Model arch barrel only	NR/GN/CIV/025	Hybrid	1.9	1.8	1.0	1.23
	CIRIA C800 (this guidance)	ULS	1.5		1.1	1.41
		PLS	1.0		1.0	0.78
B Model arch barrel and abutments	NR/GN/CIV/025	Hybrid	1.9	1.8	1.0	1.04
	CIRIA C800 (this guidance)	ULS	1.5		1.1	1.19
		PLS	1.0		1.0	0.65

5 CONCLUSIONS

A new guidance document, CIRIA C800, has been produced that provides guidance on the assessment of masonry arch bridges, building on recent research findings and advice already available in existing CIRIA guidance and in UK highway and railway assessment codes. Most significantly, the new guidance promotes the use of the Permissible Limit State (PLS), the point beyond which progressive load-induced degradation occurs under service loads during the intended life of a bridge. This is designed to allow engineers to more reliably identify which bridges are most susceptible to the damaging effects of repeated cyclic loading.

Prestressed Lead Damper for seismic protection of structures

V. Quaglini, C. Pettoruso & E. Bruschi

Department of Architecture, Built environment and Construction engineering, Politecnico di Milano, Milan, Italy

M. Sartori

Freyssinet Products Italy SpA, Milan, Italy

ABSTRACT: The study presents the design and experimental characterization of a lead friction damper with improved resistance to repeated seismic loads. The damper provides energy dissipation by the friction force triggered between a moving shaft and a lead core prestressed within a steel chamber. Thanks to the ability of lead to restore its properties by strain relief due to static recrystallization immediately after deformation, the damper is not affected by low-cycle fatigue. Prototypes of the damper were subjected to the test procedure recommended by the European standard EN 15129 for Displacement Dependent Devices, fulfilling the relevant requirements. The damper provides a stable response over repeated cycles, characterized by an essentially rectangular hysteresis loop with an equivalent viscous damping ratio $\xi_{\text{eff}} > 55\%$, a low sensitivity on the loading rate, and the ability to withstand multiple cycles of deformation without deterioration of performance, ensuring maintenance-free operation in presence of repeated ground shakes.

1 INTRODUCTION

Supplemental energy dissipation has proved, through research and practical applications, to be a viable solution to mitigate the effects of earthquakes and reduce the seismic vulnerability of ordinary constructions, such as residential, school and industrial buildings (Aliakbari et al. 2020, Gandelli et al. 2019, Garivani et al. 2020, Martinez-Rueda 2002). This strategy is generally implemented by inserting dissipative devices, or dampers, in the bays of the building frame or at column-to-beam connections, with the aim of (i) increasing the structural stiffness, with reduction of inter-story displacements, and (ii) dissipating much of the seismic energy, with limitation of floor accelerations (Bruschi et al. 2022, Bruschi & Quaglini 2022).

Among supplementary energy dissipation devices, the lead extrusion damper developed by Rodgers et al. (2007a), known as HF2V (High Friction to Volume) damper, has been revealed to provide large energy dissipation capability combined with compact dimensions (Rodgers et al. 2019, Quaglini et al. 2021, Quaglini & Bruschi 2022), which make this system suitable for the seismic upgrade of existing structures, since it has a limited impact on the architectural aesthetics or function of the building (Rodgers 2009). The HF2V consists of a steel shaft with a protruding bulge encased in a lead core which is in turn confined within a steel chamber. The deflection of the shaft causes the lead to extrude through the orifice created between the bulge and the internal wall of the chamber as it moves from one side of the bulge to the other; this mechanism ensures a constant force upon yielding, similar to the behavior of conventional steel hysteretic dampers (Rodgers et al. 2008), but avoiding at the same time the typical drawbacks that affect such devices. In fact, because of low-cycle fatigue issue and permanent deformation at unloading, steel hysteretic dampers need to be replaced after a major earthquake. The HF2V damper has been developed starting from the earlier studies of Robinson and Greenbank (1976). The dimensions of these prior devices were very large to provide

sufficient reaction forces, and for this reason their use was mainly limited as part of base isolation systems (Bruschi 2021). In this damper, as the shaft moved, the material was compressed into a smaller volume leading to the formation of a trailing void; as the bulge passes through this void, the damper experiences less resistance and dissipates less energy (Rodgers et al. 2007a). On the other hand, Rodgers et al. (2007a, 2008, 2009, 2019) disclosed to increase the force and the dissipation capability of the damper by preloading the lead core during the assembly of the device. Compressing the lead reduced the formation of trailing voids and boosted the force-to-volume ratio, allowing a more compact design, able to fit into tight volumetrically constrained applications, such as directly into beam–column joints (Mander et al. 2009, Rodgers et al. 2007b, 2008). Further research on this technology was carried out by Yang et al. (2015), Soydan et al. (2015, 2018), Patel (2017), Bruschi et al. (2020), Pettorruso et al. (2021), Quaglini et al. (2021).

Recently, a novel lead damper, called the PreStressed Lead Damper (PS-LED), has been introduced (Pettorruso et al. 2021, Bruschi & Quaglini 2022, Quaglini et al. 2022). The paper illustrates the conceptual design of the PS-LED, presents the tests performed on two prototypes of PS-LED for the characterization of the device.

2 DESIGN OF THE PS-LED

The PS-LED consists of four main components: a straight shaft, a rigid tube, a cap and a lead core (Figure 1). Tube, shaft and cap are made of high strength steel, and the shaft is plated with hard chromium. A bushing provided in the cap drives the linear motion of the shaft.

The PS-LED is intended to be inserted in conventional damped brace systems, and connected at one end of the shaft and at the opposite end of the tube. When the structure oscillates under the effects of the ground motion, the shaft moves relative to the tube, activating a friction force at the interface with the lead core, through which energy is dissipated. Since the coefficient of friction between lead and chromium plated steel is noted to remain almost steady once sliding is triggered (Pettorruso et al. 2021), the damper provides a constant force over its entire stroke with an ensuing essentially rectangular hysteretic curve, which maximizes the amount of energy dissipation. The theoretical amount of energy dissipated in a full cycle is $EDC = 4 N_0 d_b$, where N_0 is the resisting force developed by friction during deflection of the shaft and d_b is the amplitude of displacement. The axial force is controlled by prestressing the lead core during the assembling process; in this way, voids in the working material are removed, resulting in a perfect fit to the tube and the shaft and avoiding clearances at motion reversals (Quaglini et al. 2022).

Figure 1. Longitudinal section of the PS-LED (Quaglini et al. 2022).

Over the HF2V device which exploits the plastic deformation of lead, the PS-LED relies on friction only for energy dissipation. This is expected to reduce the influence of heating (which has indeed a major effect on the extrusion resistance of lead) on the output force, and increase

the stability of the damping characteristic during repeated cycles. Another feature of the PS-LED is that the straight shaft does not require complex and expensive machining operation as its bulged counterpart does, permitting the use of commercial chromed shafts and reducing manufacturing costs.

3 MATERIALS & METHODS

3.1 Description of the prototype

In the study two prototypes of PS-LED were tested. The main geometrical and performance properties of the devices are reported in Table 1, where D_s is the diameter of the shaft, D_{cyl} is the inner diameter of the tube wall, L_s is the length of the lead core – shaft interface and L_d is the axial length of the device, N_d is the design axial force and d_{bd} the design seismic displacement in either direction (i.e. one half of the total stroke).

Raw materials are the same for both prototypes. Tube, shaft and cap are made of structural steel S355, while the working material is 99.99% pure lead. The shafts are plated with 70 μm thick hard chromium in order to minimize friction and wear during sliding through the bushing provided in the cap. In order to avoid off-axis loads, self-lubricating spherical hinges with a minimum rotation capacity of $\pm 2^\circ$ are provided at both ends of the dampers, namely at one end of the shaft and on the bottom of the tube (Figure 2). A picture of the devices is shown in Figure 3(a).

Table 1. Properties of tested PS-LED prototypes.

	D_s	D_{cyl}	L_s	L_d	N_d	d_{bd}
Test	mm	mm	mm	mm	kN	mm
Prototype 1	32.5	60	80	410	220	10
Prototype 2	20	70	70	385	50	15

Figure 2. Characteristic dimensions of PS-LED prototypes.

3.2 Testing protocol

The tests were performed at the Materials Testing Laboratory of Politecnico di Milano, using a 500 kN servohydraulic testing machine (MTS Systems, Eden Prairie, MN) (Figure 3(b)), and following the testing protocol prescribed by the European Standard EN 15129 (CEN 2009) for Displacement Dependent Devices (DDD). Harmonic cycles of increasing amplitude at 25%, 50% and 100% of the design deflection d_{bd} were imposed to the specimens, performing five cycles for each intermediate amplitude and ten cycles for the maximum amplitude. The loading frequency was $f_0 = 0.5$ Hz for prototype 1, and 0.25 Hz for prototype 2. Then, a ramp test at 0.1 mm/s speed was performed to two times the amplified design displacement $\gamma_x \gamma_b d_{bd}$

Figure 3. Picture of the tested PS-LED prototypes (a); test configuration showing one prototype on the testing machina (b).

recommended in the standard (where $\gamma_b = 1.1$ and $\gamma_x = 1.2$ are the amplification factor and the reliability factor), to assess the non-failure condition under quasi-static condition.

At the end of the protocol according to EN 15129, in order to investigate the dependence of the response on the speed, three additional tests were performed at the design deflection d_{bd} for different frequencies, with 4 cycles at each frequency. The test plan is reported in Table 2.

Table 2. Test plan.

Test	amplitude	frequency	rate	Cycles
Cyclic	$0.25 d_{bd}$	f_0	0.1 mm/s	5
	$0.5 d_{bd}$	f_0		5
	$1.0 d_{bd}$	f_0		10
Ramp	$2 \gamma_x \gamma_b d_{bd}$	=	0.1 mm/s	1
	$1.0 d_{bd}$	$0.5 f_0$		4
Rate	$1.0 d_{bd}$	$1.0 f_0$		4
	$1.0 d_{bd}$	$1.5 f_0$		4

4 RESULTS

The experimental force – displacement hysteresis loop of the PS-LED is shown in Figure 4. At the beginning of loading the PS-LED shows a linear behavior, corresponding to the elastic deflection of the shaft. After the friction resistance at the lead – shaft interface is overcome and sliding of the shaft relative to the lead core is engaged, the force – deflection diagram displays a plastic branch characterized by a constant force independent of the accommodated deflection, and the same behaviour occurs after motion reversal. The axial force of the plastic branch is almost symmetric in extension ($N > 0$, shaft moving outwards) and in compression ($N < 0$, shaft moving inwards), according to Coloumb friction. It is worth noting that owing to the high elastic stiffness of the steel members, the hysteresis loop exhibits the rectangular shape assumed in design. The small changes in the output force close to motion reversals suggest that the friction between the shaft and the working material has a shallow dependence on the velocity, though this dependency does not affect too much the overall response.

The response of the PS-LED is evaluated on the basis of two quantities, namely the effective stiffness K_{eff} and the equivalent viscous damping ratio ζ_{eff} , which are determined through Equations (1) and (2):

Figure 4. Hysteresis loop of a tested prototype of PS-LED observed in a reversed cycle.

$$K_{eff} = \frac{N}{d_0} \quad (1)$$

$$\zeta_{eff} = \frac{2 EDC}{\pi d_0 N} \quad (2)$$

where N is the force at d_0 deflection, d_0 is the maximum deflection in the cycle and EDC is the energy dissipated per cycle.

The standard (CEN 2009) requires that both K_{eff} and ζ_{eff} remain almost constant during a sequence of cycles of same amplitude, and fulfilling the conditions of Equations (3) and (4):

$$\frac{|K_{eff,i} - K_{eff,3}|}{K_{eff,3}} \leq 0.10 \quad (3)$$

$$\frac{|\zeta_{eff,i} - \zeta_{eff,3}|}{\zeta_{eff,3}} \leq 0.10 \quad (4)$$

where i is the cycle number ($i \geq 2$), and $K_{eff,3}$ and $\zeta_{eff,3}$ are the effective stiffness and the viscous equivalent damping ratio evaluated at the third cycle of a test sequence at the same displacement amplitude, respectively.

Figure 5 and Figure 6 show the variation of K_{eff} and ζ_{eff} during the Cyclic test of Table 2. Disregarding the first cycle, in the most challenging test sequence at the design deflection d_{bd} , K_{eff} and ζ_{eff} respect the stability requirements, showing maximum variations (with respect to $K_{eff,3}$ and $\zeta_{eff,3}$) of 9.9% and 2.4% for prototype 1, and of 7.6% and 0.9% for prototype 2, respectively. The average value of the equivalent damping ratio over 10 cycles performed at the design seismic displacement d_{bd} is $\zeta_{eff} = 0.55$ for prototype 1 and $\zeta_{eff} = 0.60$ for prototype 2, close to the maximum theoretical value of 0.63, confirming the excellent dissipation capacity of the PS-LED. On the other hand, for standard buckling-restrained steel hysteretic dampers made of mild steel, the equivalent viscous damping ratio generally lies in the range of 20% to 40%, depending on the geometry and the design deflection (Sina et al. 2021, Sitler et al. 2020, Tonon et al. 2013).

In the Ramp test, both prototypes were able to sustain the amplified design deflection $\gamma_x \gamma_b d_{bd}$ without any cracking, demonstrating the ability of the PS-LED to accommodate the prescribed displacement without any mechanical damage or deterioration of its stiffness (Figure 7).

Figures 8 and 9 show the cyclic variation of the effective stiffness and the effective damping ratio of the two prototypes at different frequencies. The influence of the rate of deflection is quite low: for both devices the variation of $K_{eff,3}$ and $\zeta_{eff,3}$ with respect to the values evaluated

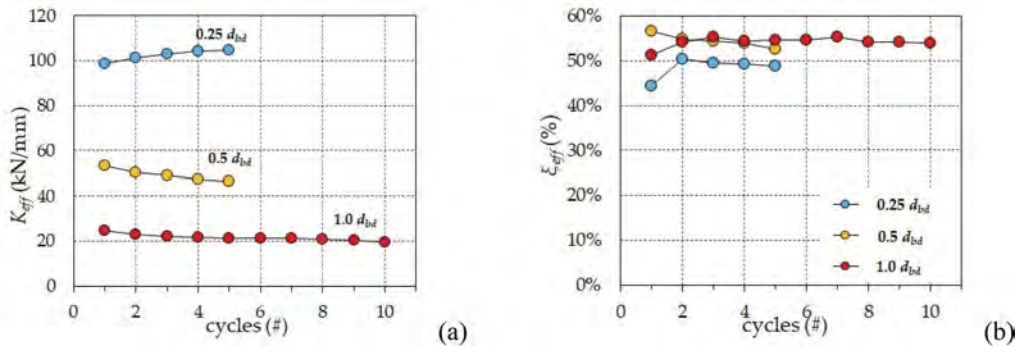

Figure 5. Prototype 1: effective stiffness K_{eff} (a) and equivalent viscous damping ζ_{eff} (b) of the PS-LED vs. number of cycles at different deflection amplitudes d_{bd} .

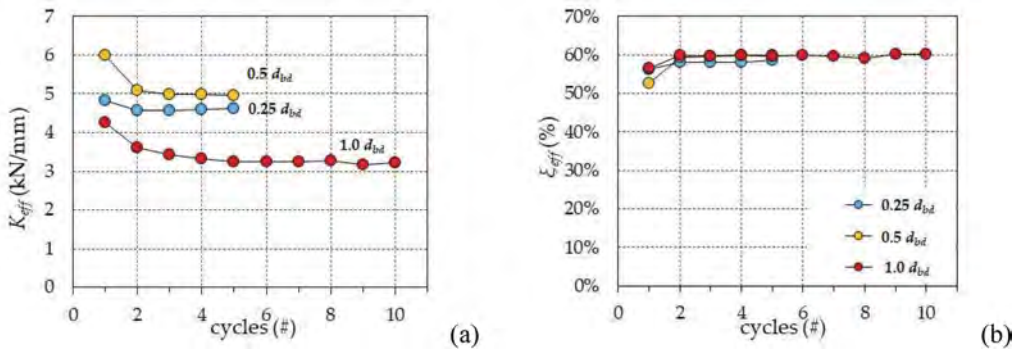

Figure 6. Prototype 2: effective stiffness K_{eff} (a) and equivalent viscous damping ζ_{eff} (b) of the PS-LED vs. number of cycles at different deflection amplitudes d_{bd} .

at the central frequency f_0 is less than 10% as required for Displacement Dependent Devices, and can be neglected in practical applications according to the standard (CEN 2009).

5 CONCLUSIONS

In this paper the design of a novel energy dissipation device, the PS-LED, has been experimentally evaluated following the provisions for Displacement Dependent Devices of the European

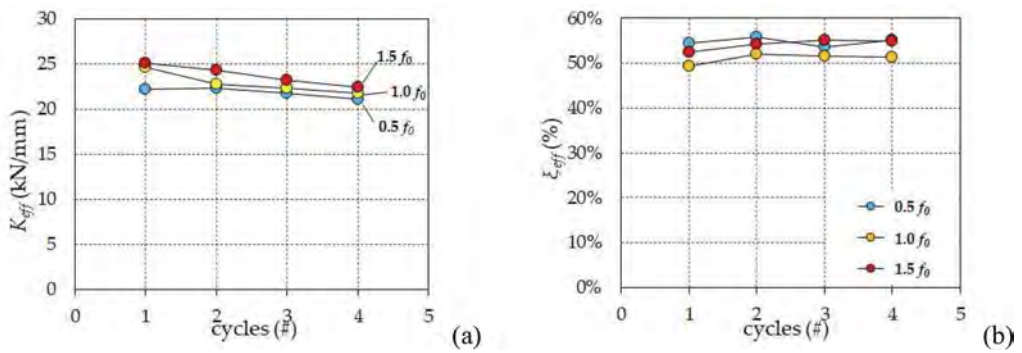

Figure 8. Prototype 1: effective stiffness K_{eff} (a) and equivalent viscous damping ζ_{eff} (b) of the PS-LED vs. number of cycles at different frequencies.

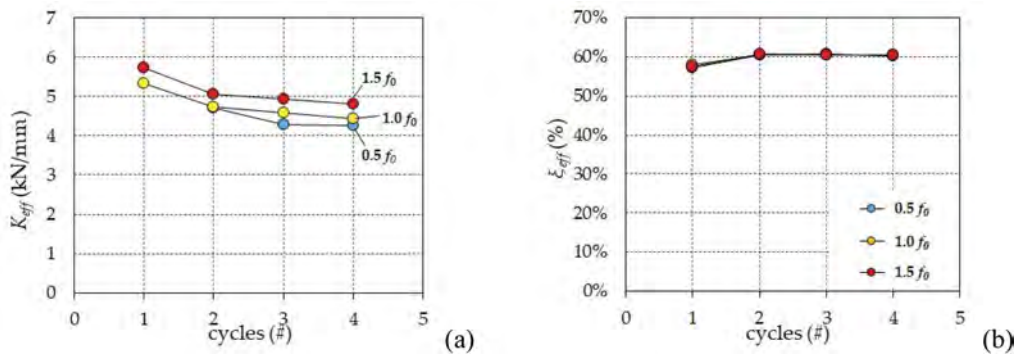

Figure 9. Prototype 2: effective stiffness K_{eff} (a) and equivalent viscous damping ζ_{eff} (b) of the PS-LED vs. number of cycles at different frequencies.

standard EN 15129 (CEN 2009). The PS-LED is characterized by an essentially rigid–plastic behaviour, with a constant axial force and an equivalent viscous damping ratio ζ_{eff} close to 60%, independent of the maximum cyclic displacement and of the rate of deformation. The two tested prototypes have shown a stable and predictable mechanical response over a series of cycles with an amplitude equal to the design seismic displacement, respecting the limits of variation prescribed in the European standard.

FUNDING

This research was partially funded by the Department of the Italian Civil Protection (DPC) in the Frame of the National Research Project DPC – ReLUIS (National Network of Laboratories of Seismic Engineering) 2019–2021, Work Package 15 “Regulatory Contributions for Isolation and Dissipation”.

Nonlinear analysis of base isolated buildings with curved surface sliders including over-stroke displacements

Felice Carlo Ponzo, Antonio Di Cesare & Nicla Lamarucciola
University of Basilicata, Potenza, Italy

ABSTRACT: Seismic isolation represents one of the most suitable strategies for mitigating the seismic risk of structures and infrastructures. Acceptable probabilities of collapse for seismically isolated buildings could be achieved by an appropriate isolator displacement capacity. This paper investigates the effects of the over-stroke capacity of double concave curved surface sliding isolators, in addition to the nominal displacement capacity, on the seismic response of base isolated structures. The case study building is a reinforced concrete frame structure designed for high hazard seismic site. The level of performance of global collapse prevention has been investigated considering the earthquake intensity levels at the Collapse Limit State (with a return period of 1000 years). The results of the nonlinear static and dynamic analysis highlights that the seismic isolation without the over-stroke capability show a limited margin against collapse for seismic intensities beyond the design limit state level.

1 INTRODUCTION

The minimization of potential seismic damaging of a building can be achieved introducing flexibility at the base of the structure in the horizontal direction and damping element to reduce the amplitude of displacements. In recent years, one of the most widespread technologies is the seismic isolation, as a practical and economical alternative to traditional seismic reinforcement.

Nowadays there are many isolation devices that differ in construction technology, materials, geometry and operation. The most common seismic devices are elastomeric isolators and sliding isolation systems. The latter are composed of a certain number of moving parts (at least two) made of steel and composite materials which slide over each other expressing a specific friction force. One of the mainly used seismic isolation system is the Curved Surface Slider (CSS), also known as Friction Pendulum Slider® (FPS), firstly developed by Zayas (Zayas et al. 1987), which includes both re-centering and good dissipation capabilities being based on the pendulum mechanic principle.

The double CSS bearing (or Double Concave Curved Surface Slider - DCCSS) consists of two facing concave stainless-steel surfaces separated by a slider which can be either articulated or rigid. The DCCSS can be modelled as two CSS in series associated with same coefficient of friction μ and effective radius of curvature R_{eff} (Fenz & Constantinou 2006, Ponzo et al. 2017).

The CSS devices can be further divided in two main groups: devices with or without a displacement restrainer, which prevent the inner slider to slid past a certain point which usually is the perimeter of the housing pad. These elements can be for example displacement restraining rings, which are made of the same material of the housing plate and can be welded, bolted to it or even form a single block with the pad itself (Bao et al. 2018). Retaining elements such as restraining ring (Figure 1a) are widely used in America (Kitayama & Constantinou 2019) in order to control displacements and to avoid the isolator disassembly when displacements higher than the design ones occur. Anyways, the impact against such retaining elements may induce significantly high acceleration onto the superstructure. On the contrary, the European Standards (UNI EN 15129:2018) do not allow the presence of restraining end-stroke element that can be damaged in case of a seismic event higher than the Maximum Credible Earthquake (MCE) and only approves

the use of structural joints separating the superstructure from the surrounding constructions, in order to safely accommodate the seismic movement. In particular, the European Standard allows the use of ground retaining walls, (Figure 1b), or specific devices such as rubber bumpers attached to the walls, to be used as end-over-stroke. Usually in Europe, the gap separating the superstructure from the retaining wall is much larger than the displacement capacity of the isolators, and consequently, the inner slider can run on the edge of the sliding surfaces for earthquakes producing displacement larger than the isolators capacity. When displacement restraining elements are not employed, and concave plates feature a flat rim (Bao et al. 2018b), the inner slider movement beyond the geometric capacity displacement d_c of the isolator is allowed entering in the so-called over-stroke displacement regime. The slider running in the over-stroke displacement regime it is capable of providing the DCCSS device with an increased displacement capacity d_{lim} and sliding force (Di Cesare et al. 2019, Ponzo et al. 2020, Di Cesare et al. 2021, Ponzo et al. 2021, Furinghetti et al. 2021a). Figure 1 shows the DCCSS in two deformed conditions: with a restraining ring and with overstroke capacity and moat wall.

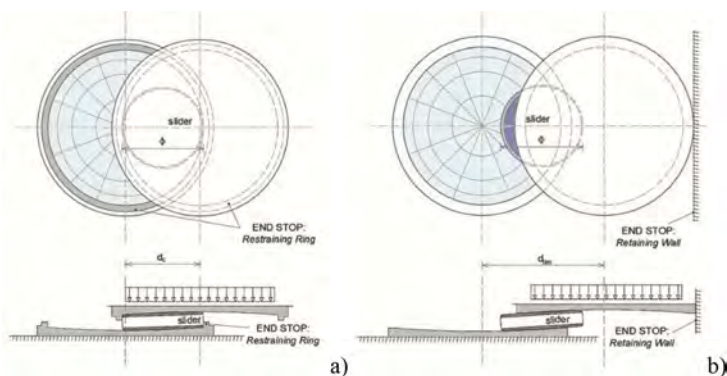

Figure 1. DCCSS bearing in deformed condition a) with a restraining ring d_c ; b) with overstroke capacity and retaining wall $d_{lim} \geq d_c$; in plan and cross section view (Di Cesare et al. 2021).

The equations of motion and the limit displacements for the over-stroke sliding regime have been characterized by (Di Cesare et al. 2022, Furinghetti et al. 2021b) but a proper argumentation is needed in order to provide designers with the accurate displacement capacities and forces of DCCSS isolators.

This paper focuses on a case study of isolated building by means of DCCSS isolators with and without over-stroke displacement and moat wall, designed following the Italian seismic code (NTC 2018, Ragni et al. 2018). The building is a six-storey concrete frame structure assumed located in the city of L'Aquila (Italy) on soil class C. Nonlinear static and dynamic analyses were performed considering earthquake intensity levels at Collapse Limit State. Analyses results in terms of global drift and base shear are presented.

2 DESCRIPTION OF THE CASE STUDY BUILDING

The prototype structure considered in this study represents a typical residential RC-frame buildings located in L'Aquila, characterized by a regular plan of approximately 240 square meters and 6 stories above ground (Figure 2). The ground level height is 3.4 m while the other stories heights are 3.05 m. The building includes a staircase, designed with knee beams, and all stories have the same 25 cm-thick slab.

Infill panels have been considered as regularly distributed in plan and elevation, with different opening percentages. Infills dead loads have been considered in the design process. More details about RC structural members and masonry infills can be found in (Ricci et al., 2019).

In the base-isolated configuration, a supplementary RC base slab has been implemented below the ground floor columns (Figure 2). Elastic beams have been added at the base floor

Figure 2. Case study building: plan view and longitudinal sections.

to realize the grid above the isolation system, consisting of 24 DCCSS isolators placed below the columns. Both concave plates of the DCCSS are characterized by the same radii of curvature and the same coefficients of friction ($R_1 = R_2$ and $\mu_1 = \mu_2$), and the assumed hypothesis is that sliding occurs simultaneously on both surfaces, considering a rigid cursor. The maximum displacement d_{max} has been assumed by catalogue, taking into account torsional effects, and the geometric capacity displacement d_c has been assumed as $d_c = 1.10 \cdot d_{max}$.

The total seismic weight W of the isolated frame is about 22380 kN and the vertical loads on the internal isolators N_{Sd} is about 1000 kN. The isolation system is designed considering the MCE spectrum shown in Figure 3a (UNI EN 1998-1:2004)

The seismic inputs considered in this study are reported in Figure 3b and consisted of a set of 20 ground motion for the intensity level corresponding to the Collapse Limit State (return period of 1000 years). The 5%-damped elastic spectra of the seismic records selected to represent the earthquake intensity level at MCE of the isolated structures is shown in Figure 3b. A reference period (conditioning period) closes to the design value of the fundamental period of vibration of $T = 3$ s has been considered. More details about the seismic hazard evaluation and the record selection for nonlinear dynamic analysis can be found in previous studies (Iervolino et al. 2018).

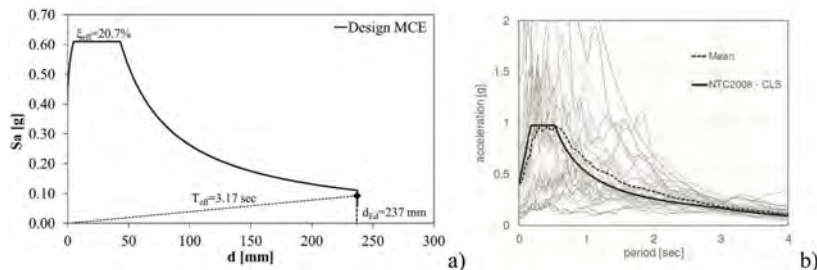

Figure 3. Acceleration response spectra of ground motion for Collapse Limit State (CLS) and Isolation systems design procedure on ADRS Spectra for LLS and CLS for L'Aquila site (Di Cesare, A., & Ponzio, F. C., 2023).

The geometric characteristics and main design parameters of the designed isolation system are reported in Table 1, in terms of: equivalent radius R_{eff} , friction coefficient μ , equivalent stiffness K_{eff} , effective period T_{eff} , effective damping ξ_{eff} , slider dimension, the maximum displacement d_{max} , the design displacement d_{Ed} of the isolation system at the MCE. For the over-stroke stage of motion the mechanical parameters are the increase of stiffness k_2 and friction coefficient $\Delta\mu$.

The oversizing due to the industrial discretization of the devices has been taken into account considering the ratio between the actual isolator displacement capacity d_c and the design displacement d_{Ed} equal to 1.4 in this study. The overstroke limit has been defined as the ratio between the ultimate displacement d_{lim} and d_c , equal to 1.25.

Table 1. Geometric characteristics and main design parameters of the isolation system at the CLS.

	R_{eff}	μ	K_{eff}	T_{eff}	ζ_{eff}	d_{Ed}	Φ	d_{max}	d_c	d_{lim}
Case Study	[mm]	[%]	[kN/mm]	[sec]	[%]	[mm]	[mm]	[mm]	[mm]	[mm]
AQ_New	3700	2.5	0.357	3.17	21	237	200	± 300	± 330	± 414

3 NUMERICAL MODELLING

The numerical model of the superstructure has been implemented in (OpenSEES 2006). A lumped plasticity approach has been considered for the structural elements of the superstructure, whereas elastic beams have been used for the base floor grid above the isolation system. The structural model also includes the staircase featuring inclined beams and cantilever steps. The cyclic degrading behaviour of plastic hinges (*modIMKmodel*) in the OpenSEES framework has been described implementing the model proposed by (Ibarra et al. 2005). In this study, 5% Rayleigh damping is used to model the viscous damping of the superstructure. Second order effects have not been considered. The masonry infills In-Plane (IP) behaviour has been modelled with an equivalent compression-only strut. The backbone curve of the diagonal strut has been defined on the basis of a modified version of the (Decanini et al. 2014) model, while the effect of openings has been taken into account through suitable strength/stiffness reduction factors. Both the Out-Of-Plane (OOP) and the IP/OOP interaction effects have been taken into account in the modelling strategy. Finally, local shear interactions, between masonry infills and adjacent RC columns, have been represented implementing shear springs at the ends of the columns to reproduce their nonlinear shear response triggered and amplified by the action of the adjacent equivalent compression-only diagonal. More information about superstructure modelling can be found in (Ricci et al. 2018).

Figure 4. Schematic representation of the base-isolated prototype building and b) IP/OOP infill panels model.

The basic *SingleFPBearing* element (Figure 5) in OpenSees (OpenSees 2006) has been implemented to describe the DCCSS cyclic behaviour composed of a zero-length sliding hinge. The basic model has been modified in order to simulate the DCCSS behaviour during the over-stroke displacement, by adding three zero length parallel elements from the top j -node to a new fixed k -node (Figure 5). Two of these three zero length parallel elements have been modelled as elastic-perfectly plastic gap elements (*elasticPPGap*) defined by a gap displacement d_c , an elastic stiffness k_2 , increased friction coefficient and a yielding force F_y , no hardening ratio or damage accumulation are considered so the gap material can recenter on load reversal. The last zero length element has been implemented considering a multi-linear elastic material (*elasticMultiLinear*), characterized by a nonlinear elastic behaviour without energy dissipation, defined by a set of stress-strain points.

The Rigid Gap has been modelled with a zero-length hinge, from j -node to s -node of Figure 5, consisting of an elastic-perfectly plastic gap element (*elasticPPGap*) with infinite stiffness ($k=\infty$) and at a gap displacement of d_c for models of rings or d_{lim} for models of rigid moat walls.

The ultimate displacement d_{lim} threshold value considered in the over-stroke regime is linked to the attainment of the first of the following conditions (Di Cesare et al. 2022): (i) vertical load instability; (ii) the displacement exceeds a limit value related to the maximum contact pressure between sliding interfaces (60 MPa) (iii) the device undergoes more than two over-stroke cycles. Plastic deformations of the end-stroke models, as example due to moat wall nonlinearity, were not taken into account. More details about numerical modelling of DCCSS in overstroke regime can be found in (Di Cesare et al. 2020, Ponzo et al. 2020, Di Cesare & Ponzo 2023).

4 NON-LINEAR STATIC AND DYNAMIC ANALYSES RESULTS

Nonlinear analyses have been performed considering different conditions of the isolation system. The seismic performance of the isolated structure and isolation system was evaluated by comparing the results of nonlinear static analysis (Pushover) in both horizontal directions with those of nonlinear dynamic analysis. A distribution of lateral forces proportional to the floor masses was used in the pushover analyses. In Figure 6 the pushover curves of not-isolated, base-isolated building, without and with overstroke and without and with rigid end-stop are compared. Pushover curves of base-isolated building model without displacement restraints (black dashed lines) show the basic behaviour of the isolation system, with a first quasi-rigid branch (pre-sliding stage), followed by a second branch accounting for isolators restoring stiffness. The isolated model with displacement restraints highlights a pushover behaviour of the not-isolated superstructure for displacement greater than the base displacement capacity d_c . In particular, as can be observed in Figure 6, for the configuration with isolation system and stop, after the pre-sliding stage and the second branch accounting for isolators restoring stiffness, the isolation system stops when the base displacement reaches d_c and superstructure pushover curve is shown again. The system with isolation system, over-stroke and stop perfectly overlaps the previous one for the first two branches, then, when the geometric capacity displacement is reached, the isolation system enters in the over-stroke regime with a third branch with increased stiffness friction force, and finally, when the end-over-stroke is reached (end of sliding), the superstructure pushover curve is shown again. It is possible to observe that the shape of the first part of the pushover curve of isolated structures can be approximated by an elastoplastic hardening behavior.

In order to evaluate the behaviour of the isolation system with and without rigid end-stop, the seismic response of base-isolated model has been investigated by means of multi-stripe nonlinear time-history analyses considering 20 real ground motions at intensity level corresponding to the collapse limit state and compared with pushover curves. The seismic input consisted of bi-directional horizontal ground motions time histories. In Figure 7 nonlinear dynamic results are expressed in terms of the acceleration displacement response spectrum, considering the maximum superstructure top displacement vs ratio between maximum base shear and total seismic weight. The dynamic results are in good agreement with the pushover curves both in sliding stage and in over-stroke stage. It is worth noting that the over-stroke regime has been reached

Figure 6. Pushover curves of not-isolated building and isolated with and without overstroke and with and without end-stop for horizontal directions.

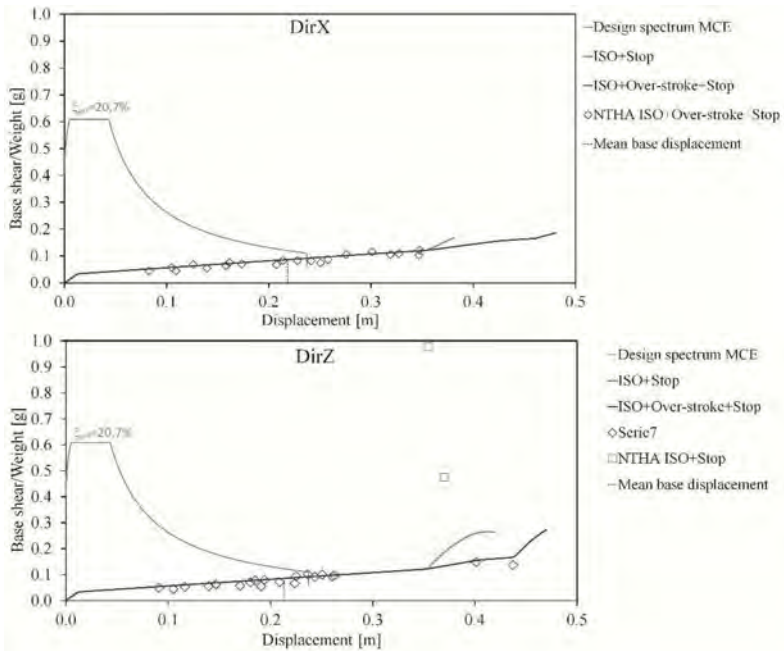

Figure 7. Nonlinear static versus nonlinear dynamic results in terms of maximum top displacement and acceleration at the base level for horizontal directions.

for two earthquakes of the spectra-compatible inputs, mainly due to the variability of the selected ground motion. For the same seismic inputs in the configuration with isolation system and rigid end-stop in the case of impact between the superstructure and the end stop dynamic analyses provide values of the base shear significantly higher than those obtained from the push-over curves, due to the dynamic effects. Figure 7 also reports the mean values of maximum base displacements and the design MCE spectrum (see Figure 3b). The mean base displacement is slightly lower than the design displacement d_{Ed} .

5 CONCLUSIONS

In this paper a case study of a seismically isolated RC frame structure with DCCSS in high seismic zone was numerically investigated based on non-linear static and dynamic analyses. Coherently with commercially available DCCSS devices, the oversizing due to industrial discretization and the over-stroke displacement capacity of the bearings before reaching the end-stroke were considered. For the case of base isolation with overstroke, characterized by a ratio between the overstroke displacement d_{lim} and actual isolator displacement capacity d_c (d_{lim}/d_c) equal to 1.25, and by a ratio between d_c and the design displacement d_{Ed} (d_c/d_{Ed}) equal to = 1.4, non-linear dynamic analyses showed that the impacts against the end-stop are avoided in all seismic inputs spectra-compatible with the MCE. In all cases, the design displacement evaluated by equivalent static analysis and the mean value of maximum base displacement evaluated by nonlinear dynamic analysis are in good agreement.

Results from nonlinear static analysis and nonlinear time history analysis pointed out that over-stroke displacement of the isolators may significantly increase the safety factor in case of earthquakes bigger than the design ones, without drawing on the plastic resources of the superstructure and changing the construction costs. Further analyses are currently underway considering different case studies of retrofitted RC frame.

ABSTRACT: The study investigates the modification in the friction coefficient of a Curved Surface Slider (CSS) due to service movements through complementary tests performed on a small-scale specimen of the sliding material and a full-scale prototype, both of them subjected to a sliding distance of 1000 m. The changes in the coefficient of friction vs. the sliding distance are compared, demonstrating that small-scale tests provide fair estimates of the friction properties of the full-scale CSS. Moreover, the seismic response of the CSS remains almost the same regardless of the sliding distance.

1 INTRODUCTION

Sliding isolation system with curved surfaces, also known as Friction Pendulum System®, or FPS® (Zayas et al. 1987, 1990, Mokha et al. 1991) in North America, and Curved Surface Sliders (CSS) in Europe, are among the most popular antiseismic hardware nowadays (Calvi & Calvi 2018). Such system accommodates the horizontal displacements of the superstructure by means of one or more pair(s) of curved sliding surfaces, which also provide a restoring force due to the effect of gravity, and dissipate the seismic energy through friction forces that are activated during sliding (Quaglini et al. 2017a, 2017b). In bridges and viaducts, the CSS behaves throughout its service life as a conventional sliding bearing, accommodating the low velocity movements induced from temperature changes and traffic loads. On the other hand, in the event of an earthquake, the CSS provides the seismic displacement, which generally occur at high speeds, on the order of some hundred mm/s.

The sliding surfaces of the isolators usually consist of a pad made of a self-lubricating polymeric material and a mating concave surface made of stainless steel or plated with hard chromium. Since the introduction of the Pendulum system in the '80s of the last century (Zayas et al. 1987), a number of self-lubricating polymeric materials have been proposed, including filled polytetrafluoroethylene (PTFE) (Zayas et al. 1990, Quaglini 2012), polyethylene (PE) and polyamide (PA) (Barone et al. 2019). A viable sliding material for CSSs must fit different requirements regarding the expected performance in both service and seismic situations, providing high load bearing capacity combined with wear endurance, low coefficient of friction at low speeds in order not to constrain service movements, and stable coefficient of friction at high speeds.

Current standards (CEN 2009, AASHTO 2020, ASCE/SEI 2017) recommend to perform displacement controlled dynamic tests on full scale prototypes of the isolators to assess the friction coefficient under seismic loading. The number of cycles in these tests is generally three for most of the loading conditions. However, since prototype tests are generally performed on

new devices, the influence of the wear of the sliding surfaces on the high-speed coefficient of friction is disregarded. Nevertheless, such wear may be not negligible in the event that the earthquake hits the isolated structure after several years of service of the isolators. On the other hand, the friction coefficient for slow and small amplitude service motions is assessed by performing cyclic tests on small-scale samples of the sliding material, considering in this case large accumulated sliding distances, up to 1000 m for buildings, and 10000 m for bridges (CEN 2009), and including also changes in the environmental temperature.

The reliability of small-scale tests for the characterization of sliding materials has been extensively debated among tribologists. In conventional tribotesting, small-scale tests performed on unidirectional rotating pin-on-disc, block-on-ring or reciprocating cylinder-on-plate test rigs are mainly used because of their cost- and time-effectiveness and ease of handling small samples (Samyn et al. 2006). However, test conditions can strongly differ from real application, and scale effects are neglected, therefore making extrapolations towards the actual working conditions hard to make, and possibly leading to substantial errors.

This study investigates the modification of the friction coefficient of a sliding isolator due to service movements through complementary investigations performed on both small-scale specimens of the sliding material and a full-scale double concave friction pendulum (DCFP). Both small- and large-scale specimens are subjected to a total sliding distance of 1000 m, and the change in the coefficient of friction vs. the sliding distance obtained in the two tests are compared. Moreover, the coefficient of friction of the DCFP at different sliding distances is evaluated experimentally under the effect of ground motion excitations.

2 MATERIALS & METHODS

2.1 *Small-scale tests*

The small-scale tests were performed at the Material Testing Laboratory of Politecnico di Milano following the method provided in the European standard on antiseismic devices EN 15129 (CEN 2009).

The specimen consists of a circular pad made of a proprietary slider material consisting of filled PTFE, combined with a mating surface made of stainless-steel mirror finished to roughness $R_z \leq 1 \mu\text{m}$, to replivate the same sliding interface used in the DCFP. The pad has a diameter of 75 mm and a thickness of 7 mm, and is recessed by 4.5 mm into a steel plate, leaving a sliding gap of 2.5 mm.

The specimen is placed in a custom testing machine at Politecnico di Milano (Quaglini et al. 2012). The machine consists of a four-column steel frame equipped with two servo-hydraulic jacks aligned at 90 degrees to each other (Figure 1). The vertical jack, rated 300 kN, applies a compression force to the specimen producing the target contact pressure on the sliding interface. The horizontal jack, rated 50 kN, drives a sledge that carries the sliding material pad. The stainless-steel mating plate is screwed to a backing plate fixed to the rod of the vertical jack. Load cells and inductive displacement transducers are used to measure the loads and the movements applied to the sliding material pad. The whole specimen is enclosed in a thermal chamber operating between $-70 \text{ }^\circ\text{C}$ and $90 \text{ }^\circ\text{C}$. A digital controller coupled with a thermal sensor allows to control the temperature within the chamber within a tolerance of $\pm 1 \text{ }^\circ\text{C}$.

The tests are performed in accordance with the long term friction test method prescribed in the standard (CEN 2009), modified to extend the maximum temperature to $+70 \text{ }^\circ\text{C}$. The sliding material pad is subjected to the application of axial load and concurrent back-and-forth sliding motion in horizontal direction. The test program consists of 3 phases as shown in Table 1 and Figure 2. In phase 1 the temperature is varied between $-35 \text{ }^\circ\text{C}$ and $+70 \text{ }^\circ\text{C}$ and the static and dynamic coefficients of friction are assessed at the velocity of 0.4 mm/s. Phase 2 is performed at $21 \text{ }^\circ\text{C}$ and at the velocity of 2 mm/s over a total sliding distance of 1000 m. The aim of this phase is to wear the sliding surfaces of the pad and the stainless steel sheet. Then, in phase 3 the coefficient of friction is assessed again at the various temperatures.

Figure 1. Testing machine for small-scale friction tests.

Table 1. Long term friction test program.

Phase Number	1	2	3
pressure on sliding material pad	45 MPa	45 MPa	45 MPa
temperature	-35 ... +70 °C	+21 °C	-35 ... +70 °C
velocity	$0.4_0^{+0.5}$ mm/s	2 ($\pm 0,1$)	$0.4_0^{+0.5}$ mm/s
distance (per phase)	30 m	1000 m	30 m

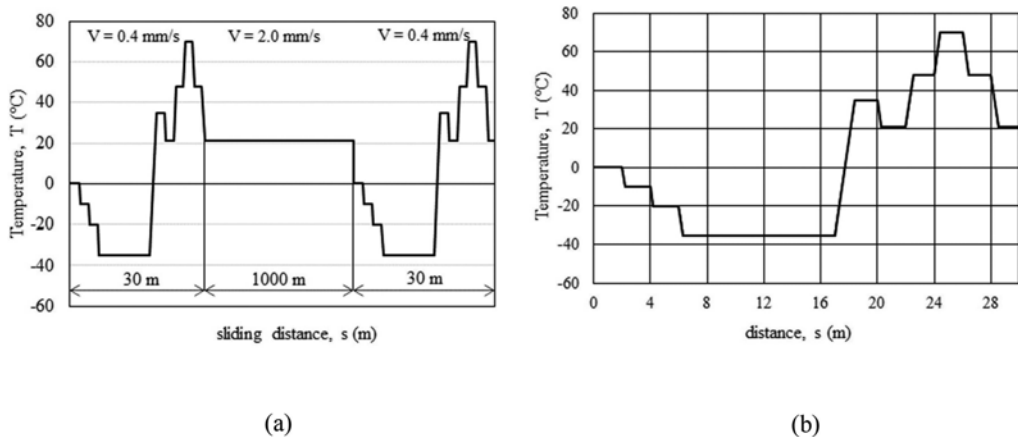

Figure 2. (a) Temperature profile vs. accumulated sliding distance in the long term friction test; (b) detail of temperature profile in phases 1 and 3.

2.2 Full-scale tests

Full-scale tests were performed at the ESQUAKE Seismic Isolator Test Laboratory of Eskişehir Technical University on a double concave friction pendulum (DCFP).

The specimen consists of a convex slider between two concave plates as shown in Figure 3(a), having two curved sliding surfaces with radius of curvature of 1800 mm each. Figure 3(b) shows the tested DCFP and its main dimensions. The equivalent radius of curvature is 2500 mm and the displacement capacity is 300 mm in any direction.

The test set-up is represented in Figure 4. The system is capable of applying force and displacement controlled dynamic motions in both horizontal and vertical directions. The maximum loading capacities are 2000 kN and 20000 kN in horizontal and vertical

directions, respectively. In the horizontal direction, the maximum stroke is ± 600 mm and the maximum loading velocity is 1000 mm/s.

Figure 3. (a) Picture of the tested DCFP, (b) geometrical properties (dimensions in mm).

The DCFP is subjected to cyclic displacements with amplitude of 70 mm. The imposed velocity is 5 mm/s and the accumulated sliding distance was 1000 m. The vertical force applied to the DCFP is 3500 kN corresponding to an average normal stress on the sliding pads of 57 MPa. The test program is composed of 20 phases of 50 m each, with a dwell period of at least 40 minutes between two consecutive phases. After accumulated distances of 250, 500, 750 and 1000 m the DCFP is subjected to scaled down displacement histories of the strong motion component of Kocaeli Yarimca record (Figure 5), scaled by factors of 0.2, 0.3, 0.4 and 0.5 which correspond to maximum displacements of 100, 150, 200 and 250 mm, respectively. The displacement histories are applied to the DCFP in order of increasing amplitude with a 15 minutes of dwell time between two consecutive tests.

The ambient temperature at the laboratory was 21.3 °C at the beginning of the cyclic motion and varied between 21.1 °C and 27.1 °C throughout the whole test.

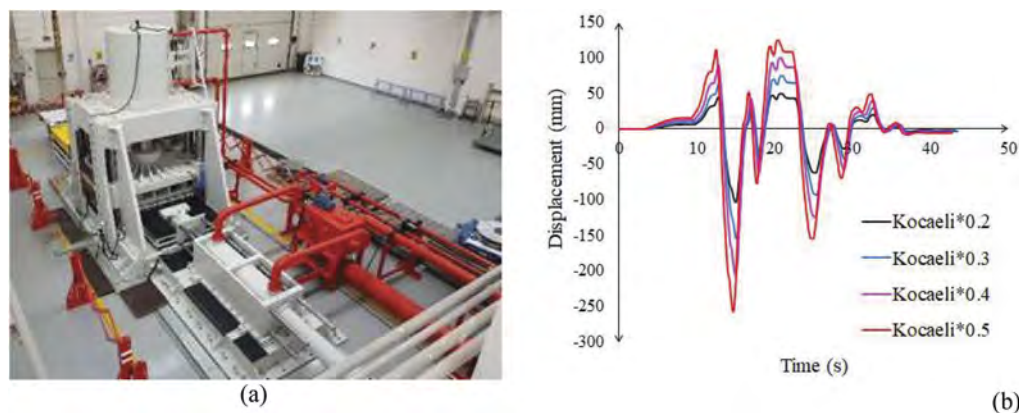

Figure 4. (a) Seismic isolator test set-up at ESQUAKE Seismic Isolator Test Laboratory; (b) displacement histories applied to simulate the seismic loading on the DCFP.

3 RESULTS

3.1 Small-scale tests

Figure 5 reports the maximum values of the static and dynamic low-velocity coefficient of friction at the relevant test temperatures, labelled as $\mu_{st}(T)$ and $\mu_{dyn}(T)$ respectively, measured in small-scale tests at the beginning of the test and after an accumulated sliding distance of 1000 m.

The coefficient of friction of the virgin material is about 7% at $T = +21^{\circ}\text{C}$, and undergoes significant variations with temperature changes: $\mu_{st}(T)$ and $\mu_{dyn}(T)$ vary from 2.1% at $T = +70^{\circ}\text{C}$ to about 16% at $T = -35^{\circ}\text{C}$. The rate of the friction coefficient vs. temperature has a steep increase below 0°C , switching from $0.073\% \text{ }^{\circ}\text{C}^{-1}$ in the range between 0°C and $+70^{\circ}\text{C}$, to $0.287\% \text{ }^{\circ}\text{C}^{-1}$ in the range between 0°C and -35°C . On the other hand, the sliding distance has a weak effect on the low-velocity coefficient of friction, which exhibits just a small growth at the end of the 1000 m path in comparison to the values assessed at the beginning of the test: the increase is less than 0.5% at every temperature but for 0°C where the variation is about +1.2%.

It is also worth noting that at each temperature the values of $\mu_{st}(T)$ and $\mu_{dyn}(T)$ are very close to each other. This behavior, which is possibly due to the fillers embedded in the sliding material, prevents the occurrence of the sticking phenomenon that affects the performance of CSS isolators characterized by a high ratio of static to dynamic friction coefficient in case of weak or moderate ground motions (Gandelli et al 2020; Gandelli & Quaglini 2020; Gandelli et al. 2019).

Figure 5. Coefficients of friction assessed in small-scale tests on the virgin specimen ($S_x = 0\text{ m}$) and after the accumulated sliding distance of 1000 m ($S_x = 1000\text{ m}$) at various temperatures: (a) static coefficient of friction, (b) dynamic coefficient of friction.

3.2 Full-scale tests

Figure 6 shows the coefficient of friction μ of the DCFP against the accumulated sliding distance observed in the full-scale test at 5 mm/s. In each test phase (of 50 m sliding distance), the coefficient of friction gradually decreases as the travelled distance increases, tending to a steady value at the end of the phase. On the other hand, at the very beginning of each phase, the friction coefficient shows a larger value than the one recorded at the end of the previous phase. The behavior is ascribed to two mechanisms: the heating of the sliding surfaces during sustained motion promotes a decrease in μ , while the cooling down of the sliding surfaces during the dwell time between two consecutive phases promotes the contrary effect (Quaglini et al. 2014, Cavdar & Ozdemir 2021, Cavdar et al. 2022). Considering the maximum value of μ (which must be considered for calculating the design force for the sizing of the anchorages of the isolator and of the adjacent elements), the low-velocity coefficient of friction of the DCFP decreases from 5.4% at 0 m to 4.8% after 1000 m, and achieves a peak of 5.6% at a distance of 600 m.

Eventually Figure 8 reports the increase in the maximum isolator force measured during the earthquake simulations performed at various sliding distances, normalized to the maximum isolator force at the beginning of the test. As a general trend, the isolator force

Figure 6. Coefficient of friction of DCFP at $v = 5 \text{ mm/s}$.

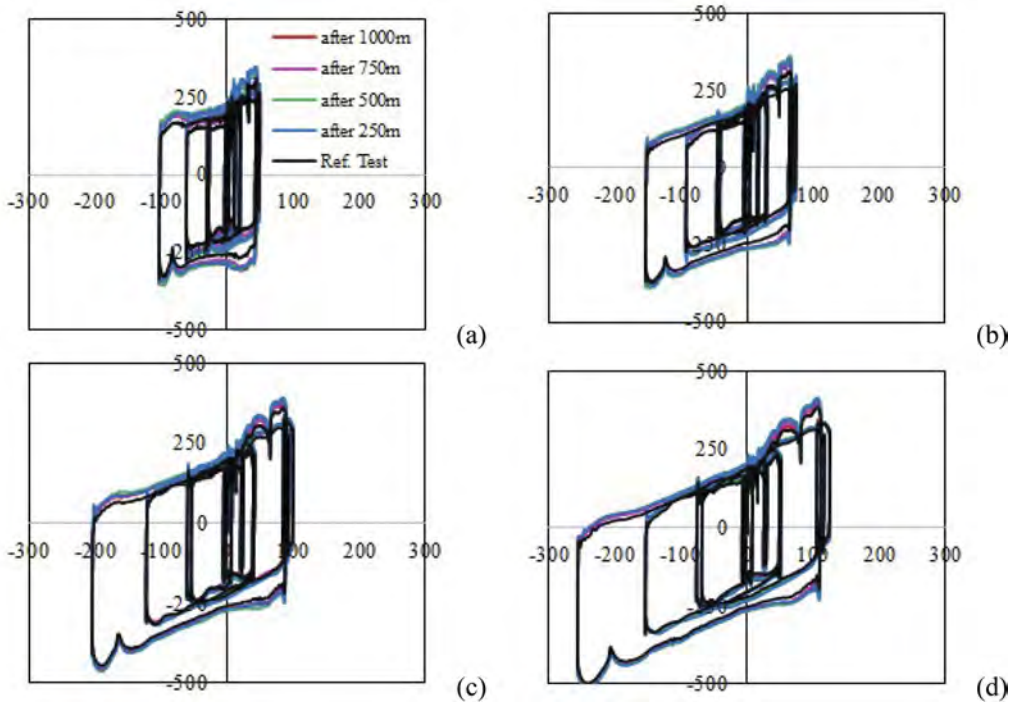

Figure 7. Force-displacement curves of DCFP obtained from ground motion excitations using modified displacement histories of Kocaeli Yarımca record by scale factors of: (a) 0.2, (b) 0.3, (c) 0.4 and (d) 0.5.

increases up to a distance of 500 m, and then it decreases as the travelled distance has a further increase. Only under the maximum amplification of the displacement history (by a 0.5 scale factor) the maximum increase is observed at 250 m, followed by a steady decrease at longer paths. In general, the stronger the seismic excitation, the lower is the effect of the sliding distance. However, it must be underlined that considering a different displacement history (i.e. with large number of cycles having large amplitude or with large number of small-amplitude cycles prior to large amplitude motion) in the tests of DCFP may lead to different results, as such a variation in the loading may affect the heating of the sliding interface and the corresponding hysteresis loops will be different from those presented in Figure 7.

Figure 8. Increase of maximum force of DCFP under ground motion excitations.

4 CONCLUSIONS

According to current practice, small-scale tests on sliding material samples are aimed at estimating the coefficient of friction activated during service movements that generally occur at low velocity, in order to derive design values for non-seismic conditions. On the other hand, full scale tests are performed to assess the coefficient of friction at high speeds during seismic movements, relevant to earthquake conditions. In the present study, full-scale tests are performed to investigate the effect of the sliding distance both the low-velocity and high-velocity coefficients of friction of a real isolator, considering a sliding distance of 1000 m. Additionally, a sample of the sliding material is subjected to a long term friction test over the same distance in order to evaluate the consistency with large-scale results.

Both small- and large-scale tests show that, for the examined slider material, the effect of the accumulated sliding distance, and the associated wearing of the sliding surface, on the coefficient of friction at low velocity is small. Small-scale tests highlight an increase of both μ_{st} and μ_{dyn} less than 0.5% after 1000 m, and in particular at +21 °C μ_{st} increases from 4.5% to 4.7%. Large-scale tests show a slight decrease of the coefficient of friction μ of the DCFP; however the value $\mu = 4.8\%$ measured at 1000 m matches the equivalent coefficient of friction of the DCFP $\mu_{st} = 4.7\%$.

Force-displacement curves of the tested DCFP obtained for dynamic loadings, simulating different seismicity levels, provide the confirmation that accumulated sliding distance has a negligible effect also on the hysteresis loop and the friction behavior of DCFP under seismic loading.

To the knowledge of the Authors, this is the first experimental study investigating the effect of wear on the coefficient of friction of full scale sliding isolators. However, it must be emphasized that the results presented in the paper concern the particular sliding material examined in the study, and other sliding materials may undergo a different effect of wear. A proper investigation is therefore required before extrapolating the conclusions of this work to other materials.

Effects of rubber shear modulus variability on the seismic response of isolated bridges

M. Marra & S. Silvestri

University of Bologna, Bologna, Italy

ABSTRACT: The mechanical behavior of bridge decks equipped with High Damping Rubber Bearings is strongly affected by the rubber shear modulus that governs their lateral stiffness. It is a random variable, which can be described by a normal distribution.

In this paper, the effects of the variability of the shear modulus are investigated in terms of displacements for both the isolators and the piers, with reference to a case-study RC bridge with continuous caisson deck over four spans. The bridge is modelled with minimal systems with a reduced number of degrees of freedom along the longitudinal and transversal directions. Linear time-history analyses have been carried out using 7 natural seismic records, by considering 10,000 samples for the shear modulus fitting the chosen distribution. A statistical analysis has been then developed on the numerical results in order to obtain percentile values. Finally, Upper and Lower Bounds are identified for design purposes.

1 INTRODUCTION

The dynamic and seismic behaviour of bridges is governed by the connection system (“bearings layout”) between the superstructure (deck) and the substructures (piers and abutments). Among all possible traditional and innovative solutions (Tubaldi et al. 2015, Silvestri et al. 2019), nowadays the seismic isolation (Naeim & Kelly 1999, Franchin et al. 2001) of the bridge deck with respect to the substructures is widely used for both the seismic design of new bridges and the seismic retrofit of existing ones. Even though in the last years the adoption of Curved Surface Sliders is fast increasing (Furinghetti 2022), High Damping Rubber Bearings (HDRBs) still represent a viable choice (De Luca & Guidi 2019). Design of HDRB isolation system is typically conducted by practitioners assuming a deterministic value of the shear modulus of the rubber material of the HDRB devices (Furinghetti 2022). However, it is a random variable with a non-negligible coefficient of variation, that can be reasonably described by a Gaussian distribution, as highlighted by the analysis of the results of several experimental campaigns carried out for commercial orders at various laboratories (Furinghetti & Pavese 2019). The objective of this paper is to investigate the effects, in terms of displacements, of the variability of the shear modulus of the rubber material of HDRBs and to eventually provide coefficients, to be applied to the displacement response parameter values obtained using the mean value of the shear modulus, for the estimation of Upper and Lower Bound coefficients, for design purposes.

2 THE CASE-STUDY BRIDGE

The considered bridge is characterised by a continuous deck over four equal spans, for a total length $L = 180$ m. The three piers are characterised by different heights, equal to 8 m, 20 m and 10 m (Figure 1). The configuration is thus symmetric with reference to the longitudinal direction, while it is slightly eccentric with reference to the transversal direction. The RC caisson deck is 11.50 m wide and 0.50 m thick (Figure 2a), whilst the RC piers have a squared cellular cross-section with side length equal to 1.75 m and thickness equal to 0.30 m (Figure 2b). On the

top of the piers there are RC prismatic transversal elements with a rectangular cross-section of 2.00 m x 1.90 m and a length of 6.40 m, which provide the support base for the isolators. There are two isolators for each pier and for the two abutments, for a total number of ten isolators. Concrete class is C40/50. The bridge is supposed to be located in L'Aquila, Italy. The weight of the RC structural elements is 37723 kN, whilst the weight of the non structural elements (slope screed and bituminous layers, such as waterproofing, binder and wear layer) is 10624 kN. Consequently, the total dead load of the bridge is 48347 kN.

Figure 2. (a) Cross-section of the RC cassoin deck and pier top. (b) Cross-section of the three RC piers.

3 MODELLING OF THE ISOLATED BRIDGE

Different models are possible for the isolated bridge depending on the objective of the analysis: (i) a Single-Degree-Of-Freedom (SDOF) idealisation, representing the deck mass connected through the lateral stiffness of the isolation system to the substructures (assumed as fixed); (ii) minimal systems, that describe the behaviour of the deck and the piers by means of a reduced number of degrees of freedom (Silvestri et al. 2019); (iii) Finite Element models, that describe the bridge behaviour by means of several nodes and beam and/or shell elements.

The first one is usually sufficient for the dimensioning of the isolation system. The second one allows to perform time-history analyses with lower computational effort than the third one.

In the minimal systems, the masses that define the degrees of freedom in the equations of motion are the mass of the deck and the masses of each half pier (the remaining parts are assumed to be directly transferred to the ground base). Figure 3 shows the minimal systems used for the evaluation of the seismic response of the bridge along the two directions (u referring to longitudinal displacements; v referring to transversal displacements):

- along the (symmetric) longitudinal direction, the minimal system is composed of four degrees of freedom: the displacement of the deck (u_{deck}) and the three displacements of the top of the piers (u_{pier1} , u_{pier2} , u_{pier3});
- along the (slightly eccentric) transversal direction, the minimal system is composed of five degrees of freedom: the displacement of the deck (v_{deck}), the three displacements of the top of the piers (v_{pier1} , v_{pier2} , v_{pier3}), and the in-plane rotation of the deck (φ_{deck}).

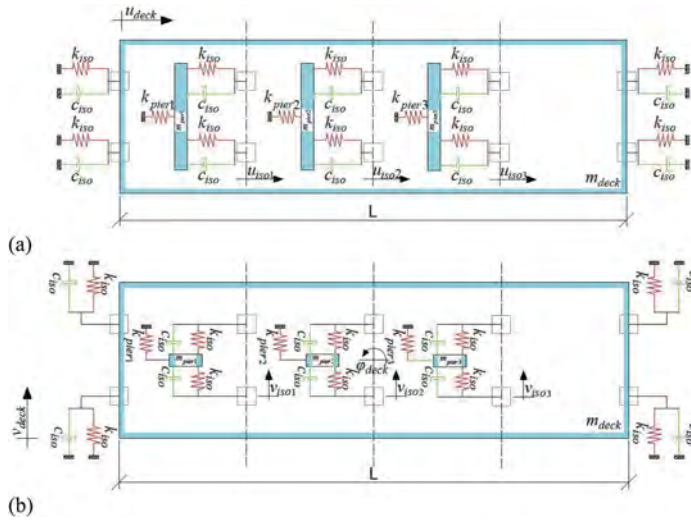

Figure 3. Minimal systems: (a) along the longitudinal direction and (b) along the transversal direction.

4 SEISMIC INPUT

The pseudo-acceleration elastic response spectrum of the horizontal component of the earthquake input is reported in Figure 4. Peak ground acceleration is equal to 0.459g. The maximum (plateau) spectral acceleration is equal to 1.103g. To perform time-history analyses seven natural earthquakes have been chosen in such a way as to result compatible with the 5% damped elastic spectrum.

Figure 4. Horizontal elastic spectrum and spectra of the seven natural seismic records.

5 PROCEDURE ADOPTED FOR THE IDENTIFICATION OF THE HDRB ISOLATORS

The isolation system (to be placed between the deck and the substructures) has been pre-identified according to a simplified procedure based on the SDOF idealization, in which the degree of freedom is represented by the horizontal displacement of the deck. The SDOF model consists of the mass of the deck (m_{deck}) concentrated at the deck level. The stiffness ($k_{iso,tot}$) and the damping coefficient ($c_{iso,tot}$) are provided by the isolation system, which is made of ten devices. Since they work in a parallel system, the values of the stiffness and the damping coefficient of the equivalent SDOF model are given by the sum of the stiffness values and the damping coefficient values of the ten isolators, respectively.

The simplified procedure is based on the following hypotheses: (i) the deck is rigid in both horizontal (longitudinal and transversal) directions, (ii) the piers are rigid in the vertical (axial) direction, (iii) the target lateral deformation γ_{iso} of the isolator is imposed to be equal to the height h_{iso} of the isolator itself (i.e. shear deformation $\gamma_{iso} = d_{iso}/h_{iso}$ equal to 100%, where d_{iso} is the displacement of the isolator), (iv) the shear modulus of the rubber material that governs the lateral stiffness of the isolator is assumed in the range 0.7-1.0 MPa (this corresponds to a normal rubber and

to a damping ratio ζ_{iso} of the isolation system around 10%), (v) the total damping coefficient provided by the isolation system is evaluated as: $c_{iso,tot} = 2 \cdot m_{deck} \cdot \omega_{iso} \cdot \zeta_{iso}$ (where ω_{iso} is the fundamental circular frequency of the isolated bridge and ζ_{iso} is the damping ratio), (vi) the isolators have radial symmetry (i.e. the procedure keeps its validity along the two horizontal directions). The procedure is summarized in the following steps:

1. Choice of the target period T_{iso} for the isolated bridge, typically in the range 2.5-3.5 s.
2. Evaluation of the spectral acceleration corresponding to the target period: $S_a(T_{iso})$. Note that it has to be evaluated on the 10%-damped elastic spectrum since an isolation system usually provides a damping ratio ζ_{iso} of around 10%.
3. Evaluation of the spectral displacement:

$$S_d(T_{iso}) = S_a(T_{iso}) / \omega_{iso}^2 = S_a(T_{iso}) \cdot (T_{iso} / 2\pi)^2 \quad (1)$$

Then, assuming that $\gamma_{iso} = d_{iso} / h_{iso} = 100\%$ leads to:

$$h_{iso} = d_{iso} = S_d(T_{iso}) \quad (2)$$

4. Choice of the diameter of the isolators in order to avoid instability phenomena. The ratio between diameter D_{iso} and height h_{iso} should be larger than 2.0 (Furinghetti & Pavese 2019, Furinghetti 2022). Therefore a typical relationship is:

$$D_{iso} = 2.5 \cdot h_{iso} \quad (3)$$

5. Calculation of the lateral stiffness of each single isolator k_{iso} , assuming that all isolators are equal to each other:

$$k_{iso} = \frac{m_{deck} \cdot \omega_{iso}^2}{n_{iso}} \quad (4)$$

where n_{iso} is the total number of isolators.

6. Check that the shear modulus G falls within the assumed range (0.7-1.0 MPa):

$$G = \frac{4 \cdot k_{iso} \cdot \chi_V \cdot h_{iso}}{\pi \cdot D_{iso}^2} \quad (5)$$

where χ_V represents the shear shape factor.

If the hypothesis is not satisfied, then G is taken equal to 1.0 MPa and the diameter of the isolator is calculated as:

$$D_{iso} = 2 \cdot \sqrt{\frac{k_{iso} \cdot \chi_V \cdot h_{iso}}{\pi \cdot G(=1\text{MPa})}} \quad (6)$$

7. Check that the isolator shear displacement roughly respects the assumption $\gamma_{iso} = d_{iso} / h_{iso} = 100\%$ (made in Step 3).
8. Evaluation of the maximum vertical axial force on the isolators. They have to carry out the function of support during the entire life of the bridge both in static conditions, with reference to the Ultimate Limit State (ULS), and in seismic conditions, with reference to the Collapse Limit State (CLS). The axial force can be evaluated either according to tributary areas afferent to each isolator or by means of a numerical model.
9. Check that the isolators satisfy the two conditions: in terms of target lateral stiffness k_{iso} (Steps 1-7) and in terms of axial force capacity (Step 8). If this latter is not satisfied, then the geometric characteristics of the isolators should be updated.

The procedure has been applied to the case-study bridge. The following data have been adopted: the elastic spectrum represented in Figure 4 reduced to account for a damping ratio of 10%, $m_{deck} = 4717$ t, $T_{iso} = 3.25$ s, $n_{iso} = 10$. The following outcomes have been obtained: $h_{iso} = 420$ mm, $D_{iso} = 1040$ mm, $k_{iso} = 1.756$ kN/mm, $G = 0.94$ MPa, $c_{iso} = 167$ kN m/s. However, the isolator obtained following Steps 1-7 does not satisfy the axial force capacity condition (Step 8). Therefore, the geometric characteristics have been slightly changed to meet this condition (the height has been reduced). The following final properties for each single isolator have been thus identified: $h_{iso} = 326$ mm, $D_{iso} =$

1000 mm, $k_{iso} = 2.99$ kN/mm, $G = 0.8$ MPa, $c_{iso} = 202$ kN m/s, leading to $T_{iso} = 2.50$ s for the SDOF idealisation, to $T_{iso} = 2.78$ s for the minimal system along the longitudinal direction (roughly including the flexibility of the three piers), and to $T_{iso} = 2.92$ s for the more refined FE model (also including the flexibility of the deck and a better representation of the piers behaviour).

6 ANALYSES PERFORMED

The effects of the aleatory variability in the shear modulus G of the rubber material of the HDRB isolators have been investigated by means of time-history dynamic analyses carried out using the minimal systems detailed in Section 3 and the seven seismic records described in Section 4. The isolators identified in Section 5 are constituted by rubber layers with mean shear modulus G equal to 0.8 MPa and equivalent viscous damping ratio of around 10%. Consequently, G is assumed as a random variable characterized by a normal distribution with mean value equal to 0.8 MPa and coefficient of variation equal to 14.5% (as per the results of experimental campaigns carried out for commercial orders at various laboratories, see Furinghetti & Pavese 2019). The following assumptions have been made:

- The shear modulus is the parameter that mainly governs the mechanical behaviour of the isolator device.
- A linear relationship is assumed between the rubber shear modulus G and the horizontal stiffness k_{iso} of the isolator device:

$$G = \left(\frac{4 \cdot \chi_V \cdot h_{iso}}{\pi \cdot D_{iso}^2} \right) \cdot k_{iso} \quad (7)$$

where the geometric parameters of the isolator have been considered as deterministic.

- The variability of the shear modulus has been taken into account by acting directly on the mean horizontal stiffness of the isolator device ($k_{iso,mean} = 2.99$ kN/mm corresponding to a mean shear modulus equal to 0.8 MPa) by means of an adimensional factor g , for which a normal distribution has been assumed:

$$k_{iso} = g \cdot k_{iso,mean} \quad (8)$$

$$g = N(\mu = 1, \sigma = \text{cov} = 0.145) \quad (9)$$

- A number of 10,000 realizations of the normal random variable corresponding to multiplication factor g have been randomly generated and seven time-history simulations have been carried out (with the seven seismic records) for each realisation.
- The damping coefficient of the isolator devices has been updated for each realisation adopting the equivalent SDOF model and assuming a damping ratio equal to $\xi_{iso} = 10\%$:

$$c_{iso} = \frac{2 \cdot \xi_{iso} \cdot \omega_{iso} \cdot m_{deck}}{n_{iso}} \quad (10)$$

- The same damping coefficient c_{iso} has been assumed in both longitudinal and transversal directions.

Figure 5. Histogram of the relative frequencies of the sample of the 10,000 realizations of factor g .

Figure 5 shows the histogram of the relative frequencies of the sample of the randomly generated 10,000 realizations, which have mean value equal to 1 and coefficient of variation equal to 14.4% (compared to the 14.5% target).

To sum up, a total number of 140,000 numerical simulations have been performed:

- 70,000 analyses along the longitudinal direction, conducted on 10,000 minimal models with 4 DOFs assuming the 7 natural accelerograms as input.
- 70,000 analyses along the transversal direction, conducted on 10,000 minimal models with 5 DOFs assuming the 7 natural accelerograms as input.

7 RESULTS OBTAINED

The results are expressed in terms of *mean displacement* of each degree of freedom of the two minimal systems along the two directions. For each direction, it is evaluated as the mean of the seven maximum values of the displacement obtained during the seven accelerograms. With reference to the nomenclature introduced in Figure 3, the attention has been paid on the following displacements:

- $u_{isoAB} = u_{deck}$ and $v_{isoAB} = v_{deck}$ are the displacements sustained by the isolators on the abutments that coincide with the displacements of the deck with respect to the abutment;
- $u_{iso1} = u_{deck} - u_{pier1}$ and $v_{iso1} = v_{deck} - v_{pier1}$ are the longitudinal and transversal displacements sustained by the isolators on pier 1 that coincide with the relative displacements of the deck with respect to the top of pier 1;
- $u_{iso2} = u_{deck} - u_{pier2}$ and $v_{iso2} = v_{deck} - v_{pier2}$ are the displacements sustained by the isolators on pier 2;
- $u_{iso3} = u_{deck} - u_{pier3}$ and $v_{iso3} = v_{deck} - v_{pier3}$ are the displacements sustained by the isolators on pier 3.

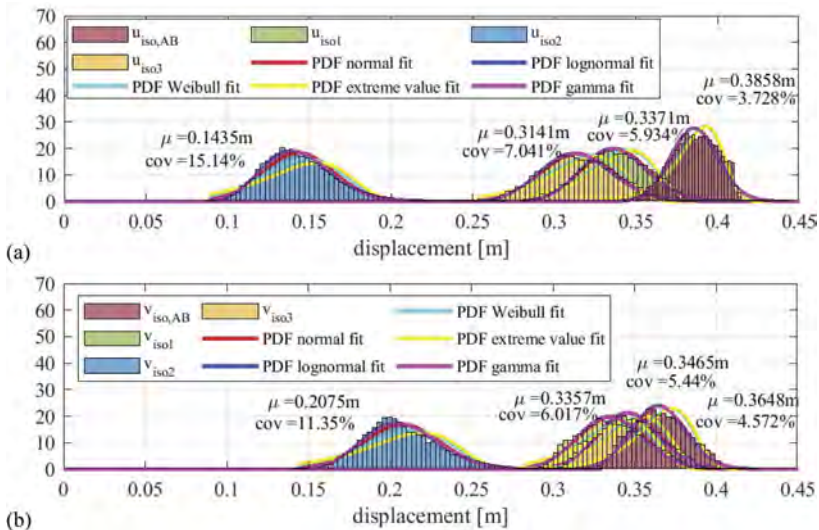

Figure 6. Results in terms of isolators displacements: (a) longitudinal direction, (b) transversal direction.

For each one of the above-mentioned displacements, a set of 10,000 *mean displacement* values (mean of the seven maximum values obtained for the seven accelerograms) are obtained. Each set is considered as a sample of a random variable whose distribution is unknown and has to be identified. A fitting has been then performed of the relative frequency histogram of each set of 10,000 values of the above-mentioned displacements with the Probability Density Function that better represents the set itself. The best fitting has been conducted by considering four well-known Probability Density Functions (PDFs): (i) Normal, (ii) LogNormal, (iii) Weibull, (iv) Extreme Values and (v) Gamma (Ang & Tang 2007). Figures 6a and b show an example of the results obtained in terms of isolators displacements, for the longitudinal and transversal directions, respectively. The

best fit has been evaluated by means of two statistical tests: (i) the Chi-Square test and (ii) the Kolmogorov-Smirnov test (Ang & Tang 2007).

On the basis of the results of the numerical simulations (or through their best fits), also the percentile values associated with selected percentages can be obtained. Then, from the values of the percentiles, it is possible to calculate the coefficients that allow considering the variability of the rubber shear modulus on the structural response of the bridge. These coefficients can be applied to the displacements of the isolators obtained considering the mean value of the rubber shear modulus. In fact, as it can be seen from Figure 6, the coefficient of variation that characterizes the variability of the shear modulus does not keep unaltered in the variability of the response parameters, i.e. of the displacements of the deck, of the top of the piers, and of the isolator devices. Therefore, starting from the theoretical probability functions for each response parameter these coefficients can be calculated according to: $c_{x\%} = \delta_{x\%} / \delta_{G_{mean}}$, where $\delta_{x\%}$ indicates the percentile of the displacement response parameter characterized by a probability of non-exceedance equal to $x\%$, and therefore by a probability of being exceeded equal to $1-x\%$, and $\delta_{G_{mean}}$ is the corresponding response parameter obtained considering the design mean value of the shear modulus G_{mean} . In this respect, Table 1 reports those coefficients for all the displacements, both in the longitudinal and transversal directions.

Table 1. Coefficients for taking into account the variability of the rubber.

DOF		C _{1%} (Lower Bound)	C _{5%}	C _{16%}	C _{50%}	C _{84%}	C _{95%}	C _{99%} (Upper Bound)
Longitudinal direction	u_{deck}	0.9132	0.9386	0.9629	1	1.0371	1.0612	1.0866
	u_{pier1}	0.7674	0.8535	0.9231	1.011	1.0769	1.1117	1.1447

	u_{isoAB}	0.9132	0.9386	0.9629	1	1.0371	1.0612	1.0866
	u_{iso1}	0.8621	0.9024	0.941	1	1.059	1.0976	1.1379
	u_{iso2}	0.699	0.7735	0.853	0.9889	1.147	1.2641	1.3993
	u_{iso3}	0.8364	0.8841	0.93	1	1.07	1.1159	1.164
Transversal direction	v_{deck}	0.8936	0.9268	0.9556	1	1.0463	1.0776	1.1064
	v_{pier1}	0.758	0.8493	0.9224	1.0137	1.0822	1.1233	1.1553
	v_{pier2}	0.9098	0.9358	0.9612	1	1.0388	1.0642	1.0909
	v_{pier3}	0.7633	0.8521	0.9231	1.0118	1.0799	1.1154	1.1479
	$\Delta v_{deck,max}$	0.717	0.8113	0.8868	1	1.1321	1.2264	1.3019
	v_{isoAB}	0.8936	0.9268	0.9556	1	1.0463	1.0776	1.1064
	v_{iso1}	0.8733	0.9105	0.9457	1	1.054	1.0837	1.1264
	v_{iso2}	0.7658	0.8265	0.8892	0.9937	1.1108	1.1947	1.2896
	v_{iso3}	0.868	0.9044	0.9404	0.9982	1.0599	1.1019	1.148

Starting from the values of these percentiles, for each structural element and for each isolator, the multiplicative coefficients have been calculated which, once applied to the result ($\delta_{G_{mean}}$) obtained assuming the mean design value of the rubber shear modulus, allow to immediately obtain the Upper Bound (here selected as the 99% percentile) and Lower Bound (1% percentile) values which take into account the variability of the rubber shear modulus: $\delta_{UpperBound} = c_{UB} \cdot \delta_{G_{mean}} = c_{99\%} \cdot \delta_{G_{mean}}$ and $\delta_{LowerBound} = c_{LB} \cdot \delta_{G_{mean}} = c_{1\%} \cdot \delta_{G_{mean}}$. Regarding the isolators displacements: (i) the Upper Bound coefficient increases as the flexibility of the underlying structural element (pile/abutment) increases; (ii) the Lower Bound coefficient decreases (and therefore deviates more and more from 1) as the flexibility of the structural element (pile/abutment) increases. Regarding the top piers displacements: (i) the Upper Bound coefficient decreases as the flexibility of the pile increases, with a trend qualitatively opposite to the coefficient for the displacement of the corresponding isolator; (ii) the Lower Bound coefficient increases (and therefore gets closer and closer to 1) as the flexibility of the pile increases, with a trend qualitatively opposite to the coefficient for the displacement of the corresponding isolator. It has been verified that, by applying a typical variability (cov = 14.5%) to the mechanical properties of the elastomeric

isolators (specifically: to the shear modulus of the rubber material), with linear dynamic analyses, a variability is obtained in the main displacement response parameters (underestimates/overestimations with respect to the results obtainable assuming the design mean values) no higher than 20% with reference to the 84th-percentile and no higher than 30% with reference to the 99th-percentile. This result is substantially in line with what is reported in the last sentence of paragraph 7.10.5.1 of the Italian code (NTC 2018).

8 CONCLUSIONS

A simplified procedure for the identification of HDRB isolators has been presented and applied to a RC bridge. The effects of the variability in the mechanical properties of the isolators (rubber shear modulus) on the structural behaviour of the isolated bridge emerged from several time-history analyses carried out on minimal models. They are characterized by few degrees of freedom, four in the longitudinal direction and five in the transversal one. The rubber shear modulus G is assumed as a random variable characterized by a normal distribution with mean value equal to 0.8 MPa and coefficient of variation equal to 14.5%. From 10,000 sets of numerical simulations (each one carried out with seven natural accelerograms) which are representative of the realizations of the random variable G , the best fitting of the probability functions of the mean values of the displacements (for both isolators and piers) have been performed. The analyses of the associated percentiles allow the definition of coefficients for taking into account the variability of the rubber, i.e. Upper and Lower bounds values.

S. Ólafsson & R. Rupakhety

Earthquake Engineering Research Centre, University of Iceland, Selfoss, Iceland

ABSTRACT: Lead-core rubber bearing is a widely used device for seismic isolation. It remains a preferred option for important structures such as bridges, nuclear power plants, hospitals, etc., mainly due to its considerable energy dissipation capability. Accurate predictive models are a prerequisite for a safe and efficient design and thus prolong the life cycle of buildings and structures. A detailed finite element model generally provides insight into the complex behavior of the lead-core rubber bearing. However, being demanding computational resources, its implementation in the base-isolated structure analysis might not be appropriate. The contribution focuses on a more efficient model from a computational point of view – a neural network. Although the neural network doesn't use the physical model, the latter is employed to produce the target data. Some technological aspects of the multilayer perceptron are discussed, such as architecture, choice of the activation function, and training strategies.

1 INTRODUCTION

The contribution considers a machine learning algorithm designed to predict the response of Lead-Core Rubber Bearings (LCRB). Specifically, a multilayer perceptron model is implemented. Such a model generally comprises an input layer, several hidden layers, and an output layer. It operates on statistical data or a set of parameters considered crucial for the complex behavior of LCRB without explicitly formulating an underlying predictive model. The output obtained for each set of input features is compared with corresponding target values providing a basis to improve the model parameters (or to train the model) in order to minimize the divergence to the desired or targeted output. Typically, such a multilayer perceptron, in contrast to, for example, a finite element model, is less demanding in computational resources. The intensive computational process related to the final element simulation might hinder its application in the investigation of the LCRB response within a base-isolated structure.

For some time, LCRB devices have been a subject of research and have been successfully implemented as a base isolation of bridges and buildings. Some early examples are the Scamperdown Bridge (Park & Blakeley 1978) and the base isolation of the William Clayton Building (Megget 1978). Because of their considerable energy-dissipation capacity, they are a preferred option for base isolation of buildings and structures of primary societal importance, such as hospitals or nuclear power plants. Generally, the lead-core rubber bearing consists of (i) elastomeric layers separated by (ii) steel shims; (iii) a central plug (or plugs); (iv) top and bottom steel plates (Figure 1).

Figure 1. Lead-core bearing device: rubber layers (1); steel shims (2); central plug (3); steel plates (4).

The steel shims provide the isolator with the vertical stiffness needed to resist loads transferred from the superstructure. Under horizontal loads, for example, during an earthquake, lateral deformation of the elastomeric layers assures the decoupling of the superstructure from the ground. Also, the yielding of the central plug material due to the horizontal forces' action leads to more-pronounced hysteresis loops in the isolator's response, thus enhancing the energy dissipation capacity. Reportedly, the lead (in the lead plug) recovers its mechanical properties quickly when subjected to deformation, and due to the confinement provided by steel and rubber plates, the lead core deforms in pure shear (Skinner et al. 1980); among the LCRB features is also the re-centering capability (Robinson & Tucker 1977). Figure 2 schematizes the response of a lead-core bearing device.

Figure 2. Idealized hysteresis response of a lead-core bearing device.

2 THE ARCHITECTURE OF THE MULTILAYER PERCEPTRON

A recurrent neural network has been instantiated. The network contains a few hidden layers of neurons equipped with the rectified linear unit activation function,

$$\eta(x) = \begin{cases} 0 & \text{if } x < 0 \\ x & \text{if } x \geq 0 \end{cases} \quad (1)$$

which provides for some argument x the nonlinear overall behavior of the machine. Figure 3 schematizes the feed-forward propagation in the multilayer perceptron (which is, in fact, recurrent).

Figure 3. Schematized architecture of the neural network.

The figure visualizes the inputs that take a given neuron of the multilayer perceptron, as well as the connections of this neuron to the neurons of the next layer. The connections between the other neurons are not shown. It depicts the first or the input layer and the following two layers. The considered neuron is $n_3^{(1)}$; the subscript denotes the neuron's position in the layer, and the superscript is the layer number. This neuron takes inputs from all the neurons in the previous layer (the input) layer. The data that this neuron sends to all of the neurons in the subsequent layer (in the dense layer network, all of the neurons in a given layer are initially connected to all of the neurons in the following layer) is provided by the following relation

$$z_3^{(1)} = \eta \left(\left(W^{(1)} \right)^T I + b_3^{(1)} \right) \quad (2)$$

where $W^{(1)}$ denotes an array containing the weights of the connections providing data from the previous layer to that neuron, $W^{(1)} = (w_1^{(1)}, w_2^{(1)}, \dots, w_B^{(1)})$, B is the dimension of the input layer, T in the superscript denotes the transpose of this array considered as a matrix, and I stands for an array containing the data provided by the previous layer (the input layer), $I = (i_1, i_2, \dots, i_B)$; $b_3^{(1)}$ is the bias of the neuron; η is a function defined in Equation (1). In Figure 3, D denotes the length of the dense layers, as all layers are designed to be equal in size.

The loss function is identified with the mean squared error.

$$\psi = \frac{1}{N} \sum_{i=1}^N (y_i - \tilde{y}_i)^2 \quad (3)$$

where y_i and \tilde{y}_i are the target and output values, respectively, and N is the number of output values.

To generate the target sets, the Bouc-Wen model is employed, named after the authors of the first contributions to the topic (Bouc 1967, Wen 1976). As pointed out by Sivaselvan & Reinhorn (2000), for various combinations of the model parameters, it can be reduced to a rate-independent model (Ozdemir 1976) or a nonlinear elastic model (Menegotto & Pinto 1973). This approach has also been used by Constantinou and Tadjbakhsh (1985); its generalized version has been implemented by Song and Der Kiureghian (2006) with introduced shape parameters capable of simulating highly asymmetric hysteresis, and it is still employed in some recent studies (Shoaei et al. 2018).

$$R = \alpha \frac{f_y}{u_y} u(t) + (1 - \alpha) f_y z(t) \tag{4}$$

$$\frac{dz}{dt} = \frac{1}{u_y} \left[A \frac{du}{dt} - \gamma \left| \frac{du}{dt} \right| z(t) |z(t)|^{n-1} - \beta \frac{du}{dt} |z(t)|^n \right] \tag{5}$$

In Equation (4), R stands for the restoring force generated in the isolator, u – for the current displacement, α is the post-yielding to initial stiffness ratio, u_y and f_y are the yield displacement, and the yield shear force, respectively; $z(t)$ is the hysteresis variable defined in Equation (5). In Equation (5), the parameters γ and β control the size and the shape of the hysteresis loops, and n is responsible for the smoothness of the transition from elastic to post-elastic behavior. The material parameters needed for the constitutive relation, an elastic-perfectly plastic model, are taken from (Doudoumis et al. 2005), and, more precisely, the elasticity modulus of the lead core is set to $E=18e^6$ kN/m², the Poisson’s ratio - $\nu=0.43$, and the unidirectional yield stress - $f_y=19.5e^3$ kN/m².

The database is split into a training and a validation set. Figure 4 displays a typical sample of target data points obtained for a current combination of input parameters.

Figure 4. A typical displacement-restoring force relationship providing a target set of data points for a given set of input parameters.

To obtain the restoring force-displacement relationship (Figure 4), the Bouc-Wen model described by Equations (4)–(5) is used. By assumption, the bottom face of the bearing is fixed, while uniaxial displacements are applied to the top surface. Figure 5 provides a simplified image of the synthetic design space of the perceptron.

Figure 5. A portion of the database.

The hyperparameters, such as the learning rate or the loss function type, are tuned to enhance the overall behavior of the network (Figure 6).

Figure 6. The loss function evolution.

3 DISCUSSION

The LCRB response is typically defined through the relationship between the generated restoring force and the applied displacement. Based on this relationship, some conventional characteristics of the bearing device (energy dissipation capacity, secant stiffness, etc.) can be assessed. A possible way to evaluate the energy dissipation capacity is the hysteresis viscous damping ratio (see for example Ahmadipour & Alam 2017).

$$\zeta_H = \frac{E_H}{4\pi E_S}, \quad (6)$$

where E_S and E_H are the elastic and dissipated hysteresis energies, respectively. These two quantities are assessed using the hysteresis loops in the bearing device's response.

The model defined by Equations (4)–(5) neglects some characteristics of the bearing device, such as the geometrical dimensions of the lead core and the rubber layers and the material properties of the rubber layers. Furthermore, it doesn't take into account the magnitude of the applied vertical force, e.g. the loads transferred from the superstructure. In this context, a more detailed model, for example, a finite element model (Figure 7a–b), could provide a more accurate output.

Figure 7. Detailed finite element model of the lead-core bearing device: steel shims and steel plates are displayed in grey, rubber layers are shown in dark blue, and the lead core is in light blue.

Besides the precise geometrical representation, constitutive relations are formulated for the lead (in the lead plug), the rubber layers, and steel (in the top and bottom steel plates and the steel shims). An elastic-plastic model with hardening after yielding is employed for the lead core, and a Neo-Hookean model is used for the rubber layer. Steel is assumed to have a linear elastic response.

It is well-known that such a detailed model might be highly computationally intensive. This might hinder their implementation in the dynamic analysis of a base-isolated structure. On the other hand, finite element models could provide data for artificial neural network training or validation.

4 CONCLUSIONS

A multilayer perceptron has been developed to predict the ‘restoring force-applied displacement’ relationship for a lead-core rubber bearing device. The model architecture, instantiation, and back-propagation rules have been discussed in the contribution.

The multilayer perceptron employs synthetic data for training and validation, which implies a restriction on the input parameters due to the choice of the model used to create the

corresponding target datasets needed for the learning procedure. Compared to models of detailed and comprehensive output, which are at the same time computationally intensive, the light Bouc-Wen type models are relatively easily implemented in the simulation of the bearing device response when considered as parts of a base-isolated structure. Collecting datasets based on detailed finite element simulation results and data found in the available literature is in progress. In this context, the number of parameters taken into account by the neural network (or the number of input parameters) will be increased.

Experimental assessment of anti-seismic devices performance

Alberto Pavese, Simone Reale & Matthew J. Fox

Civil Engineering and Architecture Department – DICAr, University of Pavia, Pavia, Italy

ABSTRACT: In the last years, anti-seismic devices have benefitted from numerous advances in the materials and technological fields, which have increased global performance in terms of durability and capacity to sustain dynamic loading and thus allowing improved design of structures. Anti-seismic devices are required, by the design codes, to sustain an experimental protocol to characterise their main response parameters and allow for a global evaluation. The tests intend to replicate the worst operative conditions the devices could face during their design life. In this paper, two residential buildings equipped with curved surface slider isolators are analysed through Non-Linear Time History Analyses using a large number of accelerograms to assess the realistic combinations of external actions applied during their life. Based on the analysis outcomes, tentative general rules to define an optimised testing protocol for devices will be derived and compared to the testing requirements given in the codes.

1 INTRODUCTION

1.1 *Principles of seismic isolation*

The principle of seismic isolation has been developed because of the need to protect human lives and reduce damage to structures during earthquakes, with seismic isolation typically being employed in high seismicity regions. The main difference between traditional seismic design philosophy and seismic isolation is that in the former the energy dissipation is achieved through the inelastic response of the building (the dissipated energy corresponds directly to structural damage) while in the latter the structure is essentially protected. It has to be pointed out that other structural systems, such as viscous dampers, allow for energy dissipation without sustaining damage. Furthermore, most isolated buildings will be designed to still sustain some damage due to inelastic behaviour in very large earthquakes. A seismic isolation system is designed employing devices with low lateral stiffness to obtain a longer fundamental period with respect to the structure without seismic isolation devices. The basic principle of seismic isolation is to decouple the building from the ground motion. Several types of devices are nowadays available to obtain this effect. The devices must be able to accommodate high levels of displacement. Out of the available devices, Curved Surface Slider (CSS) isolators have been largely employed because of their simplicity and ease of manufacturing. (Avinash et al. 2022, Calvi & Calvi 2018) In the last years anti-seismic devices have benefitted from numerous advances in the materials and technological fields, which have increased global performance in terms of durability and capacity to sustain dynamic loading and thus allowing improved design of structures. (Furinghetti 2022) To briefly introduce the devices studied in this work, CSS isolators present a sliding surface and a puck, which moves to generate the relative displacement between upper and lower parts of the device. The horizontal surfaces of the device must remain parallel through the motion. Careful consideration is given to the choice of materials for the sliding surfaces, with PTFE being a popular choice. The careful selection of materials allows a good degree of control

over the frictional behaviour during sliding, which not only dissipates energy but also prevents movement under small, frequent loading.

1.2 Experimental protocol for anti-seismic devices

As in the case of construction materials or structural components, anti-seismic devices are required, by the design codes, to sustain an experimental protocol to characterise their main response parameters and allowing a global evaluation. Examining the testing protocols given in the main design and assessment codes of practice, it can be seen that devices must be subjected to several combinations of external actions: displacement, velocity, pressure etc. These tests intend to replicate the worst operative conditions the devices could face during their design life. Testing protocols are defined by codes, like EN 15129:2009 (CEN 2009). EN 15129:2009 introduces the various types of anti-seismic devices and prescribes the properties the devices must have to be considered safe and adequate to be employed. The code is currently being reviewed. The paragraph 8.3, dedicated to CSS isolators, defines the specific testing protocol for this type of device. The factory production control tests consist in the verification of the load bearing capacity, in the calculation of the friction force in service conditions and in three symmetrical test cycles at the design displacement d_{bd} . This last production test verifies if the slider is able to slide on the curved surface with velocity v_{ed} corresponding to the Collapse Prevention Limit State (SLC) spectral velocity in presence of an acting axial force N_{ed} . The code specifies that at least the 5% of the produced CSS isolators must be tested.

The present study aims to investigate what are the most severe conditions a CSS isolator may have to face during a seismic event. Non-Linear Time History Analyses (NLTHA) will be performed on two numerical models of base isolated buildings and the analysis outcomes will be compared with the actions specified by the code for the testing protocol of CSS isolators. Based on the analysis outcomes, tentative general rules to define an optimised testing protocol for devices will be derived and later compared to the testing requirements given in the EN 15129:2009.

2 CASE STUDIES

2.1 Characteristics of the case studies

Two case study structures have been considered in this work. Each case study has been modeled and NLTHAs have been performed. The main characteristics of the case studies are briefly reported in Table 1. The first case study is a residential building with a reinforced concrete (RC) frame structure including a central core of RC walls. The interface slab with the isolation system is 0.5 m thick. 28 seismic isolation devices have been employed. It has been assumed that the structure was located in L'Aquila, Abruzzo. The second case study is a residential building with an RC frame structure, without a central core since the stairs have been modeled using frame elements. 24 seismic isolation devices have been employed. It has been assumed that the structure was located in Cosenza, Calabria.

Table 1. Characteristics of the case studies.

Characteristics	Case study 1	Case study 2
Plan dimensions [m]	26.05 x 13.08	21.05 x 11.45
Total height [m]	15.25	18.65
Fundamental period [s]	0.743	0.959
Total mass [ton]	2266	2080
Number of devices [#]	28	24

2.2 Characteristics of the seismic isolation system

The characteristics of the seismic isolation systems employed in the case studies are reported in Table 2. Only CSS isolators have been used. The motivation is that these devices are subjected to vertical and horizontal displacements during the earthquake and the vertical displacement can be accommodated only if all the devices oscillate in the same way. The main characteristics of CSS isolators are equivalent radius R_{eq} and friction coefficient μ .

Table 2. Characteristics of the seismic isolation systems.

Characteristics	Case study 1	Case study 2
Number of devices [#]	28	24
Equivalent radius R_{eq} [m]	4.23	4.23
Friction coefficient μ [#]	0.036	0.036
Diameter of the slider Φ [m]	0.184	0.190
Friction force F_{μ} [kN]	28	37
Maximum force F_{max} [kN]	60	78
Maximum displacement d_{max} [m]	0.170	0.206

2.3 Definition of the seismic input

The analyses performed in this study considered both natural and artificial accelerograms for the SLC, with analyses being performed in two orthogonal horizontal directions. For each structure:

- 7 artificial accelerograms have been generated to match the SLC response spectrum;
- 7 natural accelerograms have been selected to match the SLC response spectrum.

For the generation of artificial accelerograms, the methodology proposed by Vanmarcke and Gasparini (1977) was followed. The selection of natural records has been performed using REXEL (Iervolino, Galasso & Cosenza 2009). Spectrum compatibility has been taken into account, following the prescriptions given by the NTC2018 (D.M. 17/01/2018). Figure 1 shows the result of the spectrum compatibility check of artificial records for Case Study 1. Figure 2 shows the same results for natural records. The results for Case Study 2 are similar and so are not reported.

Figure 1. Spectral compatibility check for artificial records, Case Study 1.

3 COMPARISON BETWEEN ANALYSES OUTCOMES AND TEST PROTOCOLS

3.1 Sliding isolation tests-dynamic

In the sliding isolation tests, EN 15129:2009 requires consideration of three displacement levels (d_{bd} , $0.5d_{bd}$ and $0.25d_{bd}$) with the same velocity v_{ed} . To discuss if maintaining the same velocity for all the tests is correct, it is useful to consider separately artificial records and natural records. Considering the artificial records, the resulting displacements are never greater than d_{bd} and the velocity has values comparable with the design velocity. For Case study 1, the mean velocity in the X direction is equal to $1.05v_{ed}$, while the mean velocity in Y is equal to $1.15v_{ed}$. For Case study 2, the mean velocity in X direction is equal to $1.12v_{ed}$, while the mean velocity in Y is equal to $1.15v_{ed}$. Artificial records seem to confirm the code prescription about the velocity that has to be maintained during the tests. Considering natural records, in 6 and 8 analyses extra stroke displacements are present for Case study 1 and Case study 2 respectively. Considering only the events without extra stroke displacement in the devices, the mean velocity is around $1.08v_{ed}$, confirming the code prescriptions. Considering the events with extra stroke displacements in the devices, it has been noted that the velocity tends to scale coherently with the deformation level. The maximum value of velocity that has been reached is equal to $2.13v_{ed}$, for an extra stroke displacement of $1.18d_{bd}$. The results seem to confirm the code prescriptions for displacement levels below d_{bd} , but the code does not present tests for displacement levels higher than d_{bd} where the velocity is different.

Figure 2. Spectral compatibility check for natural records, Case Study 1.

3.2 Sliding isolation tests-seismic

In the seismic test, the device is subjected to 3 displacement cycles. The maximum displacement is d_{bd} , the test is performed with velocity v_{ed} and maximum and minimum levels of axial force, called $N_{ed, max}$ and $N_{ed, min}$ respectively, are alternatively present. Some considerations concerning the relationship between axial action and design displacement are due. Given the design axial force N_{sd} , Figure 3 shows the comparison between normalised displacement and normalised axial force of a device for the Case study 2. The analysis outcomes in Figure 3 are about an artificial record. The peak displacement is around $0.7d_{bd}$, but the contemporary axial force is $1.8N_{sd}$. Figure 4 shows the comparison between normalised displacement and normalised axial force of a device for the Case study 1. The analysis outcomes in Figure 4 are about a natural record. The peak displacement is around $0.85d_{bd}$, but the contemporary axial force is $1.3N_{sd}$. In both the examples, the maximum axial force

takes place in correspondence of the maximum displacement. However, it has to be pointed out that the oscillation frequency seems to be much higher for the axial force than for the displacement. For this reason, the correspondence between extreme axial forces and extreme displacements is not particularly frequent in the set of analyses. A significative variation of N_{sd} (at least 10%) happens in correspondence of the maximum displacement only in few analyses. A relationship between displacement and axial action oscillations was not observed.

Figure 3. Time histories of normalised displacement and axial force - Case Study 2, artificial record.

Figure 4. Time histories of normalised displacement and axial force - Case Study 1, natural record.

3.3 Load bearing capacity

EN 15129:2009 prescribes that a seismic isolation device must be able to carry a vertical load equal to $2N_{sd}$ when in its zero-displacement position, maintaining the load for 1 minute. The purpose of the test is to verify the device in an overload condition. The range $0-2N_{sd}$ contains the possible variations of axial forces in the devices during a seismic event, but some exceptions have been noted in the analysis outcomes. Joint 152 of the Case study 2 is in the corner of the isolation interface. Joint 933 of Case study 1 and Joint 156 of the Case study 2 are near the stairs. In correspondence of these points, values of axial force up to $3.1N_{sd}$ have been observed. These values are beyond the limits prescribed by the codes and happen for high displacements (extra stroke displacements, in most cases). Table 3, Table 4 and Table 5 show the axial force variation in the previously introduced points.

Table 3. Axial force variation through the set of analyses for Joint 152 - Case study 2, natural records.

3.4 Number of cycles

CSS isolators are characterised by high non-linearities and analysing the outcomes of the simulations only few relevant cycles have been observed. EN 15129:2009 prescribes three symmetrical cycles for the sliding isolation tests. Three cycles are justifiable for $0.5d_{bd}$ or $0.25d_{bd}$ displacement levels but considering the analysis outcomes seem to be excessive for the d_{bd} displacement level. To properly address this issue, it is possible to compare the numerical results with an experimental test, computing the work on the device in both cases. The work can be calculated integrating over time the product of shear, S , and displacement, d , time histories. Figure 5 shows the time histories of S and d for an experimental test and a numerical simulation. For CSS isolators positive work W^+ and negative work W^- on the device must be distinguished since S and d are not always with the same

sign. For the reported example, considering the numerical results, W^+ and W^- are equal to 35 kJ and 12 kJ respectively and a total work of 47 kJ is obtained. The work of the experimental test W_T is equal to 73 kJ. It has been observed that the work on the isolator in presence of the most intense natural event of the set is around the 64% of the work in the dynamic tests.

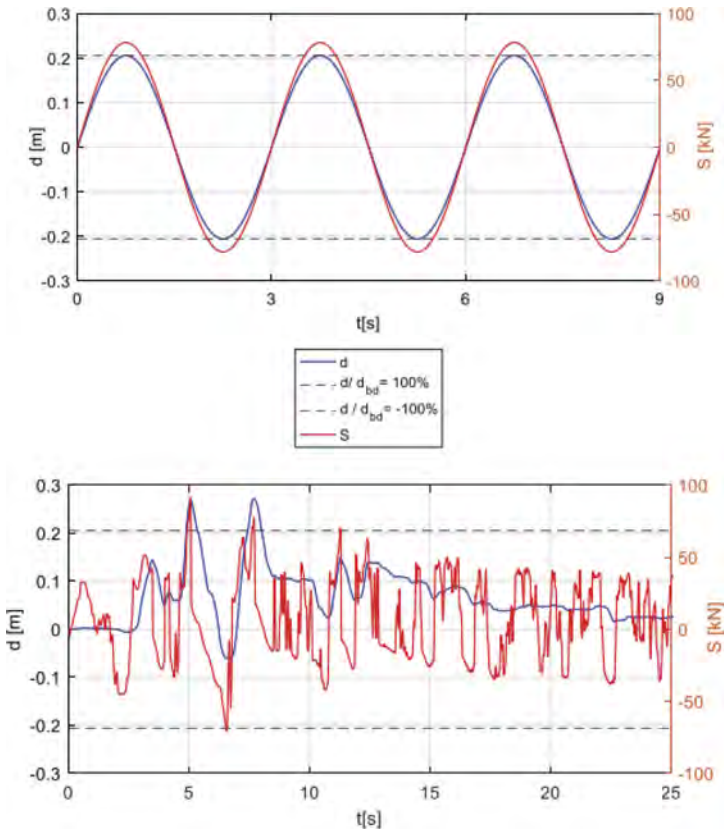

Figure 5. Time histories of shear and displacement for an experimental test (top) and a numerical simulation (bottom).

4 CONCLUSIONS

Two base isolated structures have been selected and modeled. NLTHAs have been performed using both artificial and natural records. The analysis outcomes have been compared with the testing protocols contained in the EN 15129:2009 to provide a critical evaluation of the performances required for a CSS isolator. Considering the Dynamic tests, the results seem to confirm the code prescriptions for displacement levels below d_{bd} , but the code does not present tests for displacement levels higher than d_{bd} . Considering Seismic tests, a relationship between displacement and axial action oscillations was not observed. In terms of load bearing capacity, the range $0-2N_{sd}$ contains the possible variations of axial forces in the devices during a seismic event, but some exceptions have been noted in the analysis outcomes. Regarding the number of cycles in the tests, the code prescribes three symmetrical cycles for the sliding isolation tests. Three cycles are justifiable for $0.5d_{bd}$ or $0.25d_{bd}$ displacement levels but considering the analysis outcomes seem to be excessive for the d_{bd} displacement level. It has to be pointed out that

the present study has considered only two base isolated structures, a higher number of case studies would enhance the confidence on the results.

EUCENTRE Foundation, Pavia, Italy

ABSTRACT: Bridges are fundamental for the transportation system of a nation and they can be subject to significant deterioration phenomena linked to the fact that the construction period typically dates back to the 1960s. This study involves the analysis of four case study bridges belonging to the Italian highway network. Analytical fragility curves have been constructed for each of the bridges. The case studies have also been analysed to determine the Structural and Foundational and Seismic Classes of Attention, following the approach proposed by the 2020 Italian Guidelines. It was possible to compare two different assessment approaches. In regions with higher seismicity the main problems in bridges are related to bearings and connecting elements located in the piers. These problems may be linked to the fact that at the time of the design of the structures there was less understanding of need for seismically resilient bridge design.

1 INTRODUCTION

The safety of existing bridges represents a serious problem since these structures are fundamental for the transportation system of a nation and, at the same time, they can be subject to significant deterioration phenomena linked to the fact that the construction period typically dates back to the 1960s (Fox et al. 2022). Considering that at the time durability was not one of the goals in projects and that the service life of the structures has been in most cases already reached or exceeded, proper maintenance and retrofit interventions are needed. The rise in frequency of bridge collapses is an indicator of the effects of aging and lack of maintenance (Cosenza & Losanno 2022). Proper maintenance is fundamental because the most important element in the durability of bridges is the correct evolution of the structure through the years. The main causes of collapse in existing bridges are flooding, impacts and foundational problems, while the design loads are responsible only for a small number of collapses (Deng et al. 2016). The analysis of the Italian infrastructure stock reveals that the railway system is smaller, more uniform and more organised in terms of maintenance with respect to the roadway system. Shortage of resources for the maintenance of structures and the increasing traffic are also relevant factors (Di Prisco 2019).

This study involves the analysis of four case studies belonging to the Italian highway network. The case studies have been built around the same period (early-60s to mid-70s) and all of them belong to the Italian highway network. At the time, there was a less developed understanding of the seismic behaviour of structures and crucial facets of the design process, like bearing design and anti-seismic details, were addressed with simplified approaches. Table 1 reports the main characteristics of the case studies. The available documentation provided information about the structural elements, both in terms of sections and reinforcement. The documents reported also information about the original materials. When available, results of

experimental tests performed on the structures have been taken as a reference for material properties. In the cases where there were not test results available, assumptions about the deterioration of materials have been made.

For each of the case studies, fragility curves have been computed referring to the overall response of the bridge and to the response of bearings and individual structural elements. The results have been used to evaluate the efficiency of the procedure set out by the new “Guidelines for the classification and management of risk, safety evaluation, and monitoring of existing bridges” (2020), which have been introduced in 2020 and will be herein referred to as “the Guidelines”. In particular, the Level 2 assessment has been applied to the case studies, defining Structural and Foundational and Seismic Classes of Attention, allowing for evaluation of the proposed approach.

Table 1. Main characteristics of the case studies.

Case study	Year	Structural scheme	Bearings	Number of spans	Total length [m]	Soil category (NTC2018)
Bridge 1	1960	Continuous beams with Gerber saddles	Neoprene	13	421	A
Bridge 2	1969	Simply supported beams	Neoprene and steel plates	4	124	A
Bridge 3	1973	Simply supported beams with Gerber saddles	PTFE-Steel	5	157	B
Bridge 4	1969	Simply supported beams	Neoprene and steel plates	3	87.8	A

2 THE GUIDELINES

2.1 *Bridge assessment guidelines*

The Guidelines have been introduced in 2020. The proposed multilevel and multi-risk approach is organised into six progressively more detailed levels. Level 0 involves a stocktake of bridges, gathering information about, for instance, location, structural system, period of construction and, eventually, retrofit interventions. Level 1 requires visual inspection to detect damage on the structure. At the end of the inspection, a report is produced using a standardised format provided with the Guidelines. In Level 2, Classes of Attention are defined by combining in a simplified way data related to hazard, vulnerability and exposure. There are 5 Classes of Attention (Low, Medium-low, Medium, Medium-high, High). Level 3 consists in a preliminary assessment of structural safety and is performed by comparing the design actions provided by the codes at the time of construction with the design actions provided by NTC2018 (D.M. 17/01/2018). Level 4 is a detailed safety assessment of the bridge considering current code requirements. Level 5, not directly covered by the Guidelines, is related to the resilience of the bridge network.

From level 0 to level 5 the analyses become more demanding in terms of engineering effort, but it is expected that the number of structures that have to be assessed progressively decreases. The Guidelines also introduce the structural monitoring of bridges. Considerations on structural monitoring are beyond the scope of this work, given the extremely broad nature of the topic.

2.2 *Structural and foundational class of attention*

The definition of Structural and Foundational Class of Attention for the case studies is based on the determination of hazard, vulnerability and exposure classes. In terms of hazard class, the main parameters are the load level of the bridge and frequency of commercial vehicles. To estimate the vulnerability class, level of defectiveness, structural scheme, span length, number of spans, materials, design code and speed of degradation are considered. The exposure class is defined on the basis of mean daily traffic (MDT), average length of spans, presence of road

alternatives, type of entity under the bridge and transit of dangerous goods. These three classes, defined using decisional trees that combine the parameters introduced above, are then employed to derive the Structural and Foundational Class of Attention using tables in the Guidelines.

In the definition of the Class of Attention, vulnerability is the most important factor because if it is high the Class of Attention will be High independently from the classes related to the other two factors. In fact, the vulnerability class is directly connected with the level of defectiveness of the structure. Table 2 reports the Structural and Foundational Class of Attention for each of the case studies. For all the four case studies, the Structural and Foundational Class of Attention is High.

Table 2. Assessment of structural and foundational class of attention.

Structural and Foundational Class of Attention				
Case studies	Hazard class	Vulnerability class	Exposure class	Class of Attention
Bridge 1	High	High	High	High
Bridge 2	High	Medium-high	High	High
Bridge 3	High	High	High	High
Bridge 4	High	Medium-high	High	High

2.3 Seismic class of attention

The definition of the Seismic Class of Attention follows the same approach presented for the Structural and Foundation Class of Attention. In terms of hazard class, the main parameters are PGA, topographic category and subsoil type. Structural scheme, span length, materials, level of defectiveness and design criteria are considered to derive the vulnerability class. The exposure class is derived from the level of MDT, medium length of the spans, presence of road alternatives, type of entity under the bridge, transit of dangerous goods and strategic importance of the infrastructure. Table 3 reports the Seismic Class of Attention for each of the case studies. For Bridge 1, Bridge 2 and Bridge 3 the Seismic Class of Attention is High, while for Bridge 4 is Medium-high.

Table 3. Assessment of seismic class of attention.

Seismic Class of Attention				
Case studies	Hazard class	Vulnerability class	Exposure class	Class of Attention
Bridge 1	Medium-high	Medium-high	High	High
Bridge 2	Medium-high	Medium-high	High	High
Bridge 3	Medium	High	High	High
Bridge 4	Medium-low	Medium-high	High	Medium-high

3 FRAGILITY CURVES

3.1 Methodology

Fragility curves represent the link between the seismic hazard at a site and the effects on the exposed elements. The fragility curves associated with each case study have been derived using the so-called Multiple Stripes Analysis (MSA). This approach requires structural analyses to be performed at a discrete set of Intensity Measure (IM) levels, using different ground motions at each level. Target properties of the ground motions vary at different IM levels and the selection of different accelerograms allows the variation of the seismic hazard parameters to be taken into consideration (Baker 2015). The fundamental aspects of the methodology used to derive the fragility curves are reported below.

10 code-based elastic spectra have been defined according to the NTC2018. The spectra are characterised by an increasing value of return period T_r , from 30 to 2475 years, as reported in

Table 4. The definition of these spectra is fundamental to ensure that the selected ground motions represent a broad enough range of IM levels (Manfredi et al. 2022).

The number of ground motions that have to be selected to provide reliable results in the analyses is still an open issue, but 7 ground motions appear to be the minimum requirement (Manfredi et al. 2022). 7 pairs of natural records for each IM level have been selected using the ground motion selection software REXEL (Iervolino et al. 2009). The selection of the ground motions required that seismic hazard disaggregation be undertaken first (Bazzurro & Cornell 1999, Fox et al. 2016). In the matching of the ground motions to the spectra, NTC2018 has been taken as reference for the issue of spectral compatibility. In particular, given the first period T , the highest value between $2T$ and 2 s has been selected as maximum value of the range of periods in which spectral compatibility must be ensured.

The definition of the criteria used to compute capacity and demand for each structural element is fundamental. In terms of shear actions, considering the indications of the 2019 Commentary of NTC2018, the capacity of an existing structure has to be computed taking into account the ductility demand on the elements. The main contributors to shear capacity, in this formulation, are normal actions N , concrete and steel contributions and interaction between flexural rotation of the element and plastic component of ductility demand. Considering the chord rotation capacity, in the 2019 Commentary of NTC2018, three different formulations are proposed in relation to Collapse Prevention Limit State (SLC), Life-safety Limit State (SLV) and Damage-limitation Limit State (SLD). The first two formulations refer to an ultimate capacity, while the last formulation gives a capacity correlated with yielding tension.

For bearing displacement, the chosen approach consisted in monitoring the horizontal deformations of each bearing through the analyses, defining four Limit States associated with different conditions of the devices. The definition of Limit States correlated to the seismic response of the bearings is crucial to properly describe the structural behaviour of the case studies. The Limit States specified for bearings are slightly different for elastomeric and PTFE-steel bearings. For elastomeric bearings, the shear deformation γ has been computed as the ratio between horizontal displacement d and total height of the elastomer, while for PTFE-steel devices the ratio between d and the total height of the device h has been considered.

Two Global Limit States, Damage and Collapse, have also been defined to describe the global response of the bridge. The former is associated with an operating condition of the structure while the latter defines a condition where critical failures in piers or bearings are present. It has been assumed that to reach Collapse Limit State it was necessary to exceed Damage Limit State. The criteria listed in Table 5 are alternative possibilities and reaching just one of them is enough to consider the corresponding Limit State as being exceeded.

Table 4. Values of T_r for each IM level.

IM level	1	2	3	4	5	6	7	8	9	10
T_r	30	50	101	201	475	712	975	1462	1950	2475

Table 5. Global Limit States.

Limit States	Criteria
Damage	$\gamma=0.5$; Reaching of chord rotation capacity (SLD) in at least one pier; Failures in secondary elements.
Collapse	$\gamma=2$; Reaching of shear capacity in at least one pier; Reaching of chord rotation capacity (SLV) in at least one pier; Reaching or exceeding $\gamma=1$ and failures in secondary elements.

Non-Linear Time History Analyses (NLTHA) have been performed to obtain the data required to derive the fragility curves. For each of the considered Limit States, the fraction of analyses that for a given IM level reached or exceeded the associated threshold was computed. The fitting procedure, which allowed to finally obtain the fragility curves, was performed applying the maximum likelihood method, which is the most appropriate with this type of data (Baker 2015).

3.2 Fragility curves for the case studies

Figure 1 reports the fragility curves for bearings, structural elements and global response of Bridge 1. The response of the bearings is not particularly detrimental. The pier behaviour is acceptable both in terms of shear and chord rotation.

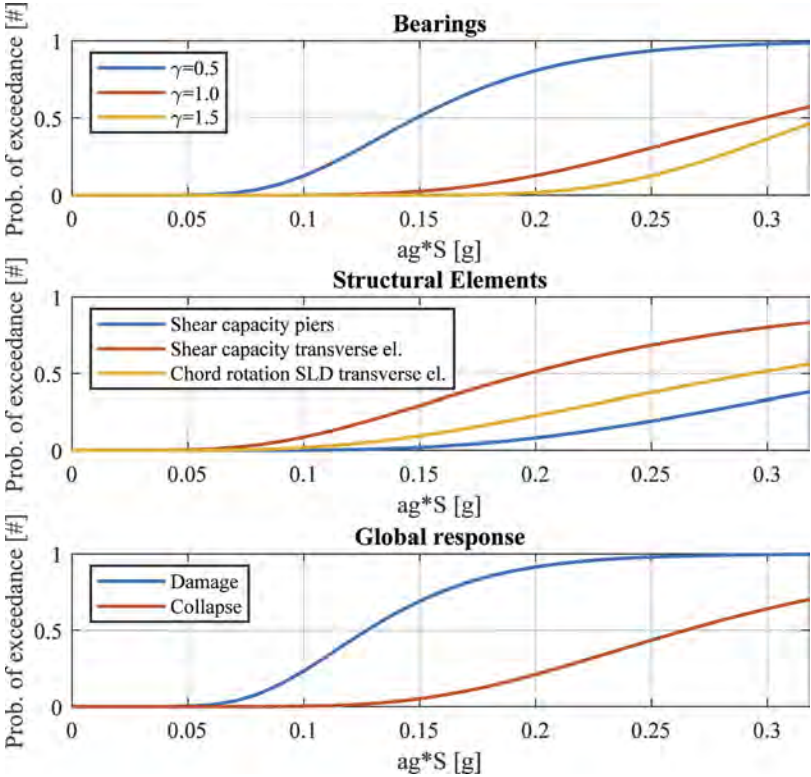

Figure 1. Fragility curves related to bearings, structural elements and global response of Bridge 1.

Local problems, mainly in terms of shear failures, are present in the transverse connecting elements of the piers. Local failures must not be underestimated because they can have an influence on the global dynamic behaviour of the structure. The global behaviour of Bridge 1 is acceptable, but the presence of local problems is relevant in the assessment of the structure.

Figure 2 reports the fragility curves for bearings, structural elements and global response of Bridge 2. The response of the bearings is critical for this case study. This result may be due to factors such as the high seismicity of the region and the structural scheme of the bridge. Also, analysing the documentation it has been noted that the design, which dates back to 1969, did not take into account seismic actions. The pier behaviour is acceptable both in terms of shear and chord rotation. Local problems, mainly in terms of shear failures, are present in the connecting element between the two parts of each pier. The global behaviour of Bridge 2 is acceptable, but the presence of local problems is relevant in the assessment of the structure.

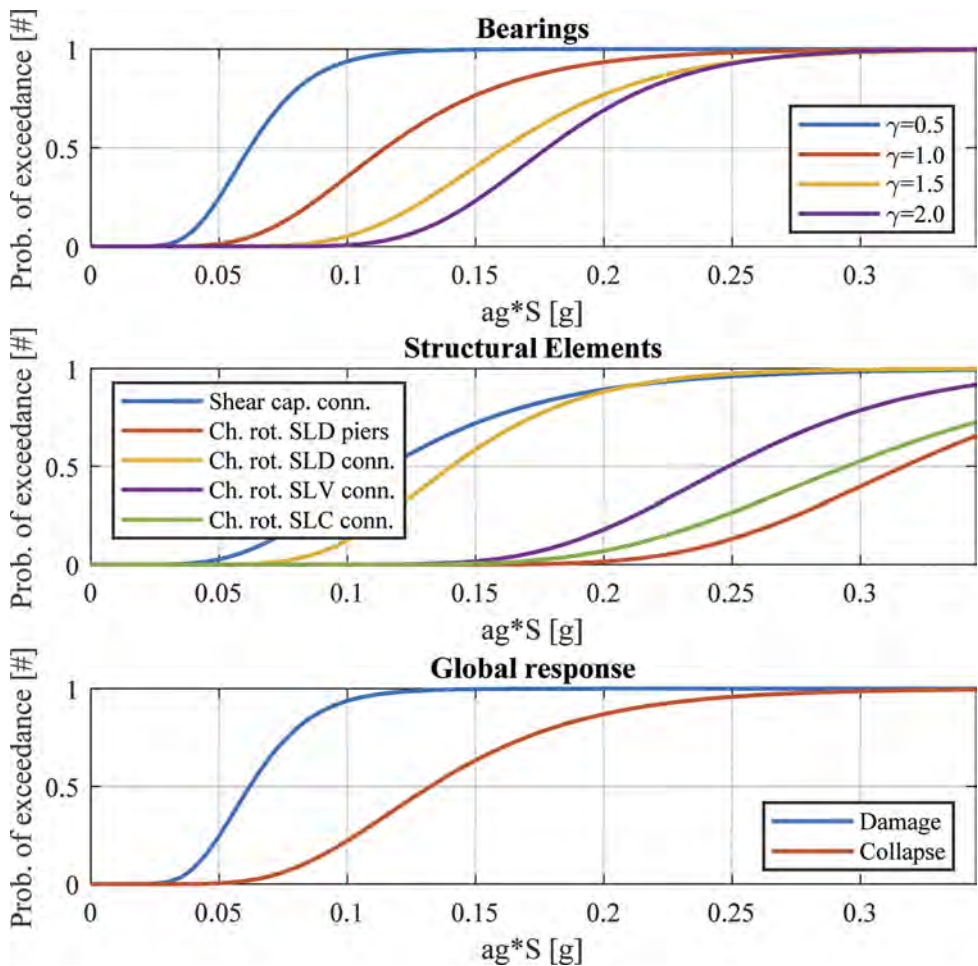

Figure 2. Fragility curves related to bearings, structural elements and global response of Bridge 2.

Figure 3 reports the fragility curves for bearings, structural elements and global response of Bridge 3. The bearings of Bridge 3 are made of polytetrafluoroethylene (PTFE) and steel. This type of devices is characterised by high displacement capacity. The seismicity of the region (the ground acceleration on rock, a_g , corresponding to $T_r = 2475$ years is equal to 0.191 g) leads to significant displacements of the bearings. In terms of structural elements, the shear response generates some problems, while the response in terms of chord rotation does not highlight particular problems. This type of behaviour can be explained considering the large spacing between the stirrups and that concrete properties have been obtained using experimental tests as reference (which showed a state of deterioration with respect to design properties).

Figure 4 contains the fragility curve related to reaching $\gamma=0.5$ in the bearings of Bridge 4. This was the only relevant curve for this case study since the other curves were not characterised by enough discrete points to perform the fitting procedure. No significant issues related to the seismic response of structural elements have been detected. The only relevant curve, $\gamma=0.5$, corresponds to a normal condition for the bearings. These results can be explained considering the low seismicity of the zone, with a_g corresponding to $T_r = 2475$ years equal to 0.081 g.

Figure 3. Fragility curves related to bearings, structural elements and global response of Bridge 3.

Figure 4. Fragility curve related to $\gamma=0.5$ for Bridge 4.

4 CONCLUSIONS

On the basis of what has been discussed in previous sections, the conclusions reported below can be drawn. In regions with higher seismicity the response of the bearings is critical, while in areas with lower seismicity there are not particular problems in the bearings. A good behaviour of the piers has been noted regarding ductile failures. Except for Bridge 3, a good response in terms of brittle failures has been found. Considering the connecting elements in frame piers, local problems (mainly in terms of brittle mechanisms) have been found. This is an aspect that must not be underestimated as failures in these elements can modify the flexural behaviour of the piers and so the overall response of the structure. The results obtained

interpreting the analytical fragility curves are in agreement with the fact that the seismic behaviour of existing bridges can be problematic, and that a higher seismicity can be associated with a more detrimental behaviour.

Considering the Guidelines, each case study is associated to the High Structural and Foundational Class of Attention. The three bridges in higher seismicity zones have been associated to the High Seismic Class of Attention, while Bridge 4 has been associated to the Medium-high Seismic Class of Attention. For bridges in areas with higher seismicity there is therefore a result in agreement with that of the fragility curves, while for Bridge 4 there is a discrepancy that could be due to the different level of conservatism of the analyses, the procedure of the Guidelines could lead to a poor reflection of the true seismic behaviour of bridges when the seismicity of the area is lower. Since the assessment of Classes of Attention is based on decisional trees and visual inspections it is expected that it will be more conservative than an analytic approach based on NLTHA.

Note that the results obtained cannot be considered as general since the number of considered case studies is relatively small and considering that this study could be developed and extended in the future, this consideration has to be intended only as a qualitative evaluation.

Life-Cycle Assessment (LCA) of fiber-reinforced reclaimed-rubber seismic isolators

F. Cilento

Institute of Polymers, Composite and Biomaterials, CNR (National Research Council of Italy), Portici, Italy

D. Losanno, C. Menna, C. Ciriello & F. Parisi

Department of Structures for Engineering and Architecture, University of Naples Federico II, Naples, Italy

ABSTRACT: During the last few years, a growing interest has been observed in the development of low-cost seismic isolation systems with the aim of reducing seismic risk in developing countries. Fibre-reinforced elastomeric isolators (FREIs) in unbonded configuration demonstrated to be an effective alternative solution to conventional steel-reinforced elastomeric isolators (SREIs). The use of reclaimed rubber compounds in FREIs has the potential to further reduce the environmental impact associated with this technology. Reclaimed rubber FREIs reinforced with polyester fabrics have shown adequate deformation capacity, stable hysteretic behaviour, and satisfactory damping properties. In this study, the environmental burden associated with the FREI technology when using reclaimed rubber compound and flexible reinforcement is computed by performing a life cycle environmental assessment. The sustainability outcome in terms of resource use/savings, energy and emissions to the environment is preliminary quantified and compared to that of classical SREIs.

1 INTRODUCTION

Base isolation is one of the most effective technologies for the seismic protection of structures. Despite all, the system is still rarely used in emerging countries and common housing projects because classical Steel-Reinforced Elastomeric Isolators (SREIs) are large, heavy, and expensive, requiring a highly labor-intensive manufacturing process. In recent years, the development of new low-cost seismic isolators made it possible to extend this technology to common building projects (Calabrese et al. 2019; Losanno et al. 2021). During the last decade, Fiber Reinforced Elastomeric Isolators (FREIs) were introduced as a lower-cost option to SREI (Konstantinidis & Kelly 2014). The use of flexible reinforcement in extension and bending, such as carbon, glass, nylon, and polyester fiber sheets, significantly reduces the weight of the device and the installation costs also increasing the ability of the device to dissipate elastic strain energy providing higher damping capacity due to friction between different layers.

FREIs could be installed in an unbonded configuration by mounting the devices between the sub-structure and superstructure without any mechanical restraint, just relying on friction at the contact surfaces (Toopchi-Nezhad et al. 2011). In terms of isolation effectiveness, FREIs take benefit of the roll-over phenomenon that reduces the bearing contact area resulting in lower secant stiffness than SREI. The lack of both flexural rigidity of internal reinforcement and external fastening significantly reduces tensile and peeling stress in the rubber compound in comparison to classical SREIs (Losanno et al. 2019; Losanno et al. 2021). Hence, virgin rubber can also be replaced by lower-performance reclaimed rubber compounds when manufacturing unbounded FREIs. This not only turns into a further cost reduction but also a positive environmental impact when comparing FREIs to traditional SREIs. Habieb et al. (Habieb et al. 2021) conducted a preliminary investigation on recycled rubber for building isolation systems in the form of reactivated (i.e. devulcanized) Ethylene-Propylene Diene Monomer (EPDM) from industrial waste. Along the same line, these

authors recently developed with the company ITALGUM and experimentally tested a prototype polyester-fabric reclaimed-rubber FREI (P-RU-FREI) showing promising performance in terms of both displacement and damping capacity (Cilento et al. 2022; Italgum S.r.l et al. 2022). Very recent experimental works on full-scale prototypes and numerical analyses on both RC frame and unreinforced masonry buildings confirmed the suitability of FREIs for protecting low-rise buildings (Calabrese et al. 2019; Madera Sierra et al. 2019; Losanno et al. 2022a; Losanno et al. 2022b).

To further address the development of sustainable solutions for the design of new buildings and retrofit existing ones both in developed and developing countries, a life cycle environmental assessment of the different isolator solutions has become necessary. Life cycle assessment (LCA) is considered an efficient and comprehensive tool to evaluate the environmental impacts of a product throughout its life cycle, starting with the extraction and processing of raw materials, manufacturing and production, product transportation, use and maintenance, until its waste disposal. The method was successfully applied in the construction sector (Ortiz et al. 2009) to evaluate the environmental performance of construction products (Napolano et al. 2015) or to support the decision-making process oriented towards environmental sustainability (Caruso et al. 2017).

To the best of the authors' knowledge, no literature has been published on the process LCA of FREI compared to SREI systems. Hence, this study aims to provide an LCA-based environmental assessment of FREIs and SREIs, with a specific focus on the product stage of the life cycle.

2 P-RU-FREI VERSUS SREI: MATERIALS AND PROCESS

Previous studies (Strauss et al. 2014; Madera Sierra et al. 2019) demonstrated the convenience of using FREIs in unbounded configuration rather than SREI due to the following features: (i) simplification of the installation process, (ii) reduction of energy consumption and cost, and (iii) reduction of internal stresses with the possibility to adopt lower performance elastomeric materials (Losanno et al. 2020).

The reference FREI prototype was assumed according to (Cilento et al. 2022) where P-RU-FREIs were dimensioned for a low-rise RC frame in a length scale of 2. In this study, the corresponding full-scale P-RU-FREI is considered as the reference geometry for the LCA study. In detail, the environmental assessment is conducted on both P-RU-FREI and its SREI counterpart sharing the same rubber geometry (i.e. equal diameter and total rubber height) and compound (i.e. equal soft compound with $G = 0.4$ MPa). However, a different source of rubber is considered in the comparative study (reclaimed rubber for P-RU-FREI against virgin rubber for SREI) to better highlight the potential environmental benefits of the different isolation systems.

The main properties of both the isolators are given in Figure 1 and listed in Table 1 where the diameter of the isolator D and the corresponding rubber height H_r , the total height of the device H , the thickness of the rubber layer t_r , and the thickness of reinforcement t_f are given. For the sake of comparison, the same value of the second shape factor $S_2 = D/H_r = 4.4$ is obtained for both P-RU-FREI and SREI, which is capable of ensuring lateral stability up to 200% shear strain-imposed deformation. The primary shape factor S_1 (defined as the ratio of the loaded area over the rubber layer free-to-bulge area) is approximately equal to 20 for both isolators in the same way.

Table 1. Properties of P-RU-FREI and SREI.

	P-RU-FREI	SREI
Reinforcement type	2D polyester fabric	Steel shim
Rubber compound	Reclaimed	Virgin
D [mm]	400	400
t_r [mm]	5	5
t_f [mm]	0.53	3
n [-]	18	18
H_r [mm]	90	90
H [mm]	99	141

Figure 1. Stratigraphy of P-RU-FREI (left) and SREI (right).

Figure 2. Manufacturing process of elastomeric isolators: (a) rubber compound preparation; (b) flexible reinforcement preparation; (c) isolator assembly.

2.1 Manufacturing process

The manufacturing process for both isolators can be divided into three main phases: (1) rubber compound preparation (Figure 2a); (2) reinforcement preparation (Figure 2b); (3) isolator assembly and vulcanization (Figure 2c).

Phase (1) consists of a mixing and milling process of the rubber compound. It follows the same steps for both types of isolators and differs only for the process duration, which is 40 min for the virgin compound and 60 min for the reclaimed compound. The latter compound was obtained as a hybrid mix of virgin rubber and tyre rubber crumb (mixture of butadiene rubber SBR, and natural rubber NR) in a weight ratio equal to 1:1.

A longer process is required in the case of steel reinforcement with respect to fibre reinforcement for phase (2), which includes sandblasting of metals, primer and adhesive application in the former case, while it reduces to fibre sheets impregnation with proper adhesive only in the latter case.

Phase (3) consists in stacking in a preheated mould alternated layers of rubber and reinforcement. This multilayer structure is vulcanized by applying heat and pressure to the mould for a sufficient time (180 min for SREI and 120 min for P-RU-FREI) to ensure that an optimal linkage activation is achieved.

3 LCA MODEL AND RESULTS

To assess the environmental performances of both seismic isolation systems in the product stage, a comparative life cycle assessment (LCA) was carried out. According to (ISO14040 2006) and (ISO14044 2006), the LCA method includes four steps: (1) goal and scope definition; (2) life cycle inventory (LCI) analysis; (3) life cycle impact assessment (LCA); and (4) interpretation (Klöppfer 2012; Curran 2013). The goal of this study is to analyze the environmental impacts of P-RU-FREI and SREI isolators with the geometry described above and assumed as a functional unit in order to compare the results for the different impact categories and determine which is the least impacting device from the production point of view. Production of the isolators is a complex process that can be divided into three steps: rubber compound preparation, reinforcement preparation, and isolator

assembly. The main processes involved in the production of P-RU-FREI and SREI isolators were included in the system boundary shown in Figure 3(a) and (b), respectively. The grey boxes refer to end-product, i.e. the isolator; the blue boxes refer to the main steps involved during the isolators production. The green boxes refer to material or energy inputs to system (raw material supply, transport to the plant, energy needed to process raw materials); the orange boxes refer to waste flows in which the dashed arrows refer to recycled material reintroduced into the process.

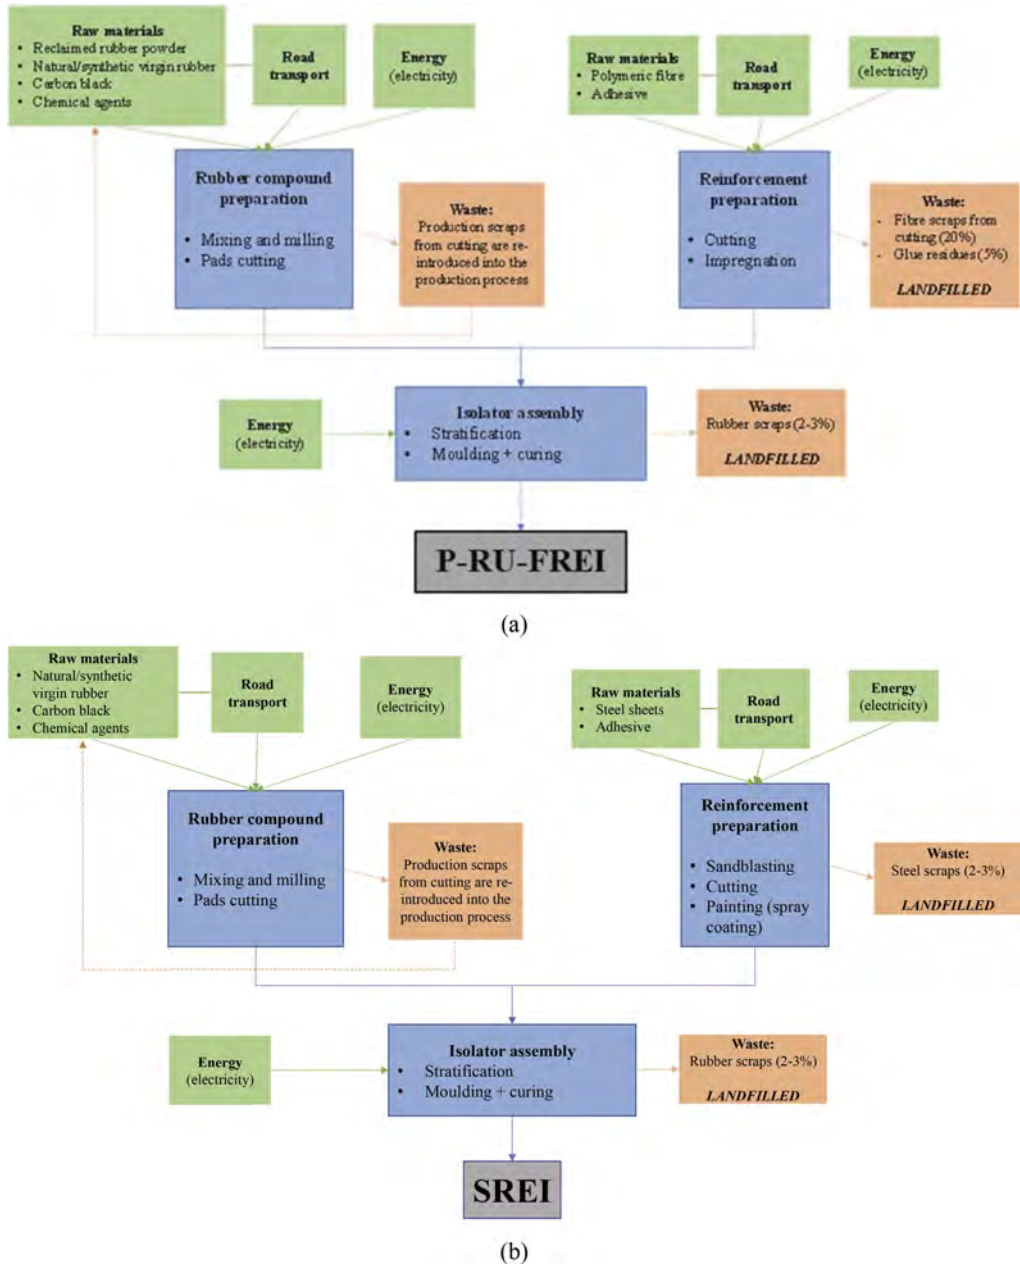

Figure 3. The system boundary of P-RU-FREI (a) and SREI (b) production stage.

Table 2. The inventory of the LCA of processing P-RU-FREI and SREI.

Step	Materials and energy	
	P-RU-FREI	SREI
Rubber compound preparation		
Input	NR/SBR tyre reclaimed rubber Natural rubber Styrene - butadiene rubber Polybutadiene Zinc oxide Paraffins Hydrocarbon resin Carbon black Naphthenic oil Transport Electricity	Natural rubber Styrene - butadiene rubber Polybutadiene Zinc oxide Paraffins Hydrocarbon resin Carbon black Naphthenic oil Transport Electricity
Reinforcement preparation		
Input	Polyester fibre/resin Chemosil 231 G Transport Electricity	Steel reinforcement Plates Adhesive Connecting plates Transport Electricity
Output	Fibre scraps Glue residues	Steel scraps
FREIs Isolator assembly		
Input	Rubber compound Reinforcement Electricity	Rubber compound Reinforcement Electricity
Output	Rubber scraps	Rubber scraps

IMPACT2002+ methodology (Joliet et al. 2003) was selected for the impact assessment phase of the study. It proposes a feasible implementation of a combined midpoint/damage approach, linking all types of life cycle inventory results via several midpoint categories to several damage categories. IMPACT2002+ considers 15 midpoint categories which are expressed in reference units of a given substance and are quantified starting from preexisting impact assessment methods. Midpoint categories are then combined to define four damage categories: human health, ecosystem quality, climate change, and resources. These four damage categories are expressed in DALY, PDF m² y, kg CO_{2-eq} and MJ, respectively. For the sake of brevity, only the results in terms of mid-point categories are considered in this study.

Environmental Impacts are first characterized; then, they are normalized with reference to mean European values representative of a certain period of time, either at the midpoint or at the damage level. Normalization allows the different categories to be plotted on the same graph, making the interpretation of results easier and contextualizing the results.

3.1 Life Cycle Inventory (LCI) analysis

LCI is a phase to list all the data collected and identify inputs/outputs (Li et al. 2010). The detailed foreground data of this study are summarized in the Table 2. Moreover, the ecoinvent database (<https://ecoinvent.org/the-ecoinvent-database/>) was applied in this study to provide detailed background data on generic materials, energy, transportation, and waste.

Data for the raw materials were further elaborated by taking into account cut-off criteria. Cut-off rules enable LCA practitioners to conduct LCA without having to model 100% of the product system. According to the ILCD Handbook (Curran 2012), the cut-off criteria refer to the omission of non-relevant life cycle stages, activity types, specific processes and products and elementary flows from the system model. In this specific case all materials with a percentage in weight less than 1% have been neglected. The use of NR/SBR tyre reclaimed rubber in the P-RU-FREI production

process was modelled as avoided impact in terms of virgin natural rubber. Data for the electricity input was selected in ecoinvent as “Electricity mix, AC, consumption mix, at the consumer, 1kV - 60kV IT S”. It represents the Italian specific electricity supply for final consumers, including electricity own consumption, transmission/distribution losses and electricity imports from neighboring countries. The transportation of raw materials (expressed in ton*Km) for both isolators was selected as “transport, freight, lorry 3.5-7.5 metric ton, EURO4”.

3.2 Life cycle impact assessment and interpretation

LCA results are summarized in Figures 4 and 5 by reporting the 15 environmental impact categories for both types of isolators after the execution of the characterization and normalization steps. For each impact category, the environmental impacts are shown by dividing the different stages of the isolator production (rubber compound preparation, reinforcement and assembly). In terms of product stage contribution, Figure 4 (a) and (b) highlight that there is a different environmental burden (in the percentage of the whole impact) associated with the rubber and reinforcement components for P-RU-FREI and SREI isolators. In particular, the rubber compound preparation in the P-RU-FREI production is responsible for the highest environmental impact in all the categories (with an average value of greater than 60%). The reinforcement production accounts for approximately 25% of the total impacts whereas the assembly phase (mostly associated with energy consumption) is responsible for 10% of production impacts. On the contrary, the highest contribution to the environmental burden of the SREI isolator is given by the reinforcement preparation with an average value of 74.7%; while the step of rubber compound preparation and assembly have an average contribution of 22 and 3%, respectively.

Figure 5 shows the results of the mid-point impact categories by comparing the P-RU-FREI and SREI systems. It can be observed that the P-RU-FREI has a lower environmental impact (i.e. 20% on average) in all the categories compared to SREI (reported as 100% in the histogram solid bars) mainly due to the dominant contribution of steel reinforcement production and transformation (orange bars). The beneficial effects of reclaimed rubber in the P-RU-FREI raw material production can be clearly identified only in a few impact categories (e.g., carcinogens, respiratory organics, global warming potential); in the remaining ones, the impacts are comparable to SREI.

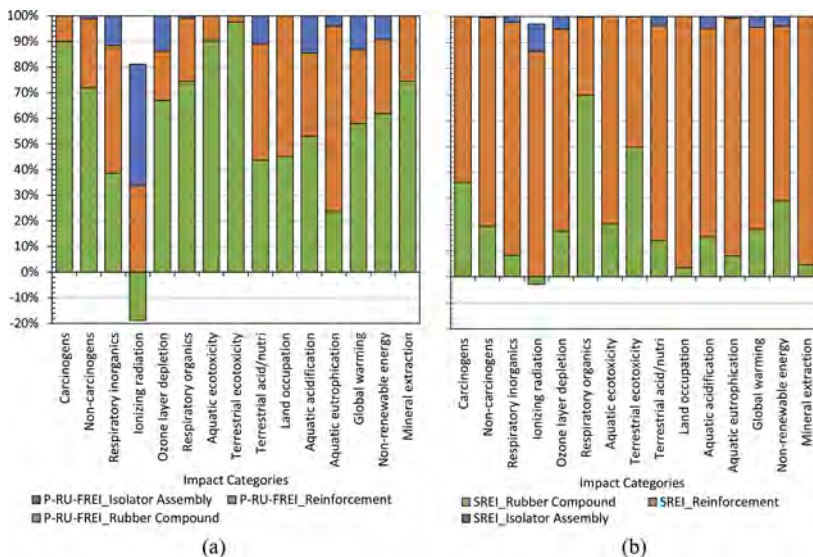

Figure 4. Characterization of environmental impacts for P-RU-FREIs (a) and SREIs (b).

Figure 5. Comparison of P-RU-FREIs and SREIs for the 15 mid-point categories (IMPACT 2002+).

4 CONCLUSIONS

In this study, the environmental performances of two isolation systems have been assessed by means of LCA. Preliminary results – focusing on the isolator production stage – demonstrate the interesting potential of reducing environmental impacts in the case of P-RU-FREI devices; lighter reinforcements compared to steel ones might be an effective solution to reduce the burden of steel-related transformation processing in SREI. The use of reclaimed rubber in the P-RU-FREI raw material production can provide additional benefits. However, further investigations should be considered to achieve a comprehensive evaluation of both systems, such as the extension of LCA to the building scale, durability and maintenance, and end-of-life scenarios.

Definition of a design procedure of seismic isolation systems based on rubber bearings

Marco Furinghetti

Civil Engineering and Architecture Department – DICAr, University of Pavia, Pavia, Italy
EUCENTRE Foundation, Pavia, Italy

ABSTRACT: Among the many protective strategies against earthquake excitations, Rubber Bearings represent the easiest solution for seismic isolation systems, even though a number of issues have to be considered, especially related to vertical buckling and limitations on the maximum vertical load which can be applied to the single isolator. In this work a fast design procedure is defined specifically for Rubber Bearing isolators, by considering initial assumptions, which can be easily managed by practitioners. With hand computations in few steps, devices can be determined in terms of both geometrical and mechanical properties, able to provide the proper period shift and energy dissipation, in agreement with the assumed performance point, avoiding buckling behavior with respect to the vertical direction. The presented procedure has been applied to a case study structure, which has been numerically analyzed, in order to assess the efficiency of the designed isolation system.

1 INTRODUCTION

Passive isolation represents one of the most effective techniques for the reduction of the seismic vulnerability of both newly designed and existing poorly designed structural systems. (Brunesi et al. 2016, Calvi and Calvi 2018). In the recent past, both numerical and experimental campaigns have led to the development of a number of devices, able to provide specific energy dissipation, associated to low values of lateral stiffness, which directly implies a period shift (Constantinou et al. 1990, Constantinou et al. 1999, De Domenico et al. 2018, Dolce et al. 2005, Fenz and Constantinou 2006, Kumar et al. 2013). Consequently, low internal forces are induced into the superstructure, and the high displacement demand expected at the isolation system can be limited. Thanks to the outcomes of experimental tests, a number of numerical models have been developed with high levels of sophistication, which are able to reproduce the force response of the implemented devices. This allows realistic numerical seismic simulations, which can return precious results for both vulnerability and risk assessments (Dall’Asta et al. 2020, Cardone et al. 2019, Mazza and Mazza 2017). On the other hand, even though come general guidelines for the design of an isolation system are provided by commonly adopted standard codes worldwide, the definition of specific design rules would help practitioners to obtain the geometrical and mechanical parameters for isolation devices, in order to guarantee a certain performance point.

In this work fast design rules for seismic isolation systems based on elastomeric devices are defined and validated, through Non-Linear Time-History Analyses. Special attention will be focused on the definition of geometrical and mechanical properties of the isolators, in order to consider eventual buckling effects since the design phase.

2 FAST DESIGN RULE

In this work, fast design rules are defined, specifically for elastomeric isolators (Figure 1). The aim is to provide a few-step procedure to come up with an initial configuration of the isolation system of a building, by accounting for buckling and local failures.

Figure 1. Internal components of a Rubber Bearing isolation device.

The adopted fast design procedure has been developed in a recent research work (Furinghetti, 2022). The presented procedure starts with the assumption of a performance point, in terms of design period and equivalent viscous damping (Figure 2). Consequently, the displacement demand of the isolation system can be computed, in terms of displacement spectral coordinate, at the design period, as a function of the assumed equivalent viscous damping.

Figure 2. Definition of the performance point.

Once the displacement demand is computed, the total height of the device can be obtained, by assuming a design shear strain, generally equal to 100% (Step (1)). Then, the horizontal diameter of the single elastomeric isolator can be computed as a function of the displacement demand, through the application of a scale factor: this is to ensure that the isolator is able to transfer the applied vertical load from the superstructure to the substructure even when the maximum displacement is achieved, with no buckling phenomena; this implies scale factors β higher or equal to 2,0. Hence, all the geometrical parameters of the single device are defined, and the lateral stiffness of the single device can be computed, as a function of the shear modulus of the adopted compound. Finally, the number of elastomeric isolators can be determined, by considering the ratio between the global stiffness of the system (as a function of the design period and the global isolated mass) and the stiffness of the single isolator; it can be noted that the overall procedure does not consider any additional force response related to the eventual Flat Sliders, needed to cover all the bearing points of the structure.

Figure 3. Steps of the fast design procedure.

Step 2) is strongly related to possible buckling phenomena of the designed isolators, especially when the device is subjected to the maximum shear deformation (De Luca et al. 2019).

To this aim, elastomeric isolation bearing can be characterized by a Critical Vertical Load, depending on two shape factors S_1 and S_2 , and accounting for the effective reduced plan area which is addressed to transfer the vertical load from the superstructure to the substructure, as shown in eq.(1) (De Luca et al. 2019).

$$\left\{ \begin{array}{l} N_{crit} = G_r \cdot A_r \cdot S_1 \cdot S_2 \\ S_1 = \frac{\phi}{4t_r} \\ S_2 = \frac{\phi}{t_e} \\ A_r = A_{iso} \cdot \left(1 - \frac{D_d}{\phi}\right) \end{array} \right. \quad (1)$$

Thus, in order to obtain a better definition of the plan diameter of the elastomeric isolator, all these parameters have been combined, by assuming a design target value of vertical pressure, defined as the ratio between the critical vertical load and the gross plan area of the device.

$$\left\{ \begin{array}{l} N_{crit} = G_r \cdot A_{iso} \cdot \left(1 - \frac{D_d}{\phi}\right) \cdot \frac{\phi}{4t_r} \cdot \frac{\phi}{t_e} \\ t_e = n_r \cdot t_r \\ \sigma_d = \frac{N_{crit}}{A_{iso}} \end{array} \right. \quad (2)$$

In agreement with such assumptions, the following expression of the design vertical pressure σ_d can be obtained, as a function of the maximum displacement D_d , the shear modulus of the elastomeric compound G_r , the diameter of the device Φ , the number and the thickness of the rubber layers (n_r and t_r respectively).

$$\sigma_d = G_r \cdot \left(1 - \frac{D_d}{\phi}\right) \cdot \frac{\phi^2}{4 \cdot n_r \cdot t_r^2} \quad (3)$$

If the thickness of the single elastomeric layer is assumed, then a second order equation with respect to the diameter of the isolator is obtained.

$$\phi^2 + (-D_d) \cdot \phi + \left(-\frac{4 \cdot n_r \cdot t_r^2 \cdot \sigma_d}{G_r}\right) = 0 \quad (4)$$

Finally, the diameter of the device can be obtained, and thanks to the proposed formulation, the returned value is directly associated to a critical vertical load, which is related to a specific design vertical pressure.

3 APPLICATION TO A CASE STUDY STRUCTURE

In order to validate the efficacy of the proposed fast design rule, a case study structure has been considered, consisting of a 6-storey reinforced concrete frame building, with all members designed according to Italian code-conforming provisions (Cardone et al. 2019). The horizontal sizes are approximately 21m and 12m for x and y directions respectively, with an interstorey height of 3.05m for all the floors, and 3.4m for the first, resulting in a total height of 19m.

The seismic mass for all the levels of the building is approximately equal to 300tons, with a total weight of the structure of 2080tons. If the modal analysis is performed, by modeling linear elastic frame elements for both beams and columns, a first mode period of vibration around 1.0 seconds is obtained. For the proper evaluation of the protection level provided by the designed isolation system, a non-linear static analysis (push-over) has been computed, through an OpenSees model of the fixed-base configuration.

In Figure 4 results are shown in terms of capacity curve of the structure.

Figure 4. Case study structure.

In order to determine the ultimate point of the building, a reduction of 20% of the maximum strength has been considered. Then, the non-linear capacity curve has been approximated through a bi-linear behavior, by implementing a special least-square procedure, which minimizes the sum of square errors of the base shear values, by ensuring the same area below each curve, corresponding to an energy balance.

Non-Linear Time History Analyses (NLTHA), performed on a linear elastic model of the building, implemented within SAP2000 (CSI 2021), by applying a selection of seven unidirectional natural seismic events (Iervolino et al. 2009). The spectrum-compatibility of the adopted suite of ground motions has been studied, in agreement with the Italian Building Code (NTC 2018), as a function of the seismic hazard level defined for the construction site: namely, L'Aquila city, with Soil class C and topography category T1. The Collapse Limit State has been assumed, corresponding to a return period of 975 years. The spectrum-compatibility has been checked, by considering 90% and 130% respectively of the code target spectrum as lower and upper bounds, in comparison to the mean spectrum of the selected events, within a period range between 0,15s and 3,0s.

Figure 5. Selection of code-based spectrum compatible seismic events.

Single-events ground acceleration time series have been scaled, in order to better achieve spectrum-compatibility prescriptions; moreover, scale factors have been bounded between 0.5 and 2.0, aiming at preserving the correct frequency content for the considered Peak Ground Acceleration (PGA) values.

For the application of the aforementioned fast design procedure, a number of mechanical and geometrical quantities have been initially assumed. Firstly, a performance point has been

detected, at a design period value of 2.8sec, together with an equivalent viscous damping of 15%, corresponding to High Damping Rubber Bearings. Then, 100% of design lateral shear strain has been considered, and the adopted compound has been characterized by a shear modulus value equal to 0.8MPa. For the proper definition of the plan diameter of the device, as a design value of the vertical pressure, 9.0MPa has been considered, as the reference value for the testing protocol for elastomeric bearings in agreement with the European Standard Code UNI:EN15129:2018 (CEN 2018 - namely 6.0MPa), increased by 50%. Finally, 12mm and 2mm have been considered as thickness values for rubber and steel layers respectively.

In Table 1 all the design parameters returned by the adopted procedure are summarized.

Table 1. Design parameters for the case study structure.

T_d [sec]	ξ_d [%]	h_{is} [mm]	γ_d [%]	G_r [MPa]	σ_d [MPa]	Φ_r [mm]	n_{is} [#]
2.8	15	252	100	0.8	9.0	516	16

As can be noted, the design procedure has led to an isolation system of 16 elastomeric devices. Since the considered case study structure has 24 bearing points, Flat Sliders have to be implemented, in order to correctly support the structural weight of the building. In addition, seismic elastomeric isolators have been placed in the most external regions of the plan view of the building, in order to increase as much as possible the resulting torsional stiffness of the isolation system, by providing a symmetric layout. In Figure 6 the final configuration of the designed isolation system is shown.

Figure 6. Distribution of devices for the designed isolation system.

4 RESULTS OF N.L.T.H.A.

In this section global results are presented, in terms of single-event and mean values of peak isolation displacement (Figure 7) and peak building base shear (Figure 8).

Figure 7. Results: peak isolation displacement.

Figure 8. Results: peak building base shear.

As can be noted, the mean isolation displacement, which represents the reference value, in agreement with the Italian building Code, is close to (but lower than) the target design displacement of the devices; in addition, also the single-event values are fairly close to the target design displacement, thanks to both the proper adopted design procedure and the high level of spectrum-compatibility of the applied suite of ground motions.

Furthermore, if the efficacy and the protection capabilities of the designed isolation system are considered, through the analysis of the single-event and the mean peak base shear of the building, it can be assessed that the building force response falls within the elastic range in almost all cases; in some seismic events larger values can be detected, with limited variation percentages (below 10%), which can still be considered as included in the elastic linear elastic response.

5 CONCLUSIONS

In this work a fast design procedure for elastomeric bearings has been presented. More specifically, special attention has been focused on the protection against the buckling critical load at maximum displacement, so that the isolator is able to provide the proper support for the whole range of applied vertical loads. The procedure has been applied to a case study structure, by performing Non-Linear Time History Analyses, and results have led to the following remarks:

- The adopted procedure has led to the proper geometrical characteristics of the implemented isolators, and the plan diameter has been computed, in order to guarantee that a specific value of average vertical pressure, as correspondent to the critical load;
- For safety reasons, the reference value of average vertical pressure has been defined as the vertical load generally applied in testing protocols, in agreement with the European Standard Code UNI:EN15129:2018 (namely 6.0MPa), increased of 50%, resulting into 9.0MPa.
- The proposed procedure leads to a sufficiently safe definition of the displacement demand for the isolation system, and low variations can be detected also for the single-event response;
- Concerning the base-shear response of the building, it can be assessed that all values are approximately lower than or equal to the maximum strength of the bi-linear capacity curve of the building, ensuring a linear-elastic response for both the single-event and the mean cases, even though slightly higher values can be detected for some earthquake simulations.

ACKNOWLEDGEMENTS

Part of the current work has been carried out under the financial support of the Italian Civil Protection, within the frameworks of the Executive Project 2017–2019 (Project 3 – Assessment

of the seismic isolation of building structures through hybrid tests with numerical substructuring) and the national Research Project DPC – ReLUIIS (National Network of Laboratories of Seismic Engineering) 2022–2024, WP15.

Inverse design of isolated structures using predicted FEMA P-58 decision variables

H.G. Pham & T.C. Becker

University of California, Berkeley, California, USA

ABSTRACT: Base isolation systems are often chosen in structural engineering to outperform conventional designs, allowing designers to achieve high performance goals. However, achieving specific performance targets requires numerous high-fidelity analyses and often involves iterative design. To address this, a database of diverse structural designs under earthquake inputs is constructed, and probabilistic loss and downtime estimation is carried out. Several machine learning models are utilized to fit the design parameters to their performance, allowing for prediction over a wide space of new design combinations. The prediction models find that accurate cost estimation relies on classification of impact against the moat wall, which is strongly predicted by the moat capacity of the isolators. The developed model is used to for an inverse design procedure in which acceptable design regions are attained by defining acceptable limits for repair cost, downtime, etc, and the resulting design is verified to outperform a typical code compliant design.

1 INTRODUCTION

Recent research into performance based engineering has significantly improved engineers' and stakeholders' capabilities in quantifying losses and risks associated with seismic threats. Past studies involving such assessments for conventional steel special moment frames found that significant losses are retained in replacement costs (Hwang & Lignos 2017) as well as lengthy disruption in the building's functionality and occupancy status (Molina Hutt et al. 2016). With regards to these societal consequences, however, the incorporation of economic performance metrics into a targeted design process remains a large challenge, even for fixed based structures. Although ASCE 7-22 (2022) code provisions provide safety measures aimed at meeting collapse risk targets, they do not ensure the functionality of buildings after an event. Under these contexts compounded with the extensive time and computational cost associated with iterative design and performance assessment, the development of a design process to optimize building performance subjected to targets in decision variables and economic metrics warrants additional research.

The FEMA P-58 (2018) methodology is the state-of-the-art loss estimation approach in structural design, but fully carrying out the performance assessment for design is a time-consuming task. Full design considering these economic metrics have been studied for conventional fixed-base moment frames (Ghasemof et al. 2022), and while the effect of base isolation on building resiliency have been analyzed in case studies (Moretti et al. 2014), the inverse design that directly targets the economic consequences as estimated by FEMA P-58 remains an unexplored topic. The continued development of data learning and prediction models offers a solution to bypass the lengthy assessment process of early estimations in structural design. This combination of machine learning aided estimations and the FEMA loss assessment has been previously utilized to evaluate the effect of design parameters and modeling uncertainty on lifetime costs for fixed based structures (Hwang et al. 2022), but has not been

used to carry out an inverse design problem, especially for isolated structures. Thus, this research seeks to provide a data learning assisted inverse design procedure that can aid in preliminary design of a broad range of isolated building given clear design goals such as desired downtime and/or costs.

2 DATABASE CONSTRUCTION

To create the database, a set of inputs is generated from which the building design is automated and a ground motion is scaled. A set of 400 points is generated to train the prediction models. The structure is a three-story steel moment frame, isolated with triple friction pendulum (TFP) bearings. The superstructure is 3 bays and 3 stories. Figure 1 shows an elevation of the structure with dimensions along with several important design parameters used in the problem.

Figure 1. Elevation view: isolated moment frame and TFP bearing.

The design of the structure is based on typically used design parameters. The descriptions and ranges for each parameter are presented in Table 1. Parameter ranges are chosen to reflect typical values that might be seen in the design of an isolated structure in coastal California. The range for the amplification of the moat gap, A_δ , is chosen to investigate potential overdesign of the displacement capacity that might be needed. The strength reduction factor, R_y , is defined as the reduction applied onto the elastic base shear for the structure and is treated as a random variable to explore the effects of increasing the superstructure strength. Its upper bound (2.0) is the ASCE 7-22 recommended value for isolated steel moment frames. For the purpose of creating a space of input variables, Latin hypercube sampling with uniform distribution is utilized to generate design input combinations to ensure that an evenly distributed input set is achieved and to provide a well-supported basis for the prediction models.

Table 1. Design inputs for Latin hypercube sampling.

Input	Description	Lower bound	Upper bound
S_1	Target spectral acceleration at $T = 1$ sec	0.8	1.3
T_M	Target effective period for bearing design	2.5 sec	4.0 sec
ζ_M	Target effective damping for bearing	0.10	0.20
μ_1	Inner slider friction coefficient	0.01	0.05
R_1	Inner slider radius of curvature	380 mm (15 in)	1140 mm (45 in)
A_δ	Amplitude for moat gap	1.0	2.0
R_y	Strength reduction factor	0.5	2.0

2.1 Design of the bearings and superstructure

The TFP bearing design is derived from the unidirectional multi-stage behavior of TFP bearings. Figure 1 shows a cross section of the bearing used in the study. For simplicity, this study examines bearings with the outer sliding surfaces sharing the same friction coefficient and radius of curvature. The expected displacement D_M under a given spectrum serves as the nominal recommended moat gap capacity by ASCE 7-22 without amplification for torsion as the analysis is

conducted with a unidirectional ground motion. For this study, to explore the effect of the moat gap on the cost and downtime, the displacement capacity is modified by multiplying by A_δ .

Given the target T_M and ζ_M and two randomly generated design parameters, the remainder of the bearing parameters can be solved. This study randomly selects inner friction coefficients (μ_1) and inner radii of curvature (R_1) to solve for the other bearing parameters as shown in Fenz & Constantinou (2008) or Becker & Mahin (2013). The superstructure is then designed following ASCE 7-22 Chapter 12 procedures, with maximum story drift at $\theta = 0.015$. The lightest compact W-shapes are selected for the beams, and then the columns are selected to ensure a strong column weak beam mechanism. The beams are selected from suitable W-shapes through the process determining sufficient second moment of area (I_x) and section modulus (Z_x) to meet the drift and strength requirements, respectively. The beams are then selected from the lightest compact shape, while the columns are selected to ensure a strong column weak beam mechanism. From the design procedure, the friction coefficients (μ), slider radii of curvature (R), moat gap (D_{moat}), column sections, and beam sections are attained.

2.2 Modeling and analysis in OpenSees

The 2-D model is constructed in OpenSees (McKenna et al. 2010). Beam and column elements are modeled as elastic elements with a rotational spring at each end using the modified Ibarra-Krawinkler material model to account for strength deterioration. Parameters for the material model are adapted to reduce the elastic beam length to 80%, placing each plastic hinge at 10% of the member length away from each joint (Lignos & Krawinkler 2011). To simulate P Δ effects, a leaning column is used to carry the loads from the unmodeled gravity frames. A rigid diaphragm using elastic elements spans the layer above the isolators. The superstructure has Rayleigh damping of 5% and 2% at the first and third superstructure modes.

The bearings are modeled with triple friction pendulum elements using simple Coulomb friction (Dao et al. 2013) without accounting for uplift failure of the bearings. The moat wall is implemented using zero-length impact elements. The impact model uses a damped Hertz contact model (Muthukumar & DesRoches 2006), and the parameters are calibrated assuming that the isolation layer diaphragm is 152 mm (6 in) thick and collides against a 304 mm (12 in) thick moat wall that is 2.74 m (9 ft) tall.

A library of 68 ground motion records from the PEER NGA-West database (Ancheta et al. 2014) from events of magnitudes ranging from 6.0 to 8.0 and distances from 0.0 km to 80.0 km is used. $V_{s,30}$ velocities were limited from 200 m/s to 600 m/s to select for site with dense soil or soft rock. Given a S_1 , the random ground motion is selected and scaled over a range of interest defined as $T = [0.2T_{\text{isol}}, 1.5T_{\text{isol}}]$, where T_{isol} is a typical average period for isolated structures, estimated as 3.0 seconds. The isolated structural model is then subjected to a nonlinear dynamic analysis for a randomly selected ground motion, scaled based on the S1 parameter. The peak interstory drift ratios, floor accelerations, and floor velocities are collected. For this study, analyses are stopped when any story drift ratio exceeds $\theta = 0.20$, and their last committed state and response are recorded.

2.3 Loss and downtime estimation

To perform repair cost and time estimation, a Monte Carlo approach is carried out as called for by the FEMA P-58 guidelines and implemented by the Pelicun (Zsarnóczy & Deierlein 2020) tool for assessment of structural performance. For each design in the database, the engineering demand parameters (EDP) consisting of the peak interstory drift ratios, peak floor accelerations, and peak floor velocities are treated as deterministic samples, and the residual story drift ratios are estimated using the methodology provided in FEMA P-58 using an assumed yield story drift ratio of $\theta_y = 0.0075$. For all structures, non-structural building content is specified assuming that all floors contain 100% office occupancy, except for the first floor which contains 80%-20% retail-office mixed occupancy. All fragility data uses FEMA P-58's database.

For the study, two replacement conditions that trigger the maximum replacement cost for the building are specified: building collapse and irreparable damage. The building collapse damage

state is determined using a collapse fragility curve dependent on story drift. The parameters for the curve is defined by assuming a dispersion of 0.25 (Yun & Hamburger 2002) and that a moment frame with 10% peak drift ratio has a 84% (mean + one standard deviation) collapse frequency. The irreparable damage state is based on values found in FEMA P-58 and has a fragility curve that assumes the risk is distributed lognormal given residual story drift with a mean of $\theta = 0.01$ and a dispersion of 0.3. For both of these cases, the replacement cost is set as 250 USD per 0.092 m² (\$250 per ft²) of floor area, which amounts to 8,100,000 USD for the example structure. Likewise, a replacement downtime is calculated using an assumption that 40% of the replacement cost is labor at the rate of 680 USD per worker-day which is typical for the San Francisco Bay Area. The assessments are then carried out using 10,000 realizations per experiment, and the statistics of the repair cost, repair time, collapse frequency, and irreparable damage frequency are recorded. In this study, the repair time is specified as the time required for a team of 25 workers to repair damaged components sequentially.

3 PREDICTION MODEL

To facilitate the inverse design of structures, several prediction models are built to estimate the expected value of the repair cost, sequential repair time, and collapse risk of a design. From the results of the time history analyses and loss estimations, response parameters and decision variables are greatly increased when the structure experiences impact with the moat wall, and their relationships with the design variables also differ when impact occurs. Additionally, regression performed without considering the effect of impact leads to predictions that underfit the true data, often underestimating loss in scenarios where impact is likely and overestimating loss in the other extreme. Thus, the expected value of a decision variable DV given design variables X is conditioned against I , impact of the moat wall, and the total expected value can be expressed as

$$E[DV | X] = E[DV | X, I = 1]\Pr(I = 1) + E[DV | X, I = 0]\Pr(I = 0) \quad (1)$$

For a single decision variable, three prediction models are then trained: a classification model to perform probabilistic estimation of impact given the design parameters and two regression models to fit decision variables under impact and no impact conditions. To form the covariate vector X that is used to predict outcomes, several important design variables are identified as variables that can characterized structures of different isolated systems and are selected as covariates for the prediction models. The first variable, $\frac{D_{\text{moat}}}{(S_{aT_M}/B_M)T_M^2}$, the moat gap ratio relates the moat gap to the elastic displacement demand and is effectively a multiplier of the displacement capacity required by ASCE 7-22. To account for the stiffness of the structural system in the design process, the variable T_M is retained as the period of the isolation system. Lastly, the variables ζ_M and R_y represent the structural damping and strength reduction factor, respectively. The list of covariates for the surrogate model is then finalized as $\frac{D_{\text{moat}}}{(S_{aT_M}/B_M)T_M^2}$, ζ_M , R_y , and T_M .

3.1 Classification model for impact

For classification of isolation impact, Gaussian process classification (GPC) is used for several reasons. Like the regression methods discussed, Gaussian process classifiers (Williams & Rasmussen 2006) allow for the usage of a kernel in order to expand its feature space to account for nonlinear interaction between variables. However, GPC is a non-parametric method that does not rely on a small weight vector to make prediction, thus allow for prediction to be directly influenced by the size of the training set. Moreover, GPC is a probabilistic model that allows for predictions of outcome's likelihood directly, which is not a well-calibrated option when support vector classifiers.

The database is split into 320 training points and 80 testing points, and the model achieved a prediction score of 90% in the testing set. Figure 2 shows the Gaussian process classification model for impact against the moat wall as predicted using the design variables.

As expected, the likelihood that the isolation layer will impact against its wall is primarily dependent on the gap ratio. The GPC model shows that higher T_M results in a lower predicted probability of impacting the moat wall, visible in the contours moving towards lower gap ratios as T_M increases. R_y and ζ_M show less effect on predicting impact, resulting in relatively stagnant contours as those variables change. The results are reasonably expected, since the gap ratio and T_M most directly affect the flexibility of the bearings as well as the capacity provided to the isolation layer. It should be noted that at higher gap ratios where fewer points lie, the model regresses to a more moderate prediction in absence of data support which results in the slight increase in impact probability seen.

Figure 2. GPC impact probabilities by variables.

3.2 Regression models for decision variables

Two machine learning methods are considered to fit the decision variables (cost and downtime) given an impact condition: support vector regression (SVR) and kernel ridge regression (KR), with the radial basis function (RBF) kernel utilized for both models. Although more complex methods like Gaussian process regression could be considered to carry out the fit, the two methods chosen achieve a similar fit at a much reduced computational cost. The models are fit against the mean decision variable value of the estimation. To fit the model, the 400 points in the database are grouped by their impact status with 188 trials experiencing impact. Each subset is then fit with a separate model, and the regression results are used as conditioned expected values in Equation 1. Ultimately, different models are chosen for different decision variables due to their fit qualities. SVR is used for cost and KR is used for downtime.

Figure 3 details the predictions of the models for repair cost and downtime, weighted by the likelihood of impact as predicted by the GPC model. When predicting cost, the SVR model shows that an increase in T_M reduces the expected mean repair cost across all gap ratios shown. In contrast, a decrease in ζ_M reduces the repair cost, with the decrease more notable at higher damping levels at larger gap ratios where impact is not expected. With respect to R_y , low gap ratios seem to suggest that either extrema of the superstructure strength bounds leads to a lower predicted repair cost, though this may be possible due to the high variance in EDPs that are experienced when impact happens. The SVR model shows that an increase in R_y at larger gap ratios leads to a very moderate decrease in repair cost. Similar trends are noted in the prediction of downtime using the GPC-KR model with the noted exception that the model perceives that lower R_y leads to lower downtime across all gap ratios.

4 EXAMPLE DESIGN

4.1 Inverse design

Upon creating the prediction models based on generalized parameters, acceptable design regions can be identified based on desired performance limits. The prediction models are applied to a design space that spans the bounds of the input space (Table 1). For this example, the final design

is selected as that with the cheapest upfront cost that satisfies a repair cost limit of \$1,620,000 (20% of the replacement cost) and a repair time of one month for a team of 25 workers.

The upfront cost for this study considers the construction and development costs of the steel in the superstructure and the land given the moat distance. The land cost is taken as \$2837 per m² (\$263 per sq ft) for a special moment frame isolated system located in San Francisco, CA, with a moat wall (Kitayama & Cilsalar 2022). To estimate the cost of the superstructure strength, a unit cost of \$4.40 per kg (\$2.00 per lb.) is taken for steel and the cost of each structure in the initial database is calculated. A linear regression is then performed for the steel cost on the design base shear for the superstructure (V_s), and the coefficients are used to estimate costs of new designs. Table 2 shows the design selected by the prediction models in conjunction with the upfront cost minimization.

Figure 3. GPC-SVR prediction of mean repair cost and downtime at different gap ratios.

Table 2. Inverse design chosen by grid search.

Variable	Source	Value
Gap ratio	Prediction models & grid search	1.383
T_M	Prediction models & grid search	3.93 s
ζ_M	Prediction models & grid search	0.20
R_y	Prediction models & grid search	2.0
S_1	Arbitrarily chosen by location	1.017 g
D_{moat}	Calculated from gap ratio	91.6 cm (36.1 in)
μ_1	Selected by designer	0.036
μ_2	Calculated from design	0.067
R_1	Selected by designer	1015 mm (40 in)
R_2	Calculated from design	2844 mm (112 in)

4.2 Validation

To validate the design, a series of nonlinear time history analyses is performed using a suite of 60 ground motions. For each ground motion ran, the set of EDPs are collected for the purpose of performance estimation with Pelicun. However, since a distribution of EDPs are now available for a single designed structure, they are processed in the FEMA P-58 framework as a single set of EDPs distributed lognormal rather than as 60 deterministic samples. Additionally, a baseline run that represents a typical code-compliant design is conducted in order to compare the inverse design against a representative one that is very likely seen in practice. The baseline has a specified gap ratio of 1.0, $R_y = 1.0$, $T_M = 3.5$ seconds, and $\zeta_M = 0.15$. Figure 4 reports the distribution of the cost estimates for both structures generated from 10,000

realizations of component damage, loss, and repair time as calculated by the Pelicun module as well as the selection limit for those criteria.

Figure 4. Distribution of estimated decision variable for designed structures.

From the distributions shown in Figure 4, the inverse design has results that are generally distributed at lesser costs and repair times than the baseline design. From the predicted values shown in Table 3, downtime (sequential repair time) is the variable that controlled the selection of the inverse design, since the predicted value lies just short of the limit compared to the repair cost. For the limits chosen, the inverse design achieved the targets more often than the baseline design. Of the 10,000 realizations shown, 91.7% of the inverse design realizations fell within the repair cost limit, and 90.1% met the repair time limit, compared to the baseline design’s 80.5% and 77.2% for cost and time, respectively.

Table 3. Performance evaluation of inverse design structure at MCE_R .

Variable	Targeted Limit	Prediction	Design performance (Δ baseline)
Mean repair cost	\$1,620,000	\$1,233,381	\$854,430 (-49.8%)
Mean downtime (days)	28.0	27.8	20.8 (-48.9%)
Upfront cost	—	—	\$348,602 (-12.0%)

Table 3 presents the performance of the inverse design compared against the baseline structure. The inverse design meets all of the required targets. Overall, the inverse design outperforms the baseline in all metrics presented, including upfront cost. The inverse design’s lower upfront cost is a result of lowering the steel cost in superstructure strength in exchange for a higher land cost to accommodate the moat gap capacity.

5 CONCLUSION

To better identify acceptable isolation designs for targeted building performance, several data learning models are developed to identify admissible design parameter ranges given performance targets without relying on high-fidelity dynamic analysis. From the support database, it is found that prediction models rely on conditioning the data on the impact against the moat wall to provide more accurate loss predictions. The inverse design is then selected by narrowing down the design space on the repair cost model predicted by a GPC-SVR model and repair downtime predicted by a GPC-KR model. The selected design is shown to achieve the targeted performance objectives with the following observations:

- The inverse design selected to achieve a repair cost amounting to 15.2% of the replacement cost and 4 weeks of downtime, achieved 10.5% of replacement cost and 3 weeks of downtime, while a typical baseline structure following code recommendation achieved 21.0% of replacement cost and 5.8 weeks of downtime.
- Depending on feasibility in increasing land plot size, an 38% increase in moat gap and displacement capacity could result in up to a 50% reduction in expected repair cost, even when

compounding with a lowered superstructure strength ($R_y = 2.0$), as shown by comparing the inverse design to the baseline design in the validation study.

The design process as assisted by prediction models is shown to be capable of meeting performance objective, with possible expansion to additional objectives to be considered, such as collapse risk, red-tag risk, or component group-specific level losses. Future work would greatly benefit from the combination of the loss prediction model with more sophisticated upfront cost considerations.

Seismic behaviour of building using damage-avoidance shearwall hold-downs

L. Budi

PT. Pertamina (Persero), Dumai, Indonesia

ABSTRACT: Concrete coupled wall is the outstanding seismic resisting system for mid to high-rise building structures. In this system, the link beam provides coupling action between the beam and the adjacent wall panel, which increases the lateral stiffness and reduces the footprint of the seismic resisting system. However, once the link beam is damaged due to a severe earthquake, it is difficult, costly, and time-consuming to repair. To deal with this issue, the Resilient Slip Friction Joint (RSFJ) is used to couple the wall limb in this study. RSFJ is a novel seismic technology which can satisfy the “life safety” and “immediate occupancy” criteria post-earthquake. An eight-storey reinforced concrete building is designed using the forced-based design method, and its seismic performance is evaluated by non-linear static pushover and nonlinear dynamic time-history simulations. The results showed that this system can provide a high level of structural ductility while providing fully self-centring behaviour.

1 INTRODUCTION

Studies showed that the concrete coupled wall is one of the most effective seismic resisting systems for mid to high-rise building structures, particularly for those located in an active seismic region. In this system, the link beam provides coupling action between the beam and the adjacent wall panel, which significantly increases the wall system’s lateral stiffness and eventually reduces the footprint for the seismic resisting system. However, once the link beam is damaged due to a severe earthquake, it is difficult, costly, and time-consuming to repair, which results in business disruption and increased building life cycle costs.

To comply with the “life-safety” and “immediate occupancy” criteria, the researchers conducted many studies to develop the low damage concept for concrete structures, where they still have the benefits of concrete shear walls. The general principle of the low-damage design concept is to control damage by using rocking connections, which are typically combined with supplemental damping devices, to dissipate energy. These damping devices act as sacrificial fuses which can be easily repairable or replaceable after moderate to severe earthquakes. Housner (1963) initially introduced the rocking concept by undertaking an experimental study on a rigid rocking block. He reported that the rocking motion had a considerable contribution in enhancing the structural stability against the overturning moment. Aslam et al. (1978) studied the rocking response of rigid structures and stated rocking resistance of the structure can be improved by anchoring it to the ground. Priestley et al. (1999) developed a hybrid post-tensioned connection on a concrete shear wall and reported that the prototype has an extremely satisfactory performance when subjected to severe seismic force. Yielding, friction, and viscous damping are proposed, tested, and used in rocking shear walls (Sritharan et al. 2015).

The above studies have advanced the concept of low-damage design for concrete structures, but there remains a significant literature gap. The poor repairability of the sacrificial elements requires the element replacement after a severe earthquake which is costly and causes business disruption for the building. In addition, as the residual capacity of these sacrificial elements will not be sufficient to resist severe aftershocks, the structure will still be vulnerable until

getting fully repaired by replacing the damaged fuses. Furthermore, regular inspection is required to deal with the creep issue in post-tensioning steel strand cables and their supporting members. Therefore, there is still a remaining step to achieve an ideal maintenance-free rocking wall system which provides an efficient and high-performance lateral load-resisting system and excellent self-centring mechanism during earthquakes and aftershocks.

To respond to the above challenges, Zarnani and Quenneville (2015) introduced a new technology, known as the Resilient Slip Friction Joint (RSFJ). It provides essential energy absorption and self-centring capability, and other excellent features, including secondary fuse activation, easy reparability, and free maintenance, to ensure life “safety” and “immediate occupancy” criteria post-earthquake. This research project proposed a concrete coupled wall structure using the RSFJ to produce an efficient and high-performance lateral load-resisting system.

The objective of this research is to analyze and assess the implementation of the RSFJ device in concrete coupled wall systems. The basic equations and the hysteresis curve of the RSFJ are introduced. The specific configuration of the RSFJ will be proposed, and the procedure to design RSFJ specifications will be developed. The effect of the RSFJ damping device in increasing the seismic performance of the building structure will be further investigated. Finally, the numerical modelling is developed, and its structural analysis result is verified.

2 RESILIENT SLIP FRICTION JOINT (RSFJ)

2.1 Analytical model

The RSFJ technology is a novel friction joint that provides energy absorption and self-centring behaviour in one compact package. The main component of the RSFJ comprises an elongated holes steel plate, metal cap plate, high strength bolts, and disc springs, as shown in Figure 1. In RSFJ, the restoring force comes from specific steel grooved plates which are tied through high-strength bolts and disc springs. By slipping of grooved plates, the input energy is dissipated through frictional resistance. Based on the free body diagrams presented in Figure 1, the design procedure is developed for the prediction of the performance of the RSFJ (Zarnani et al. 2016). The slip force (F_{slip}) and residual force (F_{res}) can be determined by Equations (1) and (2), respectively:

$$F_{RSFJ,slip} = 2 * n_b * F_{b,pr} \left(\frac{\sin\theta + \mu_s * \cos\theta}{\cos\theta - \mu_s * \sin\theta} \right) \quad (1)$$

$$F_{RSFJ,res} = 2 * n_b * F_{b,pr} \left(\frac{\sin\theta - \mu_k * \cos\theta}{\cos\theta + \mu_k * \sin\theta} \right) \quad (2)$$

Figure 1. RSFJ device: a) assembly; b) hysteresis; c) free body diagram; d) the joint at rest.

Where n_b = number of bolts on each splice, θ = groove angle, $F_{b,pr}$ is the clamping force of prestressing and the μ_s and μ_k are the static and kinetic coefficient of friction respectively, while considered $\mu_k = 0.85\mu_s$ (Hashemi et al. 2017). The general hysteresis behaviour of RSFJ

is illustrated in Figure 1(b). $F_{ult,loading}$ and $F_{ult,unloading}$ are the system forces at the maximum disc springs displacement and bolts force.

$$F_{b,u} = F_{b,pr} + K_s * \Delta_s \quad (3)$$

$F_{ult,loading}$ and $F_{ult,unloading}$ is derived by replacing the bolt forces in Equation 1 and Equation 2 by Equation 3, and μ_s, μ_k with μ_k, μ_s .

2.2 RSFJ as the hold-downs

Figure 2(a) shows the proposed rocking wall system. The free-body diagram of a rocking shear wall with RSFJ and the hysteretic behaviour of the system is shown in Figure 2(b). The deflection of the joints is related to their lever arm, which is the horizontal distance between the RSFJ centre to the rotating edge of the shear wall. Therefore, $\Delta_{RSFJ,1}/\Delta_{RSFJ,2} = L_1/L_2$, where Δ_{RSFJ} and L are, the expansion of the RSFJ and the associated lever arms, respectively.

Figure 2. The concrete rocking shear wall: (a) RSFJ as hold-downs; (b) free body diagram of the wall.

Hashemi et al. (2017) explained that the horizontal force acting at the top of the wall (F_{top}) can be calculated from the moments of the centre of rotation (the base of the wall). In this way, F_{top} can be further obtained using the following formula:

$$F_{top,slip} = \frac{1}{H} * [(W * L_w + F_{RSFJ,slip}(L_1 + L_2))] \quad (4)$$

In this equation, H is the height of the wall, W is the vertical loads, L_w is the horizontal distance from the vertical load to the centre of rotation, and $F_{RSFJ,slip}$ is the slip force of the RSFJ. After the slip stage, the force within the RSFJ corresponds to the deflection within them. Therefore, Equation (1) can be used to determine the lateral strength of the wall, $F_{RSFJ,1}$ and $F_{RSFJ,2}$ are the forces within the tensioned and compressed RSFJ, respectively. During the loading of the wall, Equation (2) can be employed to develop a correlation between $F_{RSFJ,1}$ and $F_{RSFJ,2}$. Then, Equations (1) and (2) can be combined to determine the overall load-deformation behaviour of the wall.

2.3 RSFJ as the shear links

In the coupled walls system, the coupling beam could be replaced by RSFJ (as the shear links). Similar to the single shear wall, the horizontal displacement on all columns and walls is equal because all columns and walls is connected to the floor. Sahami et al. (2019) proposed a formula to calculate the rocking base moment (M_{rock}) and rocking stiffness (k_{rock}) on the coupled wall system.

$$M_{rock} = M_{weight} + M_{damper} = W * B + n_d \quad (5)$$

$$k_{rock} = n_d * k_{d,ini} * [n_w * (L + d)^2 + (d)^2] \quad (6)$$

where n_w is the number of coupled walls and n_d is the number of dampers on each side of the walls, respectively. Meanwhile, W is the seismic weight of the wall, B is the width of the wall and d is the length of the shear link. The numerical analysis results showed that the coupled wall system using RSFJ as the shear link could achieve the capacity of two identical single walls.

3 THE DESIGN OF THE CASE STUDY BUILDING

An eight-storey reinforced concrete building structure with a concrete coupled wall as its seismic resisting system is proposed in this research project to evaluate the seismic performance of the system and the adopted design philosophy. The concrete coupled walls are used in the middle of the building to minimise the torsional effects. Meanwhile, the RSFJs are used as the hold-down at the bottom corner of the wall and as the shear link in the middle of the coupling beam. To satisfy the requirement of NZS1170.5: 2004, the following criterion is set for the design philosophy: (a) the Ultimate Limit State (ULS) lateral drifts are kept under 1.4 % to minimize the damage to structural and non-structural components (b) the structure remains elastic, the dampers are not activated and the lateral drift ratios are kept 1.5 % and 0.33 % for Ultimate Limit State (ULS) and Serviceability Limit State (SLS) cases, respectively (c) the structure has zero or negligible residual displacement at the end of the seismic event.

The building plan is 35 m by 35 m and is symmetrical about the two main axes. Along each axis, a concrete coupled wall equipped with RSFJ is used as the Lateral Load Resisting System (LLRS). A novel type of shear key is installed at the wall's base to provide displacement compatibility and transfer the shear forces from the wall to the foundation (Hashemi and Quenneville, 2017). The total building height is 28 m and has an identical storey height of 3.5 m. The building is designed for office application (i.e. importance level 3), is located in Christchurch, and is built on the soft soil layer (i.e. soil class type D). Figure 3. illustrates the developed model used in this research project.

Figure 3. The proposed model: (a) 3D Model; (b) plan view; (c) novel shear key.

The loads applied during the preliminary design are a self-weight (for the frame) of $0,006 \text{ kg/cm}^2$, a super-imposed dead load of $5 \times 10^{-3} \text{ kg/cm}^2$, a floor weight of $3 \times 10^{-2} \text{ kg/cm}^2$, a cladding weight of 10^{-2} kg/cm^2 , a floor live load of $3 \times 10^{-2} \text{ kg/cm}^2$ and a roof live load of $2.5 \times 10^{-3} \text{ kg/cm}^2$. The calculated seismic weights for the structure are $1.3 \times 10^6 \text{ kg}$ for floor one and floor two, $11 \times 10^6 \text{ kg}$ for floor three and floor four, $9.44 \times 10^5 \text{ kg}$ for floor five and floor six, $8.34 \times 10^5 \text{ kg}$ for floor seven, and $6.75 \times 10^5 \text{ kg}$ for roof.

A ductility factor of $\mu = 4.0$ and a structural performance factor of $S_p = 0.7$ are adopted for the design. The value of S_p is linked to the design ductility/level of detailing used and the value of 0.7 is appropriate for structures designed under NZS3101:2006. However, for other structural systems that use damage avoidance technologies, this value might be unconservative and may need to be re-evaluated. The period of the structure is determined as $T_1 = 0.43$ seconds using the empirical equation provided in NZS1170.5: 2004. Note that for periods equal to or more than 0.7 seconds, $k_\mu = \mu$. The base shear of the structure is specified as $V_b = 9.11 \times 10^5 \text{ kg}$ and $V_b = 1.584 \times 10^6 \text{ kg}$ for SLS and ULS cases, respectively. This base shear is distributed in the structure respecting the storey weights and heights as per the recommendations in NZS1170.5: 2004.

4 NUMERICAL ANALYSIS

In this section, a structural analysis using the SAP2000 program is performed to investigate the performance of the structure and to check the seismic lateral drift. A 3D model of an eight-storey building with concrete coupled walls and RSFJs is considered for the numerical modelling. The

beam-column connections and base connections are designed as pinned joints while the column sections are continuous as required by NZS3101.1:2006. A rigid diaphragm is assigned to each floor to constrain the horizontal displacement of the beams. The gravity loads have been applied to the beam and the seismic weights have been assigned to the nodes in each elevation.

The “Damper-Friction Spring” element in SAP2000 is adopted to represent the load-displacement behaviour of the RSFJs as the shear link and hold-down. The accuracy of using this link element for the RSFJs has previously been verified by comparing the experimental data with numerical results (Hashemi, 2017). The shear force demand and axial force demand on the wall’s toe from the elastic numerical model are used to determine the shear link and hold-down stiffness value, respectively. To achieve the rocking behaviour of the wall, the rocking foundation model which is represented by the “Gap” element in SAP 2000 is used.

Table 1. Summary of the key parameter of the RSFJ system.

Level	Parameter							
	F_{ult} (kg)	F_{slip} (kg)	$F_{restore}$ (kg)	$F_{residual}$ (kg)	$K_{initial}$ (kg/cm)	$K_{slip\ loading}$ (kg/cm)	$K_{slip\ unloading}$ (kg/cm)	Δ_{max} (cm)

The Nonlinear Push-over Analyses (NPA) are carried out to estimate the shear force for a specified lateral drift and calculate hysteresis damping values. The numerical model and analysis procedure are considered valid if the base shear and maximum roof displacement obtained from nonlinear pushover analysis is less than 5 % than that calculated using Equivalent Static Method (ESM) formula. Besides, the cyclic pushover analysis curve should represent the flag-shape hysteresis curve, which is the main characteristic of the self-centring structure. Furthermore, the nonlinear time history analysis is carried out to validate the initial ductility factor used in the design process and investigate the structure’s behaviour. Seven seismic events are selected and scaled for ULS based on method described in NZS 1170.5 for the given location and soil type. The ‘peak of three’ or the ‘average of seven’ records may be considered when designing using time-history analysis (Bradley, 2014). The numerical model and the design process are considered valid if the discrepancy between ESM estimation and NLTHA outcomes (i.e. base shear and roof displacement) are less than 5 %.

5 RESULTS AND DISCUSSION

The base shear generated from pushover analysis is 9.99×10^5 kg, which is slightly lower than that of the ESM calculation (1.0235×10^6 kg). Meanwhile, the lateral drift from pushover analysis is 1.5 % (i.e. 420 mm), which satisfies the target displacement. Moreover, the flag-shaped hysteresis curve, which is the main characteristic of the self-centring system can be reasonably achieved. It is observed from the hysteresis curve that the structure remains elastic up to 0.2 %. After this point, the RSFJs start to activate, resulting in the observed bi-linear pushover curve. It should be noted that since not all RSFJs are activated at the same time, a transition zone from the linear elastic zone to the geometrically nonlinear zone is observable in the pushover curve. Nevertheless, the entire structure remains elastic, and no material nonlinearity is expected within the transition zone. Figure 4. depicts the final hysteresis curve obtained from pushover analysis for the proposed structural system.

Figure 4. The final hysteresis curve obtained from non-linear pushover analysis.

5.1 Nonlinear dynamic time-history simulations

The NLTHA results are about 4 % lower than that calculated with the ESM. In this study, the average of seven ground motions is considered for analysis and an equivalent ductility factor of $\mu = 2.9$ is used for the developed model. Figure 5. illustrates the base shear and roof displacement obtained from NLTHA. NLTHA H1 and NLTHA H2 refers to analysis for x-axis and y-axis, respectively.

Figure 5. NLTHA Result: (a) base shear comparison; (b) roof displacement comparison.

The chart shows that the highest base shear is obtained from the Christchurch CBGS and Chi-Chi TCU event which are accounted at 1.048×10^6 kg and 1.045×10^6 kg, respectively. Similarly, the highest roof displacement is generated from the Christchurch and Chi-Chi TCU event, which are recorded at 43.1 cm and 42.6 cm. The average base shear is accounted for at 9.824×10^5 kg, which is slightly lower than that of the ESM estimation (10.235×10^5 kg). Meanwhile, the average roof displacement is calculated at 1.46 %, which is 0.04 % lower than the target drift (i.e. 1.5 %). If the mean of the recorded drifts is taken, it reasonably satisfies the target drift and confirms the predicted seismic performance of the developed structural model.

5.2 Inter-storey drifts

It can be seen in form Figure 6. that the maximum inter-storey drift of the proposed model is about 1.5 %, which is significantly lower than the requirement in the NZS 1170.5. It means that the configuration of the RSFJ and the lateral resisting system can prevent the “soft storey” formed at any building level. The highest and the lowest inter-storey drift is recorded for the Loma Prieta

LGP (1.61 %) and the Imperial 79 BCR (1.37 %), respectively. These values are well close to the target lateral drift, which shows the accuracy of the proposed design and analysis method.

Figure 6. NLTHA Result: Inter-storey drift.

5.3 The residual drift

To achieve the full self-centring behaviour, the maximum residual drift at the end of NLTHA shall be limited at 0.2% and 0.25% for the design level intensity earthquake and for the maximum considered earthquake (MCE) intensity, respectively (Henry et al., 2011). Figure 7 shows the residual drift from Chi-Chi and Christchurch event which is less than 8mm (i.e., less than 0.2%). The residual drift from other events is less than 6mm. Therefore, these residual drifts will result in the negligible structural damage and minor cosmetic repairs after earthquake. It confirms the fully self-centring behaviour (i.e., with-out relying on any supplementary devices such as the post-tensioned strands), which can be attributed to the RSFJs used in the LLRS.

Figure 7. Residual drift: (a) Chi-Chi event; (b) Christchurch event.

5.4 Response of the individual RSFJ

Overall, each RSFJ performs within its capacity and achieve its desired lateral displacement. According to the analysis results, the internal forces (i.e. shear force for the shear links and axial force for the hold-downs) are lower than their ultimate force ($F_{ult,loading}$). Similarly, their lateral displacements are slightly lower than the specified displacement. In other words, the secondary fuse activation is not needed for the proposed structural model. Furthermore, these individual responses of the RSFJs show the efficiency of the proposed structural wall system and design procedure in controlling lateral drift. It means that the self-centring behaviour does not rely on any external mechanism (i.e. gravity resisting system), which is particularly advantageous for the structural systems in which the lateral load resisting system is separated from the gravity load resisting system.

6 CONCLUSIONS

This paper discusses the seismic behaviour of building using damage-avoidance shear wall hold-downs. In this system, the application of self-centring friction damping on the building

structure is proposed and its performance is analytically and numerically observed. This innovative RSFJ system is incorporated in a coupled concrete wall system with the aim of achieving damage avoidance.

To investigate the performance of the novel concept on the system level, an eight-storey concrete building structure with concrete coupled wall as Lateral Resisting System is proposed in this study. The design philosophy used was to limit the inter-storey drift ratios to 0.33 % and 1.4 % for SLS and ULS, respectively. The results of the NLTHA showed that the structure is well designed and was able to meet the target performance criteria. Moreover, a fully self-centring behaviour was observed for all analysed cases. Therefore, the proposed model can be considered as an efficient alternative to traditionally high-damage lateral resisting systems to minimise and localise damages.

ACKNOWLEDGEMENT

The authors would like to thank Ministry of Foreign Affairs and Trade of New Zealand (MFAT) for the financial support of this research.

Preliminary investigation on the response sensitivity of masonry arch bridges subjected to scour

F. Scozzese & A. Dall'Asta

School of Architecture and Design, University of Camerino, Ascoli Piceno, Italy

E. Tubaldi

University of Strathclyde, Glasgow, UK

ABSTRACT: Flood-induced scour represents an insidious phenomenon affecting bridges. In the last 20 years, several bridge collapses have been registered all over the world. Considering that masonry bridges characterize most of the existing infrastructure heritage worldwide, it is essential to quickly and effectively deal with this problem, through inspection campaigns, continuous monitoring activities and interventions aimed at mitigating the risk. This paper analyses numerically the response of a masonry arch bridge under local scour actions. A real case study is considered and an accurate 3D finite element model of the bridge is developed in Abaqus, accounting for both mechanical and geometrical nonlinearities. This study represents a preliminary investigation aimed at quantifying the sensitivity of different response parameters to the scour evolution, information that can be used at a later stage for damage identification and quantification.

1 INTRODUCTION

Scour represents one of the main causes of bridge collapse all over the world (Pizarro et al., 2020; Tubaldi et al., 2022a; Eidsvig et al., 2021; Malena et al., 2021; Tubaldi et al., 2020).

Masonry arch bridges are a widespread typology characterizing a large part of the existing infrastructural networks (Borlenghi et al., 2021a; Leoni et al., 2021; Zampieri et al., 2021; De Matteis et al., 2021; Zizi et al. 2023) and they have proved to be very vulnerable to flood-induced scour actions, due to their high stiffness and the usually shallow foundations (Zampieri et al., 2017; Ragni et al., 2019; Solan et al., 2020).

The relevance of the problem is substantiated by the large number of scour-induced collapses registered in the last decades, as well as by the always increasing number of scientific studies on the topic. Indeed, according to the most recent scientific literature in the field, several works have been dedicated to the development of numerical modelling strategies able to describe the evolution of damage (Tubaldi et al., 2020; Pantò et al., 2022; Cannizzaro et al., 2018; Pepi et al., 2021) and numerical analysis on masonry arch bridges subjected to scour (Cabanzo 2022; Tecchio et al., 2022; Scozzese et al., 2021).

Structural monitoring represents a key strategy to identify and prevent damages on bridges (Nicoletti et al. 2023; Innocenzi et al. 2022; Gara et al. 2020). Several studies have been oriented towards the assessment and development of techniques for scour detection, based for instance on dynamic identification via operational modal analysis or similar continuous monitoring strategies (Civera et al. 2022; Borlenghi et al 2021b; Scozzese et al., 2021; Rainieri et al 2020; Malekjafarian et al., 2020; Scozzese et al., 2019); some authors (Zhang et al., 2022) have investigated scour detection methods exploiting the input provided by passing vehicles; experimental and full-scale studies have also been conducted on scoured bridge piers (Hamidifar et al., 2022; Tubaldi et al., 2022b).

In this paper, a multi-span masonry arch bridge is considered as case study and a preliminary numerical investigation is performed to quantify to which extent different response parameters, including some main global kinematic parameters (e.g., transversal displacements on piers, spandrels and arches, vertical settlements, etc.) are influenced by scour. The study results allow providing some preliminary but useful insights about the parameters that are most sensitive to scour and that can be used, at a later stage, for damage identification and quantification. They also provide useful information for the development of optimal monitoring strategies for masonry arch bridges subjected to scour.

2 METHOD

A masonry arch bridge is considered as case study and an accurate 3D finite element model is developed in Abaqus [28], accounting for both mechanical and geometrical nonlinearities.

A set of kinematic response parameters is defined, consisting in vertical and transversal displacements of several characteristic structural nodes of the bridge.

The bridge response evolution is assessed at different stages of the scour process acting underneath one of the piers, under the assumption of a meandering river configuration which only involves one single pier of the bridge.

The scour process evolution is numerically modelled according to the procedure proposed in (Ragni 2010), i.e., by gradually deactivating the boundary conditions at the pier base depending on the current level of scour excavation. In particular, a pre-fixed, simplified inverted pyramid shape is considered to represent the scour hole, which is defined entirely by the friction angle of the bed material φ , and by the maximum depth of scour y_s . The pyramid height coincides with the depth y_s , the upstream scour hole slope is assumed equal to φ , whereas the downstream slope is $\varphi/2$.

The progression of scour is simulated by considering increasing values of y_s and by removing the springs that are located into the scour hole. This approach allows to describe the two joint effects of scour, namely the loss of support and the settlements that consist in a translation and rotation at the pier base.

A schematic representation of the gradual sediments removal numerically simulated is provided in Figure 1, where the different stages of the process are characterized by increasing values of the normalized scour parameter y_s/h , i.e., the ratio between the scour depth, y_s , and the foundation height, h (assumed as fully embedded at starting conditions).

Figure 1. Geometry of the scour hole and scour excavation evolution.

3 APPLICATION

3.1 Case study

The case study is taken from a previous work (Ragni et al., 2019) and consists of a masonry arch bridge of six piers and seven spans (16.00 m long) with segmental brick vaults. Piers have shallow foundations of height $h = 4.0\text{m}$.

The bridge total length is about 130 m and its longitudinal representation is provided in Figure 2.

The river crossed by the bridge has the features of a meandering river, as testified by the photographs of Figure 3, showing the various paths assumed by the main channel of the river within its riverbed. Due to this particular feature of the river, the bridge experienced several localized scour actions over the year, where single piers were involved depending on the specific path of the water in a given year or period of the year.

Figure 2. Longitudinal scheme of the bridge.

Figure 3. Meandering path of the Aso river and modification over the years: 2012, 2013, 2016 (half bridge collapsed), 2021 (rebuilt). Source: Google Maps/Google Earth.

3.2 Solid elements model

A 3D model is developed in ABAQUS 2017, by accounting for both geometrical and mechanical nonlinearities. The bridge model is built by using continuum solid linear hexahedral 8-nodes elements of type C3D8R, with 6 degrees of freedom per node.

The non-linear response of the masonry parts is accounted for by using the Concrete Damage Plasticity (CDP) model with the parameters reported in (Scozzese et al., 2019).

For the fill material (granular mixture), the Mohr-Coulomb failure criterion is used, with friction angle of 55° and cohesion $c = 10 \text{ kN/m}^2$. The interaction between the different bridge components is simulated by means of the nonlinear frictional and cohesive interfaces (Scozzese et al., 2019): a frictional interface is used to describe the interaction between the fill and the other bridge components along the tangential direction; a “hard-contact” behaviour is assumed along the normal direction, allowing separation but preventing penetration between the parts in contact; cohesive interactions are used for the other interfaces and simulate the behaviour of mortar joints between the parts.

The main material properties are summarized in Table 1, namely: density ρ , Young’s modulus E , yield stress in compression $f_{y,c}$, peak tensile stress $f_{y,t}$, backfill cohesion c .

For what concerns the riverbed properties, the following parameters are considered: friction angle $\phi=38^\circ$, Young’s modulus $E=1065000 \text{ kN/m}^2$, Poisson’s ratio $\nu = 0.45$, shear modulus $G=370000 \text{ kN/m}^2$, soil density $\rho = 2.0 \text{ t/m}^3$, and average shear waves velocity $V_s= 430 \text{ m/s}$.

The soil-foundation interaction is modelled through three sets of springs (X, Y and Z) with equivalent soil stiffness constants taken from a previous work by the authors (Scozzese et al., 2019). However, it is worth to note that more refined impedances formulations might also be used (Carbonari et al. 2018; Morici et al., 2019; González et al. 2020; Minnucci et al., 2022).

Figure 4. Numerical model of the bridge with parts highlighted with different colors.

Table 1. Main structural material properties.

	Masonry	Masonry (Piers)	Backfill	Abutment
ρ [t/m^3]	1.80	1.75	1.70	1.90
E [t/m^2]	3100000	2900000	250000	300000
c or $f_{y,c}$ [kN/m^2]	2000	2000	10	\
$f_{y,c}$ [kN/m^2]	150	150	0	\

3.3 Scour simulation and monitored response parameters

Because of the specific (meandering) features of the river, a localized scour scenario is considered in which a single pier is involved. The selected pier is the number 6, i.e., the last pier close to the abutment 2.

A scour process characterized by values of the ratio y_s/h from 0.0 to almost 1.5 is analyzed. For value of y_s/h close to 1.5, indeed, convergence issues are encountered within the numerical simulation, testifying the attainment of a unstable structural condition (collapse).

The following nodes placed on the up-stream face of the bridge (see Figure 5) are considered to evaluate the structural displacements during the scour process evolution:

- Top spandrel nodes, namely $S5_{top}$ (on the Pier 5 adjacent to the scoured one), $S6_{top}$ (on the scoured Pier 6), and Ab2 (on the abutment 2);
- Arch nodes, namely A6 (arch on the left of the scoured pier), A7 (arch on the right of the scoured pier);
- Foundation nodes of the scoured pier, namely $P6_{top}$ (upper upstream corner of the foundation), and $P6_{bottom}$ (lower upstream corner of the foundation).

Both vertical (Z) and transversal (Y) displacements are monitored at nodes $S5_{top}$, $S6_{top}$, Ab2, A6, A7. Vertical displacements are monitored at nodes $P6_{top}$ and $P6_{bottom}$.

Figure 5. Scheme of the nodes monitored during the numerical analysis to asses the response variation induced by the scour process.

4 RESULTS

The response of the bridge is shown in Figure 6 (vertical displacements) and Figure 7 (transversal displacements). A near-collapse limit state (named failure in legend plot) is also added to the charts, highlighted by a vertical grey dotted line. This condition correspond to the development of critical diagonal cracks on the arches close to the scoured pier, as shown in Figure 8.

According to the results, the following comments can be made:

- Displacements at the nodes located on the Pier 5 ($S5_{top}$) and the Abutment 2 (Ab2) are very small (negligible);
- For what concerns the vertical displacements, the nodes most sensitive to scour are represented by those aligned along the vertical face of the Pier 6 (scoured), with magnitude rising from the bottom ($P6_{bottom}$) to the top of the bridge ($S6_{top}$);
- For what concerns the transversal displacements, the nodes most sensitive to scour are again those aligned along the vertical face of the Pier 6 (scoured) but the magnitude follows a reverse order, i.e., from the top ($S6_{top}$) to the bottom ($P6_{bottom}$);
- Nodes on the arches (A7 and A6) also show a quite important sensitivity to scour;
- The most sensitive nodes identified in this study develop displacements up to 20 mm before of the attainment of a severe irreversible damage state on the bridge (failure), thus they can be used within a continuous monitoring campaign to predict dangerous situations.

Figure 6. Vertical displacements at the monitored nodes on the up-stream face of the bridge.

5 CONCLUSIONS

This paper analyses numerically the response of a masonry arch bridge under local scour actions and aims at analyzing the sensitivity of different response parameters (transversal and vertical displacements at different structural nodes of the bridge) to the scour evolution.

A real case study is considered and an accurate 3D finite element model of the bridge is developed. Numerical simulations are carried out to describe the scour hole progression around the foundation of a single pier until the attainment of an incipient bridge collapse condition.

As a major result, it is observed that the most sensitive nodes (e.g., at the top of the spandrel on the up-stream face of the piers) identified in this study develop non-negligible displacements (up to 20 mm) before the attainment of a severe irreversible damage state on the bridge. A continuous monitoring campaign based on the observation of such response parameters might thus be suitable to predict and anticipate dangerous conditions.

The study is preliminary and calls for a deeper investigation in which the effectiveness of a wider set of response parameters shall be assessed to derive information that can be used at a later stage for damage identification and quantification.

Different scour scenario should also be investigated in future papers.

ABSTRACT: Frequency and intensity of hydrological hazards have increased. Consequently, riverine bridges are suffering damage due to flooding. Fragility functions are used to estimate such damage conditioned on hazard intensity. However, flood fragility functions are limited for riverine bridges, and generally lack for masonry bridges. This paper presents a methodology to derive flood fragility functions for masonry arch bridges accounting for component failure modes. Demand and capacity of bridge components are derived from existing analytical expressions, and account for aleatory uncertainties via Monte Carlo simulations. The methodology is illustrated using a UK masonry bridge, which collapsed due to winter flood-induced scour. The investigated bridge is divided into its components (e.g., arches, pier) and a scour fragility function is derived for the arch, based on a lognormal cumulative distribution fitting to the derived failure probability data. Future research will develop scour fragility functions for other bridge components.

1 INTRODUCTION

In recent years various bridges have collapsed because of increasing precipitations, floods, and lack of maintenance (Schaap and Caner, 2021). In the United Kingdom (UK), recent collapses have highlighted the vulnerability of masonry arch bridges to flooding (Solan et al., 2020). For instance, eight masonry bridges collapsed in the Cumbria region alone (Northwest of England) during the 2009 and 2015 floods, resulting in £10.49 million of reconstruction costs (Li et al., 2021). Flood-induced bridge damage can result from scour, hydrostatic or hydrodynamic actions (HE, 2020a). The literature indicates that scour is the leading cause of bridge damage (Sasidharan et al., 2021), including natural, general, contraction, and local scour (HE, 2020a).

Quantifying the flood risk of bridge portfolios is becoming crucial to reduce economical and human losses (Swiss Re, 2021). Risk is typically obtained as the product of hazard, exposure, and vulnerability (Ang and Tang, 1975). Vulnerability represents the likelihood of losses as a function of hazard intensity measure(s) (Galasso et al., 2021), where expected losses are given as the product of the expected level of damage and bridge restoration costs for the various levels of damage (Gidaris et al., 2017). The expected level of damage conditioned on hazard intensity measure(s) is referred as “fragility” and estimated via fragility functions (Wen and Ellingwood, 2005). For applying fragility functions in vulnerability assessments, structures within a portfolio are grouped in vulnerability classes (Burns et al., 2021; Mangalathu et al., 2017), i.e. groups of structures which do not have statistically significant different responses (e.g. reinforced concrete multi-column bent bridges).

Bridge flood vulnerability classes that explicitly account for bridge structural performance and their possible failure modes are currently scarce in the literature (Gidaris et al., 2017; Degan Di Dieco et al., 2022). When considering masonry arch bridges, Lamb et al. (2019) derived scour fragility functions by fitting lognormal fragility functions to probability data of historical failures, and flood return period as intensity measure. Eidsvig et al. (2021) and Mendoza Cabanzo et al. (2022) derived scour fragility functions via limit state analyses of load carrying capacity and flow discharge as intensity measure. George and Menon (2021) proposed scour fragility functions derived via

kinematic chain limit analyses with scour-induced pier rotation as intensity measure. Maroni et al. (2020) developed a Bayesian scour fragility function using a qualitative risk classification, scour depth data from monitoring, and relative scour depth as intensity measure. The reviewed studies show that their fragility functions do not consider failure modes of components. Subdividing a bridge into key structural components affects damage estimates of bridge portfolios (Minnucci et al., 2022; Nielson and DesRoches, 2007) and consequently their risk. As a result, the first step to build robust estimates for flood-induced damage and risk is the investigation of significant failure modes of bridge components and their interdependencies (Argyroudis and Mitoulis, 2021; Ren et al., 2019).

This paper proposes a methodology of fragility functions for masonry arch bridges which accounts for failure modes of key structural components. Figure 1 illustrates the rationale of the proposed methodology for pier local scour inducing compressive rotational failure of a masonry arch; however, the methodology is derived to accommodate further components and their failure modes. In this methodology, existing analytical expressions are used to estimate bridge component capacities, while structural analysis schemes are used to estimate demands on bridge components. As a proof-of-concept, the proposed methodology is applied to a two-span masonry arch bridge which was spanning over River Calder in Halifax (West Yorkshire, North of England) and that collapsed in winter 2015 because of flood-induced scour (Tubaldi et al., 2018). This paper is divided into five sections. Section 2 details the methodology for developing fragility functions, the approach to account for scour effects on estimates of masonry arch capacity and demand, and the case study bridge. Section 3 shows the derived fragility function. Section 4 discusses underpinning assumptions and suggests future work. Section 5 summarizes the key findings.

Figure 1. The proposed methodology for deriving flood fragility functions for masonry arch bridges.

2 METHODS

2.1 Fragility function derivation

Fragility functions can be derived empirically or analytically (Shinozuka et al., 2000). While empirical fragility functions are derived from observed damage data, analytical fragility functions are defined upon failure probability data, i.e. the ratio of the number of cases that exceed the failure state to the total number of simulations, for each investigated intensity measure (Mendoza Cabanzo et al., 2022). Based on structural reliability theory, the limit state function $M(x)$ (Mendoza Cabanzo et al., 2022) is given by:

$$M(x) = R(x) - E(x) \tag{1}$$

where $M(x)$ measures the difference between resistance effects $R(x)$ (i.e. capacity) and load effects $E(x)$ (i.e. demand), and x is a vector of a particular sample point. From Equation 1, it follows that failure is defined when $M(x) \leq 0$. Failure data can be generated via simple Monte Carlo (MC) simulations (Schmidt et al., 2019) and fitted with a cumulative distribution function, such as the lognormal fragility function (Baker, 2015). This study focuses on the limit state function for ultimate compressive strength only.

The compressive resistance of masonry elements R (i.e. capacity) is given by Equation 4.7.1 of CD 376 (HE, 2020b):

$$R(R_c) = 0.6 \cdot F_c \cdot [R_c \cdot b \cdot (t - 2e)] \quad (2)$$

where b (mm) is the element width, R_c (N/mm^2) is the basic random variable defining the masonry compressive strength, t (mm) is the overall element thickness, e (mm) is the eccentricity of the centre of compression in the element, 0.6 is a deterministic coefficient, and F_c is the condition factor and function of cracking in the arch (see Equation 6). Note that the 0.6 coefficient derives from Equation 4.7.1 in CD 376 (HE, 2020b), where $0.6 = 0.4 \gamma_M$, and $\gamma_M = 1.5$ is a partial safety factor. The masonry compressive strength R_c is assumed normally distributed with mean value \bar{r}_c and coefficient of variation CoV_c . For the normal random variable R_c , the mean value \bar{r}_c is obtained from the characteristic value f_k as follow (Melchers and Beck, 2018):

$$\bar{r}_c = f_k / (1 - k_{0.05} \cdot CoV_c) \quad (3)$$

where $k_{0.05}$ is the value of the standard normal variable for a probability of 0.05, f_k is given by Equation 3.1 of BS EN 1996-1-1:2005 (BSI, 2013):

$$f_k = K f_b^\alpha f_m^\beta \quad (4)$$

where α , β , and K are constants, function of mortar and unit type, and listed at paragraph 3.6.1.2 of BS EN 1996-1-1:2005 (BSI, 2013), f_m is the mean compressive mortar strength, and f_b is the normalised mean compressive unit strength (i.e. brick), in the direction of the applied action effect, and all these variables have been considered deterministic. Annex 2 of Morton (2012) provides the equation for f_b :

$$f_b = CF \cdot \delta \cdot f_{bm} \quad (5)$$

with both CF conditioning factor and δ shape factor related to brick tests given by Annex A of BS EN 772-1:2011 (BSI, 2015), f_{bm} is the mean compressive strength of the unit, and all these variables have been considered deterministic. The condition factor F_c , given by Equations 7.5.1a,b of CS 454 (HE, 2020c), is used to consider the material degradation defects in arch conditions:

$$F_c = F_{cM} F_j = F_{cM} (F_w F_d F_{m0}) \quad (6)$$

where F_{cM} is the arch barrel condition factor, F_j is the joint factor for arch diagonal cracks, F_w is the joint width factor, F_d is the joint depth factor, and F_{m0} is the mortar factor. The value of F_{cM} and F_j shall be determined according to Tables 7.5.1a,b,c,d of CS 454 (HE, 2020c) after a bridge inspection; however, their values have been assumed in this study, and considered deterministic.

The compressive load effect E (i.e. demand) is determined according to the assessment level 1 of CS 454 (HE, 2020c), where simple structural analyses are carried out and the masonry tensile strength is neglected:

$$E(\Gamma_m) = S_a(\Gamma_m) / \Phi_i \quad (7)$$

where $S_a(\Gamma_m)$ is the compressive force in the component, linear function of the unit weight of masonry Γ_m [see Equation 45 in Chapter 3 of Como (2013)], and Φ_i is the slenderness and eccentricity factor given by Equation 6.4 of BS EN 1996-1-1:2005 (BSI, 2013). Note that the compressive force in the component $S_a(\Gamma_m)$ is derived from the structural analysis, Γ_m is the basic random variable, Φ_i is considered deterministic and constant with scour depth, and load partial factors have been assumed equal to 1.0. The unit weight of masonry Γ_m is assumed normally distributed with mean value $\bar{\gamma}_m$ and coefficient of variation CoV_γ . The eccentricity of loads has been considered in the verification via the slenderness and eccentricity factor Φ_i (BSI, 2013)

$$\Phi_i = 1 - 2(e_i/t) \quad (8)$$

where $e_i = 0.05t$ is the minimum eccentricity at the element top and t is the element thickness.

In this study, dead loads, superimposed dead loads and pier local scour are the considered actions (HE, 2020c). To determine the thrust maximum value, Méry's method (Méry, 1840) is applied in the main plane (X-Y) of the case study bridge (Figure 2a). Méry (1840) supposed a three-hinge mechanism for the arch, with hinges located at the springing lines and crown, and the masonry material assumed linear elastic. The resulting scheme is structurally determined, the maximum thrust occurs at the springing level and e is equal to 1/6 of the arch's thickness. Therefore, the expressions for $S_a(\Gamma_m)$ was derived using equilibrium equations, and then implemented in Jupiter notebooks with Python (PSF, 2022).

Subsequently, R_c in Equation 2 and Γ_m in Equation 7 have been sampled with simple MC simulations (Schmidt et al., 2019) to estimate $R(R_c)$ and $E(\Gamma_m)$. Then, the arch probability of failure P_f has been calculated as:

$$P_f \approx n(M(x) \leq 0)/N \quad (9)$$

where N is the number of conducted simulations and $n(M(x) \leq 0)$ is the number of simulations n for which $M(x) \leq 0$ according to Equation 1. A convergence assessment of the MC estimator for both R_c and Γ_m was performed in terms of CoV following procedures in Ballio and Guadagnini (2004), i.e. root mean square of sample mean/variance divided by sample mean/variance, to identify the needed number of simulations for stabilisation of CoV values. Finally, failure probability data was fitted with a lognormal fragility function by following procedures in Baker (2015):

$$P_f = \Phi \left[\ln \left(d_{s,loc} / \hat{\theta} \right) / \hat{\beta} \right] \quad (10)$$

where $d_{s,loc}$ is the pier local scour depth, $\hat{\theta}$ and $\hat{\beta}$ are the estimates of median and log standard deviation, respectively, obtained using the maximum likelihood estimation method.

2.2 Case study

The fragility assessment was carried out on a two-span masonry arch bridge in Halifax (West Yorkshire, England), which was spanning over River Calder and that collapsed in December 2015 due to flood-induced scour (Tubaldi et al., 2018). The geometry of the bridge is typical in terms of span of various UK riverine bridge portfolios (Mathews and Hardman, 2017; Stevens et al., 2020). Figure 2a depicts the geometry of the investigated bridge, including: length of 20.30m between abutment faces; out-to-out width along the transverse direction of 3.80m; the two arches are segmental in shape, assumed of one ring, with span length of 9.26m, intrados rise of 3.45m, arch thickness of 0.50m ($r_i/L = 0.37$, $t_a/L = 0.05$); the pier has a rectangular transverse section of width 1.8m and depth 3.40m; bridge total length of 33.40m.

The masonry of arches, pier, spandrel walls, and parapet has unit weight γ_m 22 kN/m³ (Tubaldi et al., 2018), assumed as mean value $\bar{\gamma}_m = \gamma_m$, and $CoV_v = 10\%$ (Su et al., 2020), while backfill soil has unit weight of 19 kN/m³ (Tubaldi et al., 2018) and considered deterministic.

Regarding mechanical properties: (i) for general purpose mortar M4: $\alpha = 0.7$, $\beta = 0.3$, $f_m = 4$ MPa; (ii) for group 1 calcium silicate units: $K = 0.55$; (iii) for red sandstone wide blocks (Wiggins et al., 2019): $CF = 1$, $\delta = 1.18$ for air-dry brick testing, $f_b = 10$ MPa; (iv) resulting masonry: $f_k = 4.69$ MPa, $COV_c = 15\%$ (Conde et al., 2020), $k_{0.05} = 1.6449$, $\bar{r}_c = 6.23$ MPa.

Regarding the structural scheme (Figure 2b), parapet, spandrel walls, and backfill are considered as dead loads; the three-hinged arch lies on beam-like pier and abutments; the pier lies on beam-like shallow foundation, while abutments do not have any foundation; the foundation lies on Winkler-like spring soil; the soil-foundation modelling is outside of the scope of this study, as well as considering lateral earth pressures. Given the structure's vertical symmetry, the structural analysis is limited to half of a span; a one-meter arch barrel depth (i.e. $t = 1.00m$) is examined.

Before performing the probabilistic assessment, the deterministic assessment identified the arch as the component at the highest risk of failure among other components. Therefore, the

arch is the main focus of the reliability analysis performed in this study and for which the fragility function is derived.

Failure probability data was derived for six different discrete levels of local scour depth, $d_{s,loc} = [1.20, 1.50, 2.00, 2.30, 2.49, 2.54]m$, previously investigated by Tubaldi et al. (2018), and related to a not-symmetric scour hole. Scour effects on capacity and demand were considered via the empirical coefficients of Equation 6 and Equation 8, respectively, to reflect that pier local scour induces (Tubaldi et al., 2018): cracks in the arch barrel, central pier, pier-foundation interface, and eccentricity of vertical loads. Considering that the diagonal crack F_{cM} values reduce capacity the most (HE, 2020c), this case study investigates arch diagonal cracks only. Input values for F_c are: $F_{cM} = 0.3$ to 0.9 for diagonal cracks, while the variation of F_{cM} with scour depth is assumed linear between $F_{cM} = 0.3$ for $d_{s,loc} = 2.54m$ and $F_{cM} = 0.9$ for $d_{s,loc} = 120m$; $F_w = 1.0$ for width of joint = $6mm$; $F_d = 0.8$ for joints with 10% of thickness of barrel insufficiently filled; $F_{mo} = 0.9$ for loose joint condition; the multiplication of F_w , F_{mo} , and F_d leads to $F_j = 0.576$; while $F_c = 10$. For $d_{s,loc} = 1.00 m$. The assumption of F_{cM} values is based on the interpretation of arch cracking patterns and damages in tension due to pier vertical displacement and rotation determined by Tubaldi et al. (2018) via three dimensional finite element analyses. For an arch barrel depth $L/2 = 3.1m$, $e_i = 0.05 \cdot 3.1m = 0.16m$, Equation 8 gives $\Phi_i = 0.90$ and assumed constant with scour depth.

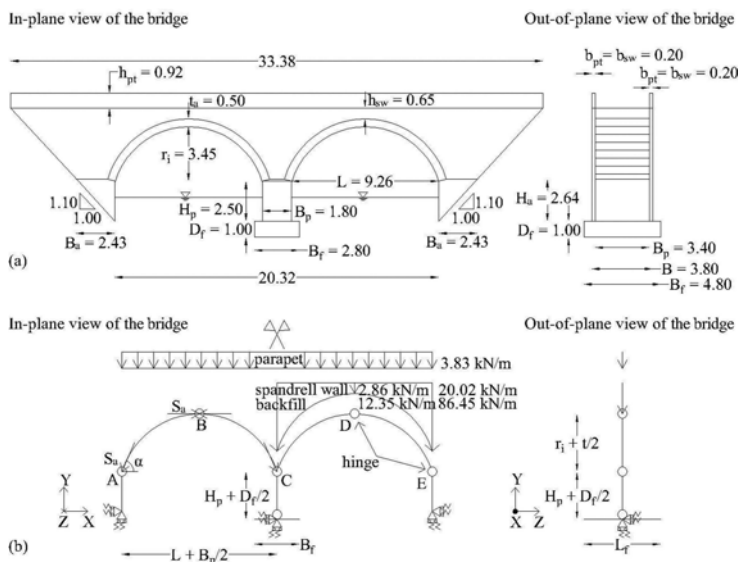

Figure 2. (a) Illustration of the case study bridge (dimensions in m); (b) model of the system bridge-river in scoured conditions.

3 RESULTS

The proposed methodology is demonstrated for the compressive failure mechanism of arches due to pier local scour for the UK case study described previously. 100.000 MC simulations were needed to obtain convergence for R_c and Γ_m in terms of CoV ; the results of MC simulations are here forth referred to as “realisations”. The 100.000 realisations of R_c and Γ_m were used to estimate capacity and demand according to Equation 2 and 7, respectively. Then, the obtained capacity and demand were used to estimate the limit state function (Equation 1) for the six investigated scour depths and the number of simulations for which $M(x) \leq 0$ was recorded. For instance, for $d_{s,loc} = 1.50m$, $F_c = 0.900$ and $\Phi_i = 0.90$, lead to 39.879 failures ($M(x) \leq 0$). Therefore, the first-not-null failure probability point is $(1.50m, 0.3988)$; further points were determined by changing F_c at each investigated scour depth, while Φ_i was considered constant, followed by performing MC simulations.

The derived scour fragility function for the arch is shown in Figure 3 for a scour depth range of 1.00m to 2.6m, where 1.0m is the foundation's depth and 2.6m is just above the 2.54m collapse scour depth estimated by Tubaldi et al. (2018). Note that the minimum value considered for scour depth is 1.20m because pier displacements develop only after scour depth exceeds the foundation depth (i.e. 1.0m). From fitting the failure probability data, a median $\hat{\theta} = 1.52m$ and log standard deviation of $\hat{\beta} = 0.05$ were estimated.

The proposed approach for deriving arch scour fragility functions could be repeated for a different bridge geometry and the resulting fragility function could be used to predict the failure probability of a masonry arch, if measurements of pier scour depth is available at the bridge site. Provided the made assumptions (see Section 4), the derived fragility function shown in Figure 3 represents one of the inputs needed to determine the bridge fragility function(s) in a failure mode analysis when multiple components are considered (e.g. piers, foundation). To the authors' knowledge, the derived arch scour fragility function represents the first attempt in the literature to determine flood fragility functions of masonry arch bridges from component fragilities.

Figure 3. Derived scour fragility function for the investigated masonry arch.

4 DISCUSSION AND FUTURE RESEARCH

The proposed deriving methodology for flood fragility functions for masonry arch bridges advances the existing literature. Towards defining reliable fragility estimates, this study investigated the fragility of a masonry arch for the compressive resistance assessment, considering effects of pier local scour on arch demand and capacity; a UK case study was used to demonstrate the methodology. Results (Figure 3) showed that the investigated arch presents a median value of pier local scour depth of approximately 1.50m.

In the calculations, assumptions were made for dimensions and quality of bricks and mortar because no information was available. The effects of scour on the arch were considered via empirical coefficients (i.e. F_c , Φ_i), subjectively linked to scour depth because no relations were found. Furthermore, this study investigated a reduction of arch capacity due to diagonal cracks only, but other cracks (e.g. longitudinal) are possible (HE, 2020c). In addition, the interaction between backfill-arch-spandrel walls shall be investigated since it may affect the bridge flood response (Sarhosis et al., 2016). Failure probability data was fitted with a lognormal fragility function, which was shown to provide equal failure probabilities of other possible functions (Lallemant et al., 2015); however, more failure data shall be generated from the discretization of the expressions of condition factor F_c and eccentricity factor Φ_i as function of scour depth.

Although this work presents a fragility function for one component only (arch), it recommends to extend the methodology to the other components, to avoid underestimating the risk failure of a bridge (Nielson and DesRoches, 2007). Future work will develop scour fragility functions for compression limit state of other bridge components, such as pier, to obtain the global failure fragility

function(s). Further studies could consider additional random variables, e.g. shear strength of the mortar, to understand if there is more than one fragility function for a considered damage state; epistemic uncertainties, e.g. variability in the parameters of the used probability distribution function, shall be addressed and validated to enable implementation of fragility functions.

5 CONCLUSIONS

This study proposes a deriving methodology for scour fragility functions of masonry arch bridges able to account for failure modes of significant bridge components, which represents a novelty in the existing literature. Using a UK case study, a fragility function for the arch of a masonry bridge subjected to pier local scour was derived via simple MC simulations and analytical design expressions as an example. Future research opportunities include: (a) applying the proposed methodology to other bridge components; (b) investigating the relations scour depth-masonry capacity and demand; (c) investigating effects of various epistemic uncertainties; (d) validating the developed fragility functions.

ABSTRACT: This paper presents the experimental test campaign to calibrate a finite element model intended to evaluate the seismic vulnerability of the SS Filippo e Giacomo historical masonry arch bridge in Ascoli Piceno (Italy). The bridge has undergone very complex vicissitudes related mainly to exceptional river floods; it was partially rebuilt twice and other strengthening works were carried out over the time. The bridge, which is almost completely built with travertine blocks, has a total length of 146 m and follows a slightly curved path. Six arches, the main of which is semi-circular with span of 25 m and the others are lancet arches with span of about 8 m, support the carriageway that is about 8 m wide. The piers and abutments are founded on the bed-rock and consequently some piers are deeply embedded in the sandy gravel deposit. A campaign of experimental tests was executed encompassing onsite measurements of stresses and modulus of elasticity, as well as laboratory measurements on specimens taken from the structures. Vibration tests were also carried out to evaluate the modal properties of the bridge. The acquired experimental data were used to calibrate a 3D Finite Element Model that has been developed considering the complex geometry of the bridge also including the deformable soil deposit. A very good consistency was achieved between experimental and theoretical behaviours.

1 INTRODUCTION

Evaluation of a historical masonry structure is a challenging task due to the numerous unknown factors surrounding the structure's actual conditions (Minnucci et al. 2022) (original structure, structural changes brought on by repair, enlargement, retrofit works, various construction systems, various materials, degradation and damages to the structure and materials, changes to the soil and foundation, etc.), as well as the complexity of modelling techniques and analysis methods (Pavia et al. 2021). In this regard, advanced measuring techniques are required to capture the true behaviour of the structure, particularly the mechanical properties of the structural materials and the overall dynamic behaviour, following a thorough study and geometrical and structural survey (Ragni et al. 2019).

Regarding the material survey, both conventional and cutting-edge techniques are accessible, however non-destructive procedures are typically favored when working with historically significant and priceless structures. A thorough material testing campaign may make it possible to fix a significant number of the key parameters used to define the structural finite element model. By employing modal identification methods and a variety of test types, such as forced, impulse, release, or ambient vibration testing, it is possible to empirically assess the structure's overall

dynamic behaviour (Aras et al. 2011, Beolchini and Vestroni 1997, Benedetti and Gentile 1994, Nicoletti et al. 2023, Dall'Asta et al. 2022, Tubaldi et al. 2021). Since no artificial excitation is needed and the test can be conducted in operational conditions with minimal disruption to the structure's use, ambient vibration tests with the appropriate output-only modal identification methods have recently emerged as the preferred test typology for evaluating the modal parameters of full-scale structures, particularly historic ones. (Gentile and Saisi 2007, Nicoletti et al. 2022a) The updated improved finite element models, which are needed for structural verifications, as well as for the design of repair and retrofit works, may then be created based on the experimental modal parameters (De Sortis et al. 2005, Ahmadian et al. 1994, Mottershead et al. 1993, Nicoletti et al. 2022b, Gara et al. 2021, Cipriani et al. 2022).

The paper presents the experimental test campaign and the updating of the finite element model of the SS. Filippo and Giacomo Bridge over the Tronto River, in Ascoli Piceno, Central Italy. The bridge was constructed in the 14th century, after which it underwent several modifications for renovation, strengthening, modernization, and enlargement work. As a result of interactions between parts with varied mechanical properties and ages, the structural organism becomes very complicated. Given these uncertainties and the significance of the bridge, a precise examination of its current state was deemed necessary in order to create a reliable predictive finite element model that would be utilized to develop the seismic retrofit design. First, a geometric survey and historical analysis of the bridge were developed. In order to assess the quality of the travertine block masonry, both destructive and non-destructive in-situ testing for material characteristics were performed. In particular, the young modulus of some materials, which was initially defined according to standard values suggested by codes, was calibrated to fit the dynamic behaviour obtained experimentally. A refined 3D finite element model was developed using these data and tuned based on the experimental modal parameters.

2 CASE STUDY: THE SS. FILIPPO AND GIACOMO BRIDGE

2.1 *General description*

In Ascoli Piceno town, the SS. Filippo and Giacomo bridge rises in a less urbanized area and spans the Tronto River in a modest straight valley located between two loops. The bridge highest height is almost 20 m, and its overall length is 146 m. The bridge is constructed between two rock escarpments, one of which has a significant slope (Figure 1). The left escarpment has a rather high slope (52°) whereas the right one is less sloping (31°). The gorge is characterized by a sandy gravel deposit on the right riverbank, with variable thickness up to 10 m, whereas the sandstone bedrock is outcropping at the left riverbank.

Figure 1. Aerial view of the SS Filippo and Giacomo bridge.

The bridge consists of six arches. The main one, which is semicircular in shape and has a span of around 25 meters, crosses the river during its normal flow. The remaining five arches have a span of roughly 8 meters and are lancet-shaped. During unusual floods, the river occupies the right bank where all of the piers are located. With a curve close to the left abutment, the plan

route is mainly rectilinear. The bridge was widened in the first part of the 20th century using a double series of pensile semicircular tiny arches, with spans of approximately 4 m, supported by stone corbels. The two-lane road is about 6 m wide and is bordered by two sidewalks of about 1 m width. With the exception of the 20th-century pensile arches and the interior lighting chambers, the bridge is entirely constructed of travertine stones.

2.2 Bridge damages during the centuries

The current SS. Filippo and Giacomo bridge's appearance is the result of a complicated series of incidents that transpired during its almost 600-year history (Figure 2).

The previous bridge, which was built in the second part of the XIV century, was most likely made up of four semicircular arches. A flood that occurred in 1453 severely damaged it, resulting in the collapse of three arches on the right side, likely as a result of the river flowing down the canyon on that side at the time, as may be inferred from geological studies.

The reconstruction of the bridge began about 1464; the portion that had survived was left intact, while the piece that had fallen was reconstructed using lancet arches with shorter spans than the original ones. The requirement to shift the pier spacing without changing the height or the original top level led undoubtedly to the selection of lancet arches. It is believed that the five new arches have not undergone any significant changes as of right now. The major arch that had survived the first flood collapsed as a result of a second exceptional flood that took place in 1528. This was rebuilt beginning in 1545 and using two parallel barrel-vaults. The downstream vault, which is about 3 m wide, has remained largely unchanged, while the upstream vault, which has a variable width, underwent a significant vertical settlement (of about 0.4 m). The vault was finally rebuilt in 1667 by installing wooden and iron ties intended to tighten together the two parts. A poorly designed wall collapsed in 1721 due to a fresh flood (probably a wing wall or a part of the abutment at the left riverbank). In 1794, a cutwater was constructed to safeguard the main pier. Between 1835 and 1836, the two arches supported by the main pier were repaired. In order to make maintenance of the structure easier, two barrel-vaults were constructed at the conclusion of these works rather than reinstalling the earth fill at the extrados of the main arch. The spandrel walls of the bridge support the two vaults. Between 1849 and 1850, work was done to lessen the slope of the upper road. The spandrel walls were lifted and filled with dirt after transverse ties were put two meters from the previous top level to support the structure. In order to enlarge the roadway, the final curve was changed by adding side travertine corbels with various spans up to 1 m. These corbels were subsequently joined by 0.30 m thick brick arches. During this phase, a new arrangement of interior lighting rooms was constructed over the main arch; the rooms are spaced equally between the external pensile arches to allow for the installation of stone corbels in the walls dividing the rooms. Each chamber has an orthogonal vault to the previously realized lower level. The bridge's current configuration was determined by the last significant intervention, which took place in 1932. By using a series of pensile arches similar to those previously mentioned, the remaining portion of the bridge is widened.

Figure 2. Bridge damages and reconstructions over centuries.

3 EXPERIMENTAL CAMPAIGN

3.1 Tests on construction materials

On-site experiments, including two tests using single flat jacks and one test using double flat jacks, were used to characterize the construction materials. Additionally, three compression experiments on travertine specimens obtained via masonry coring, were carried out. Locations for sampling and testing are reported in Figure 3.

Masonry coring allowed for the observation that the pier structure is made up of a significant internal rubble stone infill that is characterized by the presence of water in the lower parts, as well as an external curtain that is made of Ascoli Piceno travertine square blocks and has a variable thickness. Compressive tests carried out on the three specimens gave scattered results with minimum strength 16.9 N/mm^2 . The double flat jack test carried out at the base of pier P2 provided a linear behavior in the stress range investigated (up to about 4 N/mm^2), characterized by Young modulus of about 6600 N/mm^2 . At the bases of piers P1 and P2, single flat jack tests were conducted to estimate the stress status in the exterior brickwork curtains. As anticipated, the stress state for pier P1 is greater than that for pier P2. In particular, the normal vertical stress in pier P1 is approximately 1.3 N/mm^2 , whereas that for pier P2 is around 0.5 N/mm^2 . Testing was not done for the inner vaulted rooms masonry since it was clear through examination and laser scanner survey that it is a solid brick masonry. Nonetheless, it is important to note that, with the exception of the mass, these elements are not anticipated to have a substantial impact on the structure's overall behaviour. The two kinds of masonry constituting the bridge structure can be classified according to catalogs reported in design guidelines and standards (Decree 17/01/2018, Circular 21/01/2019), and the main characteristics are reported in Figure 3.

Figure 3. Experimental campaign and estimated properties of the construction materials.

3.2 Ambient vibration tests and operational modal analysis

The accelerations of the deck recorded during ambient vibration measurements, which are mostly caused by traffic, wind, and microtremors, are used to experimentally determine the modal characteristics of the bridge, including natural frequencies, damping ratios, and mode shapes. Eight low noise piezoelectric uniaxial accelerometers, a 24-bit data collecting device, and coaxial cables are used to conduct the testing.

Many tests were used to determine the bridge overall dynamic behaviour, but only those helpful to explore the transversal behaviour are described and analyzed in this work. The chosen measurement setup is seen in Figure 4a and consists of 8 accelerometers that are positioned in the middle of each span and measure in a transversal direction. The minimum sampling rate for the utilized data collecting equipment was 2048 Hz, and time histories measuring 1000 seconds in length were obtained. According to Cantieni (2005), this length of time gives adequate data to accurately determine the modal parameters, and a collection duration greater than about 1000–2000 times the

fundamental period is advised (in this case a value of about 2.5 Hz was obtained by preliminary measurements, which leads to 400-800 s). Before performing the operational modal analysis all the recorded data were processed by means of suitable signal processing techniques: trend removal, low pass filtering (to eliminate the contribution of high frequencies and to avoid aliasing phenomena) and down-sampling at 51.2 Hz, in order to decrease the amount of data and make faster the successive analyses.

Based on the accelerations collected during the ambient vibration test, the modal parameters are estimated using the Covariance-Driven Stochastic Subspace Identification (SSI-Cov). This approach converts the second-order system of differential equations that describes the dynamic issue into a first-order system using a stochastic state-space model (Juang 1994, Van Overschee & De Moor 1996). Depending on the model order employed in the state-space model, the SSI-Cov enables the estimate of a variety of modes. The stabilisation diagram (Figure 4b) allows the separation of the physical modes from the spurious ones, allowing the identification of the stable modes, i.e., natural frequencies, damping ratios, and mode shapes that remain consistent as the model order increases. In this work models with up to 40 order are used and the modes are considered to be consistent if, when increasing the model order one by one: natural frequency variation is less than 1%, damping ratio variation is less than 2%, and MAC between the modes is greater than 98%.

In the frequency range of 2–6 Hz, Table 1 lists the natural frequencies with the pertinent damping ratios, and Figure 5 displays the normalised modal shapes derived using the SSI-Cov approach. These modes are the transversal modes typical of a masonry bridge of this type.

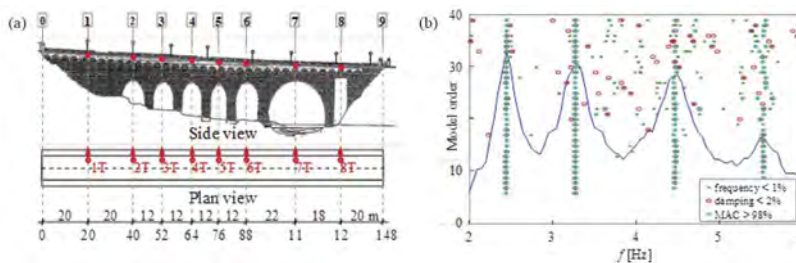

Figure 4. Ambient vibration tests: (a) sensor configuration, (b) stabilization diagram from SSI-Cov.

Table 1. Experimental modal parameters.

Mode	f [Hz]	ξ [%]	Mode shape
1	2.46	2.11	1 st transverse

4 NUMERICAL MODELLING

4.1 Finite element model of the bridge

Utilizing data from the laser scanner survey, a model for the overall structural analysis has been developed in Straus7. To account for the specific geological arrangement and capture the impacts of soil-pier interaction, the 3D model contains an appropriate area of the soil deposit with varying depth (Figure 6). A mesh of 4-node tetrahedral elements with linear interpolation shape functions is used to create the finite element model (Tetra4). By importing a closed poly-surface that approximates the geometry discovered by the laser scanner survey, the mesh is automatically generated. All internal chambers and the earth fill are modelled in order to accurately reflect the true stiffness and mass distribution of the structure. This avoids over-refinement of the mesh owing to features that do not directly affect the general behaviour of the bridge. The maximum length imposed to the element edge is 1.0 m, while it is extended to 4.5 m for the elements of the soil deposit. The deposit foundation and the structural portions engaging with the sand stone formation are both fixed with restraints. The model has a total of 75,204 degrees of freedom and is made up of 120,545 elements. All of the materials, including soil deposits and earth fills, are regarded as being linear elastic and isotropic.

Figure 6. Finite element model of the bridge (Straus7).

4.2 Finite element model updating

By matching the experimental modal parameters with numerical ones pertinent to the finite element model previously stated, the mechanical parameters of the finite element model are calibrated adopting the manual tuning technique. Figure 7 displays the first four mode shapes that were achieved by calibrating the model by merely altering the elastic modulus of the travertine masonry that makes up the structure. Moreover, the comparison among the first four experimental and numerical mode shapes is reported as well, while Table 2 reports the percentage errors relevant to the frequencies and the approximation of the mode shapes by means of the Modal Assurance Criterion (MAC) (Allemang and Brown 1982). The parameters achieved at the end of the updating procedure are reported in Table 3. The soil parameters are supposed based on available geotechnical tests, while infill materials are hypothesized.

Table 2. Comparison between experimental and numerical modal parameters after the model updating.

Mode	Frequency [Hz]		Error [%]	MAC [%]
	Experimental	Numerical		
1	2.46	2.42	1.55	98
2	3.30	3.45	-4.67	95
3	4.54	4.87	-7.34	93
4	5.61	6.23	-10.99	86

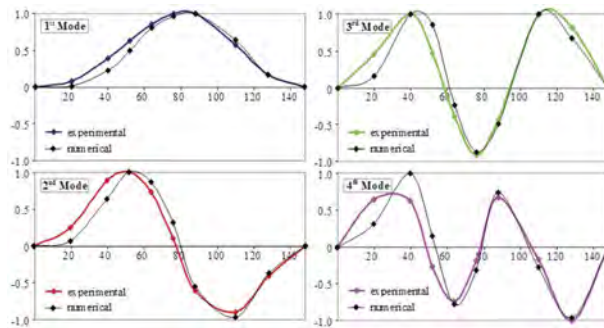

Figure 7. Comparison between experimental and numerical mode shapes.

Table 3. Comparison between experimental and numerical modal parameters after the model updating.

Material	E [N/mm ²]	G [N/mm ²]	W [kN/m ³]
Travertine masonry	7000	2414	22
Brick masonry	1282	427	18
Earth fill	666	238	18
Soil deposit	666	243	19

5 CONCLUSIONS

A finite element model of a mediaeval masonry bridge with distinctive geometry resulting from extremely complicated historical vicissitudes, has been calibrated through an experimental test campaign that has been presented. The bridge is built on a sand-stone deposit that is outcropping at the abutments and rises in a canyon. The bridge is made up of six separate arches, each supported by piers that extend up to 10 meters into the river deposit of sandy-gravel soil. The piers are built on a sand-stone formation. In order to create a model that included all significant aspects of the original building, including the interior lighting rooms highly asymmetrical geometry and the pensile arches built to widen the highway, a laser scanner survey was essential.

The onsite tests permitted to evaluate the main mechanical characteristics of the materials and to estimate the stress state in critical sections of the piers. The operational modal analysis, used to detect the dynamic behavior of the bridge, was decisive for tuning a finite element model capable of predicting the overall behavior of the bridge.

The calibrated model very well reflect the dynamic behaviour of the real bridge and it could be a fundamental support in the numerical analyses required for the bridge safety verifications.

Influence of site effects on the seismic vulnerability of masonry arch bridges

Ö. Saygılı

Department of Civil Engineering, Yeditepe University, Istanbul, Turkey

J.V. Lemos

National Laboratory for Civil Engineering (LNEC), Lisbon, Portugal

ABSTRACT: Historical masonry structures are vulnerable to seismic loadings due to their architectural characteristics, unsuitable strengthening or retrofit techniques, according to post-earthquake scenarios observed in Turkey during the previous 50 years. Masonry arch bridges are among the most important architectural heritage buildings vulnerable to earthquake motion. Historic masonry bridges that have suffered severe damage highlight the need for preventive and focused risk reduction strategies. This study aims to analyze the seismic vulnerability of two historical masonry arch bridges located in the Northeast and Northwest of Turkey, considering the seismotectonic parameters of the region. Nonlinear behavior of the masonry arch bridges under the seismic excitations that can be expected at the site was simulated in order to predict the potential damage levels. Discrete element method based on the numerical integration in time of the equations of motion of the system by means of an explicit finite difference method was used. The explicit solution procedure uses small time steps for numerical stability and this methodology allowed a general analysis to assess the joint separation and sliding of stone blocks. The seismic responses of these two masonry bridges showed that the geometry of the bridge has a significant effect on the structural performance, especially the arch span, which increases the seismic vulnerability of the bridges. More research is still needed on the approaches available to improve the seismic safety of damaged masonry arch bridges while preserving their historical value.

1 INTRODUCTION

Many old stone and brick bridges from the past still stand in Turkey, serving as important transportation infrastructures that were built long ago to help people get around. Most of these bridges have a round or pointed arch shape and rise high on both sides of the river. These bridges are specifically designed to withstand floods, and their lengths and heights depend on the width and depth of the valley where they are located. The investigation of the structural behavior of masonry structures is an active research subject, as evidenced by several studies (Çaktı et al., 2016; Karaton et al., 2017; Özmen & Sayın, 2018; Pulatsu et al., 2019; Saygılı, 2019, 2020; Saygılı & Lemos, 2020, 2021). To understand the structural behavior of these bridges, it is essential to know about the structural elements that contribute to their weight. The arch is the primary load-bearing element in a masonry bridge, transferring the compressive forces to the piers or foundation. Other structural elements, such as spandrels, abutments, and piers, also play an important role in resisting the loads. Stone arch bridges of various sizes and shapes are among the most common masonry bridges, belonging to different historical periods. Generally, the arch is made of cut stone, and the spandrels are made of gravel or rubble stone. The stone material resists gravity forces with its high compressive

strength, while the mortar between the stones acts as binding. Steel/metal elements are sometimes used to resist tensile forces. Parapets of these bridges are formed with a single row of cut stones on both sides of the bridge road.

This study focused on the seismic behavior of two historical masonry bridges located in Turkey. The Historical Kazan Bridge is a historic bridge that originally belonged to the Ottoman city's water systems. It has a rectangular plan with projected spandrel walls that are pierced by a pointed arch. The arch is made of cut stones, and other parts are made of rubble stone. The pointed arch span is 7.18 meters, composed of 37 stones, with a width of 6 meters. The keystone at the top of the arch is larger than the other stones. Along the roadway, the bridge has parapet stones above its spandrel wall, and the inclination on both sides of the roadway is around 6%. The outer shells of the spandrel walls are cut limestone, and two abutments support each end of the bridge. The thickness of the spandrel wall is 0.7 meters, and filling materials are placed between the stone walls. The second case study is about Şenyuva Bridge, which is made of stone and is an arch bridge. The arch is made of regular stone, and the side walls are made of regular rubble stone. The bridge has a pointed arch with a span of 24 meters and a width of 3.5 meters. The thickness of the spandrel walls is 0.5 meters, and filling materials are present between the cut stones. The bridges were found to be vulnerable to earthquakes, and it is crucial to assess their structural response to ensure their safety for the future. This was done by using 3-D non-linear numerical analyses to see how the bridges responded under simulated and real ground motions. The material properties of Kazan Bridge were established by relying on experimental data obtained from masonry structures constructed during the same period. In contrast, Bayraktar et al. (2009) conducted ambient vibration tests on Şenyuva Bridge to determine its dynamic characteristics through experimental means. These tests enabled the calibration of the existing data on the material properties of Şenyuva Bridge.

2 SEISMICITY

2.1 Kazan Bridge

This article explores the history of the first masonry bridge, known as the Historical Kazan Bridge, currently located in Edirne, a city with a rich cultural and historical background. The city boasts a variety of ancient buildings and monuments that reflect the religious and cultural life of different periods. The tectonic setting of the region is controlled by the Anatolian and

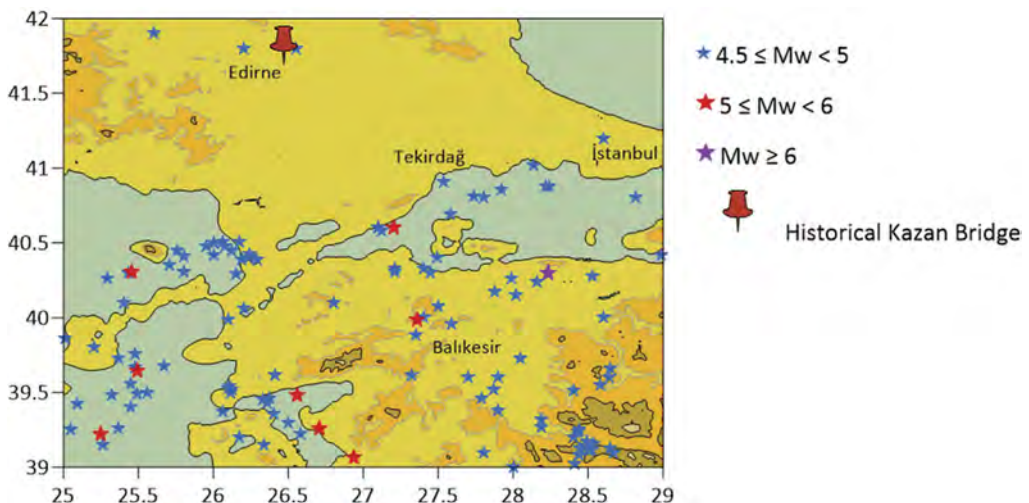

Figure 1. Seismic activity of the Thrace region.

Eurasian Plates, which rotate in opposite directions (Ambraseys & Finkel 1991, Gök et al. 2016). Additionally, there are several active and inactive faults in the area. Seismic activity is concentrated on the southern side of the Edirne provincial border, with less activity to the north of the city center (see Figure 1). The most significant earthquake in the region occurred in 1912, resulting in casualties and the destruction of many masonry buildings.

2.2 Şenyuva Bridge

The Şenyuva Bridge, a historical landmark, can be found in the city of Rize, located in the eastern Black Sea region. The area surrounding the Black Sea basin is characterized by geological fault lines such as the Southeast Black Sea Fault in the south, the North Anatolian Fault (NAF), and the North-East Anatolian Fault (NDAF) in the north, and the Eastern Pontide active deformation zone in the east. This region is known for experiencing earthquakes caused by thrust mechanisms, particularly on the northeast coast of the Black Sea where compressional tectonics are prominent. Research has revealed that the compressional zone of the region has caused an increase in crust thickness, ranging from 42-46 km, due to the convergence of the Arabian Plate and the Eurasian Plate. The Eastern Pontide active deformation zone is responsible for creating three distinct seismic belts from south to north: The South seismic zone (NAF and EAF Erzincan-Erzurum), the Middle seismic zone (Eastern Black Sea Region and coastal zone), and the Northern seismic zone (Black Sea). Seismic activity increases in magnitude from north to south, as observed in the 1939 Erzincan earthquake with a magnitude of $M_w=7.9$ occurring in the south seismic zone. Furthermore, earthquake focus depths also increase from north to south, which could be attributed to the nature and thickness of the earthquake-generating crust, transitioning from oceanic crust to continental crust (Figure 2).

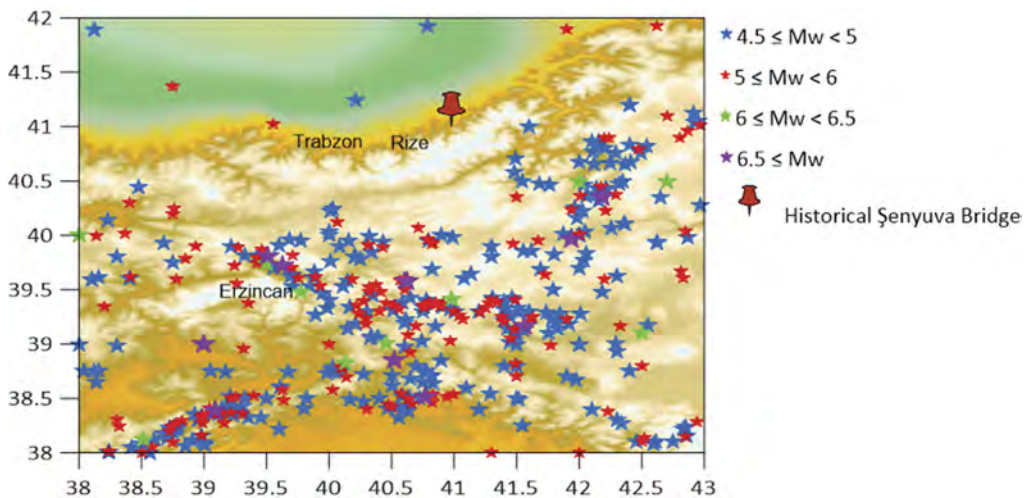

Figure 2. Seismic activity of the Rize region.

3 SELECTION OF SEISMIC MOTION RECORDS

3.1 Synthetic strong ground motions

Artificial ground motions are commonly used in dynamic analyses of seismic structures to simulate the effect of an earthquake on a structure. These simulations are crucial in determining the likely response of a structure to a specific earthquake, or in comparing the responses of different structures to each other. In this study, artificial ground motions were generated to

match the target spectrum of a specific earthquake and produce a realistic ground motion. To generate these artificial ground motions, the method of matching the target spectra was employed, which involved adjusting the acceleration, velocity, and displacement of the ground motion to fit a specific target spectrum. Figures 4 and 5 provide visual representations of the target spectra and the resulting artificial ground motions.

In addition to the artificial ground motions, real ground motions were also used as inputs in response history analysis. Three real ground motions were selected from the Pacific Earthquake Engineering Research Center (PEER) ground motion database for shallow crustal earthquakes in active tectonic regimes. These ground motions were chosen based on their compatibility with the target spectrum. Furthermore, eight records were scaled to the target spectrum ordinate using the method of minimizing the Mean Squared Error (MSE). This technique was applied in the frequency domain over a specified period range according to the requirements given in the Turkish Building Seismic Code 2018 (TBSC 2018).

Figure 3. Artificial ground motion data set for historical Kazan Bridge.

Figure 4. Artificial ground motion data set for historical Senyuva Bridge.

4 DAMAGE STATES OF THE BRIDGES

4.1 Continuum and discrete models

This study employed two different modeling approaches to create models of historical stone-masonry bridges. One model was based on a continuum approach, while the other was based on a discontinuum approach. To create these models, the finite element method was used with a macro modeling strategy, using the SAP2000 (CSI 2004) computer program. The models consisted of four components: a spandrel wall, a barrel, fill material, and a roadway (slab). The mechanical behavior of these components was assumed to be linearly elastic, and Hooke's law was used to model the elasticity of the system. The continuum models were only used for elastic analysis, while more elaborate macro-models were used for nonlinear analysis.

For the discontinuum models, the code 3DEC computer program was used (Itasca 2016). This approach allowed for the modeling of the discontinuities and fractures that are inherent in stone-masonry bridges, providing a more accurate representation of their behavior under load. Bending mode shapes of the numerical models are given in Figure 5, providing a visual representation of the deformation patterns that occur when the bridges are subjected to loading. These mode shapes can help to identify potential failure modes and guide the design of interventions to improve the safety and resilience of these historic structures.

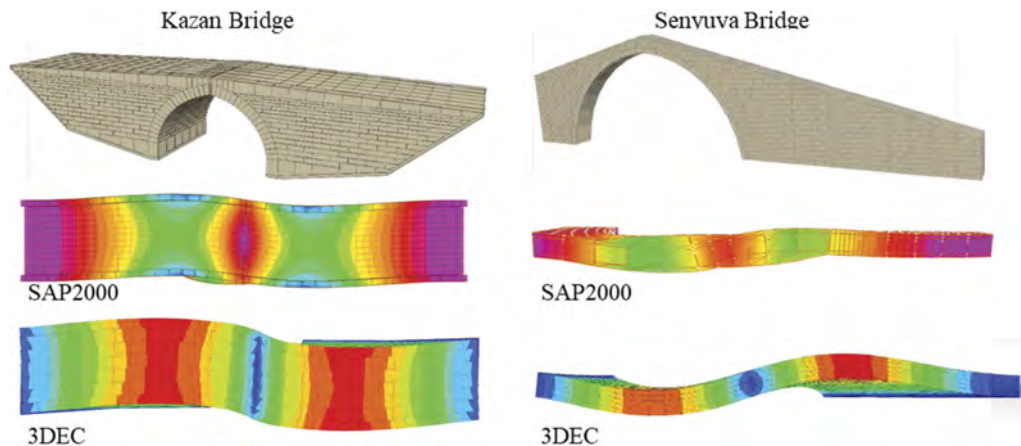

Figure 5. Bending mode of the Kazan Bridge and Şenyuva Bridge.

4.2 Kazan Bridge

To model the seismic response of different ground motions, nonlinear dynamic analyses were performed using the 3DEC program (Itasca 2016). The input was defined in terms of velocity time series, which were applied at the base of the model. This approach allowed for a detailed evaluation of the behavior of the bridge under seismic loading, taking into account the complex nonlinearities and material behavior that are present in such structures. The results of the analysis showed that the maximum displacement occurred in the middle of the transverse span during seismic excitation. Furthermore, the maximum vertical stress and tensile stress were observed at the same location. These findings are consistent with the expected behavior of stone-masonry bridges under seismic loading, where the mid-span region is subjected to the greatest stresses and deformations. Interestingly, the results also indicated that the brick bridge under artificial seismic data experienced higher velocities than scaled or unscaled seismic data (Figure 6). This may be due to the fact that the artificial record was specifically designed to match the design spectrum, which represents the envelope of multiple earthquakes. In contrast, the scaled or unscaled seismic data may not fully capture the range of

possible seismic events that the structure could be subjected to. However, it should be noted that the use of artificial records could potentially lead to further deformation of the structure under artificial recording.

4.3 Senyuva Bridge

Şenyuva Bridge was found to be vulnerable to severe damage or collapse under artificial earthquakes, with a return period of 2475 years. The damage process typically involved a series of shear cracks and openings around the eastern part of the downstream side of the bridge, starting from the crown of the arch and extending towards the support region. This type of failure is consistent with the expected behavior of stone-masonry arch bridges under seismic loading, where shear and tensile stresses can cause cracking and separation in the masonry blocks. The analysis also revealed that areas of significant stress concentration developed in the upper part of the arch curve during the seismic excitation. This finding highlights the importance of accurately modeling the complex geometry and material behavior of stone-masonry bridges when assessing their seismic performance. The variation of permanent displacement magnitudes in the Şenyuva Bridge at the end of the dynamic analysis using artificial ground motion data sets is

Figure 6. Permanent displacement magnitudes in Kazan Bridge.

Figure 7. Permanent displacement magnitudes in Senyuva Bridge.

shown in Figure 7. These results provide important insights into the long-term behavior of the bridge under seismic loading, and can help guide efforts to improve its safety and resilience in the face of future seismic events.

5 CONCLUSION

This study investigated the seismic behavior of two historical stone masonry bridges located in Turkey. The bridges were subjected to both artificial and real ground motions to assess their vulnerability to seismic excitation. The results showed that Kazan Bridge would experience some damage from the stresses produced by dynamic effects. However, based on the results of all cases presented, it was found that the bridge can withstand the applied seismic excitations. Moderate damage, especially from AGM records, occurred at the mid-span of the arch, mostly as slight openings. The bridge demonstrated a stiff behavior, confirming its durability, strength, and ability to sustain the seismic loading prescribed by present regulations.

The author indicates that the Şenyuva Bridge is significantly vulnerable to earthquakes and that its structural behavior is influenced by the bridge's geometry. The bridge has a 2475-year return period, and its performance under artificial ground motion is worse than that of the Kazan Bridge. This study concluded that dynamic analysis is a useful tool for assessing the seismic safety of masonry bridges. Under strong ground motions, DEM models provide insight into the levels of damage and the collapse patterns that may be expected. Further research is necessary to understand the impact of structural design features on the seismic safety of deficient masonry bridges.

Computational strategy for the design of monitoring for masonry arch bridges using DIC procedures

S. Grosman, Q. Fang, L. Macorini & B.A. Izzuddin
Imperial College London, London, UK

ABSTRACT: Masonry arch bridges are old structures characterised by a complex behaviour. Detailed monitoring is essential to improve the understanding of the response under different loading conditions, to identify damaged structures, and to validate numerical models for accurate structural assessment. Generally, standard monitoring techniques necessitate direct access and contact to the analysed structure, which can be problematic in many cases. The use of Digital Image Correlation (DIC) overcomes these critical limitations offering an improved potential for detailed and streamlined monitoring. This work focuses on the development of advanced computational tools to support the practical application of DIC monitoring in field conditions. The proposed procedure utilises results from 3D numerical models to generate synthetic video files representing the bridge response under traffic loading, which can be subsequently employed to calibrate camera setups for DIC monitoring.

1 INTRODUCTION

A substantial part of European bridge infrastructure consists of masonry bridges and viaducts. Maintaining good condition of such structures is paramount to their continued use and to ensuring effective and safe transportation links. To this end, it is necessary to establish robust approaches for bridge monitoring. While there are multiple techniques to accurately measure deflections, they usually necessitate direct access to the bridge structure, which might be difficult to achieve especially for structures featuring tall piers and long spans. This access problem can be tackled by utilising non-contact monitoring methods (Feng et al., 2015, Xu et al., 2018). Among these monitoring strategies, vision-based methods utilising pattern matching between temporal sets of images of the considered structure (Koltsida et al., 2013, Busca et al., 2014) are of particular interest, as they guarantee an effective approach for monitoring the response at multiple points at once while maintain reasonable levels of accuracy (Kim & Kim, 2011, Wang & Li, 2020). However, the utilisation of vision-based systems poses new challenges for monitoring. In particular, stable camera mounting becomes critical to achieve accurate measurement (Lava et al., 2009, Brownjohn et al., 2017). Sudden lighting changes present another source of vulnerability as they might cause over- or under-exposure of some images in the analysed sequence (Acikgoz et al., 2018b). Another source of uncertainty comes from the environmental condition that affects the light refraction, which becomes especially pronounced in long range measurements (Lages Martins et al., 2015).

Considering all of these issues, it is important to plan monitoring work very carefully to maximise the amount of useful output that can be collected. This paper focuses on ways to provide information on the design of monitoring setups to achieve this goal. To this end a “Numerical Camera” technique is proposed. In this procedure, prior to monitoring, the structure under investigation is analysed using a 3D finite element (FE) model considering realistic traffic loading scenarios. The numerical results from the FE simulations are then used

to construct a “digital twin” of the bridge to be monitored, that is used to create a series of synthetic videos capable of simulating different camera positions and properties. The obtained videos are then processed with Digital Image Correlation (DIC) tools to obtain 3D displacements at some key points on the structure. These results are then compared against numerical results for the structure, to validate the accuracy of the proposed strategy. This approach can be used to determine DIC setup requirements for each point of interest. The following section will provide a brief overview of DIC techniques as well as a more detailed description of the “Digital twin” generation and the “Numerical camera” capabilities. Finally, an application of the developed approach is presented for the determination of key camera parameters (frame rate, resolution) for the monitoring of a realistic masonry viaduct.

2 METHODOLOGY

DIC is a vision-based technique used to measure displacements and strains of the monitored object by comparing temporal sets (captured over a continuous time frame) of images of the object surface. In DIC, the process of matching or “correlating” corresponding points is typically done using algorithms that compare the intensity of pixels values in different images, as well as their spatial relationship to each other (Feng et al., 2015). Once the corresponding points have been identified, the displacement and strain between them can be calculated based on the difference in their positions in subsequent images.

Masonry bridges are complex structures that exhibit pronounced 3D behaviour under loading. This behaviour should be reflected in the dataset obtained via monitoring. A substantial obstacle to practical DIC application is the fact that 2D DIC was originally developed under the premise that the camera viewing angle would remain normal to the object plane. One way to address this is by installing targets on the monitored bridge (Lages Martins et al., 2015) that would be normal to the camera orientation. The other relies on a complex calibration to correct for the perspective distortion that occurs due to non-orthogonality of the viewing angle. A typical approach to achieve such a correction is to use vanishing points (points where projections of parallel lines intersect) to construct transformation matrix (Santana-Cedr es et al., 2017). In practice this is usually realised by defining a series of geometric features on the image that will be used for perspective correction in conjunction with camera intrinsic parameters (Acikgoz et al., 2018b).

Prior research (Lava et al., 2009, Feng et al., 2015, Acikgoz et al., 2018a) indicates a clear need for pre-monitoring calibration of DIC techniques to achieve the best result. When it comes to field monitoring, it becomes exceedingly difficult to achieve consistent calibration, as environmental factors are unique and uncontrollable. To address this Lava et al., (2009, 2020) suggests the utilisation of finite element models as substrates for the DIC analysis, where FE model deformations are used to morph the image of the patterned structure, that are then utilised in the DIC analysis. This work extends such a technique to larger structures with naturally occurring patterns (masonry bond), generating an effective digital twin of an actual bridge. A “digital twin” is a virtual representation of a physical object or system that can be used for monitoring and analysis. In the context of masonry arch bridge monitoring, such model can be created from two sources of information: 1) displacement data obtained from the FE simulation of the considered structure, and 2) general bridge geometric data combined with brick size and bond pattern.

According to the proposed approach, a FE macroscale model of the masonry structure is generated using a recently developed parametric modelling tool for masonry arch bridges and viaducts (Grosman et al., 2023). For large-scale masonry bridge structures, the use of the macroscale approach (Tubaldi et al., 2020, Grosman et al., 2021) is shown to yield good results, especially in the serviceability loading range. According to the macroscale modelling strategy, masonry is modelled using continuum solid elements, sized independently from the actual dimensions of masonry units and mortar joints, resulting in computationally efficient models. Material models combining plasticity and damage are employed in this approach (Lee & Fenves, 1998, Chisari et al., 2020) to represent material nonlinearity in the masonry assumed as

a uniform material. The developed model (Figure 1) is then analysed using the advanced non-linear FE software ADAPTIC (Izzuddin, 1991) considering realistic traffic loading scenarios.

Figure 1. Numerical model of the Mill Road Viaduct.

Bridge geometric data is utilized for generation of the façade mesh on top of the bridge external surfaces. This process can be subdivided into the following two steps: 1) the geometric features and bounding surfaces of the bridge are identified, including the arches, which may have a different bond pattern; 2) a new façade mesh is then created to cover the entire structure, with each brick being subdivided into four triangular segments with a point in the center. To accurately represent the appearance of the brick surface, a small variation of color is added to each mesh segment to account for the natural patterning on the brick faces. The resulting mesh provides a detailed virtual representation of the bridge that can then be used for monitoring.

All of this data is utilised inside a MATLAB software environment (The MathWorks, 2012) to generate a virtual model of a bridge that can be interacted with via a newly developed tool – “Numerical Camera” – that connects MATLAB in-built visualisation properties with camera hardware specifications. This tool allows users to capture synthetic videos of the bridge as if it were being viewed through a real camera. The “Numerical Camera” has a number of features that can be controlled by the user (Figure 2). These include control over the field of view, via the size of the camera sensor and the focal distance. The camera can also be repositioned and rotated around the bridge to change the perspective from which the bridge is being viewed. The frame rate and resolution of the camera can also be adjusted to control the desired video output.

3 NUMERICAL EXAMPLE

The potential of the developed computational strategy for the design of DIC monitoring tests is illustrated in a numerical example investigating the response of a realistic masonry viaduct under traffic loading.

3.1 *Mill Road Viaduct*

Mill Road Viaduct (Figure 3) is a multi-span masonry bridge located in Lewisham, South London. A portion of the viaduct serves as a platform for the Lewisham train station. This is a busy junction that experiences a high volume of relatively slow-moving traffic, in both directions. The viaduct consists of four straight masonry arches and two skew masonry arches with the last one crossing the Ravensbourne River.

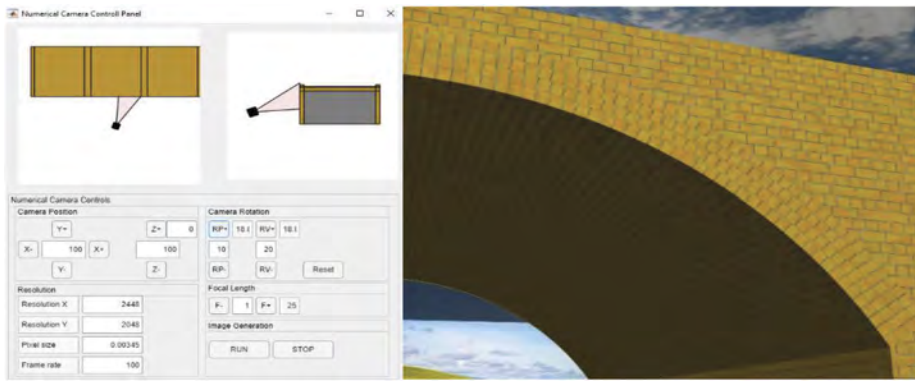

Figure 2. Numerical camera rotation control panel.

Figure 3. Mill Road Viaduct.

Out of the six spans, only three internal spans are considered in the numerical simulation, with edge spans serving as boundary conditions for the mid span (Span 3 in Figure 4). On average, the span of the considered arches is 7400 mm long with a rise of 2000 mm. The arch bridge is 8510 mm wide, with piers of 1930 mm high and 920 mm length.

Figure 4. Mill Road Viaduct sizing information.

The analysed bridge structure is modelled in ADAPTIC (Izzuddin, 1991) and analysed under the effects of traffic loading due to the passage of a ballast train (65 km/h) consisting of 10 coaches. The specific axel loading for each coach, as well as the order and number of coaches in considered train are presented in Figure 5. The material properties utilised in the numerical simulations are presented in Table 1.

Table 1. Material properties used in the numerical analysis.

Material Properties	Masonry	Backing	Backfill
Young's modulus [N/mm ²]	7000.00	2500.00	2500.00
Poisson ratio	0.15	0.15	0.15
Tensile strength [N/mm ²]	0.20	0.15	0.05
Fracture energy in uniaxial tension [N/mm]	0.05	0.05	0.05
Maximum uniaxial compressive strength [N/mm ²]	25.00	10.00	5.00

Figure 5. Traffic loading considered in the analysis.

3.2 Numerical camera verification

3.2.1 DIC setup

To verify the proposed approach for the design of DIC monitoring tests on the analysed bridge, the numerical model (Figure 1) described in the previous section is processed, and its visually accurate counterpart (Figure 6) is generated in MATLAB. Utilising nodal displacements obtained during the time-history FE analysis, a series of synthetic images corresponding to specific time frames are generated and combined into a video file to be analysed using DIC. To remove uncertainty associated with the generated videos, image compression is not utilised when generating images.

Figure 6. Tiled model of the Mill Road Viaduct spans 2 – 4.

The generated video are then processed with “Imetrum: Video Gauge” software (Imetrum, 2016). To address perspective correction, rectangular regions are specified in 3D space for each target to determine vanishing points and to provide calibration for transformation from the image scale to the real scale. Displacements are calculated based on an 80×80 pixels target defining the region of interest where the correlation procedure takes place. Each target is defined in such a way as to include bond features, specifically orthogonal bond intersections or mortar loops, to improve correlation accuracy.

The conducted simulation pursues the following goals: 1) verification of the proposed procedure via direct comparison of DIC and numerical displacements at the monitored points; 2) establishment of minimal camera parameters (frame rate and resolution) ensuring a good match; 3) preliminary investigation of the influence of the camera standoff distance (from the bridge face) on the quality of DIC result.

3.2.2 Comparison between DIC and numerical results

An initial trial is conducted considering a camera resolution of 2448×2048 pixels and a frame rate of 100 frames per second (fps). The camera is positioned at the middle of span 3, at a 5 m distance from the bridge face, resulting in a camera elevation of 20 degrees (Figure 7a). Good agreement is generally observed for the monitored points (Figure 7b).

Figure 7. Camera view for verification test a) and verification results b).

The next investigation considers the effects of the assumed camera frame rate on the DIC result. To this end 5 different frame rates are considered: 100, 50, 25, and 12 fps. It is important to note that the frame rate should always be selected based on train speed, as faster trains generally require higher frame rates. Comparisons of different DIC curves and associated numerical results are presented in Figure 8a. In general, all the results indicate reasonable agreement, with only the 12 fps option showing reduced accuracy.

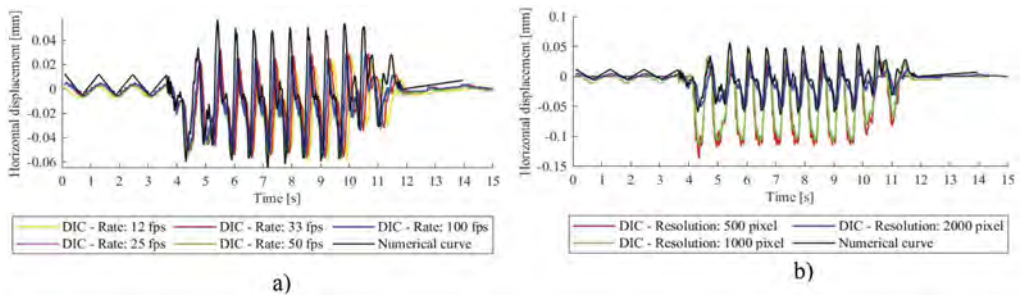

Figure 8. Influence of camera parameters on DIC results: a) frame rate; b) resolution.

The camera resolution is also investigated to establish its influence on the observed DIC response. Three options are considered: 1) 2448×2048 pixels denoted as 2000 for brevity from now on; 2) 1224×1024 pixels denoted as 1000; and 3) 612×512 pixels denoted as 500. Comparison results are presented in Figure 8b. In this case emphasis is put on horizontal deformations on the arch due to their small magnitude, as this can be more readily affected by camera resolution. Obtained results support this conclusion, as only the 2000 pixel camera led to good agreement with numerical inputs, for displacement range of 0.1 mm. It should be noted that although results obtained with 1000 and 500 pixel cameras do not conform with numerical results magnitude, they do depict all of the response features.

In a final investigation, the effects of different stand-off distances between the camera and monitored bridge are considered. This numerical test was conducted considering a camera

resolution of 2448×2048 pixels and a rate of 100 fps and standoff distances of: 1) 3.5 m (Figure 9a); 2) 5 m (Figures 7a); and 3) 10 m (Figure 9b).

The results obtained for 10 m standoff highlight that an increased distance can result in a drastic drop in accuracy of the DIC prediction, as shown in Figure 9c. It is also worth noting that the standoff distance is connected to the camera elevation, with a small standoff corresponding to larger elevation, where an increase in camera elevation can cause some discrepancy in the response prediction as well (Figure 9c). The performed study confirms that the developed approach can be effectively used to maximize the effectiveness of on-site DIC monitoring establishing acceptable levels for standoff and elevation and camera characteristics.

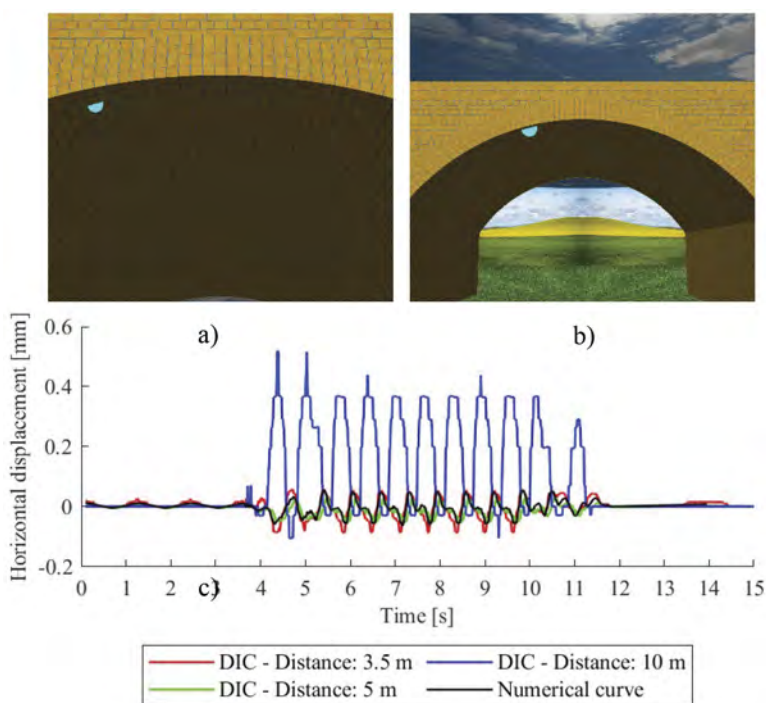

Figure 9. Influence of standoff distance on DIC result: a) camera view 3.5 m; b) camera view 10 m; c) results comparison.

4 CONCLUSIONS

Masonry arch bridges constitute a substantial portion of bridge infrastructure. A considerable proportion of these bridges is older than 100 years, resulting in an increasing need for monitoring due to regular deterioration due to environmental factors as well as increasing loading due to the evolution of rolling stock and locomotive design. This study investigated the applicability of DIC to displacement tracking of bridges under typical traffic loading in field conditions, where small displacements and environmental noise can substantially affect the accuracy of DIC algorithms. To this end, a numerical strategy was developed to verify the applicability of DIC in ideal conditions. The proposed approach utilises results from 3D FE simulation of the analysed structures to construct a realistic representation of the bridge under traffic loading, which can then be captured via a Numerical Camera as a synthetic video to be processed with DIC algorithm. This approach can be used to assist the design of the monitoring work, taking into account topographic constraints, possible configurations for the camera lenses, camera position and camera orientation.

The proposed strategy is verified by comparing numerical input against DIC output, where good agreement is found for the monitored data point, for some of the considered monitoring strategies. Ability of camera to accurately capture structural response is shown to be heavily dependent on camera resolution with 2448×2048 pixel resolution proving to be sufficient for the considered testing options. Further simulations highlight applicability of the developed approach to maximising the effectiveness of on-site DIC monitoring establishing acceptable levels for standoff and elevation and camera characteristics. It is worth noting though that obtained results characterise ideal recording conditions, and may be adversely affected when conducting monitoring in adverse weather situations (e.g. wind, rain, dust pollution).

Influence of uncertain mechanical parameters on the load-bearing capacity of multi-span masonry arch bridges

M. Zizi, C. Chisari & G. De Matteis

Department of Architecture and Industrial Design, University of Campania “Luigi Vanvitelli”, Aversa (CE), Italy

ABSTRACT: The present paper deals with the assessment of the load-bearing capacity of existing masonry arch bridges by means of numerical models. The problem related to the selection of uncertain parameters is addressed by reproducing a past experimental test performed on a reduced-scale bridge prototype vertically loaded until its collapse. The test is reproduced in Abaqus software by representing masonry elements through the Finite Element macro-modelling approach, in which masonry is considered as a homogeneous material having a plastic-damage constitutive behaviour in the nonlinear field. The fill material is introduced by means of a nonlinear continuum behaving under similar Mohr-Coulomb hypotheses. An appropriate interaction law that entails a frictional response in the tangential direction, avoids interpenetration, and allows for the separation between the two materials, is also considered. A wide parametric investigation is performed to obtain a good fitting with the experimental evidence by varying the uncertain mechanical parameters (i.e. Elastic Modulus of backfill, tensile strength of masonry and contact law between the two materials). Thus, a reliable numerical model exhibiting a response consistent with the experimental outcome in terms of both failure mode and force-displacement curve is proposed. The influence of each investigated parameter on the overall response of the bridge is then deeply analysed and discussed, also with the aim to identify possible retrofitting strategies.

1 INTRODUCTION

The structural safety of the worldwide existing infrastructural heritage is a complex challenge that, in recent times, has involved an ever-increasing number of researchers and practitioners (Zizi et al. 2023). In this field, reliable numerical models to interpret the response under external loads of in-service infrastructures, on the one hand, are considered one of the most valuable tools, while, on the other, their calibration still represent a serious issue to be addressed. Whilst, nowadays, the suitability of the available assessment methodologies for existing reinforced concrete and steel structures and infrastructures are widely corroborated, the study of masonry structures is generally recognized as an open issue, mainly related to the mechanical complexity of the base materials, as well as their interaction (Melbourne 1990, Sokolovic et al. 2021, Zampieri et al. 2021, Zhang et al. 2018, Pantò et al. 2022).

Several assessment methodologies, including for instance limit analysis and various space- and time-discretisation numerical approaches, may be adopted for the study of masonry structures. In this context, numerical methods as finite element or discrete element modelling are considered very effective tools to interpret the response under vertical and horizontal loads of these structures, despite characterized by a certain difficulty in the selection of the mechanical parameters adopted for describing the material behaviour. Within such methods, the behaviour of masonry structures is simulated by discretizing the structural elements according to different detail levels (i.e. mono-dimensional, bi-dimensional or three-dimensional elements in combination with detailed or simplified micromodelling and macromodelling discretization), and post-elastic material descriptions (e.g. plastic, damage, damage-plastic, etc.) (Lourenço 2009).

Focusing on finite element methods based on a macro-modelling discretization, masonry infra-structures, and in particular masonry arch bridges, may represent a very interesting benchmark case study, being their response dependent on (i) the material description adopted for the masonry material, generally constituting arch rings, piers, abutments and spandrel walls, (ii) the material description adopted for the backfill material, generally characterized by a soil-like behaviour, and (iii) the laws adopted for describing the interaction between the two materials. In this sense, a rational selection of the mechanical parameters adopted for the assumed material descriptions and interaction laws is required since they can significantly affect the overall response of the numerical model.

Based on this premise, in the present study, the calibration of a reliable finite element model in Abaqus software for reproducing the evidence of a past experimental test retrieved from the literature is proposed (Melbourne et al. 1997). Given the uncertainties related to the definition of some mechanical parameters, an iterative calibration procedure has been performed, entailing the execution of 27 numerical analyses. Such a calibration allowed for identifying the most influencing parameters on the response of the investigated case study.

2 THE REFERENCE EXPERIMENTAL TEST

2.1 Test description: Set-up and characteristics of the material

The reference experimental test consisted of a three-span arch bridge prototype vertically loaded until collapse at one-fourth of the central span. Hereinafter, some general notions about the adopted test set-up and materials are provided, but further information can be found in Melbourne et al. (1997), referring to “*Bridge no. 2*”.

The specimen counts three 3 m-long spans. The two piers are characterized by a height of 1.5 m and a length of 0.44 m, while the abutments have a height and a length equal to 0.92 m and 1.8 m, respectively. The segmental arch rings present a thickness of 0.215 m and a height (from the impost to the keystone at the intrados) of 0.75 m. A backfill material is also present over the arch rings and abutments, with a height of 1.095 m and 0.13 m at the abutments and arch keystones, respectively. No spandrel walls are present in the specimen, but detached walls guaranteed the confinement in the transversal direction of the backfill material. Arch rings, piers and abutments are in brickwork masonry while a cohesionless soil is adopted as fill material. The width of the specimen is equal to 3.54 m and 2.88 m for masonry elements and fill material, respectively.

As regards the characteristics of the material, the following parameters were provided by the authors of the test:

- Compressive strength of the masonry $f_c = 26.8$ MPa;
- Elastic modulus of the masonry $E_m = 16,200$ MPa;
- Specific weight of the masonry $\gamma_m = 22.4$ MPa;
- Cohesion of the backfill $c = 0$ MPa;
- Internal friction angle of the backfill $\phi_b = 60^\circ$;
- Specific weight of the backfill $\gamma_b = 22.2$ MPa.

Thus, no information was provided about the elastic modulus of backfill, tensile strength of masonry, backfill-arch interface behaviour and the post-peak response of any of the materials. This is rather usual in experimental characterisation of masonry arch bridges, and thus it is of great interest to understand how the uncertain/missing parameters should be selected and how they affect the final prediction of the numerical simulation.

2.2 Experimental test results

The tested specimen exhibited a capacity of about 320 kN. The test was interrupted at a radial displacement of the intrados point in correspondence with the load application of about -45 mm due to the damage occurred. In particular, the damage interested the central and the north (opposite side with respect to the load application point) arches, as well as the in-between pier at the base. The results in terms of force-displacement curve and crack pattern are shown in Figure 1.

Figure 1. Main results of reference experimental test: (a) damage pattern and (b) force-radial displacement curve (adapted from Melbourne et al. 1997).

3 FINITE ELEMENT MODELLING

3.1 Description of the model

The bridge at hand was modelled in Abaqus software by means of 8-node solid elements. In particular, elements with reduced (C3D8R) and full (C3D8) integration were adopted for backfill and masonry elements, respectively. Reduced integration for the backfill was adopted to decrease computational efforts. Such a choice has been preliminary validated by checking that it did not substantially influence the analysis results. An average mesh size of 0.1 m was adopted for both materials, after a preliminary sensitivity analysis.

Given the symmetry with respect to the longitudinal axis and in order to reduce the computational efforts, half bridge has been modelled and appropriate boundary conditions have been assigned to the nodes lying on the longitudinal cutting plane. Also, the transversal displacements of the backfill were restrained to simulate the presence of the additional walls. The base node at piers and abutments were considered fully fixed. A three-dimensional view of the model is provided in Figure 2.

Perfect node continuity was considered between masonry elements, while their contact with the backfill material was modelled by an interaction law. The adopted law avoids the interpretation but allows the node separation in case of tensile stresses once the contact is occurred. Moreover, a frictional behaviour with $\mu = \tan(30^\circ)$ in the tangential direction has been also considered.

The masonry material was represented as a homogeneous material. The Concrete Damage Plasticity (CDP) material model (Lubliner et al. 1989, Lee & Fenves 1998), available in the software's library, was assumed to describe the masonry behaviour in the non-linear field. A parabolic law was assumed in compression (Sawko 1982), while in tension a linear softening was considered as function of the fracture energy.

Figure 2. The adopted finite element model.

The mechanical parameters assumed for the masonry, i.e. elastic modulus and compressive strength, were the ones reported in Melbourne et al. (1997). As for the behaviour in tension, a strength $f_t=0.2$ MPa was assumed, while the fracture energy $G_{f_t}=13.2$ N/m was defined according to Lourenço (2009), as per Equation 1.

$$G_{f_t} = 0.025(2 \cdot f_t)^{0.7} \quad (1)$$

Also, linear damage laws in both compression (d_c) and tension (d_t) were introduced: the onsets of damage were defined at maximum compression or tension stresses, while at the maximum inelastic strain (compression) and displacement (tension) the maximum damage values (100%) were considered attained. The remaining parameters for defining the CDP behavior were set by considering conventional values: i. uniaxial-to-biaxial compressive strength ratio $f_{c0}/f_{b0}=1.16$; ii. dilation angle $\psi_{CDP}=10^\circ$; iii. $K_c=0.667$; iv. eccentricity $\varepsilon=0.1$.

The backfill material was simulated by means of a Mohr-Coulomb-like formulation with an elastic modulus $E_b=50$ MPa and a perfectly plastic post-elastic behaviour. At this purpose, and to avoid convergence issues when the stress state approaches the corner of the failure surface, the linear Drucker-Prager material model implemented in Abaqus software was adopted. To approximate the outer cone of the Mohr-Coulomb failure surface with the Drucker-Prager constitutive relationship, a friction angle $\beta=50.5^\circ$ was assumed. Moreover, a small cohesion was also introduced ($c=0.001$ MPa) to ensure robustness to the analysis.

3.2 Numerical calibration

The numerical analysis was phased in two steps: in the first step the gravitational load was applied, while in the second one the increasing vertical load until collapse was introduced at one-fourth span of the central bay. Given the complexity of the model, as well as the significant displacements attained in the real experimental test, a dynamic/implicit analysis method was adopted in the second step with a velocity of the load application such that guaranteeing the quasi-static load transmission (i.e. 0.01 mm/s). A fictitious damping coefficient equal to 20% was also introduced for both materials to avoid abrupt losses of strength and consequent convergence issues. The validity of this approach was verified against the static approach, showing that in such a way convergence issues were avoided and computational effort reduced without affecting the accuracy of the analysis.

Whilst some mechanical parameters were known and reported in the reference literature work (i.e. elastic modulus and compressive strength of the masonry, cohesion and friction angle of the backfill soil and specific weights of the material), no information were available with reference to tensile strength of the masonry f_t and elastic modulus of backfill material E_b . Moreover, in the considered case, it must be mentioned also the uncertainty affecting the friction coefficient μ defining the tangential law adopted for describing the interaction between the different materials.

Based on this, the proposed model has been defined by performing a parametric study where the unknown parameters were varied according to the following values:

- Tensile strength of the masonry: $f_t = 0.2$ MPa, 0.4 MPa, 0.8 MPa;
- Elastic modulus of the backfill material: $E_b = 25$ MPa, 50 MPa, 100 MPa;
- Friction coefficient for the interaction law: $\mu = \tan(15^\circ)$, $\tan(30^\circ)$, $\tan(60^\circ)$.

Moreover, the fracture energy in tension was obtained from the selected value of tensile strength. These preliminary analyses were pushed until a vertical displacement of the point of load application of -20 mm. This was sufficient to operate a comparison between reference and numerical curves, which was performed by evaluating, for each displacement level u , the absolute total relative percentual error $E_{r\%}$ of the force values. In particular, the percentual error $E_{r\%}$ was estimated according to Equation 2:

$$E_{r\%} = \int_0^{u_{\max, \text{num}}} \frac{|F_{\text{num}}(u) - F_{\text{exp}}(u)|}{F_{\text{exp}}(u)} du \quad (2)$$

where: the vertical displacement u ranges from 0 to the maximum displacement of the numerical curve $u_{max,num}$ and $F_{num|exp}(u)$ indicates the force value in the numerical or experimental curve obtained at each displacement value.

3.3 Validation of the implemented numerical model

Based on the described calibration procedure, the unknown parameters were defined by selecting the case that returned the lowest value of the relative percentage error. In particular, when $E_b=50$ MPa, $f_i=0.2$ MPa and $\mu=\tan(30^\circ)$ were adopted, the minimum value of the relative error ($E_{r\%}=3.1\%$) was obtained.

The calibrated model returned, at the end of the analysis, results strongly consistent with the experimental evidence. This is confirmed by the comparison in terms of both failure modes and force-displacement curves shown in Figure 3. In particular, in Figure 3a the tensile damage at the last displacement value is plotted together with the experimental crack position overlapped, while in Figure 3b the comparison between the numerical and experimental curves is shown.

Figure 3. Results of numerical analysis in comparison with experimental evidence: (a) damage pattern and (b) force-radial displacement curves.

4 EFFECTS OF UNCERTAIN PARAMETER ON BRIDGE RESPONSE

4.1 Influence of the uncertain parameters

The wide set of analyses performed for calibrating the numerical model has led to make some considerations about the effects of the investigated parameters on the bridge response. A first consideration about the effects of uncertainty relate to the unknown parameters has been performed by quantifying their influence on the response of the bridge in comparison with the reference case.

Firstly, the percentage variation $\Delta F_{max,i}$ between the i -th numerical ($F_{max,num,i}$) and experimental ($F_{max,exp,i}$) capacities (maximum force) has been determined for each analysed case, as per Equation 3.

$$\Delta F_{max,i} = \frac{F_{max,num,i} - F_{max,exp,i}}{F_{max,exp,i}} \quad (3)$$

Considering the design of experiments described above, triplets of these values have been defined by considering the cases where two of the unknown parameters were constant and one sole parameter was varied. This leads to 9 triplets for each investigated parameter.

For each of these triplets, the influence has been assessed by calculating the range R_i , according to Equation 4.

$$R_i = \max(\Delta F_{max,i}) - \min(\Delta F_{max,i}) \quad (4)$$

R represents the variation in accuracy due to the variation of the single parameter, since all the other parameters are fixed.

Clearly, R changes depending on the basic point, i.e., the fixed value assumed by the other parameters. Thus, a quantitative measure of the influence of the parameters under

investigation (i.e. E_b , f_t and μ) is represented by the distribution of R , and in particular by the average and standard deviation over the 9 triplets. The results are shown in Figure 4 where the obtained R_i values are plotted together with their average R_m and standard deviation σ_R .

Figure 4. Influence of uncertain parameters.

As it can be observed, according to this elaboration, the most influencing parameters resulted the tensile strength of the masonry f_t ($R_m=47\%$) and the tangential friction μ ($R_m=45.3\%$). Conversely, the elastic modulus of the backfill material resulted the less influencing parameter on the bearing capacity, being $R_m=18.4\%$.

4.2 Effects of the uncertain parameters on the capacity

Once the most influential parameters have been identified, their effects on the capacity of the bridge have been estimated. In particular, in Figure 5, the influence of the f_t and μ parameters is shown for each value of E_b by means of 3d bar charts where the ΔF_{max} values are plotted on the vertical axis.

According to Figure 5, a dependency of the overall vertical loading capacity of the bridge on all parameters can be clearly recognised. Such a dependency is even more evident in the graphs of Figure 6, which represent the F_{max} dependency on f_t and μ given a value of the E_b parameter. In particular, in Figure 6, the filled indicators refer to the primary horizontal axis (f_t) and show the F_{max} for constant values of the tangential friction, while the empty indicators refer to the secondary horizontal axis (μ).

Figure 5. Influence of unknown parameters on strength capacity by means of 3d bar charts.

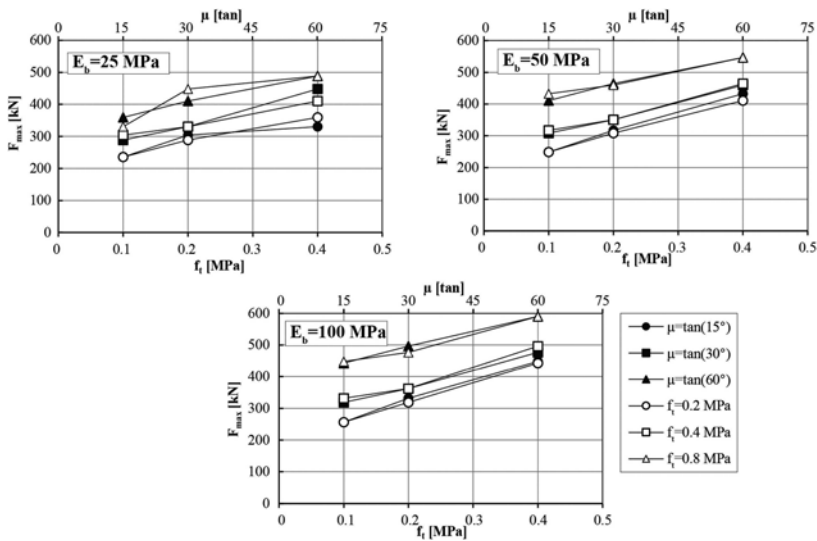

Figure 6. Influence of unknown parameters of strength capacity by means of dispersion graphs.

The graphs of Figure 6 show that generally a linear dependency can be identified between the variations of the investigated parameters and the maximum strength capacity exhibited by the numerical model with respect to the reference experimental case.

5 CONCLUSIONS

In the present study, the calibration of a reliable numerical model for reproducing the evidence retrieved from a literature experimental test has been addressed. The calibration entailed a parametric study including a number of numerical analyses aimed at fixing the mechanical unknown parameters. Such a calibration procedure allowed for some considerations about the influence of some parameters on the response of the bridge, as well as identifying possible retrofitting solutions for existing masonry arch bridge.

In general, it has been observed that the response of masonry arch bridges is mostly influenced by the tensile strength of masonry elements and the law describing the interaction between masonry and backfill material. Whilst the strong influence of the former parameter (i.e. f_t) on the capacity of the bridge was expectable, on the other hand, the parametric study highlighted that selection of the μ value, for which closed-form methodologies are actually missing, can considerably affect the bridge response. Nonetheless, in other similar literature applications, an approach consistent with the one proposed in this study was adopted, confirming the reliability of the calibrated finite element model, as well as of the determined μ value (e.g. Scozzese et al. 2019).

It has been also observed that the stiffness of the soil material used as backfill can modify the capacity of the bridge, even though in a less influential manner: the stiffer the backfill material, the higher the capacity of the bridge in facing external vertical loads.

Therefore, it can be concluded that conferring tensile strength (i.e. by means of steel-, FRP or FRCM-based techniques) to masonry arch elements in existing bridges may represent one of the most effective and convenient retrofitting solutions for structural enhancement. This holds true also if a better connection between masonry and backfill is guaranteed despite, further studies need to be performed aimed at identifying compatible, sustainable and convenient retrofitting solutions based on this concept. Finally, a beneficial effect can be also obtained by stiffening the backfill material for instance by means of injections by means of mortar or materials of other nature. Nonetheless, given that when such a solution is also

expected to modify the dynamical characteristics of the entire structure, hence having effect on its seismic response, and considered the smaller influence of backfill stiffness on the capacity assessed by this study, in many cases this may not represent the most convenient solution.

Simplified analysis on multiring masonry arch bridges

R. Piazzon, P. Zampieri & C. Pellegrino

Department of Civil, Environmental and Architectural Engineering, University of Padua, Padua, Italy

ABSTRACT: Multi-ring brickwork masonry arch bridges in service in the European railway and roadway network represents a typology of masonry bridges that generally have lower load carrying capacity with respect to masonry arch bridges with different arch texture. These bridges differ from the single-ring arches for their peculiar mechanical behaviors and collapse modality. This paper presents the evaluation of the load carrying capacity of multi-ring masonry arches by means of a simplified numerical strategy, that permits to investigate the in-plane failure mechanism of the element. In the simplified approach the arch geometry is subdivided in rigid elements, interacting along their rigid edges through non-linear bidimensional links in which the stiffness and the material nonlinearities are concentrated. The numerical results obtained with the proposed approach are compared with experimental outcomes.

1 INTRODUCTION

The multi-ring brickwork masonry arch bridge is a bridge category diffuse all around the world. The majority of them were built over a century ago and the increasing of the traffic loads demand and the deterioration of the materials bring the necessity of the static and seismic assessment of these structures. The peculiarity of this category is the presence of the rings joints that can be potential surfaces of weakness for the arch (Melbourne & Gilbert 1995). For this reasons, several different numerical approaches have been developed to perform the structural safety assessment of this type of bridge. Among them, the Finite Element Method (FEM), the Rigid Block analysis Method and the Discrete element method are most diffuse.

The FEM models, despite the high computational cost and the problems with the convergence of the solution, can reaches accurate prediction of the response of the bridge (Zampieri & Tetougueni & Pellegrino 2021). One among the FEM models, is the mesoscale approach (Zhang & Macorini & Izzuddin 2018) that reproduces the geometry subdividing the bricks into 3D solid elastic elements and the mortar joints into 2D non linear interface elements in which the nonlinearities are concentrated obtaining good prediction of the results.

The Rigid block analysis considers the geometry of the arch as a mesh of rigid block, investigate the structural equilibrium and collapse model through limit analysis obtaining with less computational cost good results (Melbourne & Gilbert 1995).

The discrete element method has the possibility of using deformable or rigid element and non-linear interfaces recreating the arch geometry (Kassotakis & Sarhosis & Forgács & Bagi 2017).

The aim of this paper is to present a simplify numerical method for the evaluation of the capacity of multi-ring masonry arches, capable of simulate the failure modes typical of this category, for example the detachment between rings, using less computational cost than another sophisticated methods.

2 DESCRIPTION OF THE NUMERICAL STRATEGY

The approach considered in this paper simulates the geometry of the original arch by means of rigid panels connected through a distribution of 2D nonlinear links capable of simulating

the flexural and shear-sliding masonry behaviors and coupling between them (Zampieri & Piazzon & Pantò & Pellegrino 2022, Caddemi & Calì & Cannizzaro & D'Urso & Pantò & Rapicavoli & Occhipinti 2019, Cannizzaro & Pantò & Caddemi & Calì 2018) (Figure 1).

The interface link is composed by two in series mono-dimensional springs, the normal spring is disposed perpendicularly to the edge meanwhile the tangential spring is parallel to it (Figure 2). The mechanical coupling is obtained according to the Mohr-Coulomb yield criterion, based on the friction coefficient (μ) and the cohesion (c). The links are capable of simulate the material cracking that leads to the formation of the hinges, typical mechanism of the masonry arches.

Figure 1. Real masonry arch (left); numerical representation of the geometry with discrete elements (right).

Figure 2. Discrete element interface with nodes connected with links (left) and numerical representation of the 2D link (right).

3 MODEL CALIBRATION

The normal springs reproduces the joint and brick compressive behaviour by means of a parabolic relationship reaching the peak-strength, followed by a linear softening and a residual strength. The tensile behavior is simulated with a linear elastic law with linear softening after the peak-value. The linear softening ends with a zero force residual, that corresponds to the cracking of the material. The link that simulates cracked masonry maintains the original behavior in compression but, if tensile displacement occur, it is considered detached and it doesn't contribute in the normal and tangential directions. The initial normal stiffness $K_{N,0}$, the peak force in tension and the peak force in compression are modelled considering

the potential mortar joint and unit failure modes. The tangential spring describes the sliding behavior with an linear elasto-plastic constitutive law with linear softening, controlled by a damage function that reduces cohesion, friction coefficient and tangential stiffness. Considering the Mohr-Coulomb yielding surface, the peak force value $F_{T,lim}$ is calculated as:

$$F_{T,lim} = \mu \cdot F_N + F_0 \tag{1}$$

Where the μ is the friction coefficient, F_N the normal force acting in the link, $F_0=c \cdot \lambda \cdot s$, c the cohesion, λ is the influence length in the direction parallel to the edge, and s is the thickness of the arch represented.

The shear stiffness is calibrated in function of the shear moduli of the brick and the mortar, and the actual thickness of the joint.

4 NUMERICAL SIMULATIONS OF TESTS ON MASONRY ARCHES

To evaluate the effectiveness of the proposed method, two experimental tests, one executed on a two-rings masonry arch with 3m span and one on a three-rings arch with 5m span, are numerically simulated (Melbourne & Wang & Tomor 2007). Both arches has the span-rise ratio of 4:1. The arches, built using high quality bricks and cement mortar, were pre-loaded using hydraulic jacks at $\frac{1}{4}$ and $\frac{3}{4}$ of the arch, each of which applies 10 kN for the 3m-span arch and 22.5 kN for the 5m-span arch. In the experimental tests the live vertical load is applied monotonically with load control at $\frac{1}{4}$ of the span and the vertical and horizontal displacement at the previously reported points are recorded. In the numerical simulation, permanent non-structural loads(G2) are implemented as concentrated forces meanwhile the live load (Q) is applied as imposed displacement to a single control point positioned at $\frac{1}{4}$ of the span considering displacement control, condition that permits to analyzing the post-peak behavior as resumed in the Figure 3. The meshes reproduce the actual number of rings and number of bricks utilized in the experimental tests. The numerical mechanical properties are calibrated on the materials properties obtained from previously cited work.

Figure 3. Test set-up.

The results are reported in Figure 4 and Figure 5, compared to the experimental findings, in terms of load-displacement curves, considering the vertical displacement of a point in the intrados in correspondence of $\frac{3}{4}$ of the span for the 2-rings arch and $\frac{1}{4}$ of the span for the 3-rings span.

Figure 4. Comparison between the experimental and numerical results for the 2-rings arch.

Figure 5. Comparison between the experimental and numerical results for the 3-rings arch.

5 DISCUSSION OF THE RESULTS

In the Figure 6 and Figure 7, the numerical deformed shapes are reported, in comparison with the experimental deformed shape for the 2-ring arch and a representation of the position of the 4 hinges for the 3-rings arch. The results highlight good correspondence between the numerical and the experimental tests in terms of peak load, initial stiffness and failure mode. In particular the first arch, with two brick rings, exhibit the typical 4-hinges mechanism, even

in the highest hinge is diffuse and it is not assimilable to a unique crack. Neither the experimental and the numerical model present between-rings separation. The numerical capacity curve (Figure 4) approximates the experimental one especially in the initial and final part, reproducing the effective initial stiffness of the arch. The numerical test ends because of convergence limits. The 3-rings arch's exhibits a first phase in which it manifests the 4-hinges mechanism meanwhile the failure mode is governed by the shear/sliding mechanism between rings and between elements of the same ring. As presented in the deformed shape, the sliding between rings is the primary failure mode, at which result the sliding in the opposite direction. In the Figure 5 can be observed the well prediction of the model in terms of initial stiffness and degradation of the stiffness before the failure point. The peak load corresponds to the rings separation/sliding and the activation of the mechanism presented in the Figure 7, after which the load registered decreases in value.

Figure 6. Failure mechanism of the experimental test for the 2-rings arch (left) and deformed shape obtained from the numerical model, considering an amplification factor of 50 (right).

Figure 7. Failure mechanism of the experimental test for the 3-rings arch (left) and deformed shape obtained from the numerical model, considering an amplification factor of 50 (right).

6 CONCLUSIONS

This paper introduces a simplified numerical strategy for the simulation of the nonlinear in-plane response of masonry multi-rings arches. The geometry of the masonry is represented by a mesh of discrete elements, connected with links able to simulate the flexural and shear-sliding collapse modes typical of masonry material. The case studies present two typical failure mode of masonry arches, well reproduced in the numerical tests. In particular, the proposed model is able to reproduce the sliding between rings, failure mode not visible in the single-ring arches.

Effects of changing temperature in the vibration-based model updating of a masonry bridge

P. Borlenghi, A. Saisi & C. Gentile
DABC, Politecnico di Milano, Milan, Italy

ABSTRACT: FE model updating of structures is commonly based on the modal parameters evaluated in a single vibration test. Nevertheless, the influence of changing temperatures on modal parameters – especially on natural frequency – is well known. The paper presents an investigation on the effects of (temperature-induced) frequency variations on the estimate of the elastic properties of a historical masonry bridge. Firstly, documentary research, geometric survey, minor destructive tests and ambient vibration tests were performed. Subsequently, the numerical model of the masonry bridge is developed based on the collected data, and the updating procedure is performed by using the two sets of modal parameters identified in July 2018 (average temperature 30.4°C) and April 2021 (average temperature 13.2°C). The results show that the (temperature-induced) frequency decrease seems to affect more significantly the estimate of the Young's modulus of spandrels and backing.

1 INTRODUCTION

The calibration of FE models is fundamental to obtaining reliable results in the structural assessment of existing bridges and infrastructures. In the engineering practice, the modal parameters identified from vibration data are often used as targets for the model parameters adjustment (see e.g. Costa et al 2015, Pepi et al. 2021, Aytulun et al. 2022 for recent applications on masonry bridges); however, the influence of environmental factors (e.g. outdoor temperature) on modal parameters, and especially on natural frequencies, is well known and extensively documented in the scientific literature (Ramos et al. 2010, Saisi et al. 2015, Ubertini et al. 2017, Roselli et al. 2018). Consequently, when a FE model is calibrated for structural assessment purposes, it would be appropriate to consider that the identified structural parameters also result from specific environmental conditions and the related variability might propagate along the structural identification process.

Figure 1. The *Olla* bridge: (a) picture from the Stura River; (b) existing damages on the second arch.

In the present paper, the effects of temperature-induced frequency variations on FE model updating of a historical masonry arch bridge are investigated. The selected structure is the *Olla* bridge, a masonry viaduct built in the second half of the 19th century in the northwest of Italy. High piers characterise the bridge; therefore, operational modal testing and analysis are well suited for evaluating its dynamic behaviour. Firstly, the numerical model is developed by integrating topographic survey, historical research, visual inspections and limited tests on materials. Subsequently, two ambient vibration tests are performed in different environmental conditions and the two different sets of identified modal parameters are used to estimate the optimal structural parameters. The presented results highlight that major variations of the optimal estimates are observed in the structural elements with lower compressive forces.

2 THE *OLLA* BRIDGE: DESCRIPTION AND PRELIMINARY ANALYSIS

The investigated structure (Figure 1a) – called *Olla* bridge (Borlenghi et al. 2023) – is a multi-span masonry arch bridge that crosses the Stura River between the small municipalities of Gaiola and Borgo San Dalmazzo. The structure is approximately 120 m long and comprises 5 arches, with a maximum span of 25 m, 4 piers and end abutments, with the tallest pier being 26 m high. Piers and abutments are in a good quality ashlar stone masonry, whereas arches and spandrel walls are in brick masonry.

The documentary research revealed the collapse of the central arch in 1944 (Figure 2) and the subsequent reconstruction in 1945.

The complete representation of the structure was obtained with the Terrestrial Laser Scan and topographic survey. The processing of the point clouds allowed the extraction of an accurate 3D model and a series of conventional 2D drawings from which the FE model was developed. In addition, the visual inspections highlighted the presence of local damages on the arches (Figure 1b) and diffused surface decay.

Figure 2. The collapse of the central arch occurred in 1944.

3 EXPERIMENTAL SURVEYS

The experimental survey on the *Olla* bridge included some Minor Destructive Tests (MDTs) to retrieve information on internal morphology and material distribution and two series of Ambient Vibration Tests (AVTs) to characterise the dynamic behaviour of the structure under different environmental conditions.

The MDTs – consisting of limited coring tests – were performed to obtain information on arches, spandrels and fill. Due to the limited extension of the core drill machine, no information on the backing was obtained. The coring tests were performed in the Autumn of 2018. Six coring samples were taken from the following elements: 2 on the arches, 2 on the spandrels and 2 on the deck (Figure 3a). The tests revealed that the arches are constituted only by brick masonry while the spandrels are a mixture of stone and brick masonry. The fill consists of compacted soil and pebbles. The thickness of the asphalt over the fill is equal to 20 cm.

Figure 3. (a) Layout of the samples coring; (b) Sensor layout adopted for the AVTs.

Overall, the adopted measuring devices for the AVTs included 14 high-sensitivity piezoelectric accelerometers (WR model 731A, 10 V/g sensitivity and ± 0.50 g peak) and a multi-channel acquisition system with 4 DAQ modules (NI 9234, 24-bit resolution, 102 dB dynamic range and anti-aliasing filters). In addition, each accelerometer was connected with a 1-meter cable to a power unit/amplifier (WR P31) to improve the performance of the acquisition chain: the power unit/amplifier was aimed at providing a constant current to power the accelerometer's internal amplifier, signal amplification and selective filtering.

Regarding the dynamic testing, a preliminary prompt test was performed with a single triaxial geophone (SARA GEOBOX SS45), revealing that the fundamental vibration mode of the structure involved the transversal motion of the deck. Therefore, the sensor layout for both tests was arranged to guarantee a complete representation of the lateral mode shapes and a partial reconstruction of the vertical ones (Figure 3b): the transversal response was recorded in 11 measuring points, while the vertical response was measured in 3 points (i.e. the centre of the three major arches). The tests were performed with one lane open to vehicular traffic.

The sampling frequency adopted in both AVTs was equal to 200 Hz, which is more than enough for the considered structure whose dominant frequencies are below 10 Hz. Therefore, low pass filtering and decimation were applied to down-sample the data to 40 Hz, obtaining a Nyquist frequency of 20 Hz. The modal identification was performed with time windows of 2400 s using the covariance-driven Stochastic Subspace Identification technique (SSI-Cov, Peeters & De Roeck 1999). The reader can refer to (Cabboi et al. 2017) for full details on the applied SSI-Cov procedure.

Figure 4. Modal identification from Dataset 1, July 2018: L denotes the dominant lateral vibration modes, and V denotes the dominant vertical vibration modes.

The first dynamic test was performed on July 31st, 2018, with an average temperature of 30.4°C, while the second dynamic test was performed on April 22nd, 2021, with an average temperature of 13.1°C. Overall, 5 transverse and 3 vertical vibration modes are identified in

both tests for the frequency range of 0-10 Hz. The identified mode shapes are shown in Figure 4. It should be noticed that: (a) the transverse modes exhibit an increasing number of half-sine waves and inflexion points; (b) each identified vertical mode is characterised by the dominant deformation of one of the three longer spans, respectively.

The comparison of identified natural frequencies is shown in Table 1. The decrease in the outdoor temperature among the two tests is equal to 17.3°C, and the corresponding average reduction of natural frequencies is equal to 4%.

4 FE MODELLING AND UPDATING CONSIDERING ENVIRONMENTAL EFFECTS

In a previous study (Borlenghi et al. 2020), a simplified model of the *Olla* bridge was developed to investigate the contribution of backing and spandrels in the dynamic response of the structure in operational conditions. The simplified model emphasised the importance of the stiffening effects given by the structural elements above the arches. Nevertheless – due to the simplified nature of the model – a good experimental-numerical correlation was obtained for the lateral modes while an imperfect correlation was obtained for the vertical modes. Consequently, the 3D FE model herein presented reproduces as closely as possible the external geometry of the bridge with reasonable assumptions on its internal morphology. Therefore, spandrels, backing and fill material have been modelled along with arches, abutments and piers, considering a perfect connection among each structural element.

4.1 Development of the FE model

The 3D FE model of the bridge was developed in the ABAQUS software using ten-node tetrahedral elements (C3D10). The regular distribution of masses, the accurate description of geometrical details and the negligible mesh sensitivity on natural frequencies were obtained using a relatively large number of elements. Overall, the FE model consists of 45604 tetrahedral elements with 211818 degrees of freedom and an average mesh size of 1.15m.

Regarding the adopted geometry, the geomatic survey allowed the definition of all external dimensions with high accuracy; in contrast, the thickness of arches, the thickness of spandrels, and the height of backing were identified with a multi-step procedure. The characteristics of the internal morphology were initially assumed from historical research and then verified with local tests. For the spandrels, it was possible to assume a constant thickness equal to 1.0 m, while for the arches, the thickness visible from outside corresponds with the internal one. Due to the limited length of the drilling machine, no information on the backing was retrieved from the local tests. Consequently, the height of the backing was directly assumed from the construction handbook of Curioni (1873) and then validated with the FEMU procedure.

Furthermore, the main assumptions regarding the definition of the numerical model are herein listed: (i) the effect of soil-structure interaction was neglected, and the boundary conditions of piers and abutments were assumed fixed; (ii) all the materials were considered isotropic; (iii) the Poisson's ratio of masonry materials was held constant and equal to 0.15; (vi) the weight per unit volume of each structural component was held constant and equal to 20 kN/m³ for the piers and abutments, 17 kN/m³ for the arches, 19 kN/m³ for the spandrels, 21 kN/m³ for the base of the central piers, 18 kN/m³ for the backing, and 16 kN/m³ for fill. In view of the clear presence of superficial rocks at the river level (Figure 1a), the base nodes of piers and abutments were assumed as pinned. Similarly, the longitudinal translation of the abutments was restrained.

Different materials were considered for each structural element: (a) piers and abutments are built in ashlar stone masonry, (b) arches are in solid brick masonry, (c) spandrels are characterised by a first layer of bricks, and then rough-cut stones, (d) the bases of two central piers are in regular ashlar stone masonry, (e) the backing – as shown in the historical pictures of Figure 2 – is in masonry, (f) the fill is made up of loose soil and pebbles. In addition, the information coming from the historical research was considered: the central arch was rebuilt after the second world war, and so it was for the backing above the nearby piers. Consequently, different material properties were considered for the central arch (rebuilt in 1945) and the backing over the central piers. Figure 5 summarises the adopted elements with constant material properties.

Figure 5. FE model of the Olla bridge with the indication of different materials.

4.2 FE Model Updating (FEMU)

Firstly, the (frequency) sensitivity of the selected Young's modulus was checked: all the parameters have a certain influence on the natural frequencies, with the only exception of the fill material. Due to its low sensitivity, the Young's modulus of fill was set equal to 0.30 GPa like a gravels/sand well-graded.

Subsequently, the selected structural parameters were manually updated until an acceptable solution was reached. The adopted values of the Young's modulus are the following: 16.5 GPa for the piers and abutments, 4.50 GPa for the arches, 15.0 GPa for the spandrels, 22.0 GPa for the base of the central piers, and 2.0 GPa for the backing. A one-to-one correspondence of the experimental-numerical modes was obtained, providing a preliminary verification of the main modelling assumptions. However, a maximum frequency discrepancy ($DF = 100 \cdot (1 - f_i^{FEM}/f_i^{AVT})$) equal to 7.4% showed the need for model updating.

The adopted FEMU procedure was implemented in MATLAB environment and it is based on the Douglas-Reid method (Douglas & Reid 1982) with the Particle Swarm Optimisation (PSO) algorithm: the updating parameters are iteratively corrected in a constrained range until a stable minimum solution for an objective function is found. Particularly, the following objective function was adopted:

$$J(\mathbf{x}) = \frac{100}{n} \sum_{i=1}^n \left| 1 - \frac{f_i^*(\mathbf{x})}{f_i^{AVT}} \right| \quad (1)$$

where f_i^{AVT} are the i -th experimentally identified natural frequency and $f_i^*(\mathbf{x})$ are the i -th polynomial approximations (Douglas & Reid 1982) of the numerical natural frequencies, expressed as functions of the \mathbf{x} updating parameters. The interested reader can refer to Borlenghi et al. 2023 for full details on updating procedure.

4.3 Discussion of the effects of environmental parameters on optimal models

Table 1 shows the comparison between the experimentally identified and numerically estimated natural frequencies in the two considered ambient conditions: July 2018 with a $T_{mean}=30.4^\circ\text{C}$ and April 2021 with a $T_{mean}=13.1^\circ\text{C}$. In both cases, an excellent

Figure 6. Vibration modes of the updated FE model (modal data from July 2018).

experimental-numerical correlation is obtained with an average frequency discrepancy DF of 0.15% and 0.57%, respectively, and an average mode shape correlation MAC of 0.95 in both cases. As expected, the numerical natural frequencies follow the variations of the experimental ones, with an average decrease equal to 4%, while the mode shapes exhibit negligible changes.

Table 2 lists the optimal estimates of the updated structural parameters of the two models. The differences between the Young's modulus of the central and lateral arches, as well as the one of the backing, are motivated by the reconstruction of 1945. As demonstrated by the coring tests, the spandrels are made of bricks externally and stone internally, justifying the high values elastic modulus obtained. Finally, the base of the central piers is built in a better-quality stone masonry with respect to the rest of the piers and, moreover, the optimal elastic modulus conceivably accounts for the stiffening effect provided by the compacted soils surrounding the piers.

The decrease in temperature between July 2018 and April 2021 implies a decrease in natural frequencies, which, in turn, determines an average reduction in Young's modulus equal to 8%. In detail, Table 2 shows the percentage of decrease for each parameter. The Young's modulus of piers, abutments, central arch, the base of central piers, and the backing of central piers exhibits a variation of less than 2%, while the Young's modulus of lateral arches shows a decrease of about 4%. However, major variations of the Young's modulus estimate are observed for spandrels and lateral backing.

The interpretation of structural parameter variations due to temperature-induced frequency changes is not straightforward. The natural frequencies of the *Olla* bridge tends to increase with increased temperature. Similar behaviour has been observed in long-term monitoring of masonry towers (Ramos et al. 2010, Saisi et al. 2015, Ubertini et al. 2017), as well as, from the repeated dynamic testing of a masonry viaduct (Roselli et al. 2018). The most accepted explanation is that the thermal expansion of materials induces the closure of micro-cracks, minor discontinuities or mortar gaps (defects typically present in masonry elements). Hence, the temporary compacting of the masonry induces a temporary increase of stiffness and natural frequencies, as well. In addition, small gaps and micro-cracks are expected to be more frequent in structural element with a low level of compressive stresses. It is worth noting that spandrels and backing are bearing less compressive forces than piers and arches. Consequently, it might be expected that the relatively high temperature measured during the first test of July 2018 generated a significant stiffening effect on backing and spandrels due to the expansion of masonry material and the consequent closure of micro-cracks, resulting in an apparent higher elastic modulus.

Table 1. Comparison between experimental and numerical natural frequencies considering different environmental conditions: July 2018 with $T_{\text{mean}}=30.4^{\circ}\text{C}$ and April 2021 with $T_{\text{mean}}=13.1^{\circ}\text{C}$.

5 CONCLUSIONS

The paper illustrates the effects of different environmental conditions on the model updating procedure of a historical masonry viaduct called *Olla* bridge.

The investigations in the *Olla* bridge included documentary research, geometric survey, minor destructive tests and ambient vibration tests. Particularly, the AVTs were performed in different environmental conditions: the first test was performed in July 2018 with an average temperature of 30.4°C , and the second test was performed in April 2021 with an average temperature of 13.2°C . Based on the information collected onsite, a 3D FE model was developed, and the uncertain structural parameters were estimated using the modal parameter identified in the two dynamic tests.

In summary, the following conclusions can be drawn:

- The onsite visual inspections highlighted the presence of local damages on the arches and diffused surface decay;
- During both dynamic tests, 5 lateral and 3 vertical vibration modes were identified in the frequency range of 0-10 Hz;
- The outdoor temperature variation between the two tests (July 2018 and April 2021) is equal to 17°C ;
- The percentage of variation in natural frequencies between the two tests has an average of 4%, a maximum of 6.7% for mode V₁ and a minimum of 2.3% for mode V₂;

- The Young's modulus of selected structural elements is estimated for both environmental conditions, showing an average variation of 8%;
- The Young's modulus of spandrels and lateral backing is the most affected by the changes in environmental conditions, with a decrease of 29% and 18%, respectively;
- The more pronounced variation in the elastic modulus of spandrels and backing is most likely related to the expansion of masonry material and the consequent closure of micro-cracks and small gaps during the hot season.

The reported results have demonstrated the importance of accurately evaluating the temperature effects for model updating purposes in masonry structures: the apparent stiffening effect given by the high temperatures of the hot season can lead to an over-estimation of the elastic properties of structural elements characterised by low loading levels. However, the apparent increase of stiffness is negligible for the main load-bearing elements, i.e. arches and piers. Consequently, the influence of testing conditions (and consequently of temperature-induced frequency variations) is conceivable negligible in the structural safety assessment of the investigated bridge.

ACKNOWLEDGEMENTS

The support of ANAS (Struttura territoriale Piemonte e Valle d'Aosta) is gratefully acknowledged. Sincere thanks are due to M. Cucchi and M. Iscandri (LPMSC, Politecnico di Milano) who assisted the authors in conducting the field tests.

Numerical approaches to assess the load capacity of FRCM strengthened masonry bridges

D. Santinon, P. Zampieri & C. Pellegrino
University of Padova, Padova, Italy

D. Ricci, F. Iodice, A. Vecchi & F. Iacobini
Rete Ferroviaria Italiana RFI, Roma, Italy

ABSTRACT: Numerous railway masonry arch bridges located in regions with high seismic hazard, are still part of the Italian railway networks. In order to increase the safety level of masonry bridges with respect to the seismic action, as it is required by the Italian technical Standards (NTC2018), strengthening interventions are necessary. The use of FRCM (Fiber Reinforced Cementitious Matrix) system applied onto the masonry arch intrados represents an alternative to the traditional retrofit techniques common used in the past. This strengthening method allows to increase the masonry bridge capacity without changing: the weight, the geometry and the stiffness of the structure. Moreover, the railway line can still in service during the realization of the strengthening intervention. In this work, based on the results obtained from experimental tests, a simplified numerical approach is calibrated for the evaluation of the load carrying capacity of masonry arch bridges strengthened with FRCM system applied onto arch intrados. The calibration process provides simple and practical guidelines for modelling masonry bridges strengthened with FRCM.

1 INTRODUCTION

Nowadays, more and more masonry buildings with several decades of life are in need of restoration, improvement or retrofitting (Zizi, et al., 2023). In Italy, the masonry construction heritage, both buildings and bridges, represents the majority of all present constructions and, therefore, their study and preservation require special attention. Masonry is known to be an anisotropic material with multiple failure modes, which contributes to making masonry constructions difficult to study and evaluate. In current practice, simplified but functional approaches are preferred in order both to limit errors due to excessively complex and unmanageable modelling and to limit computational time. The aim of this paper is to present a simplified methodology for evaluating the load-bearing capacity of masonry semicircular arch bridges, both reinforced and not (Chisari, et al., 2021). Nowadays, there are several studies proving the ability of natural and sustainable materials to reinforce arch bridges (Gioffrè, et al., 2023; Gioffrè, et al., 2021), however, these materials may have durability problems. Both to avoid this problem and due to the presence of established studies, the choice has turned to the use of carbon fibre (CFRCM). The numerical methodology applied to the results of two masonry arch specimens, realised with the contribution of the Italian railway network (RFI, Rete Ferroviaria Italiana), will be illustrated in this paper.

2 DESCRIPTION OF EXPERIMENTAL SPECIMENS

Two masonry arches were constructed with lime mortar-based conglomerate backfill (Zizi, et al., 2023), with a net length of 3.00 m and a rise of 1.32 m. In particular, the arches were built using pressed fired clay bricks measuring 250x120x55 mm, using the four-headed laying technique shown in Figure 1, with a lime mortar thickness of 10 mm at the intrados. The resulting section of the arch is 250 mm in thickness and 510 mm in width. The backfill is made of a lime mortar-based conglomerate with 450 mm in width and 650 mm in length.

Figure 1. Example of a four-headed laying technique.

Finally, an FRCM reinforcement with both fabric and spike anchors made of a dry carbon fiber were applied to the intrados, of one of them, for a total thickness of 10 mm.

The arches are supported on rigid substructures that were fixed to the laboratory slab, by means of special tie rods, when the tests were carried out by applying an eccentric load.

Figure 2. Front view and side view of the semicircular arches, here represented also with the reinforcement; measure are in cm.

3 DESCRIPTION OF THE FEM MODELS

3.1 Modelling

The numerical study of reinforced and unreinforced arch specimen was carried out through the use of the MidasFEA software. Two-dimensional elements were used for the masonry and the backfill, since the failure mechanism is symmetrical with respect to the longitudinal axis x , and one-dimensional “truss” type elements were used for the intrados reinforcement. The restraints used are interlocking, with the exception of the vertical direction y , for which infinitely rigid springs reacting only to compression were used. The interaction between the arch and backfill was taken into account by using a “discrete cracking” interface, while a special interface between the arch and the reinforcement was not used. This either because the spike anchors severely limit the sliding and also because the maximum tension attributed at the fabric is equal to the debonding tension, which implicitly allows for the detachment of the net.

Figure 3. Model for the semicircular arches, here represented also with the reinforcement (blackline at the intrados).

3.2 Materials

Masonry is a tensile low-reactive material with mechanical behavior that can be represented by a stress-strain constitutive bond with a non-linear law. Since masonry consists of blocks and joints, it is generally characterized by anisotropy. However, there are numerous mathematical models in the literature that are able to approximate the real behavior of masonry by modelling a continuous homogeneous and isotropic material. One of the most used and adopted models for the modelling of masonry is the “Total Strain Crack Model”, it allows to treat the elements that discretize the masonry in an isotropic way until a stress-strain point is reached, which leads to the formation of a crack, beyond this point the behavior becomes anisotropic.

This model, in addition to the definition of the classical mechanical parameters (elastic modulus, Poisson’s coefficient, density, etc.) is uniquely defined by assigning the following parameters: compressive and tensile stress-strain law, compressive strength f_c , tensile strength f_t , tensile fracture energy G_t , compressive fracture energy G_c and type of crack modelling. In particular, the constitutive law for masonry and backfill in tension adopted is a non-linear relation with exponential softening (Figure 5) while in compression a parabolic law was used (Figure 4).

Figure 4. Compression law for masonry and for the backfill.

Figure 5. Tensile law for masonry and for the backfill.

The mechanical and deformation parameters used for masonry and the backfill are summarized in Table 1:

Table 1. Parameters used for the finite element modelling of masonry and backfill.

Parameter	Masonry	Backfill
Tensile strength f_t [MPa]	0.08	0.173
Compressive strength f_c [MPa]	3.45	1.725
Tensile fracture energy G_t [N/mm]	0.004	0.005
Compressive fracture energy G_c [N/mm]	1	1
Average FEM element size h [mm]	50	50
Elastic modulus E_m [MPa]	1500	750
Poisson's coefficient ν	0.25	0.2
Volume weight W [kN/m ³]	18	17

These values were determined from the Italian code “Norme Tecniche per le Costruzioni” considering a confidence level LC2 and the material safety coefficient $\gamma_m = 1$, as the analyses were non-linear. The tensile fracture energy was determined using the empirical formulations (1) and (2) (Ghiassi & Milani, 2019), in order to define the range of possible values:

$$G_{t1} = 0.025(f_c/10)^{0.7} \quad (1)$$

$$G_{t2} = 0.029f_t \quad (2)$$

Finally, the compression fracture energy was set at 1 N/mm².

The parameters used for the discrete cracking interface are: normal stiffness $k_n = 50\text{N}/\text{mm}^3$; tangential stiffness $k_t = 20\text{N}/\text{mm}^3$ and tensile strength $f_{ct} = 0.04\text{N}/\text{mm}^2$. The value of the normal stiffness (following a parametric analysis) was set at $50\text{N}/\text{mm}^3$, a value for which successive increases in stiffness do not lead to significant changes in the solution, while the value of f_{ct} was defined again from a sensitivity analysis in order to capture the detachment mechanism between the backfill and the arch as shown by the experimental tests. The tangential stiffness value was determined by imposing $k_t/k_n = 0.4$ (Gaetani, et al., 2017).

Finally, for the strengthened arch specimen, a brittle-type tensile law with residual strength was imposed on the fabric (Figure 6), while an elasto-plastic relation was adopted in compression.

Figure 6. Tensile law for the fabric.

The fabric area was determined as the product of the width of the arch by the equivalent thickness, determined with the Equation (3), following the indications of the Italian code “Linea Guida per la identificazione, la qualificazione ed il controllo di accettazione di compiti fibrorinforzati a matrice inorganica (FRCM) da utilizzarsi per il consolidamento strutturale di costruzioni esistenti”:

$$t_{eq} = 1000 \cdot \frac{G}{g} = 0.0648mm^2 \quad (3)$$

Where $G = 0.11kg/m^2$ weight of the wires only in the resistant direction, $g = 1700kg/m^3$ density of the carbon fiber.

The mechanical parameters of the fabric are summarized in the Table 2:

Table 2. Parameters used for the finite element modelling of the fabric.

Parameter	
Area A [mm ²]	33.04
Poisson's coefficient ν	0.2
Volume weight W [kN/m ³]	24
Compressive strength f_c [MPa]	3.45
Debonding tensile strength f_b [MPa].	470

The debonding tensile strength value is the average debonding value obtained from appropriate shear-lap tests with a radius of curvature equal to the arches here presented. These experiments produced an average tensile strengths of 470 MPa for the semicircular arch specimen.

3.3 Applied loads

In addition to the elements' own weight, a yielding constraint is applied to reproduce the load in displacement control relative to the experimental test. Loads are applied in two phases:

- Phase 1: gravitational loads only;
- Phase 2: displacement-controlled load with a maximum value of 10 mm, applied using 100 incremental steps.

4 RESULTS COMPARISON

Comparisons between numerical and experimental test results in terms of load-displacement are given below.

Figure 7. Comparison graph between experimental and numerical test results.

As regards the failure modes, a representation of the real failure mode with that obtained numerically for the unreinforced arch is shown in Figure 8 and for the reinforced one in Figure 9.

Figure 8. Comparison of the actual rupture pattern, upper image, with the numerically determined pattern, lower image. Unreinforced case.

Figure 9. Comparison of the actual rupture pattern, upper image, with the numerically determined pattern, lower image. Reinforced case.

5 CONCLUSIONS

From the analysis introduced above, it can be seen that, despite the approximation derived from the continuous modelling of the masonry, it is possible to obtain good results in terms of both load-displacement and failure modes. Indeed, for the semicircular arch, the results show a good correspondence in the elastic phase between the numerical case and the experimental one. In particular, the numerical method shows a slightly lower elastic peak load and stiffness, which is positive as it provides a margin of safety. In the post-peak, some more marked differences can be seen, but only for the cases with reinforcement.

As far as failure modes are concerned, the numerical models show a good correspondence with the hinges formed in the experimental specimens. In particular, the numerical models cannot show a perfect hinge, due to the continuous modelling approximations, however, the higher damage zone of the finite elements (red region) for unreinforced arches approximates the experimental evidence correctly.

3D collapse mechanisms of masonry bridges subjected to horizontal actions

L. Niero, P. Zampieri & C. Pellegrino

Department of Civil, Environmental and Architectural Engineering, University of Padova, Padova, Italy

ABSTRACT: A large number of existing masonry arch bridges are still in use in the Italian roadway and railway networks. Most of them were built more than one hundred years ago, designed considering only gravitational loads without any seismic analysis. To keep these works in service, it is necessary to have tools that can describe and predict the structural behavior of the bridge when subjected to extreme actions. For this reason, a three-dimensional rigid-block analysis for masonry arch bridges has been developed. In the model, the main structural masonry elements (vault, pier, abutments, spandrel wall) are discretized as an assemblage of rigid blocks, which interact via no-tension contact surface with Coulomb friction. This approach allows reproducing with good accuracy the tri-dimensional collapses mechanisms of some real masonry arch bridges recently collapsed due to extreme events.

1 INTRODUCTION

Masonry is one of the most widely used materials in ordinary structures and monumental buildings in Italy and, for this reason, there are several masonry arch bridges in the Italian road and rail network which are still in service today. Most of them were built more than a hundred years ago and were designed considering only gravity loads, without taking into account any seismic or extreme actions. For this reason, several existing bridges are characterized by structural and functional deficiencies: first, they were designed for less severe service conditions than those required today and, in addition, besides suffering progressive damage and natural deterioration, they can also be subjected to extreme actions such as earthquake, flooding and foundation settlements. In addition, flood-induced scour problems can occur on masonry piers because of the erosive effect and removal of bank material from bridge foundations located within the riverbed (Ragni, et al., 2019; Scozzese, et al., 2019).

To keep existing masonry arch bridges in service, it is necessary to have tools that can describe and predict their behavior. Currently, in the literature there are several structural models that enable the analysis of these structures up to the collapse condition (Zizi, et al., 2022; Galassi, 2023; Galassi & Zampieri, 2023) but, one of the most popular is rigid blocks analysis, which quickly provides an estimation of the carrying capacity of the structure and the associated failure mechanism. Koocharian (1952) and Heyman (1969) were among the first to apply plastic limit analysis theorems to masonry structures, assuming constituent blocks have infinite compressive strength, joints have zero tensile strength and sliding failures are not allowed. In the 1970s Livesley (1978) developed a formal linear programming (LP) procedure to compute the load factor of structures and plot their collapse mechanisms, considering also sliding failures. A similar approach was used by Melbourne & Gilbert (1995) to successfully model two-dimensional masonry arch bridges, assuming an associative friction model governed by Mohr-Coulomb law. Subsequently, to achieve more realistic behavior of structures, several authors such as Gilbert (2006), Ferris & Tin-Loi (2001), Orduña & Lourenço (2003) extended the formulation of the problem considering also a finite compressive strength of the material and a non-associated flow law. Some authors

Figure 1. Three-dimensional rigid block model of a masonry arch bridge.

like Orduña & Lourenço (2005) and more recently Portioli et al. (2014) and Cascini et al. (2020) have proposed a three-dimensional formulation of the problem by applying it to out-of-plane loaded walls and arches.

This paper aims to develop a three-dimensional rigid block analysis for masonry arch bridges, capable of capturing the out-of-plane behavior of the structures subjected to extreme actions. The main structural masonry elements, such as vaults, pier, abutments and spandrel wall are discretized as an assembly of rigid blocks, interacting through contact surfaces with no-tensile strength and Mohr-Coulomb friction. The developed code, based on rigid-block analysis, defines the collapse multiplier and the associated failure mechanism without taking load history into account, using a linear optimization procedure and an associated flow law.

2 THE RIGID BLOCK MODEL

To analyze the three-dimensional behavior of the masonry arch bridge in Figure 1, its structural elements (arches, central pier, side abutments and spandrel wall) are modeled using a set of rigid blocks to study the interaction between the different elements. Instead, the backfill and road pavement are considered as external forces acting on the structural masonry elements, proportional to their load area.

Rigid blocks typically have larger geometric dimensions than physical blocks to also account the mortar joint, which is not modeled explicitly. This approach is particularly appropriate for analyzing existing masonry structures characterized by poor quality mortar (Baggio & Trovalusci, 1993). In fact, some experimental tests (Trovalusci, 1992) have validated the use of discrete, rather than homogeneous and isotropic, models and have shown how the global behavior of the structure is strongly influenced by the size, arrangement and orientation of the different elements rather than by their mechanical properties. For this reason, in the rigid-block analysis the collapse multiplier is obtained from local equilibrium conditions, assuming the hypothesis of: i) absence of tensile stresses at the interface and ii) the impossibility of crushing failure. In fact, masonry bridges are old structures subjected to cyclic loading, fatigue phenomena and freeze-thaw cycles for a long time so it is realistic to assume zero tensile strength in mortar joints. Finally, the attritive resistance at the interface is considered using the Mohr-Coulomb law and an associated flow law. The presented model is therefore capable of predicting the three-dimensional behavior of a masonry arch bridge subject to both vertical loads and hazard events such as earthquakes. In this paper, the constraint and loading conditions shown in Figure 2 are applied to the discrete model of a masonry arch bridge.

Figure 2. Loading and constraint condition of the masonry arch bridge.

3 LINEAR PROGRAMMING FOR RIGID-BLOCK ANALYSIS

The numerical model of a masonry arch bridge is composed of n rigid blocks and m contact points, located at the vertexes of interfaces (Figure 3). External loads and the displacement rates applied to the centroid of each 3D rigid block are respectively collected in vector $\mathbf{f} \in \mathbb{R}^{6n}$ and $\mathbf{u} \in \mathbb{R}^{6n}$:

$$\mathbf{f} = [f_{x1}, f_{y1}, f_{z1}, m_{x1}, m_{y1}, m_{z1}, \dots, f_{xn}, f_{yn}, f_{zn}, m_{xn}, m_{yn}, m_{zn}]^T \quad (1)$$

$$\mathbf{u} = [u_{x1}, u_{y1}, u_{z1}, u_{\theta x1}, u_{\theta y1}, u_{\theta z1}, \dots, u_{xn}, u_{yn}, u_{zn}, u_{\theta xn}, u_{\theta yn}, u_{\theta zn}]^T \quad (2)$$

The loads in \mathbf{f} can be expressed as the sum of the known dead loads \mathbf{f}_D and live loads \mathbf{f}_L , multiplied by an unknown scalar factor α :

$$\mathbf{f} = \mathbf{f}_D + \alpha \mathbf{f}_L \quad (3)$$

The three internal resultant forces (i.e., axial force n_k , shear force t_{1k} and t_{2k}) acting at each k -th point of contact can be arranged in vector $\mathbf{x} \in \mathbb{R}^{3m}$:

$$\mathbf{x} = [n_1, t_{11}, t_{21}, \dots, n_k, t_{1k}, t_{2k}, \dots, n_m, t_{1m}, t_{2m}]^T \quad (4)$$

The kinematic variables $\mathbf{q} \in \mathbb{R}^{3m}$, that correspond to the static variables \mathbf{x} in a virtual work sense, are the relative displacement rates at the contact points (i.e., normal displacement rates ε_{1k} , tangential displacement rates γ_{1k} and γ_{2k}) defined as:

$$\mathbf{q} = [\varepsilon_1, \gamma_{11}, \gamma_{21}, \dots, \varepsilon_k, \gamma_{1k}, \gamma_{2k}, \dots, \varepsilon_m, \gamma_{1m}, \gamma_{2m}]^T \quad (5)$$

The compact equilibrium equation can be written as follows

$$\mathbf{B}\mathbf{x} = \mathbf{f}_D + \alpha \mathbf{f}_L \quad (6)$$

where $B \in \mathbb{R}^{6n \times 3m}$ is the equilibrium matrix.

The following constraint conditions are then specified for each contact point:

$$\begin{aligned} y_{rk} &= n_k \geq 0 \\ y_{sk} &= -\sqrt{t_{1k}^2 + t_{2k}^2} + \mu n_k \geq 0 \end{aligned} \quad (7)$$

where μ is the friction coefficient and the compressive force n_k is positive according to the convention shown in Figure 3. Equation (7) represent the failure modes by opening and sliding but the interaction of contact points considers other failure modes that may occur such as rocking and twisting.

Figure 3. (a) Static and (b) kinematic variables at the block centroid i and contact point k (rearranged from Portioli et al., 2014).

In order to use linear programming techniques, the Lorentz cone, which describes the sliding failure condition, is linearized using 8 hyperplanes. The constraint conditions can be written as follows:

$$\begin{aligned} y_{rk} &= n_k \geq 0 \\ y_{s1,k} &= -t_{1k} \cos \frac{k\pi}{4} - t_{2k} \sin \frac{k\pi}{4} + \mu n_k \geq 0 \quad k = 1, \dots, 8 \end{aligned} \quad (8)$$

In general, constraint conditions are defined as:

$$\mathbf{y} = \mathbf{N}^T \mathbf{x} \leq \mathbf{0} \quad (9)$$

where \mathbf{y} is the vector of failure conditions and \mathbf{N}^T is the matrix that collects the constraints conditions.

Both the static and kinematic approaches of limit analysis (Ferris & Tin-Loi, 2001; Portioli, et al., 2014; Zampieri, 2020; Hua & Milani, 2023) are used to identify the collapse condition of the masonry arch bridge, then solving the problem through linear programming techniques. In particular, the LP related to the static theorem is given by

$$\begin{aligned} &\text{maximize} && \alpha \\ &\text{subject to} && \mathbf{B}\mathbf{x} - \alpha \mathbf{f}_L = \mathbf{f}_D \\ &&& \mathbf{N}^T \mathbf{x} \leq \mathbf{0} \end{aligned} \quad (10)$$

whereas the LP arising from the kinematic theorem is

$$\begin{aligned}
& \text{minimize} && -f_D^T u \\
& \text{subject to} && f_L^T u = 1 \\
& && -B^T u + N z = 0 \\
& && z \geq 0
\end{aligned} \tag{11}$$

where z is the vector of resultant strain rates (analogous to plastic multipliers in classical plasticity).

4 RESULTS AND DISCUSSION

In this section, the results of a rigid block analysis performed on a masonry arch bridge, expressed in terms of load multiplier and associated mechanism, are presented.

The structure under consideration is composed by two arches with a thickness of 0.55 m, a span $L = 6.0$ m and rise $f = 2.4$ m. They are connected to a central pier of height 5.0 m and two side abutments of height 3.5 m. A coefficient of friction at the interface of 0.75 is assumed.

Figure 4. (a) Representation of the external horizontal force applied with variable angle β ; (b) Failure mode for $\beta = 0^\circ$ (c) Failure mode for $\beta = 70^\circ$ (d) Failure mode for $\beta = 90^\circ$.

In addition to considering the self-weights of each element, calculated proportionally to the geometry of the block assuming a unit weight of 22 kN/m^3 , variable horizontal loads are applied on each element, proportional to their weight force (Figure 4).

A parametric analysis is then performed, calculating the collapse multiplier and the associated failure mechanism when the angle of inclination $\beta \in [0; 90]$ of the horizontal force f_L is varied (Figure 4). For $\beta = 0^\circ$ the variable load acts in the longitudinal direction while for $\beta = 90^\circ$ the horizontal action is parallel to the transverse direction.

Analyzing Figure 5, an increment in collapse multipliers is observed as the angle β increases, representative of a greater resistance of the structure to transverse actions than to longitudinal ones.

The collapse mechanisms shown in Figure 4 highlight that, for values of $\beta \geq 60^\circ$, there are transverse failures affecting the central pier and the two masonry arches. In fact, the discretization employed is functional to the failure mechanisms: the pile is a slender element in the plane, subject to failure by rocking and sliding. In contrast, transversely it has a considerable size and a discretization with more elements is made in order to capture the classical mechanisms of rocking and sliding but also diagonal shear failure, evident in Figure 4(c,d).

Figure 5. Collapse multiplier vs. tilt angle β of the external horizontal action.

Like most bridges in Italy, the arches are discretized with a single element on the thickness, allowing for rocking and sliding mechanisms. In contrast, multiple elements are used at depth to also capture diagonal cracking mechanisms and localized sliding.

5 CONCLUSIONS

In this paper, results on the collapse condition of masonry arch bridge subject to inclined horizontal inertial action have been presented.

To identify the collapse condition, expressed in terms of load multiplier and associated failure mechanism, rigid-block analysis has been performed, assuming the absence of tensile stresses at the interfaces and the impossibility of crushing failure. An attritive resistance at the interface has been considered, using the Mohr-Coulomb principle and an associated flow law.

A parametric analysis has been performed on the structure, varying the angle of application of the horizontal external actions, expressed as a function of the self-weight of each block. The results obtained showed that the use of a three-dimensional analysis of the structure is also capable of capturing transverse failure mechanisms, which occur on the structural elements of the masonry arch bridge for out-of-plane actions, in addition to longitudinal in-plane actions.

Near-collapse deformed configuration of masonry arch bridges

G. Stagnitto

University of Pavia, Pavia, Italy

P. Zampieri

University of Padova, Padova, Italy

ABSTRACT: The near collapse-deformed configuration of a structure can be evaluated directly through mathematical programming, without the classical nonlinear incremental analysis. In this work, with the assumption of no elastic returns of the material, the theoretical deformed shaped at collapse of masonry bridges is directly defined using a variational principle, in the simplifying assumption of perfect elastoplastic behavior. The proposed approach is an extension of the well-known paper of Heyman. In the Heyman work, the final configuration of the structure that respect the restrain conditions is due to two contributions: the contribution of the elastic deformations of the structure portions between plastic-hinges and the contribution of the rotations concentrated in the plastic-hinge sections. In this work, the final configuration of the masonry bridges is evaluated considering the elastoplastic deformation of the structure obtained by the integration of the curvature that tends to infinity in the plastic-hinges sections and the rotations concentrate in the plastic-hinge sections

1 THE ELASTIC-PLASTIC DEFLECTION OF BEAMS AT THE POINT OF COLLAPSE (THE PROCEDURE PROPOSED BY HEYMAN)

Heyman proposed a procedure to assess the deformed configuration (rotation and displacement functions) at the incipient collapse condition of fixed-ended beam of Figure 1a (Heyman 1961).

The simplification adopted by Heyman is the absence of elastic-plastic behavior: the maximum elastic moment M_e coincides with the plastic moment M_p .

When the limiting moment is reached, concentrated plastic rotation θ_i is formed in the section i (Figure 1b). The concentrated rotations θ_2 and θ_3 at the point of collapse are given by the conditions that the θ_1 rotation is zero because in 1 the last plastic hinge forms. The rotations θ_i have limited value and are not the rotations concentrated in the plastic hinges ϕ_i (with unlimited value and limited ratio) when the structure is reformed in a kinematic mechanism (Figure 1b).

Heyman uses the Principle of Virtual Work (PVW) for the determination of the beam deflection at the point of collapse. Considering Figure 1a, M is the bending moment distribution that is equal to the elastic curvature distribution if the beam flexural stiffness (EJ) is equal to 1; m is a most general bending moment distribution specified in terms of end moments m_1 e m_2 ; m^* is one moment distribution that is in equilibrium with the unit load P (Figure 1a).

Considering the moment distribution m , the unknown plastic rotation and the elastic curvature distribution ϕ_i , by the equation of the PVW:

$$\sum m \theta_i + \int m \frac{M}{EJ} ds = 0 \quad (1)$$

Figure 1. Elastic-plastic deflection and collapse kinematic.

The second term is equal to zero because the virtual work of the external forces considering an auto-equilibrated moment distribution m is zero.

Considering the independent distribution of moment m_1 and m_2 (Figure 1a) the plastic rotations different to zero are defined as follow:

$$\theta_2 = \frac{M_p \cdot b}{2EJ} \theta_3 = -\theta_2 = -\frac{M_p \cdot b}{2EJ} \quad (2)$$

The sign of rotations agrees with that of moment distribution: then the last plastic hinge is in the section 1. Considering the bending moment distribution m^* in equilibrium with the load $P=l$ (Figure 1a) and the rotations θ_2 and θ_3 then, by the equation of virtual work is possible to define the deflection f :

$$f = \sum m^* \theta_i + \int m^* \frac{M}{EJ} ds = \frac{2}{3} \frac{M_p b^2}{EJ} \quad (3)$$

2 THE ELASTIC-PLASTIC BEAMS DEFLECTION AT THE COLLAPSE POINT: THE PROPOSED PROCEDURE

The procedure proposed by Heyman is general and is applicable to beams and frames. In this paper an alternative simplified procedure is proposed. The procedure, valid for beams or and (open) frames, allows to evaluated the structure deflection at the collapse considering the plastic bending moment distribution without the application of the PVW for writing the compatibility equations. The procedure is still valid if an elastoplastic bending moment distribution is considered.

From the “moment area theorems” (Ghali et al 2003) in the fixed-ends beam, the area of the curvature distribution and the static moment respect to the beam ends are zero. Fixed the origin of referring system in the left end and considering a generic beam section: the curvature integral from the right end to the generic section is the beam rotation in the considered section and the static moment of the same curvature area respect to the vertical axis is the beam deflection. The theorems are applicable also in the case of concentrate rotations (R^+ , R^-).

The deflection of section 1 is equal to:

$$u_1 = \left(M_p \frac{b}{2} \right) \cdot \left(\frac{4}{3} b \right) - \left(M_p \frac{b}{4} \right) \cdot \left(\frac{2}{3} b \right) = \frac{M_p \cdot b^2}{2} = \left(M_p \frac{b}{2} \right) \cdot b \quad (4)$$

In the hypothesis that the last plastic hinge is in 1: the concentrate rotations in sections 2 and 3 must equal with opposite sing: $|R^+| = |R^-| = M_p \frac{b}{2}$.

Figure 2. Curvature distribution: (a) elastic and plastic concentrated, (b) elastic, elastoplastic and plastic concentrated.

The deflection of section 2, considering also the contribution of the concentrate rotation, is equal to:

$$u_2 = -\left(M_p \frac{b}{4}\right) \cdot \left(\frac{2}{3}b\right) - \left(M_p \frac{b}{2}\right) \cdot b = -\frac{2}{3}M_p b^2 \quad (5)$$

3 THE ELASTOPLASTIC BEAMS DEFLECTION AT THE COLLAPSE POINT: THE PROPOSED PROCEDURE

Considering a beam portion Δ between section a and section b . Suppose that in section a the bending moment is equal to M_e and in section b is equal to M_p .

Figure 3. Bending moment a) and curvature b) distribution.

The curvature is equal to M/EJ for bending moment values lower and equal to M_e , otherwise:

$$\chi = \frac{1}{EJ} \cdot \frac{M_e}{\beta}, \quad \beta = \frac{h'}{h} = \sqrt{3 - 2 \frac{M(x)}{M_e}} \quad (6)$$

The curvature integral ($EJ = 1$), in the interval $(a-b)$, is evaluated in the hypothesis of linear distribution of the bending moment as follows:

$$\begin{aligned}
y = \frac{x}{\Delta}, M_p = \frac{3}{2} \cdot M_e \rightarrow M(y) = M_e + y(M_p - M_e) \rightarrow \frac{M_e}{\beta} &= M_e \cdot \left[3 - 2\left(1 + \frac{y}{2}\right) \right]^{-\frac{1}{2}} \\
&= M_e(1 - y)^{-\frac{1}{2}} \\
\theta_{ab} = \int_0^{\Delta} \frac{M_e}{\beta} dx = \Delta M_e \int_0^1 \frac{1}{\sqrt{1-y}} dy = \Delta M_e \left[-2\sqrt{1-y} \right]_0^1 &= \Delta M_e \cdot 2
\end{aligned} \tag{7}$$

The interesting result is that the relative rotation θ_{ab} between section a and section b is 2 time the maximum elastic moment time Δ (if $EJ=1$)

Then, the center of the curvature in the considered beam segment (Δ) is equal to:

$$\begin{aligned}
\eta\Delta &= \frac{\int_0^{\Delta} x \frac{M_e}{\beta} dx}{\int_0^{\Delta} \frac{M_e}{\beta} dx} = \frac{M_e\Delta^2 \int_0^1 y \frac{1}{\beta} dy}{M_e\Delta \int_0^1 \frac{1}{\beta} dy} = \frac{M_e\Delta^2 \int_0^1 y \frac{1}{\sqrt{1-y}} dy}{2\Delta M_e} = \frac{M_e\Delta^2 \left[-\frac{2}{3}(2+y)\sqrt{1-y} \right]_0^1}{2\Delta M_e} \\
&= \frac{M_e\Delta^2 \frac{4}{3}}{2\Delta M_e} = \frac{2}{3}\Delta
\end{aligned} \tag{8}$$

The second interesting result is that the center of the curvature diagram between section a and section b is $2/3 \Delta$.

For the symmetry of the positive and negative areas, the elastoplastic curvature diagram (Figure 2b) has global area equal to zero: then the rotation of the section 1 is equal to zero. Therefore, the deflection in section 1 is equal to:

$$u_1 = \frac{10}{9} M_e \cdot b^2 = \frac{20}{27} M_p \cdot b^2 \tag{9}$$

Because the arm of the concentrate rotations is equal to b , and because $M_e = \frac{2}{3} M_p$, the rotation $|R^+| = |R^-| = R$ are defined as follows:

$$R = \frac{u_1}{b} = \frac{10}{9} M_e \cdot b = \frac{20}{27} M_p \cdot b \tag{10}$$

Therefore, the deflection in section 2 is equal to:

$$u_2 = -\left(M_e \frac{1}{6} b\right) \frac{8}{18} b - \left(M_e \frac{2}{6} b\right) \frac{16}{18} b + R \cdot b = -\frac{40}{27} M_e \cdot b^2 = -\frac{80}{81} M_p \cdot b^2 \tag{11}$$

These results were compared with a numerical procedure: the Figure 4a shows the elastoplastic deformation of the fixed-ends beam. The Figure 4b, instead, shows the elastoplastic deformation of the beam and the additional term due to the concentrate rotations (R^+ , R^-). It is important to observe: The beam deformation (Figure 4b) respect the boundary condition in the left end, in the section 2 and in section 3 there is a beam axis discontinuity and in section 1 the beam deformed axis tangent is zero.

Assuming $M_e = 12 \rightarrow M_p = 18 : u_1 = 13.3333, R = 13.3333 u_2 = -17.7777$

Figure 4. Beam deflection at the collapse point, the elastoplastic contribution (a) and the elastoplastic contribution plus the plastic concentrated rotations (b).

4 THE ELASTOPLASTIC ROTATIONS AROUND THE NEUTRAL AXIS METHOD

A method that extends the validity of the *moment area theorems and related corollaries* (Ghali et al 2003) to the elastoplastic no-tension arched structures is presented here. The idea of the method is to consider the relative rotations applied to the neutral axis (instead of the beam axis) to automatically take into account the axial force contribution (Stagnitto 2022).

Figure 5 shows the collapse thrust line of the masonry arch railway bridge for the critical position of the moving load. The elastoplastic analysis, conducted using a variational procedure (Stagnitto et al 2022), considering the collapse load multiplier, finds the same solution of the limit analysis (Zampieri 2020, Zampieri et al 2019, Stagnitto et al 2019).

The relative rotation $\Delta\theta_k$, concentrated in the arch interface k and obtained by integrating the curvatures of each arch block considered, is represented as a vector applied on the neutral axis position of each section (Figure 5). Moreover, the plastic hinges are located in sections 1, 11, 19, 27.

Figure 5. Arch thrust line at the point of collapse, neutral axis diagram, relative rotations vectors.

For example, the calculation of the rotation and the displacement components of point 1 on the axis of the section 1, if (x_k, y_k) are the coordinates of the intersection between the neutral axis and the trace of section k with respect to a reference system with origin in point 1, is given by:

$$\theta_1 = \sum_{k=1}^n \Delta\theta_k \quad u_x^1 = \sum_{k=1}^n y_k \cdot \Delta\theta_k \quad u_y^1 = \sum_{k=1}^n x_k \cdot \Delta\theta_k \quad (12)$$

5 THE CURVATURE INTEGRAL OF ELASTOPLASTIC NO-TENSION STRUCTURES

Figure 6. The curvature integral of elastoplastic no-tension structures.

If Δ is the integration interval of the elastic-plastic curvatures $\chi(x)$, the relative rotation between sections a and b (unit width beam) is equal to:

$$E \cdot \Delta \vartheta = \int_0^\Delta \chi(x) dx \quad (\text{where } E = 1) \quad (13)$$

$$\chi(x) = \frac{f}{c(x)-p(x)} = \frac{f^2/2\sqrt{3}}{\sqrt{2 \cdot f \cdot N(x) \cdot u(x) - 3 \cdot N^2(x)}}$$

c is the section compressed area and p is the plasticized section zone. If we assume a linear trend of the functions $N(x)$ and $u(x)$ between section a and b , we obtain (Abramowitz and Stegun 1972):

$$y = \frac{x}{\Delta} \rightarrow \int \chi(x) dx = \Delta \int \chi(y) dy = \Delta \int \frac{f^2/2\sqrt{3}}{\sqrt{2fNu-N^2}} = \Delta \frac{f^2}{2\sqrt{3}} \int \frac{1}{\sqrt{Ay^2+By+C}} \quad (14)$$

$$\int \frac{1}{\sqrt{Ay^2+By+C}} = \frac{1}{\sqrt{A}} \ln \left| 2\sqrt{A} \cdot \sqrt{Ay^2+By+C} + 2Ay+B \right|$$

Since at b the curvature is infinite, $\chi(y)$ diverges for $y = 1$; therefore, the denominator of the integrand function is zero for $y = 1$ and therefore $\chi(y)$ can be expressed in the form: $\chi(y) = F(y) \cdot \frac{1}{\sqrt{1-y}}$.

Inverting the transformation function $t = \sqrt{1-y}$ we obtain: $y = 1 - t^2 \rightarrow dy = -2t \cdot dt$

Changing the sign of the integrand (and consequently inverting the extremes of integration) we obtain a different integral equation:

$$\Delta \cdot \int_0^1 \chi(y) dy = \Delta \cdot \int_{\sqrt{1-1}}^{\sqrt{1-0}} \chi(1-t^2) \cdot 2t \cdot dt \quad (15)$$

The integral obtained, free of singular points, is calculated numerically using Gauss's formulae.

6 LINEAR SYSTEM OF EQUATIONS IN UNKNOWN PLASTIC ROTATIONS

The direct method proposed to derive plastic rotations in elastoplastic beams can be extended to masonry arches.

If we suppose that the hinge in 1 is the last: $R_1 = 0$.

Let us denote by (x_2, y_2) , (x_3, y_3) , (x_4, y_4) , the coordinates of the first three plastic hinges with respect to a reference system in point 1.

Figure 7. The elastoplastic deflection of the no-tension arch.

Figure 7 shows the elastoplastic deformation, i.e. the deformation produced by relative rotations obtained by integrating the elastoplastic curvatures corresponding to the solution of the limit analysis, including curvatures tending to infinity.

The relative rotations were applied at the neutral axis points of the limit analysis solution. At point 1 (center of section 1) we have the two displacement components u_1^x , u_1^y e and the rotation θ_1 .

The three concentrated plastic rotations R_2, R_3, R_4 , applied consecutively from the fixed right-end, must return point 1 to its original position, also cancelling the rotation θ_1 .

The solving system is therefore as follows:

$$\begin{aligned} R_2 + R_3 + R_4 &= -\theta_1 \\ R_2 \cdot x_2 + R_3 \cdot x_3 + R_4 \cdot x_4 &= -u_1^y \\ R_2 \cdot y_2 + R_3 \cdot y_3 + R_4 \cdot y_4 &= -u_1^x \end{aligned} \tag{16}$$

A linear system of three equations in three unknowns was obtained; the coefficient matrix is defined by the coordinates of the first three plastic hinges:

$$\begin{bmatrix} 1 & 1 & 1 \\ x_2 & x_3 & x_4 \\ y_2 & y_3 & y_4 \end{bmatrix} \cdot \begin{bmatrix} R_2 \\ R_3 \\ R_4 \end{bmatrix} = \begin{bmatrix} -\theta_1 \\ -u_1^y \\ -u_1^x \end{bmatrix} \tag{17}$$

The calculation should be performed assuming the hinge develops last and is correct when the three rotations are in agreement with those corresponding to the limit thrust line (obtained from the limit analysis).

A case study in which the proposed procedure is applied is illustrated in Figure 8, which shows the elastoplastic arch deformation before the application of concentrated plastic rotations (Figure 8a) and the elastoplastic-plastic collapse arch deformation (Figure 8b), drawing with amplification of displacements.

Figure 8. The elastoplastic arch deformation before the application of concentrated plastic rotations (a) and the elastoplastic-plastic collapse arch deformation (8b).

Figure 9. Arch deformation at the point of collapse and arch deformation during the collapse.

For the sake of clarity, this deformation corresponds to the incipient arch collapse condition (Figure 9). From this configuration, the effects of the four plastic rotations of the collapse kinematism are summed when the structure is transformed into a mechanism.

7 THE CENTER OF ELASTOPLASTIC ROTATIONS

Based on the elastoplastic arch deflection (obtained by integrating the elastoplastic curvatures), one can derive the center of instantaneous rotation G of the initial section of the arch,

which we will call *the center of elastoplastic rotations* of the initial section or the *center of gravity of the elastoplastic weights* (by analogy to the center of gravity of the elastic weights in the theory of the ellipse of elasticity).

With respect to point 1, the center G is positioned at a horizontal distance of $\frac{u_c}{\vartheta_1}$ and a vertical distance of $\frac{u_c}{\vartheta_1}$.

As seen, concentrated plastic rotations must cancel the displacement and rotation of the center point of the initial section, i.e. they must cancel the rotation ϑ_1 around the elastoplastic center.

It is useful to verify that the vector composition of the concentrated plastic rotations is a rotation applied at the same point G and of equal and opposite value to the elastoplastic rotation.

The graphical method to derive the center G of the resultant of the three rotations R_1 , R_3 , R_4 is as follows.

The vector R_3 is plotted in 1 and 4. The two vectors are plotted in 3:

- R_4 on the same side as R_3 (with respect to the conjunction 4-3) since they are discordant;
- R_1 on the opposite side of R_3 (with respect to conjunction 1-3) since they are concordant.

The points of the vectors are joined, obtaining intersections 1-3 and 4-3 on sides 1-3 and 4-3 (or on their prolongation). We join 1 with 1-3 and 4 with 4-3: the center G , intersection of these two conjunctions, must correspond to the center of the elastoplastic rotations.

Figure 10. The center of elastoplastic rotations.

ABSTRACT: Through the variational method based on the Somigliana's Double Dislocation, the theoretical elastoplastic solution of a masonry arch bridge is evaluated under a generic load condition, obtaining the live loads multiplier, which corresponds to the achievement of a predetermined ductility limit. The well-known experimental campaign performed by Schwartz e Thürlimann showed that the ultimate limit state of a masonry wall subjected to high eccentric compressive axial force is reached when there are high rotational capacity of the critical sections. From these results, the Swiss national standard proposed a ductility check at sectional level. In this work, the final configuration of the masonry bridges is evaluated considering the elastoplastic deformation of the structure obtained by the integration of the curvature that tends to infinity in the plastic-hinges sections and the rotations concentrate in the plastic-hinge sections necessary for the respect of the restrain conditions of the structure. Using this approach, a double ductility check is possible: at point and section level.

1 CONSIDERATION ABOUT THE PUNCTUAL AND SECTIONAL DUCTILITY IN A MASONRY CROSS-SECTION

The solution of the limit analysis is theoretically valid if the ductility of the material is assumed infinite. In fact, the final equilibrated solution - which corresponds to the theoretical collapse of the structure - must effectively be reached without local collapses of the structure that would prevent the development of the plastic deformations necessary to reach the tensional state associated with the final equilibrated solution.

However, in a masonry arch, the no-tension solution that respects the prefixed material ductility $\mu_e \leq \bar{\mu}_e$ at every point in some cases does not justify the collapse loads observed in real bridges (Page, 1993). In fact, it has been found experimentally (Schwart and Thürlimann 1988) that collapse of masonry sections subjected to eccentric compressive axial force occurs for high local values of rotation (up to 0.1 rad) as shown in Figure 1 where the results of experimental tests performed by Thurlimann and Schwartz (Schwart and Thürlimann 1988) are reported.

The conclusion of the authors (Schwart and Thürlimann 1988) (which is taken from the Swiss standard SIA 266/2) is as follows: if the dimensionless limit axial force $v=N/(s f_c)$ (in an arch of unit width, section of thickness s and made of masonry with compressive strength equal to f_c) is less than 0.25, no limits should be considered on the rotation capacity of the section.

Figure 1. Experimental results obtained by Schwartz and Thurlimann, 1988.

2 SIMPLIFIED VERIFICATION WITH TWO PARALLEL ANALYSES AND PROPOSED SINGLE VERIFICATION

The considerations of the previous points suggest a simplified load capacity of a masonry bridge that determines the minimum strength required to reach the limit situation (for each load combination and for each position of the moving load). This can be done by means of two structural analyses conducted in parallel: the classical limit analysis using the static method (Stagnitto and Pederzani 2019, Zampieri 2020 and Zampieri et al. 2019) (and kinematic admissibility check) and the nonlinear elastoplastic analysis (Stagnitto et al. 2022).

In the first case, the required strength is derived in a way that the rotational capacity of the sections is not limited; in the second case, the required strength is derived in a way that the predetermined ductility is respected at each point.

If a single verification is to be defined, the most reasonable procedure would seem to be that of checking the concentrated rotations actually required to reach the ultimate theoretical collapse situation; as we will see, the concentrated rotations must also include the integrals of the curvatures in the areas near the plastic hinge where the punctual ductility limit value has been exceeded.

The purpose of this paper is to define a method for checking total concentrated rotations, verifying that they are internal to the domain of allowable rotations as a function of axial action.

3 COLLAPSE DEFORMATION DUE TO ELASTOPLASTIC DEFORMATIONS ONLY

For the understanding of the method, we focus on an example of a masonry arch railway bridge of about 20 meters net span (Stagnitto et al. 2022).

The load combination that maximizes the dissymmetric effects of vertical loads is considered: vertical and horizontal forces for permanent [G] and variable [Q] loads are considered in the analysis, multiplied by the corresponding safety coefficients: $1.0[G] + \lambda[Q]$.

Theoretical collapse corresponds to $\lambda=1$.

From the limit analysis, the critical position of the railway load is the one identified in Figure 2, corresponding to the highest value of the required resistance f_c equal to 3.50 MPa: this stress value is located in the four sections 1, 11, 19, 27 where the plastic hinges are formed. Therefore, the set of equilibrated solutions subjected to $0 \leq \sigma \leq f_c$ is theoretically reduced to the equilibrated solution obtained by limit analysis.

Internal actions in plastic hinges correspond to points that pertain to the limit domain:

- Figure 3a, in the space of dimensionless internal actions v , μ : $\mu = \frac{1}{2} \cdot (v - v^2)$;

Figure 2. Critical load condition in a railway masonry bridges.

-Figure 3b, in the space of axial action and dimensionless eccentricity: $\frac{\varepsilon}{s} = \frac{t}{v} = \frac{1}{2} \cdot (1 - \nu)$ (since we have considered the absolute values of eccentricities, we graphically overlap the values of sections 1 and 27).

Figure 3. Limit domains (v, μ) and $(v, \mu/v)$.

Since the equilibrated collapse solution is the only one that, under ultimate load, respects the strength conditions, the elastoplastic calculation conducted by variational procedure (Stagnitto et al 2022) can only find the same solution.

We observe that the final equilibrium solution (theoretically valid under the assumption of non-limited ductility) does not depend on the elastic parameters of the arch and is valid even in the presence of elastic returns. A rigorous, only in the absence of elastic returns can the diagrams of unit strains be derived directly from those of stresses.

Any local unloading would still have a negligible influence on the deformation profile of the arch at collapse (Maier et al. 1977).

On the basis of the equilibrated collapse solution, we calculate, at each node, the relative rotations $\Delta\theta$ by integrating the curvatures χ over the arc length of the corresponding segment.

In the four plastic hinges, appropriate integration techniques are used because the curvature theoretically tends to infinity (Stagnitto and Zampieri 2023). Although this theoretical assumption is unrealistic, finite values of the concentrated rotations are obtained that have the same order of magnitude as the experimentally enslaved ones.

As we shall verify the elastoplastic deformation thus obtained does not verify compatibility with the hyperstatic constraint, and therefore concentrated plastic rotations will form in the first three plastic hinges.

In the presence of such concentrated rotations there is a discontinuity of absolute rotation; concentrated rotation is the result of a process of abstracting on a phenomenon that always actually concerns a finite length of an arch.

Thus, at each node, the relative rotation is equal to:

- (i) to Simpson’s integral if the section is not a plastic hinge: $\Delta\vartheta_i = \frac{L_i}{6} \cdot (\chi_1 + 4\chi_2 + \chi_3)$
- (j) to the improper integral over the relevant ashlar + the concentrated rotation, if any, if the plastic hinge is not the initial or final section of the arch: $\Delta\vartheta_j = \int_0^{L_j} \chi ds + (R_j)$
- (k) to any concentrated plastic rotation if the plastic hinge is the initial or final section of the arch:

$$\Delta\vartheta_k = (R_k) \quad k = 1, n$$

In fact, the elastoplastic rotations of the extreme segments are located at the additional nodes (in the middle of the initial and final elements, of shorter length) 1^* and n^* :

$$\Delta\vartheta_{1^*} = \int_0^{L_1} \chi ds \quad \Delta\vartheta_{n^*} = \int_0^{L_n} \chi ds$$

Figure 4. Curvature diagram and concentrated rotations.

Deformation is obtained by the method of elastoplastic rotations around the neutral axis: the “key” of the method is to place the relative rotations on the neutral axis instead of the geometric axis, so as to automatically account for section partialization and the influence of axial force (Stagnitto and Zampieri 2023).

Positioning on the neutral axis the relative rotations in the nodes preceding each section, their sum gives the rotation in section θ , the sums of their static moments, with respect to the vertical and horizontal axes passing through the center of gravity of the section, give the vertical displacements u_y and horizontal displacements u_x of the center point of the section. The resulting elastoplastic deformation (drawing with amplification of displacements) is plotted in Figure 5.

Figure 5. Elastoplastic deformation of the arch (x10).

4 CONCENTRATED PLASTIC ROTATIONS IN THE FIRST THREE PLASTIC HINGES

As can be seen from Figure 5, the elastoplastic deformation does not verify compatibility with the constraint: at point 1 (geometric center of the initial section) there are nonzero values of the absolute rotation $\theta_1 \cong 0,05 \text{ rad}$ and vertical displacements $u_1^y \cong 37,5 \text{ cm}$ and horizontal displacements $u_1^x \cong 37,5 \text{ cm}$.

A nominal value of $E=1000 \text{ MPa}$ was assumed, which is suitable for catching the deformation at full-scale collapse (Figure 6).

These three components of the displacement of node 1 are canceled by the plastic rotations in the first three plastic hinges (Stagnitto and Zampieri 2023), since the equilibrium solution obtained corresponds to the last possible equilibrium, i.e., to the act of formation of the fourth plastic hinge. From this point on, plastic rotations of unlimited value appear, affecting all four hinges.

By sequential elastic-plastic analysis (Stagnitto et al. 2022), it is found that the last plastic hinge is formed in section 11. If only the limit analysis is carried out, the last plastic hinge can still be identified: the calculation should be performed assuming one of the four hinges as the last and is correct when the three rotations agree with those that would cause the limit analysis thrust line.

We report, in Figure 6, the deformation configuration at incipient collapse. This deformation takes into account the partialization of the sections, the elastic rotations in the sections that remained elastic (compressive), the elastoplastic rotations in the sections where the maximum compression f_c was reached, and the concentrated plastic rotations in the sections that reached the ultimate limit state.

Figure 6. Final deformation of the arch and rotations diagram at bridge collapse (with plastic rotations).

We observe how, in the absolute rotations diagram, the three plastic rotations concentrated in sections 1, 19, 27 appear as discontinuities (and there is no discontinuity in section 11, however, because that is the last hinge to be formed). However, the total concentrated rotations actually needed to reach the collapse situation (before the mechanism is triggered) must still include a contribution.

5 CONCENTRATED TOTAL ROTATIONS IN THE FIRST THREE PLASTIC HINGES

It has been found experimentally (Page 1933) that in a plasticized arch section the rotations are concentrated in a single section at the plastic hinge. To reproduce this situation with a mathematical model, the relative rotations of the ashlar near the plastic hinge are calculated and considered as an increase in the rotations in the plastic section.

The assumption at the basis of the verification is as follows: the fiber-level ductility check in each section is replaced by an internal action-level check in a single section, in which the plastic rotation of the section itself, the elastoplastic rotation of the relevant ashlar and the elastoplastic rotations of adjacent segments with greater ductility than allowed are added together. When the concentrated rotations are internal to the domain of admissibility, it is justified to calculate them in a one-dimensional model that, for the advantage of safety, maximizes them by admitting infinite curvature at the plastic hinges. For simplicity, let us consider the limit case, i.e., suppose we accept a maximum ductility of 1: then all elastoplastic rotations (derived

from compressive strength) are concentrated in plastic hinges. The total concentrated rotations (see Figure 7) include the concentrated plastic rotations (R) of the fully plasticized sections, the elastoplastic rotations of the related segments ($|\chi| \rightarrow \infty$), and the elastoplastic rotations of the neighboring segments with ductility greater than the allowable ductility ($\mu_\epsilon > \bar{\mu}_\epsilon$).

Therefore, the ductility verification:

- or is positive in segments where the distribution of elastoplastic curvatures ($\mu_\epsilon \leq \bar{\mu}_\epsilon$) and the resulting regularity of absolute rotation are accepted;
- or is replaced, for the other segments (regarded as infinitely stiff) by the verification of the total rotations that are concentrated in the critical sections.

Figure 7. Curvature diagram (elastic and elastoplastic range).

Even assuming, for simplicity $\bar{\mu}_\epsilon = 1$, the solution does not correspond to the classical elastic-plastic solution, which, instead, considers the entire arch elastic with the exception of the sections where plastic hinges are formed.

In the proposed method, however, the solution must be called elastoplastic-plastic because the transition zones between the elastic state and the plastic final state, and concentrated plastic rotations are considered.

The deformation obtained after concentration of the elastoplastic rotations (Figure 8) is a more “angular” than that in Figure 5.

Figure 8. Elastoplastic deformation of the arch (x10), after concentration of elastoplastic rotations.

When plastic R rotations are applied, the deformation and absolute rotations diagram (Figure 9) show that the displacements and rotation of the initial node are all canceled.

Keeping the total rotation of the last hinge (sec. 11), the diagram of absolute rotations according to the collapse kinematism (in dashed line) was plotted for comparison.

If all relative rotations, including elastic ones, were concentrated according to their sign (regarding all ashlar as infinitely rigid), the two diagrams would be coincident: this suggests

Figure 9. Final deformation of the arch and rotations diagram at bridge collapse (with total rotations).

simplified methods that assume for collapse deformation estimation the rigid kinematism calibrated according to the total rotation of the last hinge.

For a nominal value of $E=1000$ MPa, the maximum (vertical) displacement is about 22 cm, in section 19; for comparison, under the forces $1.0[G] + 0.8[Q]$ the maximum displacement—also at the same point 19—was about 7 cm (Stagnitto et al. 2022), compared to a bridge of about 20 meters of span.

6 ASSESSMENT OF ADMISSIBILITY OF TOTAL ROTATIONS

In the following figure, based on the experimental evidence cited by Schartz and Thurliman (1988), the domain of permissible rotations as a function of the dimensionless axial force v was plotted as an example.

The limit domain, drawn for conceptual purposes only to illustrate the proposed assessment method, contains all the points in Figure 1.

Instead, the actual domain for design purposes will have to take into account other experimental evidence and other considerations, including statistical ones, in order to define a design domain as a function of a given fractile, in probabilistic terms. On the domain we reported the four total concentrated rotations, placing them according to the value of the axial force. The maximum concentrated rotation is in section 19, where, for $E=1000$ MPa, it is equal to 0.09 radians (Figure 10a).

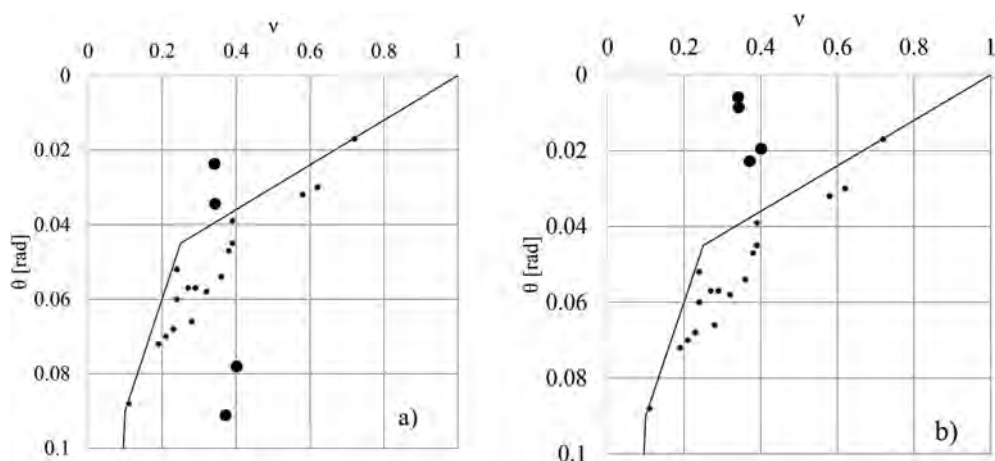

Figure 10. Assessment of admissibility of total rotations ($E = 1000$ $E = 4000$).

Assuming $E = 4,000$ MPa (realistic value for bridges: Cappini et al. 2010), the rotations are 4 times smaller and the maximum rotation (in 19) becomes: $0.09 \text{ rad}/4 = 0.0225 \text{ rad} = 1^\circ, 30$.

Therefore, the verification of the total rotations is positive (Figure 10b) and the equilibrated collapse solution can actually be achieved.

7 CONCLUSIONS

For the purpose of realistic estimation of the collapse multiplier, a calculation of the rotations actually required to reach the theoretical collapse solution has real practical utility.

The method presented in this contribution derives the elastoplastic deformation associated with the equilibrated solution of the limit analysis, taking into account the concentrated rotations in the plastic hinges that precede the formation of the final hinge.

Analytical developments of the method are explained in (Stagnitto and Zampieri 2023). The concentrated rotations thus estimated must be less than those allowed—based on experimental evidence—as a function of the dimensionless axial force in the section.

Since it has been experimentally observed that, in a plasticized arch section, rotations are concentrated around a single section, the estimation of the total rotation must also include the integral of the curvatures in the adjacent zones where the point ductility limit value is exceeded. In this way, the verification considers both failure conditions, at the point level and at the sectional level.

Assuming elastoplastic idealizations, in the presence of progressive plasticizations, the proposed method does not know the disadvantage of convergence problems when the load multiplier increases.

Discrete Macro-Element structural assessment of a railway masonry arch bridge subjected to pier settlements

D. Rapicavoli, F. Cannizzaro, S. Caddemi & I. Calìò

Department of Civil Engineering and Architecture, University of Catania, Catania, Italy

ABSTRACT: Settlements in bridges can induce structural damage that can be limited and affect only the serviceability of the infrastructure or, in the worst scenario, can cause local or global failure. To assess the structural behaviour of masonry arch bridge and identify the occurrence of damage, also in presence of structural health monitoring, reliable numerical models to perform sufficiently accurate nonlinear simulations are needed. The innovative strategy known as discrete macro-element model (DMEM) is here employed to assess the performance of a masonry arch bridge in presence of piers settlements. The adopted numerical strategy assures an easy and geometrically consistent model characterized by a low computational burden with very accurate results. The numerical investigation here reported is also devoted to detect the main structural parameters that have to be controlled in health monitoring bridge survey and to identify threshold levels to be considered for automatic early warning alerts. A masonry arch bridge located in Maletto (Italy), belonging to the rail network of Ferrovia Circumetnea (FCE), which was subjected to a retrofitting intervention due to the presence of extensive damage at the haunches of the arches, is here studied in its original configuration. A sensitivity analysis with respect to the settlement magnitude of a pier foundation is performed considering the operational loads by conducting nonlinear static analyses. The role of the settlements in masonry arch bridges and the relevant effects on the structural performance are shown and discussed also with the aim to associate the severity of damage to the structural performance of the bridge.

1 INTRODUCTION

Masonry arch bridges can be subjected to structural damage that can be induced by different causes, such as degradation of the materials (Tecchio et al. 2022), scours (Ragni et al. 2019, Scozzese et al. 2019, Solan et al. 2020, Zampieri et al. 2017), settlements (DeJong 2016, Malena et al. 2021, Grillanda et al. 2022). Damage in masonry arch bridges can be also due to settlements of the pier foundations induced by scour, under-sizing of the foundations, soft soil (Bayraktar and Hökelekli, 2021).

The interpretation and the prediction of the reduction of structural performance due to damage related to different causes require advanced numerical models capable to perform nonlinear static and/or dynamic analyses. Refined Finite Element (Tubaldi et al. 2020, Pepi et al. 2021) or Discrete Element (Saygılı and Lemos, 2021) simulations have been proposed in the scientific literature. An alternative modelling strategy, specifically introduced for the numerical modelling of masonry structures (Caddemi et al. 2017), known as discrete macro-element model (DMEM) was recently extended and applied for the simulation of the complex nonlinear static and dynamic behaviour of masonry arch bridges (Caddemi et al. 2018, Caddemi et al. 2019, Caddemi et al. 2020). The DMEM is based on the adoption of shear deformable three-dimensional macro-elements interacting with each other by means of nonlinear zero-thickness interfaces, and its main advantages rely on the limited amount of degrees of freedom required by each element, on the adoption of simple but effective constitutive laws based on a fiber

discretization, which make the numerical approach reliable, robust and characterized by a simple interpretation of the results. In addition, the low computational cost allows to perform static and dynamic nonlinear analyses in reasonable computer time even for large models.

The DMEM strategy is here applied for modelling a four span railway masonry arch bridge located in Maletto (Italy), and belonging to the Ferrovia CircumEtna (FCE) company. The bridge is a curved one with a constant slope, and was characterised by a diffused crack pattern at the intrados of the arches evidenced during an inspection made in 1984, caused by settlements at the base of a central pier. The precarious safety condition of the bridge required a retrofitting intervention. Here the bridge is studied in the original structural layout for different severity of the settlement of the central pier with the aim to evaluate the structural performance of the bridge due to central pier settlements and assessing the bridge capacity as a function of the settlement magnitude. The study is also motivated by the need to define thresholds levels of foundation displacements to be assigned to health monitoring system that could be installed in the masonry bridge.

2 THE CASE STUDY: A MASONRY ARCH BRIDGE IN MALETTTO

2.1 Description

The case study is a masonry arch bridge (Figure 1) built in the 19th century and located in the south of Italy, in the municipality of Maletto (Sicily) at km 62 on the FCE rail network. It is a four-span bridge with 0.60 m thick circular arches separated by three piers with an average span length of 7.30 m, rises ranging from 3.37 m to 4.05 m. The arches are composed by regular volcanic ashlar; the spandrels, whose thickness is equal to 0.40 m, and the piers are made by rectangular shaped volcanic stones.

The railway has a 1.1% slope and a constant radius of curvature equal to 97.3 m and belongs to a single-track non-electrified non-standard railway line where the distance between the inner edges of the rails is 0.95 m allowing a maximum velocity of 35 km/h. In November 1984 an inspection of the structure revealed a severe crack pattern at the arch haunches due to settlements at the central pier, whose cause was attributed to the characteristics of the soil (sandy clay), and to an insufficient size of the foundations, Figure 2. Due to the findings of the inspection, the maximum velocity over the bridge was limited to 10 km/h, and a structural reinforcement was applied. The retrofitting solution included the introduction of a concrete layer at the intrados of the vaults confined by an external steel corrugated thick plate used as formworks. The new structure was founded on a new reinforced concrete enlargement of the existing masonry foundation.

Figure 1. Railway Maletto masonry arch bridge: pictures (a) of 1926 (Sergi 2019) and (b) 2014.

The bridge was further investigated in 2022 within a research project involving the University of Catania, as a consultant, the FCE and the private company Systemia. The main focus of the project is on the health monitoring of bridge by means of innovative sensor boxes (Ferritta et al. 2020). The campaign of research activities also included a detailed survey of the bridge with a Terrestrial Laser Scanning (TLS) and Unmanned Aerial Vehicle (UAV) techniques, and a geological risk assessment. The outcome of the mentioned activities included the

Figure 2. Crack pattern at the haunches of the arch evidenced during the inspection of 1984.

definition of a geometrical digital twin of the bridge by capturing digital images and applying photogrammetric processing technique (Garozzo et al. 2022), Figure 3, results here employed as a base to implement the numerical structural model of the bridge.

Figure 3. 3D point cloud of the Maletto Bridge.

3 DAMAGE SCENARIO AND NUMERICAL MODELING

Based on the geometrical survey of the bridge, a numerical model of the structure was implemented in a DMEM software environment HiStrA Bridge (Caliò et al. 2015). The adopted model, whose theoretical approach is described in references (Caddemi et al. 2017), is based on shear deformable spatial macro-element interacting with other elements through nonlinear zero-thickness interfaces embedding the membrane element deformability. In the model here adopted each element is governed by seven degrees of freedom only, associated to the six rigid body motion and a single additional degree of freedom associated to a shear deformability of the element with respect to a significant plane.

The computational model here implemented is characterized by 4844 shear deformable spatial elements and 238 rigid elements, Figure 4, with a total amount of 35336 degrees of freedom. Four different materials have been identified in the bridge, depicted with different colors in Figure 4, corresponding to the fill, the zero-thickness friction interfaces connecting the fill to the other components of the bridge, the stone volcanic arches and spandrel walls. The overall views of the different parts of the bridge and a legend associated to the different material are reported in Figure 4. The adopted mechanical properties, estimated according to realistic values for the adopted material typologies, are summarised in Table 1. The constitutive laws adopted for each structural element are specialized for the flexural, shear and sliding behavior. The arches and spandrel walls are characterized for the flexural behavior by a parabolic constitutive law in compression and exponential softening in traction; the shear-diagonal behavior is assumed elastic while the shear-sliding is ruled by a Mohr-Coulomb criteria. The fill is considered as elasto-plastic with almost zero tensile strength and membrane behavior lumped in the interfaces; an elasto-plastic constitutive law, associated with a Turnsek-Cacovic yielding

criteria, is adopted for the generalized shear diagonal behavior, at the macro-scale. The interaction of the fill with the arches and the spandrel walls are ruled by ad hoc interfaces with zero cohesion. All the adopted parameters are reported Table 1.

Figure 4. The implemented numerical model: exploded and overall views of the bridge.

Table 1. Mechanical parameters.

Material	E	G	f_c	f_{ct}	G_{fc}	G_{ft}	c	μ_c	τ_0	μ_τ	w
	MPa	MPa	MPa	MPa	N/mm	N/mm	MPa	-	MPa	-	kN/m ³

Fill	300	115	0.5	0.01	∞	∞	-	-	0.0005	-	18
Friction interfaces	300	115	1.0	0.01	∞	∞	0.0	0.6	-	-	-

where E = normal elastic modulus; G = shear elastic modulus; f_c = compressive strength; f_{ct} = tensile strength; G_{fc} = compressive fracture energy; G_{ft} = tensile fracture energy; c = sliding cohesion; μ_c = sliding friction ratio; τ_0 = diagonal shear strength; μ_τ = diagonal shear friction ratio; w = self-weight.

The piers are founded on elastic soil foundation whose normal flexibility k_n has been assumed equal to 12.75 kg/cm³ corresponding to a sandy clay soil.

To investigate the effect of the settlement of the soil on the nonlinear response of the superstructure, some numerical analyses have been conducted applying different levels of vertical settlement enforced on the central pier. Precisely, three-stage nonlinear static analyses are performed, including the following steps: i) application of the self-weight of the structure, ii) application of the settlement in the central pier, iii) incremental analyses till collapse associated with the operational load. For stage ii) four configurations have been considered corresponding to no settlement ($u=0.0$ m) and five magnitudes of the vertical settlements ($u=0.01$ m, $u=0.025$ m, $u=0.04$ m, $u=0.08$ m, $u=0.12$ m).

The operational load is evaluated according to the actual locomotive model currently in service in the FCE rail network, that is called ADe 21-25, Figure 5. The total weight of the vehicle

is 310 kN and the vertical load on each wheel axle is $Q_{vi}=38.75$ kN. Push-down analyses have been performed considering 5 different abscissae $x_i = \{2.00, 12.39, 22.25, 32.32, 43.26 \text{ m}\}$ of the loading scheme, corresponding to locating the centre of gravity of the locomotive in correspondence of the axes of the abutments and of the piers. The reference gravity and the operational loads have been magnified by coefficient equal to 1.35 and 1.45, respectively, according to the Italian regulation for ultimate limit state combinations (see tab. 5.2.V in D.M. 17.01.2018).

Figure 5. (a) Adopted locomotive ADe 21-25 for the evaluation of the operational loads and (b) corresponding scheme (measures expressed in m).

4 INFLUENCE OF SETTLEMENTS ON THE STRUCTURAL PERFORMANCE

The considered positions of the operational load and the adopted loading scheme are summarised in Figure 6, together with two positions of monitored displacement considered in the following.

Figure 6. Applied loads and positions of the operational load, base settlement u , monitored vertical displacements.

The results of the performed analyses are reported in terms of deformed shape and crack patterns at the end of the stages ii) and iii) of the analyses for a specific position of the operational load (x_2) in Figure 7. The reported configurations correspond to the configuration in absence of settlements (top), $u=0.04$ (middle) and $u=0.12$ m (bottom).

The results, expressed in terms of distribution of damage, show that the settlement of the central pier leads to a crack pattern consistent with that observed during the bridge inspection in 1984 and reported in Figure 2. In terms of collapse mechanism associated to the magnification of the operational load, all the models, with and without settlement, show the involvement of the second arch and the rotation of the central pier. A more pronounced rotation of the pier, partially involving the third arch, is shown for the configurations with settlement of the central pier with different extension associated to the settlement magnitude.

In Figure 8, the load-displacement curves are reported for the first two positions of the operational load associated with the different magnitude of settlements. As expected, for the second position, higher values of the vertical settlements lead to a loss of the capacity of the bridge. In the worst scenario, the bearing capacity is about 75% of that associated to the configuration in absence of settlements.

Unexpectedly, for the first position of the operational load higher values of the settlements lead to slightly higher load multipliers than in the absence of settlements. The latter circumstance could be due to the state of compression induced by the settlement in the first arch (the

Figure 7. Deformed shapes and damage patterns (a-b) in absence of settlements and with settlements $u=0.04\text{m}$ (c-d) and $u=0.12\text{m}$ (e-f): before (a, c, e) and after (b, d, f) the application of the operational load magnified until collapse.

part of the bridge mainly involved in the collapse mechanism), which slightly delays the development of damage.

It is also worth to mention that the considerable load multipliers are due to the low weight of the adopted locomotive (310 kN), currently operating on the line, if compared with the weight corresponding to the standard D4 operational load indicated in the UIC Code-700 (900 kN).

Figure 8. Load-displacement curves for all the analysed settlement configurations at positions (a) x_1 and (b) x_2 of the operational load: vertical displacement δ_1 and δ_2 at the crown of the vault respectively of the first and second arch (see Figure 7).

Finally, in Figure 9, the influence line reporting the abscissa x_1 of the centre G of the operational load versus the vertical bearing capacity of the bridge is reported for all the analysed configurations. Except for the first position of the operational load (which has been already discussed), in all the other cases the collapse load multiplier reduces as the magnitude of the vertical settlements increases (with a maximum reduction of 56% for the third position). Positions x_2 and x_4 of the operational load are associated to the lowest and highest load multipliers respectively (for settlements lower than 0.08 m), whereas for large settlements the weakest performance of the bridge occurs for position x_3 of the operational load. In absence of settlements the load multiplier ranges between 10.29 and 13.30, whereas for $u=0.12\text{m}$ it ranges between 5.56 and 12.44. The results highlight how the slope of the bridge, affecting the rise of the arches (ranging from 3.38 m of the first arch to 4.03 m), has a direct effect on the load capacity of the bridge, and the importance of an accurate geometry modelling of the bridge.

Figure 9. Bearing capacity of the bridge versus the abscissa x of the centre of gravity of the operational load.

5 CONCLUSIONS

In this study, a nonlinear numerical strategy based on a DMEM approach has been applied for the assessment, under operational loads, of a four span railway masonry arch bridge. The study required to upgrade the modelling strategy with respect to two aspects: i) allowing a more complex geometry accounting for a curved track with slope and ii) upgrading the non-linear static procedure analysis introducing the pier settlements after the application of gravitational loads and before the incremental operational load phase till collapse.

The Maletto railway bridge was numerically investigated considering different magnitudes of settlements of the central pier, which induce a loss of the bearing capacity of the bridge compromising the operational conditions of the line. The performed sensitivity analyses allowed to evaluate, for each position of the operational load, the influence of the settlement magnitude in the collapse mechanism and the load bearing capacity of the bridge. The role of the settlements in masonry arch bridges and the relevant effects on the structural performance have been also evaluated with the aim to associate the severity of the settlement to the structural performance of the bridge in view of the design of health monitoring system of masonry bridges and the definition of typical early warning thresholds to be considered in advanced monitoring systems taking into account also the possible occurrence of piers settlement.

ABSTRACT: The colossal impact of tsunamis has been responsible for a significant loss to coastal infrastructure world-wide. However, due to the sea-level rise effects, the life-cycle risk assessment associated with the cumulative loss becomes intractable since hazards due to tsunami are time-dependent. A more accurate life-cycle tsunami risk assessment is needed to enhance the disaster preparedness of coastal communities. This paper presents a framework for life-cycle risk assessment of coastal residential buildings subjected to tsunami under sea-level rise effects. Earthquake occurrences are predicted probabilistically using a Poisson process based on historical data. Time-variant sea-level rise hazard assessment is carried out based on various climate models considering the uncertainties of emission scenarios. Monte Carlo simulation-based tsunami hazard assessment is performed to estimate the tsunami hazard curves considering sea-level rise effects. With the fragility curve of building structures developed from historical tsunami damage data, the tsunami risk of coastal building is estimated based on tsunami hazard considering sea-level rise effects, fragility curve, and the unit loss of individual buildings. An illustrative example is presented by applying the proposed framework to several municipalities in Kochi Prefecture of Japan. The effects of sea-level rise and earthquake occurrence on the life-cycle risk are discussed.

1 INTRODUCTION

In the last two decades, tsunami disasters have severely affected the coastal infrastructure, including massive disaster waste and road network disruption (Akiyama et al., 2020). One notable instance was the 2011 Great East Japan earthquake that generated a massive tsunami and eradicated the coastal infrastructure of the Tohoku region. The loss was estimated at around 16.9 trillion yen, constituting one of the most expensive natural disasters in history (Kajitani et al., 2013). However, progressive sea-level rise due to climate change has become an uprising issue and is projected to cause not only coastal inundation but also the extension of future natural disasters such as tsunamis (Alhamid et al., 2022a). Therefore, the existing tsunami risk assessment should be improved by considering the effects of sea-level rise to enhance the disaster preparedness of coastal communities.

Life-cycle risk assessments have been widely implemented as a basis for evaluating the socio-economic impact of natural disasters over the lifetime of an infrastructure (Mechler, 2016). For instance, De Risi et al. (2018) performed a life-cycle cost assessment of urban areas under flood risk in developing countries. Furthermore, since the number of earthquake arrival times is the governing variable in determining the cumulative monetary loss, Pandey & van der Weide (2018) presented a life-cycle cost assessment of seismic damage based on a compound Poisson process. Nevertheless, these studies have not integrated the nonstationary sea-level rise effects on the life-cycle tsunami risk assessment.

Due to the nonstationary sea-level rise effects, the tsunami hazard and risk become time dependent. In addition, the number of earthquake arrivals and their corresponding arrival times are of great importance in the life-cycle tsunami risk assessment (Sepúlveda et al., 2021, Alhamid et al., 2022b). Therefore, a more comprehensive life-cycle tsunami risk assessment that considers the abovementioned aspects should be established to promote a more accurate assessment of potential infrastructure loss due to tsunamis.

This paper presents a framework for life-cycle risk assessment of coastal residential buildings subjected to tsunamis under sea-level rise effects. Probabilistic earthquake occurrences are developed based on historical data under a Poisson process. On the other hand, time-variant sea-level rise hazard assessment is carried out based on various climate models considering the uncertainties of emission scenarios. Monte Carlo simulation-based tsunami hazard assessment is employed to estimate the tsunami hazard curves considering sea-level rise effects. With the fragility curve of building structures developed from historical tsunami damage data, the tsunami risk of a coastal building is estimated based on tsunami hazard considering sea-level rise effects, fragility curve, and the unit loss of individual buildings. An illustrative example is presented by applying the proposed framework to several municipalities in Kochi Prefecture of Japan. The effects of sea-level rise and earthquake occurrence on the life-cycle risk are discussed.

2 BASIC PROCEDURE FOR LIFE-CYCLE TSUNAMI RISK UNDER SEA-LEVEL RISE

The procedure for life-cycle tsunami risk assessment considering nonstationary sea-level rise effects mainly comprises probabilistic earthquake occurrence modeling, tsunami hazard assessment considering sea-level rise effects, fragility assessment, and risk assessment. In addition, the structural types, location, and failure probability of the corresponding structures are integrated with the aid of the Geographic Information System (GIS). A compound renewal theory (Alhamid et al. 2022b) is developed to consider the effects of nonstationary sea-level rise in the life-cycle tsunami risk assessment. The flowchart for estimating the life-cycle tsunami risk of a building portfolio, including the overview of the MCS-based numerical solution associated with the compound renewal process, is presented in Figure 1.

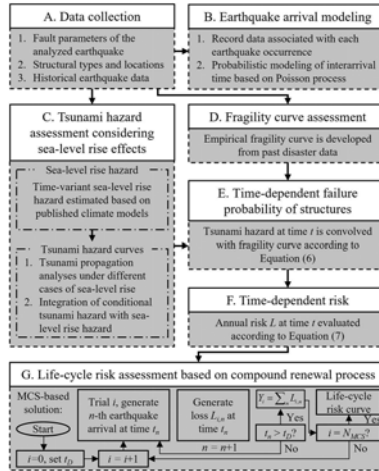

Figure 1. Procedure for life-cycle tsunami risk assessment of building portfolio under nonstationary sea-level rise effects.

2.1 Probabilistic earthquake arrival modeling

The probabilistic earthquake occurrence can be developed by inferring the statistics associated with the interarrival times from the historical record data of the corresponding analyzed

earthquake. A key parameter from the statistical inference is the mean annual rate of occurrence of tsunamigenic earthquakes (hereafter denoted as λ). Various probabilistic models of natural disasters can be developed based on the mean recurrence rate. Specifically, the Poisson process has been widely adopted, where each event is assumed to occur randomly in time and independently of each other. Under the Poisson point process, the interarrival time of the earthquake event is described as an exponential distribution with a generic form:

$$f_W(t) = \lambda e^{-\lambda t} \quad (1)$$

where W is the random variable associated with the interarrival time of the earthquake event.

2.2 Time-variant sea-level rise hazard assessment

The nonstationary sea-level rise hazard assessment has been reported in Alhamid et al. (2022a) and is briefly presented herein. The regional sea-level rise hazard at time t is estimated by multiplying each global mean sea-level rise component with its corresponding spatial variability and can be expressed as (Alhamid et al. 2022a):

$$\begin{aligned} \psi(\mathbf{x}_r, t) &= FG_{STR}(\mathbf{x}_r) \cdot S(\mathbf{x}_r, t) + FG_{GLA}(\mathbf{x}_r) \cdot G(\mathbf{x}_r, t) + FG_{ICS}(\mathbf{x}_r) \cdot I(\mathbf{x}_r, t) \\ &= \omega(\mathbf{x}_r, t) + \zeta(\mathbf{x}_r, t) + \eta(\mathbf{x}_r, t) \end{aligned} \quad (2)$$

where $\psi(\mathbf{x}_r, t)$ is the total regional sea-level rise value at time t and coordinate vector \mathbf{x}_r of the corresponding analyzed fault, $FG_{STR}(\mathbf{x}_r)$, $FG_{GLA}(\mathbf{x}_r)$, and $FG_{ICS}(\mathbf{x}_r)$ are the sea-level spatial variability associated with sterodynamic, glacier, and ice-sheet sea-level rise, respectively, $G(t)$ and $I(t)$ are the global mean glacier and ice sheet sea-level rises at time t , respectively, $S(\mathbf{x}_r, t)$ is the sterodynamic sea-level rise, $\omega(\mathbf{x}_r, t)$, $\zeta(\mathbf{x}_r, t)$, and $\eta(\mathbf{x}_r, t)$ are the total, sterodynamic, glacier, and ice sheet regional sea-level rise values, respectively.

The cumulative distribution function (CDF) of each regional sea-level rise component described in Equation (2) can be developed from statistical analysis of the published climate models, as described in Alhamid et al. (2022a). Considering the emission scenarios (i.e., Representative Concentration Pathways (RCPs)), the CDF of total regional sea-level rise hazard can be expressed as (Alhamid et al. 2022b):

$$F_\psi(\psi(\mathbf{x}_r, t)) = 1 - \int_0^\psi \sum_{RCP=1}^4 \left[\iint_{\Omega_{G,I}} f_{SGI}(\omega(\mathbf{x}_r, t), \zeta(\mathbf{x}_r, t), \eta(\mathbf{x}_r, t) | \Pi_{RCP}) d\zeta d\eta \right] \cdot P(\Pi_{RCP}) d\psi \quad (3)$$

where $F_\psi(\psi(\mathbf{x}_r, t))$ is the CDF of the regional total sea-level rise, $f_{SGI}(\omega(\mathbf{x}_r, t), \zeta(\mathbf{x}_r, t), \eta(\mathbf{x}_r, t) | \Pi_{RCP})$ is the multivariate probability distribution based on sterodynamic, glacier, and ice sheet sea-level rises given climate change scenario Π_{RCP} , where Π_1 , Π_2 , Π_3 , and Π_4 correspond to RCP 2.6, RCP 4.5, RCP 6.0, and RCP 8.5, respectively, $\Omega_{G,I}$ is the joint domain of integration for regional glacier sea-level rise ζ and ice sheet sea-level rise η , and $P(\Pi_{RCP})$ is the occurrence probability of climate change emission scenario Π_n , where $P(\Pi_{RCP}) = 1/4$ is assumed.

2.3 Tsunami hazard assessment considering nonstationary sea-level rise effects

The tsunami hazard curve considering sea-level rise effects is evaluated by performing tsunami propagation analyses under several sea-level rise cases. The fault movement models and their associated parameters (i.e., average stress drop and rake angle) adopted from the Cabinet Office Government of Japan (2012) and Ishibashi et al. (2021) are employed in the surface deformation formula developed by Okada (1986) to generate initial tsunami heights. Sea-level rise effects are taken into account by modifying the bathymetry and roughness coefficient data prior to the propagation analyses. Based on the tsunami's initial height and sea-level rise model, 2D tsunami propagation simulations are performed according to the nonlinear long-wave theory for each case of sea-level rise.

To reduce computational time, Radial Basis Function (RBF) network surrogate model is constructed to develop the relationship between tsunami inundation depth and its corresponding fault parameters. The conditional tsunami hazard curve given a specific sea-level rise is evaluated based on the constructed surrogate model and fault movement uncertainties via MCS. The details of the RBF network model and its validation of the conventional MCS-based tsunami hazard assessment can be found in Alhamid et al. (2022a). Finally, the tsunami hazard curve considering sea-level rise effects is estimated according to the total probability theorem as (Alhamid et al. 2022a):

$$F_{H(\mathbf{x}_r, t)}(h) = \int_0^\infty \left\{ F_{H|\Psi}(h|\psi(\mathbf{x}_r, t)) \cdot \left| -\frac{dF_\Psi(\psi(\mathbf{x}_r, t))}{d\psi} \right| \right\} d\psi \quad (4)$$

where $F_{H(\mathbf{x}_r, t)}(h)$ is the tsunami CDF considering sea-level rise effects over the analyzed target earthquake fault \mathbf{x}_r at time t , and $F_{H|\Psi}(h|\psi(\mathbf{x}_r, t))$ is the conditional tsunami CDF given sea-level rise intensity over the analyzed target earthquake fault \mathbf{x}_r at time t equals ψ . The tsunami hazard described in Equation (4) is utilized to evaluate the time-dependent reliability and risk of structures.

2.4 Fragility assessment of individual structures subjected to tsunami

The fragility of an individual structure subjected to tsunamis can be evaluated from an analytical or empirical approach. This study adopts the empirical fragility curve from De Risi et al. (2017) to reflect realistic post-earthquake conditions. In addition, the fragility curve has considered the prior damage due to seismic and has been used for risk assessment in Japan (Goda, 2020).

By approximating the fragility curve as a lognormal distribution, the probability of a structure jb with structural type st having damage state ds_q given a tsunami inundation depth h (i.e., $P_{jb(st)}(DS = ds_q | H = h)$) can be expressed as:

$$P_{jb(st)}(DS = ds_q | H = h) = \Phi \left[\frac{\ln h - \ln(\nu_{t,q}(st))}{\sigma_{t,q}(st)} \right] \quad (5)$$

where ds_q with $q = 1, 2,$ and 3 correspond to none, moderate, and complete damage state, respectively, $\Phi(\cdot)$ denotes the CDF of the standard normal distribution and $\nu_{t,q}(st)$ and $\sigma_{t,q}(st)$ are the mean and standard deviation of the tsunami fragility curve associated with damage state q and structural type st , respectively. For illustrative purposes, two structural types, wooden and nonwooden structures, are considered and denoted as $st = 1$ and $st = 2$, respectively. The fragility curves for each structural type are presented in Figure 2. It should be noted that the nonwooden structures' fragility adopted herein is equivalent to the concrete fragility in De Risi et al. (2017).

Figure 2. Tsunami fragility curves for building structures (adapted from De Risi et al. 2017).

2.5 Time-dependent failure probability of structures

The failure probability of an individual structure is calculated by convolving the tsunami hazard with the fragility curve. However, due to the nonstationary sea-level rise effects, the failure probability of an individual structure is no longer constant and becomes time-dependent. The time-dependent failure probability of structure jb with structural type st can be evaluated as:

$$P_{jb(st)}(DS = ds_q, T = t) = \int_0^\infty \left\{ P_{jb(st)}(DS = ds_q | H = h) \cdot \left| -\frac{dF_{H(x_r, t)}(h)}{dh} \right| \right\} dh \quad (6)$$

Based on the time-dependent failure probability described in Equation (6), the life-cycle risk of building portfolios under nonstationary sea-level rise effects is developed according to a compound renewal process.

2.6 Life-cycle risk assessment based on a compound renewal process

Due to the effects of sea-level rise, the distribution associated with annual risk becomes conditionally dependent on the earthquake arrival time. The procedure for life-cycle risk assessment under such nonstationary conditions is developed herein.

The direct economic loss L incurred by a building portfolio due to a single earthquake at a particular time t can be expressed as:

$$L(t) = \sum_{st=1}^{nst} \sum_{jb=1}^{njb(st)} \sum_{q=1}^3 P_{jb(st)}(DS = ds_q, T = t) \cdot R_{Ljb(st)}(ds_q) \cdot C_{Rjb(st)} \cdot A_{jb(st)} \cdot g_{DR}(r, t) \quad (7)$$

where $njb(st)$ is the total number of buildings of structural type st , nst is the total number of structural types considered ($nst = 2$), $R_{Ljb(st)}(ds_q)$ is the loss ratio of the damage state q for building structure $jb(st)$, $C_{Rjb(st)}$ is the unit replacement cost of building structure $jb(st)$ per unit area depending on the structural type st , $A_{jb(st)}$ is the floor area associated with structure $jb(st)$, $g_{DR}(r, t)$ is the discounting function to convert loss at time t into net present worth with discount rate r . The building loss ratios $R_{Ljb(st)}(ds_q)$ is assigned as 0.0, 0.3, and 1.0 for none, moderate, and complete damage, respectively, following Goda (2020).

In this study, the structures are assumed to be restored to those in the pre-hazard stage after each earthquake. Furthermore, let T_n describe the earthquake's n -th arrival time, such that $T_n = W_1 + W_2 + \dots + W_n$. The interarrival time W_i is assumed to be an independent and identically distributed random variable with PDF described in Equation (1). Furthermore, let $Y(t_D)$ represents the cumulative economic loss resulting from all possible earthquake occurrences from the last earthquake occurrence until an analyzed time t_D . Therefore, the probability of cumulative economic loss $Y(t_D)$ exceeding a value y can be expressed as:

$$P(Y(t_D) > y) = P(L(t_1) + \dots + L(t_n) > y | \mathbf{T} = \mathbf{t}) \cdot P(\mathbf{T} = \mathbf{t}) \quad (8)$$

$$P(L(t_1) + \dots + L(t_n) > y | \mathbf{T} = \mathbf{t}) = 1 - \int_0^\infty \dots \int_0^\infty \left\{ f_{L_1 | T_1} \left(\left[y - \sum_{a=2}^n l_a \right] | t_1 \right) \cdot \prod_{b=2}^n f_{L_b | T_b}(l_b | t_b) \right\} dl_1 \dots dl_n \quad (9)$$

where $\mathbf{T} = \{T_1, T_2, \dots, T_n\}^T$ represents the combination of random variables associated with arrival time with a value of $\mathbf{t} = \{t_1, t_2, \dots, t_n\}^T$, and $f_{L | T}(l | t)$ is the conditional PDF of economic loss L with a value l given $T = t$.

The term $P(\mathbf{T} = \mathbf{t})$ in Equation (8) represents the joint probability distribution of arrival time, which can be defined according to Jung (1963) as:

$$P(\mathbf{T} = \mathbf{t}) = \lambda^n e^{-\lambda t_D} dt_1 dt_2 \dots dt_n \quad (10)$$

As shown in Equations (8) to (10), the cumulative economic loss $Y(t_D)$ depends on the number of earthquake occurrences n and arrival time T , where both variables are substantially uncertain. To circumvent this difficulty, an MCS procedure is proposed and employed to carry out the life-cycle risk assessment, as presented in Figure 3. A case study is provided in the following subsection to illustrate the effectiveness of the proposed framework.

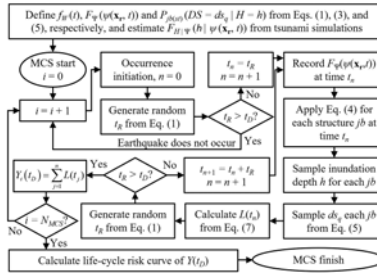

Figure 3. MCS procedure to estimate life-cycle tsunami risk of building portfolio under nonstationary sea-level rise effects based on the compound renewal process.

3 ILLUSTRATIVE EXAMPLE

As an illustrative example, the framework is implemented for building portfolios in Kochi Prefecture of Japan subjected to the anticipated Nankai Trough earthquake, namely Kochi and Kounan cities. The analyzed municipalities and their corresponding building population are shown in Figure 4.

Figure 4. (a) Location of Kochi Prefecture and the Nankai Trough fault movement, and (b) location of the analyzed municipalities and the corresponding building population.

3.1 Tsunami hazard assessment considering nonstationary sea-level rise effects

To estimate the inclusive tsunami hazard curve considering sea-level rise effects, sea-level rise hazard information over the analyzed earthquake is necessary. The time-variant sea-level rise hazard curve evaluated over the Nankai Trough earthquake is adopted from Alhamid et al. (2022b) and shown in Figure 5.

Tsunami propagation analyses are carried out using 15 tsunami fault movements from Ishibashi et al. (2021) considering the uncertainties associated with average stress drop and rake angle. The average stress drop is modeled as a lognormal distribution with a mean and standard deviation of 1.2 and 1.0 MPa, respectively, truncated at 3.0 MPa. As for the rake angle, a normal distribution is assumed with a mean and standard deviation of 0° and 10°, respectively. To convert the fault parameters into slip dislocation for initial tsunami height, the following formula is used (Alhamid et al. 2020a):

$$D_f = \frac{16(\Delta\sigma)S_f^{0.5}}{f_R \cdot 7\pi^{1.5}} \quad (11)$$

where D_f is the slip dislocation, $\Delta\sigma$ is the average stress drop, S_f is the fault area, and f_R is the fault rigidity.

The tsunami propagation analyses are performed based on the RBF network surrogate model described in Alhamid et al. (2022b). Based on the RBF network, the conditional tsunami hazard curve is evaluated and convolved with sea-level rise hazard according to Equation (4) to obtain the tsunami hazard curve considering sea-level rise effects.

Figure 5(a) and (b) show the tsunami propagation analysis results in Kochi and Kounan cities for average stress drop and rake angle of 2 MPa and 10°, respectively, under 0.6 meters

of sea-level rise. The tsunami intensity is greater in Kounan city, while Kochi city shows a higher inundation area due to lower topography. Therefore, the tsunami impacts considerably depend on the geographical characteristics of the analyzed municipalities. To develop the tsunami hazard considering sea-level rise effects, the sea-level rise hazard over the Nankai Trough fault movement is evaluated following the procedure in Alhamid et al. (2022a) and is shown in Figure 5(c).

Figure 5(d) shows the tsunami hazard curve for the analyzed cities assuming that the anticipated Nankai Trough earthquake will occur in 2022 and 2100. Due to the effects of sea-level rise, the tsunami hazard curves for both analyzed cities are exacerbated.

Figure 5. (a) Tsunami inundation map in Kochi city, (b) Tsunami inundation map in Kounan city, (c) Sea-level rise hazard evaluated over the Nankai Trough fault movement (Alhamid et al., 2020b), and (d) Tsunami hazard evaluated in the analyzed grid.

3.2 Life-cycle tsunami risk of building portfolio under nonstationary sea-level rise effects

The life-cycle tsunami risk is assessed according to the procedure described in Figure 3. In this study, the replacement cost $C_{R/b(st)}$ is assumed as 160,000 JPY/m² and 150,000 JPY/m² for wooden and nonwooden structures, respectively (Goda, 2020). For illustrative purposes, a discount rate of 0.3% is assumed. In addition, building structures in the same tsunami grid cell depicted in Figure 5 are assumed to be under the same tsunami hazard and share the same failure probability.

Figure 6 shows the life-cycle tsunami risk of building portfolios in the analyzed municipalities, assuming a Poisson process of earthquake occurrence with a mean recurrence interval of 117 years/event. With an exceedance probability of more than 0.2, the risk associated with cumulative loss in Kounan city is higher than that in Kochi. However, the risk in Kochi city increases and exceeds that of Kounan when the exceedance probability is lower than 0.2. Comparing this result to previous tsunami disasters such as the 2011 Great East Japan earthquake, Nankai Trough earthquake is expected to cause a more significant loss when other affected cities are accounted.

According to the results presented in Figure 6, when the effects of sea-level rise are considered, the tsunami risk in Kochi city is consistently higher than in Kounan city for all exceedance probabilities. Therefore, considering sea-level rise is imperative to enhance the accuracy of life-cycle tsunami risk assessment and improve disaster preparedness for coastal communities.

Figure 6. Life-cycle tsunami risk of building portfolios in the analyzed cities under the Poisson process.

4 CONCLUSIONS

The following conclusions are drawn:

1. A framework for estimating the life-cycle tsunami risk of building portfolios under nonstationary sea-level rise effects is established. The framework systematically considers the uncertainties associated with the number of earthquake occurrences and their arrival time.
2. An MCS-based compound renewal process is proposed to integrate the nonstationary sea-level rise effects with cumulative economic loss assessment. Based on the MCS numerical solution, the proposed framework promotes a better risk information decision by enabling the estimation of the risk curve of cumulative loss.
3. Sea-level rise affects the life-cycle tsunami risk of the analyzed municipalities differently depending on the associated geographical characteristics. Nevertheless, the life-cycle tsunami risks substantially increase when considering sea-level rise effects.

To enhance the life-cycle tsunami risk assessment, future studies should try to develop a more realistic model of earthquake occurrence such as the non-Poisson model and consider various mean recurrence intervals of earthquake occurrence.

Life-cycle design of concrete highway bridge decks under climate change

H. Shirkhani, Z. Lounis & J. Zhang

National Research Council of Canada, Ottawa, ON, Canada

ABSTRACT: Chloride-induced corrosion is the main deterioration mechanism that governs the service life design of many concrete structures such as concrete bridge decks in Canada. The annual average surface air temperature over Canada has warmed historically and is projected to rise approximately twice the global average due to climate change. The temperature increase will lead to an increase in the probability of corrosion initiation of reinforcing steel and a shortening of service life of concrete structures. Current approaches for life cycle design of concrete bridge decks do not consider the impact of climate change. A probabilistic and mechanistic approach is proposed and demonstrated through an illustrative test case to assess the impact of climate change on life cycle design of concrete bridge decks exposed to corrosive environments. The time-dependent probability of corrosion was found to increase with temperature. In corrosive environments, corrosion-resistant steel reinforcement and high performance concrete can be used to reduce the corrosion probability significantly in the changing climate.

1 INTRODUCTION

Infrastructure systems, such as bridges, are critical to the social welfare, growth of the economy and protection of the environment. Bridge systems in North America are aging and deteriorating which can be exacerbated by climate change. Corrosion is one of the most costly deteriorating mechanisms and causes the most widespread damage in reinforced concrete (RC) and steel bridges, particularly in regions with harsh winters that require the use of road de-icing salts. The Federal Highway Administration (FHWA, 2002) estimated the annual direct cost of corrosion of highway bridges in the U.S. at \$8.3 billion and consisting of \$3.8 billion to replace structurally deficient bridges over ten years. In particular, climate change can also exacerbate the RC infrastructure corrosion-induced deterioration. Corrosion processes are known to be temperature dependent. For instance, RC samples can experience higher rates of corrosion at increasing temperatures (Guest et al., 2020). Moreover, the increasing ambient temperature will reduce the chloride threshold of reinforced concrete (Zhang et al., 2018; Shirkhani et al., 2020). Therefore, it is essential to consider the climate change impacts in the design of RC structures against corrosion.

Development of methodologies for the prediction of service life of RC bridge decks built in corrosive environments and subjected to changing climate is therefore of great importance. These methodologies can help with the effective design and management of bridge infrastructure through reducing the risk of failure and extending the service life. A comprehensive model for the estimation of the service life of RC bridge decks may include various stages of corrosion. However, many important RC infrastructures consider the corrosion initiation time as the design service life, which conservatively assumes the initiation of corrosion as the limit state (Zhang and Lounis 2006 and 2009; Sudret et al., 2008). In addition, there are different approaches for the assessment of the probability of failure of infrastructure systems and components. Some of these approaches, such as Markovian-based models require limited amount of data on the condition of the infrastructure. These approaches rely on statistical deterioration modelling methods that use historical data to predict the future deterioration of bridges (e.g. see Roelfstra et al. 2004; Agrawal, et al. 2010). The main drawbacks of these

models include dependency on the availability, quality, and applicability of historical data as well as lack of consideration of ambient climatic conditions and de-icing agent applications.

On the other hand, mechanistic and probabilistic approaches require more data on loads, material properties, and ambient climatic conditions as well as the uncertainties in the governing parameters and models (Lounis and Daigle, 2008; and Lounis and McAllister, 2016). Considering the physical corrosion processes, mechanistic models allow for the simulation of bridge deck deterioration over time, which makes these models an appropriate choice for considering the effects of climate change.

Most of the current approaches for service life design are based on prescriptive requirements regarding the minimum concrete cover depth, maximum water/cement ratio, etc. Current prescriptive requirements and inadequate design and maintenance have led to a large number of structurally and /or functionally deficient concrete infrastructures in North America, including highway bridges. In addition, between 1948 and 2016, the best estimate of mean annual temperature increase is 1.7°C for Canada, and depending on the level of greenhouse gas (GHG) emissions, the average temperatures in Canada are expected to rise by an additional 1.5 to 6.3°C by 2100, which is approximately twice the global average (Bush and Lemmon, 2019). It is expected that increases in temperatures will lead to increases in the diffusion coefficients and reductions in the chloride threshold levels, which in turn will lead to reduced service life of concrete infrastructures built in corrosive environments (Zhang et al. 2018). On the other hand, the increase in temperature may lead to a reduction of the surface chloride concentration due to a reduction in the use of de-icing salts during winter in some regions in North America, which is not considered in this study.

Previous research studied the service life design of RC bridge decks. Zhang and Lounis (2009) presented a performance-based approach for the service life design of RC structures by analyzing the relationships and sensitivity of four design parameters that govern the time to corrosion initiation of reinforced concrete structures built in chloride-laden environments. However, the literature lacks studies on climate change impacts on the corrosion of RC structures. Wang et al. (2010a,b) studied the impacts of climate change on the corrosion of concrete structures by taking into account the change of CO₂ concentration in the atmosphere and the temperature effect on the diffusion of chlorides into concrete. Shirkhani et al. (2020) studied the impact of temperature rise on the design service life of concrete bridge decks under different climate change conditions in different regions of Canada. Guest et al. (2020) developed a bridge deck design model by simulating three deterioration stages of concrete bridge decks, including the initiation of steel corrosion, the generation of concrete cracks, and the propagation of cracks.

In this paper, a probabilistic-mechanistic approach is used to assess the impact of climate change on life cycle performance of RC bridge decks in corrosive environments. Chloride-induced corrosion is the main deterioration mechanism that is assumed to govern the service life of RC bridge decks. The Monte Carlo approach together with a chloride diffusion-based model are used to determine the probability of corrosion initiation of steel reinforcement, which is assumed as the design service life of RC bridge decks. This assumption is adequate for critical concrete infrastructures such as RC bridge decks, while for other structures the service life can be assumed the sum of the corrosion initiation time and a corrosion propagation time such as time to cracking, spalling, or delamination. The proposed methodology can help achieve a long service life and minimize the risk of failure of RC bridge decks, including the minimization of the risk of capacity and/or functionality loss due to excessive deterioration. In this paper, the focus is on the probabilistic modeling of the service life and durability design of concrete infrastructures subjected to corrosion from de-icing salts and climate change-induced temperature rise.

2 METHODOLOGY

2.1 Corrosion model

The corrosion of concrete structures is a two-stage process that includes a corrosion initiation stage and a corrosion propagation stage (Tuutti 1982). In this study, the service life is defined as the time to the onset of corrosion of bridge decks exposed to chlorides. Equation 1 shows a simplified diffusion-based model that is implemented to estimate the time variation of chloride ingress into concrete using Crank's (1975) solution of Fick's second law of diffusion:

$$C(x, t) = C_s \left[1 - \operatorname{erf} \left(\frac{x}{2\sqrt{Dt}} \right) \right] \quad (1)$$

where $C(x, t)$ is the chloride concentration at depth x (cm) after time t (year), D is the chloride diffusivity (cm^2/year) corresponding to the type of the concrete, C_s is the surface chloride concentration (kg/m^3), which is a measure of the environmental corrosion load applied on the RC structure, and erf is the error function. The time to the onset of corrosion (t_i) is defined as when the chloride concentration C at the rebar level (i.e. $x=d_c$ the concrete cover depth) exceeds the rebar chloride threshold (C_{th}), which depends on the type of the reinforcing steel and its resistance to chloride ions.

It should be noted that uncertainties are associated with the parameters in the model. For instance, the concrete chloride diffusivity (D) is not a constant but rather depends on time, temperature, and depth. Moreover, the chloride threshold value of the rebar (C_{th}) is reported with a considerable scatter in the literature, and the level of uncertainty of the concrete cover depth (d_c) depends on the quality of construction. In addition, the surface chloride concentration (C_s) is subjected to a continually changing chloride exposure. Given the level of uncertainties and the stochastic nature of the problem, we will consider these uncertainties through the application of a probabilistic approach, which will be explained in the following section.

2.2 Impact of temperature on time to corrosion initiation

Temperature can directly affect the oxidation and reduction rates in corrosion as an electrochemical process, and it also affects the diffusion of chlorides in the concrete. The dependence of the chloride diffusion coefficient on temperature is given by the following Arrhenius relationship (Saetta et al. 1993):

$$D_T = D_{T_0} e^{\frac{E_a - D}{R} \left(\frac{1}{T_0 + 273.16} - \frac{1}{T + 273.16} \right)} \quad (2)$$

where D_T is a function of temperature T ($^{\circ}\text{C}$) and D_{T_0} is the reference chloride diffusion coefficient at the reference temperature T_0 , with R being the gas constant ($R=8.314 \times 10^{-3}$ kJ/mol). There is considerable uncertainty associated with the estimation of the chloride diffusion coefficient. It was shown by Zhang et al. (2018) that the mean value of D can be considered to be $0.32 \text{ cm}^2/\text{year}$ for high performance concrete (HPC) and $2.52 \text{ cm}^2/\text{year}$ for normal performance concrete (NPC), with corresponding activation energy values of $E_a - D = 47$ and 30 KJ/mol, respectively.

As Equation 2 shows, the chloride diffusion coefficient varies with temperature. We consider the temperature rise of ΔT , which indicates the difference between the temperature in the future (T_{fut}) and baseline (T_{base}) time periods due to climate change. The relative change in the chloride diffusion coefficient due to the temperature rise can be then estimated from Equation 3:

$$\frac{D_{fut}}{D_{base}} = \exp \left[\frac{E_a - D}{R} \left(\frac{1}{T_{base}} - \frac{1}{T_{fut}} \right) \right] \quad (3)$$

With the temperature-dependence assumption of the corrosion rate and following the Arrhenius law, the chloride threshold value can be assumed inversely proportional to the corrosion reaction rates and follows thus inversely the Arrhenius law with temperature. Temperature can also affect the rebar chloride threshold value in a different way through concrete chemistry. With a rising temperature, the chloride threshold value is reduced due to the release of more chloride ions from concrete with higher temperatures, and at the same time by accelerated corrosion reactions. These two mechanisms can be assumed independent of each other, and the chloride threshold values with temperature is thus expressed as follows (Zhang et al., 2018; Shirkhani et al., 2020):

$$C_{th-T} = C_{th-T_0} \exp \left[\frac{(E_{Cl-concr} + E_{Cl-steel})}{R} \left(\frac{1}{T} - \frac{1}{T_0} \right) \right] \quad (4)$$

where (C_{th-T_0}) is the chloride threshold value at the reference temperature T_0 , and $E_{Cl-concr}$ and $E_{Cl-steel}$ are the activation energy for release of free chlorides and the rebar activation energy, respectively. The above analysis is based on the assumption that the chloride threshold value of rebar decreases with temperature following the inverse of the Arrhenius law based on very limited available studies. The activation energy value can range from 22 to 48 KJ/mol depending on the mechanisms.

Similar to the chloride diffusion coefficient, Equation 4 can be used to estimate the relative change in the chloride threshold value due to temperature rise as follows:

$$\frac{C_{thfut}}{C_{thbase}} = \exp\left[\frac{(E_{Cl-concr} + E_{Cl-steel})}{R}\left(\frac{1}{T_{fut}} - \frac{1}{T_{base}}\right)\right] \quad (5)$$

As Equations 2 to 5 show, the time to corrosion initiation is a function of temperature. Therefore, the temperature variation within the future periods under climate change will lead to deviations of the design service life from the indented design service life obtained under historical climatic conditions.

2.3 Life cycle performance prediction model

In this paper, the time to corrosion initiation is assumed as the service life of RC bridge decks. As discussed above, the values of chloride concentration at the rebar level and the rebar chloride threshold are not deterministic parameters but are associated with high levels of uncertainty. The chloride concentration at the rebar level is a random variable which depends on several uncertain parameters including the chloride diffusion coefficient, and concrete cover depth. The uncertainty in these parameters can be reflected through assuming a specific type of statistical distribution (e.g. normal, lognormal, gamma, Weibull, uniform, etc.), which can be obtained from field measurements, experience or literature.

Given the uncertainty in the performance model parameters, we formulate the model to estimate the probability that the chloride concentration at the reinforcing steel level is higher than the chloride threshold level i.e. $P[C(d_c, t) > C_{th}]$ as a probabilistic problem. This probability represents a realistic measure of the probability of corrosion of RC bridge decks, which can be expressed as:

$$P_{cor}(t) = P[C(d_c, t) > C_{th}] \quad (6)$$

Assume that both $C(d_c, t)$ and C_{th} are independent random variables with probability density functions (pdf) $f_C(d_c, t)$ and $f_{C_{th}}(c_{th})$ and cumulative distributive functions (cdf) $F_C(d_c, t)$ and $F_{C_{th}}(c_{th})$, respectively. Then, the probability of corrosion at time t , can be determined as follows:

$$P_{cor} = \int_0^{\infty} F_{C_{th}}(x) f_{C(d_c, t)} dx \quad (7)$$

We employ the Monte Carlo method in order to compute the probability of corrosion over the corrosion domain. In this method, we identify first the parameters and variables in Equation 7 that are considered as random variables. Then, a distribution will be assigned to each parameter. We then generate inputs randomly from a probability distribution over the domain and perform a deterministic computation and aggregate the results to determine to the probability of corrosion.

3 TEMPERATURE RISE UNDER CLIMATE CHANGE

Since 1950, the annual average surface air temperature over Canada's landmass has warmed by 1.7°C, and average temperatures in Canada are expected to rise by an additional 1.5°C to 4.5°C by 2070, which is approximately twice the global average (Bush and Lemmen, 2019). The rate of warming is even higher in Northern Canada.

The projected annual mean temperature change across Canada is presented in the Canadian Climate Change Report (Bush and Lemmen, 2019). Both low (RCP 2.6) and high (RCP8.5) emission scenarios are considered with two time periods of: (i) near term (2031–2050) – when differences in emission scenarios are modest; and (ii) the late century (2081–2100) – when climatic

responses to the low and high emission scenarios will have diverged considerably – are selected and the changes are estimated relative to the baseline period of 1986–2005 (see Figure 1).

As it can be seen, all regions across Canada are warming under both low and high emission scenarios with enhanced warming at higher latitudes. In the near term (2031–2050), the differences between the low and the high emission scenarios are in the order of 0.5°C to 1°C and not significant. However, for the late century (2081–2100), the differences become very large. For instance, for Canada as a whole the projected temperature increases are roughly 4°C higher under the high emission scenario while regional temperature increase can be as high as 11 °C.

4 ILLUSTRATIVE TEST CASE

We consider a bridge deck located in Ottawa, Ontario with a deck thickness of 225 mm and reinforced with isotropic reinforcement with a percentage of 0.3% for both top and bottom layers in both longitudinal and transverse directions.

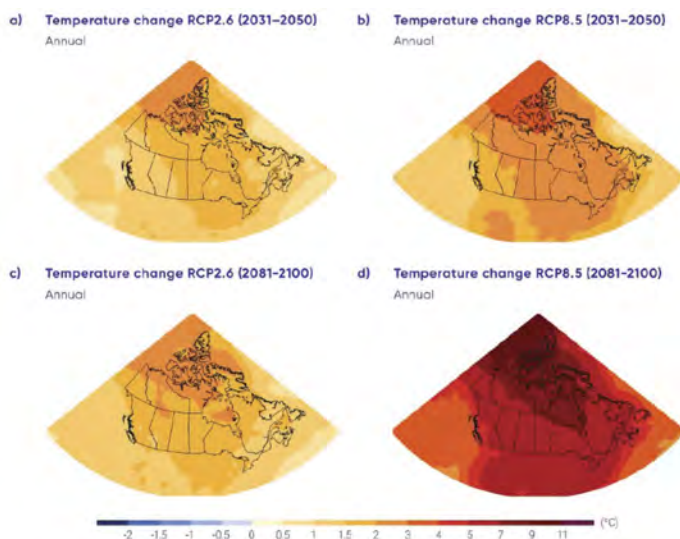

Figure 1. Projected annual mean temperature change (°C) relative to 1986–2005 for the 2031–2050 (top) and 2081–2100 (bottom) periods under RCP2.6 (left) and RCP8.5 (right) [Bush and Lemmen, 2019].

We assume a baseline scenario together with three future scenarios considering temperature increase of $\Delta T = 2, 4$ and 6°C , which can be achieved under low and high emission scenarios in southern Canada. The average annual temperature for the baseline scenario is estimated using the Environment and Climate Change Canada historical climatic data for the period of 1986–2005 for Ottawa, Canada ($T_{\text{base}}=6.3^\circ\text{C}$). Then, for each parameter in Equation 1, we assume the distribution type and its corresponding mean and coefficient of variation. For instance, for the high performance concrete in the baseline scenario, we set the mean value of the diffusion coefficient as $0.20\text{ cm}^2/\text{year}$ with a coefficient of variation of 25% (Lounis and Daigle 2008). Moreover, we assume log-normal distributions for all parameters.

For the investigated bridge deck, the corrosive environment is defined by the surface chloride concentration with a mean value of 6 kg/m^3 and a coefficient of variation of 25%, while the concrete cover depth has a mean value of 70 mm and a coefficient of variation of 25% (Lounis and Daigle 2008). Two types of reinforcing steel are investigated: (i) Conventional black steel with a mean chloride threshold value of 0.70 kg/m^3 and a coefficient of variation of 20% (Lounis and Daigle 2008); and (ii) Corrosion-resistant steel with a mean chloride threshold value of 1.4 kg/m^3 and a coefficient of variation of 20% (Lounis and Daigle 2008). The selected corrosion-resistant steel has a chloride threshold value that is double that of black steel, which could correspond to the case of galvanized steel reinforcement.

Table 1. Mean value and coefficient of variation (COV) for parameters in baseline and future scenarios.

Parameter	Baseline		$\Delta T = 2^\circ\text{C}$		$\Delta T = 4^\circ\text{C}$		$\Delta T = 6^\circ\text{C}$	
	Mean	COV	Mean	COV	Mean	COV	Mean	COV
Surface chloride content (kg/m^3)	6	25	6	25	6	25	6	25
Concrete cover depth (mm)	70	25	70	25	70	25	70	25
Threshold chloride content (kg/m^3) for black steel	0.70	20	0.63	22	0.56	24	0.51	26
Threshold chloride content (kg/m^3) for corrosion-resistant steel	1.40	20	1.25	22	1.13	24	1.01	26
HPC diffusion coefficient (cm^2/year)	0.20	25	0.23	27	0.27	29	0.31	31
NPC diffusion coefficient (cm^2/year)	0.30	25	0.33	27	0.36	29	0.39	31

To design long life concrete bridge decks, one may consider using high performance concrete or ultra-high performance concrete, which have lower apparent chloride diffusion coefficients compared to normal concrete (Table 1). In this test case, we consider two concrete types: (i) High performance concrete (HPC) with a mean value of the diffusion coefficient of $0.20 \text{ cm}^2/\text{year}$ and a coefficient of variation of 25%, and (ii) Normal performance concrete (NPC) with a mean value of the diffusion coefficient of $0.30 \text{ cm}^2/\text{year}$ and a coefficient of variation of 25%.

Using the Arrhenius relationship (Equations 3 and 5), the mean values of the chloride diffusion coefficient and chloride threshold value for the temperature rise scenarios are estimated. It is assumed that the increase of diffusion coefficient and decrease of chloride threshold value with temperature are time-invariant; i.e. we assume that the temperature rise occurs on the average of the annual temperature over the design life of the RC bridge deck. Since the future projected changes in temperature rise is uncertain, we assume that the uncertainties in the diffusion coefficient and chloride threshold value with temperature rise are higher than the base case. Hence, for these two parameters, the coefficient of variation is assumed to increase with temperature rise in future scenarios.

5 RESULTS AND DISCUSSION

We consider different scenarios of the test case to evaluate the impact of climate change and the role of using HPC and corrosion-resistant steel in achieving better performance. In all simulations, we use 100,000 random samples for the model variables in the Monte-Carlo simulations, and consider a 50-year planning horizon.

In the first test case, we assess the impact of climate change on a bridge deck with NPC and black steel rebar. Figure 2a shows the variations in the probability of corrosion with time. It can be seen that the climate change induced temperature increase can significantly affect the performance of bridge decks. The probability of corrosion under climate change induced warming becomes larger with time. The probability of corrosion at almost half of the planning horizon (26 years) is about 20% in the baseline scenario (i.e. with no warming) while it increases to 30%, 40% and 50% for warming levels of $\Delta T = +2^\circ\text{C}$, $+4^\circ\text{C}$ and $+6^\circ\text{C}$, respectively.

The second test case examines the performance in terms of time-variations of probability of corrosion of RC bridge decks made with corrosion-resistant steel in a changing climate. We compare the performance of two NPC bridge decks, one reinforced using black steel and the other one using corrosion-resistant steel. Figure 2b illustrates the time-variations of the probability of corrosion for these two RC bridge decks subject to various warming levels under climate change. As expected, the time-varying probability of corrosion of concrete bridge decks reinforced with corrosion-resistant steel is much lower than the one corresponding to black or carbon steel. For example, under the warming level of $\Delta T = +2^\circ\text{C}$ after 30 years, the probability of corrosion of a bridge deck with corrosion-resistant steel is 28%, which is 40% lower than the corrosion probability of the deck with black steel (68%). The results show the benefit of using corrosion-resistant steels for designing long life concrete infrastructures.

In the third test case, we examine the use of HPC as an alternative for designing long life RC bridge decks as HPC benefits from having lower chloride diffusion coefficients. In this example,

the probability of corrosion of bridge decks made with HPC is compared to that of NPC under $\Delta T=+2^{\circ}\text{C}$ and $\Delta T=+6^{\circ}\text{C}$. Figure 2c illustrates that after 50 years, the probability of corrosion of the bridge deck made with HPC is about 48% and 72% while the probability of corrosion for NPC deck is about 68% and 83% under $\Delta T=+2^{\circ}\text{C}$ and $\Delta T=+6^{\circ}\text{C}$ warming levels, respectively.

These examples illustrate the importance of the consideration of climate change in service life prediction and service life design of RC bridge decks, and the essential role of using high performance concrete and corrosion-resistant rebar materials in reducing the probability of corrosion. It should be noted that the final choice of the optimal design should include a comparison of the life cycle costs of the different design alternatives (Lounis and Daigle 2008).

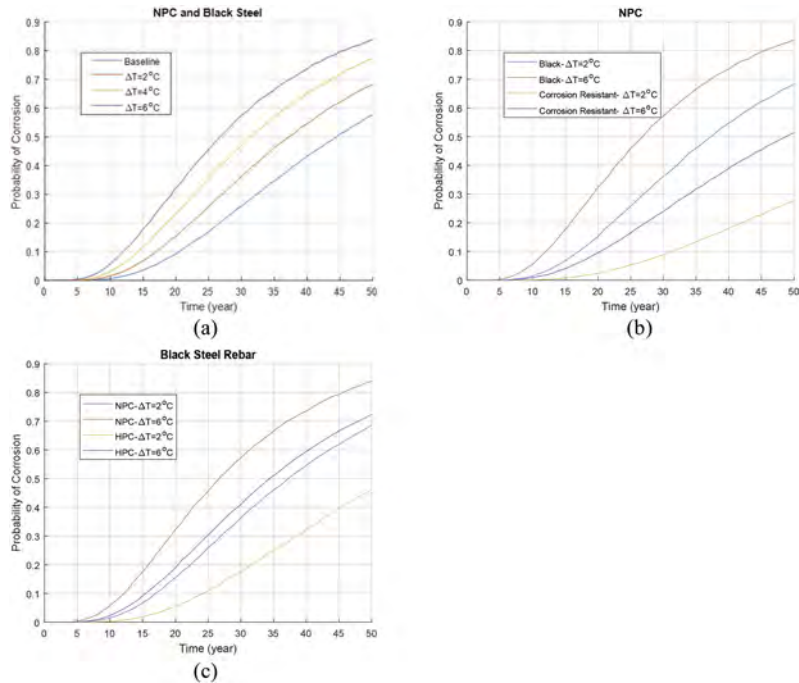

Figure 2. Probability of corrosion under various warming levels for RC bridge decks with (a) NPC and black steel reinforcement (b) black steel and corrosion-resistant steel reinforcement and (c) NPC and HPC.

6 CONCLUSIONS

Temperature increase due to climate change can lead to an increase in chloride diffusivity of concrete while decreasing the threshold chloride values of rebars, which yields an increase in the probability of corrosion and a shortening of service life of RC bridge decks. Using a probabilistic-mechanistic approach, the impact of temperature rise due to climate change on the probability of the time of corrosion onset of RC bridge decks is modelled. We employed a simplified diffusion-based model to estimate the time variation of chloride ingress into concrete and used the Arrhenius relationship to quantify the impact of temperature increase on the chloride diffusivity of concrete and the threshold chloride values of rebars. Based on the projected changes in annual average temperatures in near term and late century time periods under low and high emission scenarios, we defined warming levels of $\Delta T = +2^{\circ}\text{C}$, $+4^{\circ}\text{C}$ and $+6^{\circ}\text{C}$ and compared the performance of RC bridge decks to a baseline scenario with no warming. Uncertainties in the parameters governing the service life, such as concrete cover depth, chloride threshold, chloride diffusion, and surface chloride concentration are considered by modeling them as random variables using the Monte Carlo method. The service life of concrete structures can be defined as the time at which the probability of corrosion reaches an acceptable value for the different types of concrete, reinforcing steel and concrete cover depths. Different test cases were illustrated to assess the impact of temperature increase on RC bridge decks and investigate the effects of using HPC and corrosion-

resistant steel for designing long life RC bridge decks. The results illustrated that the time-dependent probability of corrosion increases with temperature. For the RC bridge decks made with NPC and black steel, the results indicated that at the end of a 50-year planning horizon, the probability of corrosion increases approximately by 10% per 2°C temperature increase. To reduce the high probability of corrosion due to temperature increase, corrosion-resistant steel reinforcement and HPC can be used. For instance, the use of corrosion-resistant steel reduced the corrosion probability by 40% and 30% after 50 years for the warming levels of $\Delta T = +2^{\circ}\text{C}$ and $+6^{\circ}\text{C}$, respectively compared to black steel reinforcement. The final selection of service life design should take into account the life cycle costs incurred within a given life cycle of RC bridge decks.

Climatic design data for buildings and infrastructure under changing climate in Canada

H. Shirkhani & Z. Lounis

National Research Council Canada, Ottawa, Canada

ABSTRACT: This paper investigates the future climate data required for the design and evaluation of buildings and infrastructure systems considering climate change. Currently, the climatic design data of buildings and infrastructure are based on historical observations, which due to climate change, can result in higher risks of failure. The future climatic conditions largely depend on human-induced greenhouse gas emissions described by emission scenarios. The responses of different climate models to the future emissions result in uncertainty in climatic data projections. Moreover, the projected climatic data are expected to vary with time, which is known as climate non-stationarity, which depends on the type of the climatic parameter and the design life. The building or infrastructure with longer design life are more prone to uncertainty and non-stationarity. A number of climatic design values for locations across Canada are analyzed to illustrate the implications of climate change for climatic design parameters.

1 INTRODUCTION

Buildings and infrastructure systems such as bridges, roads, transit, water supply and wastewater systems provide basic and core services, which are critical to the stability of the economy, wellness of the environment and people's quality of life. According to the Canadian Infrastructure Report Card (CIRC, 2019), one third of Canada's municipal infrastructure is in fair, poor or very poor condition, which can be exacerbated by climate change impacts.

It is certain that Canada's climate has warmed and that it will warm further in the future. Between 1948 and 2016, the best estimate of mean annual temperature increase is 1.7°C for Canada as a whole and 2.3°C for northern Canada. Both the observed and projected increases in mean temperature in Canada are about twice the corresponding increases in the global mean temperature, regardless of future emission scenario.

Current approaches for design, evaluation and rehabilitation of buildings and infrastructure are based on historical climatic data that: (i) do not consider the projected changes in the magnitude of the climatic loads; and (ii) assume stationary loads and resistance. However, climate change may increase climatic loads while decreasing the resistance of buildings and infrastructure systems. As a result of the combined effects of climate change and aging, the probability of failure of buildings and infrastructure could exceed the prescribed target values assumed in current codes, standards and guides, which in turn may lead to early failure (shortened service life) as well as higher probability of failure with serious social, economic and environmental consequences (Figure 1).

Nearly 35% of infrastructure assets are in need of maintenance, repair and rehabilitation, which means that Canada's infrastructure deficit estimates ranging from \$50 billion to \$570 billion (INFC 2018). Therefore, there is a need to develop design codes, standards and guidelines based on future climatic loads to build climate-resilient buildings and infrastructure. There are existing climate resiliency studies in the literature including climate change resiliency adaptation (Lounis and Daigle 2008; Lounis and McAllister, 2016; Knott et al., 2019). However, the selection and use of the projected climatic design data is a challenging task due to the high level of uncertainty associated with climate projections as well as the time variation of climatic

design values and their statistics – known as non-stationarity. Previous studies observed a high level of non-stationarity in climatic data (Rootzen and Katz 2013; Lee and Ellingwood 2017).

In order to predict the GHGs concentration trajectory, the Intergovernmental Panel on Climate Change (IPCC) developed emission scenarios including four Representative Concentration Pathway (RCP) scenarios, RCP2.6, RCP4.5, RCP6.0 and RCP8.5, as well as a core set of five scenarios based on the Shared Socioeconomic Pathways (SSPs): SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5. Previous studies investigated these uncertainties for various engineering applications (Shirkhani et al., 2020; Shirkhani et al., 2015; Stott et al., 2002). Selection of an appropriate emission scenario to obtain future climatic data is a non-trivial and delicate task.

In this study, the challenges for selection and use of the future climatic data required for the design and management of climate-resilient buildings and infrastructure systems are presented. In order to illustrate these challenges, we use the future-looking climatic design data, which was generated as an outcome of the Climate Resilient Buildings and Core Public Infrastructure (CRBCPI, 2020) initiative led by the National Research Council Canada (Cannon et al., 2020). In this paper, the projected changes of selected climatic design data are presented for various locations across Canada in order to illustrate the impact of climate change across various climatic regions over Canada. In addition, to shed some lights on the challenges for selection of an appropriate emission scenario, the future climatic design parameters are presented under various emission scenarios. The concept of global warming levels (GWLs) and timing of these waring levels are also presented. The role of the infrastructure design life in the time horizon of climatic projections and selection of emission scenarios are discussed for short and long life assets. The non-stationarity issue of projected climatic design data is discussed through assessing the time variation of selected climatic design parameters under various emission scenarios.

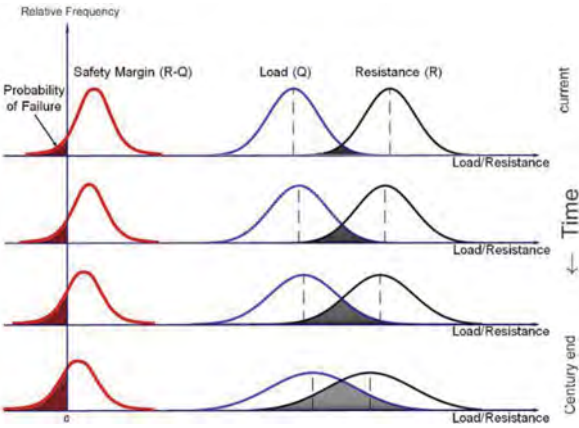

Figure 1. Impact of climate change on climatic load and probability of failure of infrastructure: increasing probability of failure with time (from top to bottom) due to the non-stationary climatic loads and accelerated deterioration.

2 CLIMATE CHANGE DRIVER AND EMISSION SCENARIOS

2.1 Climate change driver

Future global climate change is driven primarily by emissions, and hence increasing atmospheric concentrations of GHGs and changing concentrations of aerosols. Human influence on the climate system is now an established fact (IPCC, 2014; IPCC, 2022; USGCRP, 2018; Bush and Lemmen, 2019) and that human influence is the principal driver of many changes observed across the atmosphere, ocean, cryosphere and biosphere. The Sixth Assessment Report by IPCC (AR6; IPCC, 2022) concludes that it is now an established fact that human-induced GHG emissions have led to an increased frequency and/or intensity of some weather and climate extremes, in particular for temperature extremes. In addition, evidence of observed changes and attribution to human influence

has strengthened for several types of extremes, in particular for extreme precipitation, droughts, tropical cyclones and compound extremes.

2.2 Emission scenarios: RCP and SSP

The future emissions of GHGs and aerosols are highly uncertain and depend on several socio-economic factors. Therefore, different emission scenarios or “pathways” of future GHG concentrations, aerosols, and land-use change were specified by Intergovernmental Panel on Climate Change (IPCC, 2014). The emission scenarios that were used in AR5 (IPCC, 2014) and were widely used in the literature before AR6 report (IPCC, 2022) were called “Representative Concentration Pathways” (RCPs). RCPs were identified by approximating the radiative forcing at the end of the 21st century: RCP2.6, RCP4.5, RCP6.0 and RCP8.5.

IPCC (2022) used a core set of five scenarios based on the Shared Socioeconomic Pathways (SSPs) in AR6: SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5. Figure 2 shows the global warming under RCP and SSP emission scenarios.

Figure 2. Increase in surface temperature under SSP (left) and RCP (right) emission scenarios relative to 1850-1900 [IPCC, 2022; IPCC 2014].

Although, like RCPs, SSPs are also labelled by the level of radiative forcing they reach in 2100 and can in principle be related to the core set of SSP scenarios, the RCPs and SSP-based scenarios are not directly comparable since: (i) the gas-to-gas compositions differ; (ii) the projected 21st-century trajectories may differ; and (iii) the overall effective radiative forcing tends to be higher for the SSPs.

3 GLOBAL WARMING LEVELS AND TIMING

Traditionally, projections of climate variables are summarized and communicated as a function of time and emission scenarios. However, for many indicators of climate change, such as seasonal and annual mean and extreme surface air temperatures and precipitation, the geographical patterns of changes are well estimated by the level of global surface warming, independently of the details of the emission pathways that caused the warming, or the time at which the level of warming is attained. Therefore, recently, quantifying global and regional climate at specific global warming levels (GWLs) has become widespread. In this approach, scenario-based climate projections are translated into GWLs by aggregating the climate model response at specific GWL across scenarios.

This approach is also implemented in the CRBCPI initiative (Cannon et al., 2020). However, in the CRBCPI initiative, the regional climate projections are translated into GWLs by aggregating single-model initial-conditions large ensembles under one emission scenario (RCP8.5). The timing of when a certain GWL is reached under a particular scenario needs to be estimated. In AR6, results of 20-year averaged change in global surface temperature were estimated relative to the 1850–1900 reference period using the CMIP6 output through a combined assessment taking into

account the observed warming. The timing of GWLs in CRBCPI are estimated using 31-year averaged changes relative to 1986-2016 baseline period based on the CMIP5 ensemble under RCP emission scenarios. Canadian Regional Climate Model (CanRCM4) simulations driven by Canadian Earth System Model (CanESM2), for which the warming levels relative to the 1986-2016 baseline are approximately 1°C lower than levels relative to the preindustrial period (Cannon et al., 2020). Using this approximation, and for the level of global warming that are available in both Cannon et al. (2020), and the AR6, Table 1 presents the timing of the global warming under both RCP and SSP emission scenarios.

4 FUTURE CLIMATIC DESIGN DATA

4.1 Methodology and data

As part of the CRBCPI initiative, future-looking climate data were developed to be implemented in future editions of building and infrastructure codes and standards. In this section, we will provide an overview and summary of the methodology and findings of Cannon et al., (2020) for the projected changes in climatic data across Canada.

The output of a 50-member initial-conditions large ensemble of the Canadian Regional Climate Model (CanRCM4-LE) forced by RCP 8.5 emission scenario was used to estimate the projected changes in the selected climatic design data at specified GWLs. CanRCM4 dynamically downscales Canadian Earth System Model (CanESM2) to a grid with 0.44° (~50km) resolution over North America (Scinocca et al., 2016). In order to associate the projected climatic data under RCP8.5 with other emission scenarios, the timing of GWLs under each RCP emission scenario is estimated using the CIMP5 ensemble relative to the baseline period of 1986-2016 (See Table 2). Years that are presented in Table 1, indeed, indicate the centre year of the 31-year period for which the average change in global mean temperature is reached by the corresponding RCP emission scenario. For example, the future time horizon of 2070 corresponds to the time period of 2055-2085. For the end of the century time horizons, however, the time period might be shorter due to the data availability up to the end of century (year 2100). For instance, the warming level of $\Delta T = 3.5^\circ C$ is projected to be reached under RCP8.5 scenario by 2090 time horizon, which corresponds to the 2080-2100 period. It should be noted some ΔT warming levels do not occur before 2100 under specific emission scenarios (shown as dash in Table 2).

4.2 Projected changes in climatic data

The climatic loads that are required for design of new and evaluation and management of existing buildings and bridge infrastructure include wind, snow, rain, temperature, ice and flood. Figure 3 provides examples of projected changes in climatic design data used in the National Building Code (NBCC, 2015) and Canadian Highway Bridge Design Code (CHBDC, 2014).

The projected changes in the wind load are relatively small for most of locations across Canada. The wind load decreases at some stations and increases at other locations. Due to the increasing temperature, both hot and cold extremes are projected to become warmer in future for all locations across Canada. The minimum mean daily temperature is projected to increase significantly with larger changes in the North. The scientific confidence in climate change projections varies depending on the climate variable and, in some cases, region. Confidence in temperature change is higher than confidence in precipitation change, in large part because temperature change is a direct consequence of the radiative imbalance associated with changing GHG and aerosol emissions while precipitation change is affected by a number of complex processes that cannot be resolved or simulated by climate models. Moreover, confidence about changes in compound events, involving multiple variables, e.g., snow loads, driving rain wind pressures, etc., is lower.

Figure 3. Projected changes corresponding to GWL of $\Delta T = 3.5^{\circ}\text{C}$ (see Table 2) for: Minimum Mean Daily Temperature (top) and 50-year Wind Pressure (bottom).

Table 1. Timing of global warming levels under RCP and SSP emission scenarios (relative to 1850–1900 reference period) as the period during which the average global surface temperature change exceeds the specified level. For RCP and SSP emission scenarios 31-year and 20-year periods are used, respectively.

$\Delta T^{\circ}\text{C}$ (GWL)	Timing of Global Warming							
	RCP 8.5	SSP5-8.5	RCP 6.0	SSP3-7.0	RCP 4.5	SSP2-4.5	RCP 2.6	SSP1-2.6
+1.5	2008-2038	2018-2037	2008-2038	2021-2040	2008-2038	2021-2040	2008-2038	2023-2042
+2.0	2020-2050	2032-2051	2031-2061	2037-2056	2031-2061	2043-2062	-	-
+3.0	2044-2074	2055-2074	2074-2100	2066-2085	-	-	-	-
+4.0	2065-2095	2075-2094	-	-	-	-	-	-

Table 2. – Year at which indicated GWL is exceeded under different emission scenarios (Cannon et al., 2020).

$\Delta T^{\circ}\text{C}$ (GWL)	RCP 8.5	RCP 6.0	RCP 4.5	RCP 2.6
+0.5			2023	
+1	2035		2046	-
+1.5	2047		2070	-
+2	2059	2087	-	-
+2.5	2069	-	-	-
+3	2080	-	-	-
+3.5	2090	-	-	-

5 CLIMATE CHANGE UNCERTAINTIES AND NON-STATIONARITY

Climate models are computer models that simulate the global climate system driven by future GHG emission scenarios, and provide projections of future climatic variables. Since climate change is driven by GHG emissions, the future projections of climatic variables highly depend on the assumption of the future emission scenario. The spread of climatic projections under various emission scenarios represents a measure of uncertainty due to future GHG emissions. In addition, climate models respond differently to the same GHG emission forcing, which represents the model uncertainty associated with future climate change projections. The future

GHG emissions and the climate model are two major sources of uncertainty associated with future climate projections that can be captured by performing a multi-model multi-scenario approach (Vetter et al., 2017; Shirkhani et al., 2015, Shirkhani et al., 2020). The third source of uncertainty in climate projections is the internal climate variability, which stems from the natural chaotic variability of the climate system. This uncertainty is irreducible as it is intrinsic to the climate system’s behaviour. The spread from output of simulations from a single-model initial-conditions large ensembles can represent uncertainty due to internal climate variability. The relative influence of internal variability, forcing uncertainty, and model uncertainty on future climate projections depends on the variable, spatial scale, and time horizon of interest.

The current codes and guidelines for the design of infrastructure are based on the assumption of the stationarity of the climate. However, in the presence of non-stationarity the conventional methods and models for load estimation as well as reliability and risk assessment are not valid. The nonstationary of climatic data is illustrated in Figure 4, which shows the time variation of projected changes in 50-year wind pressure and minimum mean daily temperature under various emission scenarios. As can be seen, the projected changes in wind pressure show a trend with time and emission scenarios. The level of non-stationarity of climatic design values clearly depends on the length of the design life and the climate non-stationarity may become more critical for infrastructure with longer design life.

6 SELECTION OF EMISSION SCENARIO

The design life of the buildings and infrastructure determines the planning horizon and the future time frame required for projections of climatic design data. Appropriate selection of a future emission scenario is a complex task, which presents a challenge to engineering communities. Cannon et al., (2020) provided preliminary recommendations. For the 50-year horizon (i.e. infrastructure with design life of up to 50 years, such as buildings), it is recommended that RCP8.5 scenario in the period with the center year of 2069 be used since the incremental change in design values relative to those for RCP4.5 or RCP6.0 is not large for this time frame. This means that for the infrastructure with design life of 50 years or shorter, the RCP8.5 can be used.

For the 75-year time horizon (such as bridges), the selection of an appropriate scenario is more complicated because the difference between different scenarios near the end of the century can be quite large (as can be also seen in Figure 2 for the global average temperature). In this case, a judgment must be made on which scenario to adopt. Consultation with experts to assess the probability of different forcing scenarios may be needed to arrive at a final decision. For most design values, a conservative choice would be the RCP8.5 scenario in the time period with the center year of 2090, acknowledging that this could lead to more expensive designs or greater risk associated with the underestimation of some types of loads, such as snow loads.

The projected changes in 10-year and 50-year wind loads as structural climatic design parameters for buildings with a 50-year planning horizon are compared under various emission scenarios in Figure 5 for different locations across Canada. As Table 2 shows, the GWLs of $\Delta T = +2.5^{\circ}\text{C}$ and $\Delta T = +1.5^{\circ}\text{C}$ correspond to the 50-year planning horizon under RCP8.5 and RCP 6.0/RCP 4.5 respectively. Figure 5 shows that the projections of wind pressures are relatively close under various scenarios for most locations. It should be noted that the projected changes in wind pressure remain relatively small, therefore, even high differences in projected changes under various RCPs may not be significant.

Figure 4. Time variation of projected changes in 50-year wind pressure and minimum mean daily temperature for Toronto under RCP8.5 (blue), RCP6.0 (red) and RCP4.5 (black) emission scenarios. Changes are relative to 1986-2016 baseline period.

For bridge infrastructure with a design life of 75-year, in Figure 6 we compare the projected changes in ice thickness and minimum mean daily temperature under RCP6.0 and RCP8.5 for the 75-year time horizon. As Table 1 shows, we may approximate the 75-year horizon by GWLs of $\Delta T = + 2^{\circ}\text{C}$ and $\Delta T = + 3.5^{\circ}\text{C}$ under RCP6.0 and RCP8.5, respectively. As for the extreme temperatures, the results of RCP8.5 are consistently higher than those of RCP6.0, at least by 2°C . The difference is higher for 75-year planning horizon and in the northern region, particularly for the cold extreme temperatures. The differences between the projected changes of extreme temperatures under RCP8.5 and RCP6.0/4.5 are higher for the extreme cold temperatures (up to 4°C in most of locations) while it is lower for the extreme hot temperatures (up to 2°C for most of the locations).

Figure 5. Comparison of projected changes in 10-year (left) and 50-year (right) wind loads under RCP8.5 and RCP6.0/4.5 for 50-year time horizon.

Figure 6. Comparison of projected changes in ice thickness (left) and minimum mean daily temperature (right) under RCP8.5 and RCP6.0 for 75-year time horizon.

The role of the infrastructure design life in the time horizon of climatic projections and selection of emission scenarios were discussed for short and long life assets. It was shown that selection of an appropriate emission scenario is a complex task and is more challenging for long-life assets.

7 CONCLUSIONS

In this study, the future climatic data for design and evaluation of buildings and infrastructure systems are discussed. The challenges for the selection and use of the future climatic data are presented. For selected climatic design data that are used in NBCC (2015) and CHBDC (2014), future-looking climatic data from the NRC-led CRBCPI initiative were presented. The average warming across Canada is twice the global average, with even greater warming occurring in the North. For temperature-related elements, every region of Canada is projected to experience warming. The extreme cold temperature is projected to increase even more than extreme hot temperatures. The shift in phase of precipitation from snow to rain with warming leads to larger relative increases in rain across Canada. The future ice accretion loads are projected to increase in several locations, particularly for latitudes higher than 50°N . While the future projections of wind loads are lacking in confidence due to the gap in climate science, the future changes in wind load over Canada will be relatively small.

The concept of GWLs and timing of these waring levels are also presented. It was shown that the GWLs under RCP and SSP emission scenarios can be linked through the timing when GWLs are attained. It was discussed that there is relatively high uncertainty associated with the

climate change projections. There are different sources of uncertainties including future emission scenarios, climate model uncertainty and natural internal variability of the climate system. It was noted that scientific confidence in climate change projections varies by region and by climate variable. The confidence in temperature change is higher than confidence in precipitation change and wind speed. Furthermore, confidence about changes in climatic loads involving multiple variables, e.g., snow loads, driving rain wind pressures, and ice accretion is lower than individual parameters. The extreme values are also more uncertain compared to cumulative and averaged ones. These uncertainties are significant obstacles for the design and management of infrastructure systems under climate change. The non-stationarity issue of projected climatic design data is discussed through assessing the time variation of selected climatic parameters. The stationarity assumption may not be valid anymore given the changing climate. In a non-stationary climate, the climatic design value can change over the design life of the infrastructure. The projected climatic design data at the end of the design life will then be different, and depends on the infrastructure design life and the choice of the emission scenario.

Life-cycle structural reliability of RC bridge piers under corrosion in a changing climate

G.V. Nava, L. Capacci & F. Biondini

Politecnico di Milano, Milan, Italy

L. Casti

Université Gustave Eiffel, Champs-sur-Marne, France

ABSTRACT: Aging and deterioration processes of structures and infrastructure systems can be severely affected by the long-term evolution of environmental conditions expected in a changing climate. This paper aims at investigating the interaction between climate change and environmental aggressiveness on the probabilistic life-cycle performance of concrete structures under corrosion. A simulation-based framework is proposed for life-cycle structural reliability analysis under climate change scenarios. The framework is applied to a bridge pier with hollow core cross-section exposed to chloride-induced corrosion. The results allow to quantify the impact of climate change on long-term probabilistic structural response and highlight the need for proper modeling of the environmental parameters and climate evolution over the entire lifespan of aging structures for optimal life-cycle maintenance and management of structural and infrastructural facilities.

1 INTRODUCTION

Civil engineering structures are designed to guarantee the functionality and resilience of the served communities and the safety of its users over a service life spanning several decades. Multiple deterioration processes may affect the original performance of materials and structures and severely impair the level of structural safety and reliability over time (Ellingwood 2005). Design practice and management strategies of structural and infrastructural facilities should therefore account for the detrimental impact of deterioration processes, taking into account multiple factors such as durability of construction materials, quality of structural detailing, type of structural systems, and environmental exposure (Biondini & Frangopol 2016, 2019).

Daily weather fluctuations and long-term change in climate conditions can influence structural deterioration as well as the intensity and frequency of natural hazards. As highlighted by the Intergovernmental Panel on Climate Change (IPCC), climate change is unequivocal and the non-stationarity of climate and weather conditions is substantially connected to greenhouse emissions (IPCC 2021). It is hence important to investigate the impact of climate change effects on structural systems exposed to aging and deterioration, including bridges and infrastructure facilities (Nasr et al. 2020). To support the decision making process of new and existing assets, incorporating climate factors in structural performance indicators is critical to inform design, assessment, maintenance, retrofit, and repair in a life-cycle perspective (Capacci & Biondini 2019).

This paper presents a probabilistic framework for life-cycle assessment of aging structural systems exposed to environmental aggressiveness, with emphasis on Reinforced Concrete (RC) structures under corrosion processes (Biondini et al. 2004, Biondini & Vergani 2015). Climate change effects are incorporated in the proposed framework considering the long-term evolution of climate parameters affecting the deterioration rate, such as temperature and relative humidity.

The methodology is applied to a RC bridge pier subjected to chloride-induced corrosion. The results allow quantifying the detrimental impact of climate change on corrosion damage and related effects on lifetime structural safety and reliability of aging RC bridge structures.

2 LIFE-CYCLE STRUCTURAL ASSESSMENT IN A CHANGING CLIMATE

2.1 Climate change scenarios

The future climate is predicted through the definition of emission scenarios in relation to the evolution of population, economy, technology, energy, land use and agriculture, and described by different reference scenarios, such as the four Representative Concentration Pathways (RCPs) (Van Vuuren et al. 2011). RCP 2.6 is a mitigation scenario, RCP 4.5 and RCP 6.0 are medium stabilization scenarios and RCP 8.5 is a very high baseline emission scenario. These RCPs are representative of a larger set of scenarios reported in the literature and their denomination is associated to the value of Radiative Forcing predicted in 2100. The choice of an even number of scenarios is linked to the decision of avoiding a middle RCP, providing a manageable set of scenarios able to describe also extreme projections. RCPs have been recently integrated with the Shared Socioeconomic Pathways (SSPs) in order to characterize a range of uncertainties in the mitigation efforts required to achieve particular climate outcomes and in the adaptation efforts that could be taken to cope with the climate change effects (O'Neill et al. 2016).

Predicting spatially and temporally dependent environmental parameters considering different scenarios is a complex task. Indeed, the future climate projection depends on the selected Global Circulation Model (GCM), which is subjected to several sources of uncertainty classified in internal, model and scenario uncertainty (Madsen 2013). The inner variability of the climate systems is referred as internal uncertainty, while model uncertainty is related to the assumption and simplification considered for the definition of the GCM. Lastly, scenario uncertainty is associated with the assumptions implemented in the definition of the different climate scenarios. These uncertainties evolve in time depending on the selected environmental parameter projection and the spatial scale considered. Different analyses should be applied in order to deal with these uncertainties for the assessment of climate change impact on civil engineering structures, e.g. using different trajectories from the same GCM and considering different scenarios.

The spatial resolution of GCMs is usually ranging from tens to hundreds of kilometers while civil engineering problems often require the evaluation at the local scale. For this purpose, downscaling techniques are used in order to retrieve environmental projections for specific location. Advantages and disadvantages of the most common techniques, i.e. statistical and dynamics downscaling, are discussed in Trzaska & Schnarr (2014).

2.2 Conceptual framework for life-cycle structural assessment

The proposed methodology for life-cycle assessment of aging structures under climate change is illustrated in Figure 1. The structure of the flowchart comprises three constitutive dimensions: climate scenario modeling, mechanical damage assessment, and structural performance analysis.

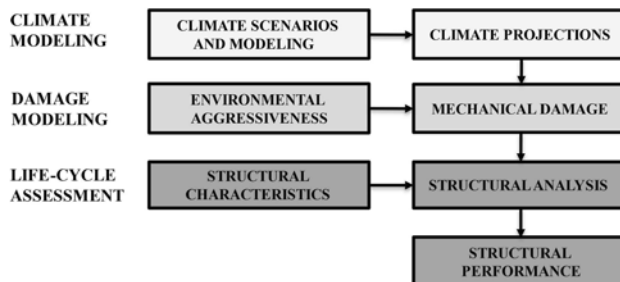

Figure 1. Methodology flowchart for performance assessment of aging structures in a changing climate.

Climate modeling provides the projections of relevant environmental parameters affecting the deterioration process based on the investigated climate scenario (e.g., RCP selection) and the input data required by the selected predictive model for climate change (e.g., site, timeframe). The projections retrieved in this phase concern the climate parameters that affect capacity deterioration and hazard rate of the investigated structural problem (e.g., temperature, relative humidity, wind speed). Then, mechanical damage is governed by environmental aggressiveness exacerbated by detrimental projections of climate parameters. Based on analytical or empirical formulations, this phase allows to describe onset and propagation of aging and deterioration processes (e.g., corrosion, freeze-thaw cycles, sulphate attacks). The characterization of mechanical damage informed by non-stationary climate conditions allows to establish the numerical models for structural analysis over time (e.g., sectional analysis, static and dynamic analysis). The problem can be formulated in probabilistic terms and integrated for practical implementation within a Monte Carlo simulation framework to account for uncertainties of basic modeling parameters encompassing all dimensions of the life-cycle structural assessment.

3 CORROSION MODELLING UNDER TIME-VARIANT ENVIRONMENTAL FACTORS

For RC structures exposed to chloride ingress, damage induced by the diffusive attack follows corrosion initiation and propagation and may involve corrosion of steel reinforcement and deterioration of concrete (Bertolini et al. 2013).

3.1 Corrosion initiation

The initiation time can be defined as the time necessary to achieve a critical chloride concentration at the reinforcing steel surface. Chloride ingress in concrete is generally modelled using the Fick's diffusion equation in the one-dimensional formulation:

$$D \frac{\partial^2 C}{\partial x^2} = \frac{\partial C}{\partial t} \quad (1)$$

where D is the concrete diffusivity and C is the chloride concentration at the depth x and time t . This simplified approach is considered in this paper. However, it is worth noting that for structural members with complex geometry and non-uniform chloride concentration exposure the diffusion process should be more accurately described by two- or three-dimensional patterns of concentration gradients (Biondini et al. 2004, Titi & Biondini 2016).

Over time, the aging process and the evolution of the environmental parameters, such as temperature and relative humidity, may affect the concrete diffusivity. Experimental studies show that the diffusion coefficient increases with temperature (Stewart et al. 2011). Moreover, chloride penetration occurs in the presence of water in the capillary pores. Indeed, a small relative humidity hinders chloride penetrations (Saetta et al. 1993). In order to account for non-stationary climatic conditions, the diffusion coefficient at time t is evaluated as follows:

$$D(t) = D_{ref} f_T(t) f_{RH}(t) f_a(t) \quad (2)$$

where D_{ref} is the reference diffusion coefficient for $T=20$ °C and $RH=75\%$, f_T accounts for the variation of temperature, f_{RH} accounts for the variation of relative humidity, and f_a is an aging function.

The function f_T is evaluated as follows based on the Arrhenius law (Peng & Stewart 2016):

$$f_T(t) = e^{\frac{E}{R} \left(\frac{1}{293.15} - \frac{1}{273.15+T(t)} \right)} \quad (3)$$

where E is the activation energy of the chlorides diffusion process, R is the gas constant (8.314×10^{-3} kJ/mol), and T is the temperature in Celsius degrees. The function f_{RH} is defined based on following empirical model (Saetta et al. 1993):

$$f_{RH}(t) = \left[1 + \frac{(1 - RH(t))^4}{(1 - 0.75)^4} \right]^{-1} \quad (4)$$

where RH is the concrete pore relative humidity. Finally, the function f_a is evaluated as follows:

$$f_a(t) = \left(\frac{0.0767}{t} \right)^a \quad (5)$$

where a is an aging coefficient.

3.2 Corrosion propagation

Corrosion initiates with the attainment of a critical concentration threshold C_{cr} . The propagation phase is described based on the Faraday's law in terms of corrosion penetration rate (mm/year):

$$\frac{\partial p_s}{\partial t} = 0.0116 R_f i_{corr} \quad (6)$$

with p_s = corrosion penetration depth (mm), i_{corr} = corrosion electric current density ($\mu\text{A}/\text{cm}^2$) and R_f = pitting factor, i.e. the ratio between the maximum depth measured at pit and the average penetration calculated indirectly from the weight loss of the steel bar (Stewart & Al-Harthy 2008).

Corrosion propagation may be significantly affected by the variation of environmental parameters. Indeed, a gradual reduction in the concrete resistivity along with an increase in temperature leads to increase the corrosion rate (Stewart et al. 2011). In addition, the corrosion rate is low for relative humidity values lower than 50%, it increases exponentially for relative humidity ranging from 50% to 65%, it remains nearly constant for relative humidity from 65% to 85%, and then tends to decrease (Guo et al. 2015). Moreover, the corrosion rate increases over time due to the increase of chloride concentration (Liu & Weyers 1998) and decreases due to the formation of corrosion products (Vu & Stewart 2000). Based on these results, the influence of environmental parameters on the time-variant corrosion penetration rate is investigated in this paper based on the following relationship (Casti 2021, Nava 2022):

$$i_{corr}(t) = i_{corr,ref} \varphi_{RP}(t) \varphi_T(t) \varphi_{RH}(t) \varphi_C(t) \quad (7)$$

where $i_{corr,ref}$ is the reference corrosion rate for $T=20$ °C and $RH=75\%$, and the time-variant functions $\varphi_{RP}(t)$, $\varphi_T(t)$, $\varphi_{RH}(t)$, and $\varphi_C(t)$ account for the effects associated with formation of rust products and variation of temperature, relative humidity, and chloride concentration, respectively. The function φ_{RP} is described as follows (Vu & Stewart 2000):

$$\varphi_{RP}(t) = 0.85 t_p^{-0.29} \quad (8)$$

where t_p is the corrosion initiation time. The function φ_T is based on the following stepwise linear relationship (Stewart et al. 2011):

$$\varphi_T(t) = [1 + K_T(T(t) - 20)] \quad (9)$$

where $K_T=0.025$ or $K_T=0.073$ for temperature $T \leq 20^\circ\text{C}$ and $T > 20^\circ\text{C}$, respectively. Finally, the functions φ_{RH} and φ_C are based on the following formulations (Guo et al. 2015):

$$\varphi_{RH}(t) = e^{-6000(RH(t)-0.75)^6} \quad (10)$$

$$\varphi_C(t) = \frac{C(t) + C_{cr}}{2 C_{cr}} \quad (11)$$

Sensitivity analyses on the proposed corrosion model are reported in Nava (2022).

3.3 Mechanical damage modeling

Corrosion damage is modeled considering the reduction in the mass of steel reinforcement, concrete strength, and steel ductility as proposed in Biondini & Vergani (2015). The reduction of cross-sectional area A_s of steel bars is the most relevant damage induced by corrosion:

$$A_s(t) = [1 - \delta_s(t)]A_{s0} \quad (12)$$

where A_{s0} is the area of the undamaged bar and δ_s is a damage function of the corrosion penetration depth related to the type of corrosion, i.e. uniform or localized (pitting) corrosion. Delamination and spalling are related to the propagation of longitudinal cracks along the concrete cover due to the formation of oxidation products on the steel bars. The effects of such degradation process can be modelled by reducing the effective concrete compression strength f_c in terms of the damage indices evolution of the steel longitudinal reinforcement. Furthermore, reduction of steel ductility is experimentally reported to be related to percentage of steel mass loss induced by corrosion to brittle failure. This effect can be modelled reducing the ultimate strain capacity ε_{su} of the steel bars.

4 APPLICATION

4.1 RC bridge pier

The proposed methodology is applied to life-cycle reliability assessment of the RC two-column bridge pier shown in Figure 2. Each column has hollow-core rectangular cross-section with overall dimensions $3.8 \text{ m} \times 3.4 \text{ m}$ (Figure 2a). The steel reinforcement varies over the length of the pier with a concrete cover of 75 mm. The bending capacity of the RC cross-sections A-A' (Figure 2b) and B-B' (Figure 2c), with overall reinforcement $A_s=1491 \text{ cm}^2$ and $A'_s=745 \text{ cm}^2$ for cross-section A-A' and $A_s=718 \text{ cm}^2$ and $A'_s=583 \text{ cm}^2$ for cross-section B-B', is investigated. An axial force $N=67.09 \text{ MN}$ associated with dead loads is considered. The cross-sections are modelled based on a fiber approach in OpenSees (Mazzoni et al. 2006). The constitutive model for concrete (Concrete04) accounts for confinement (Figure 2d). The stress-strain law for steel bars is elastic-plastic with strain hardening (Steel01). The bridge pier is assumed to be exposed to chloride attack over internal and external surfaces with uniform concentration C_s .

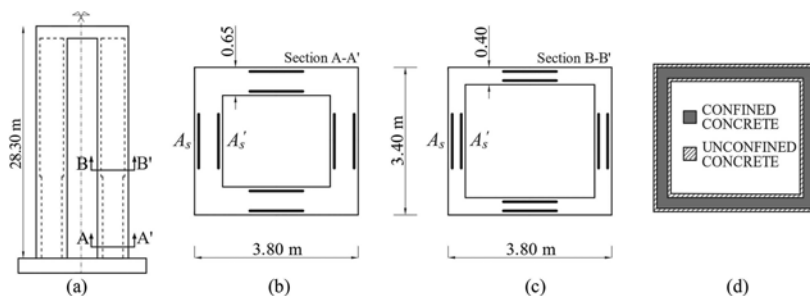

Figure 2. (a) RC bridge pier; (b) cross-section A-A'; (c) cross-section B-B'; (d) concrete confinement.

The analysis timeframe ranges from the year 2000 to the year 2100. The three climate scenarios shown in Figure 3 are considered: (1) very high baseline emission scenario (RCP 8.5); (2) mitigation scenario (RCP 2.6); and (3) No Climate Change (NCC). Temperature projections in Figure 3a are based on the fourth version of the Community Climate System Model (Gent et al. 2011). Projections are downscaled with respect to the station located in Viale Marche, Milan, Italy (Casti 2021) and the analyses are performed considering annual time scale for scenario NCC and monthly time scale for scenarios RCP 2.6 and RCP 8.5, by taking into account also cyclic temperature variations. Linear projections of relative humidity as shown in Figure 3b are considered based on Bastidas-Arteaga et al. (2013).

Figure 3. Temperature and relative humidity projections under different climate scenarios.

The probabilistic analysis accounts for uncertainties in mechanical and environmental damage stressors, including surface chloride concentration C_s , critical chloride concentration C_{cr} , reference diffusivity coefficient D_{ref} , aging coefficient a , reference current density $i_{corr,ref}$, pitting factor R_f , concrete strength f_c , and steel strength f_y . Probability distribution types, probabilistic descriptors and bounds of the random variables are listed in Table 1.

Table 1. Random variables, distribution types, and descriptors. Adapted from multiple sources (Nava 2022).

Random Variable	Distribution Type	Mean μ	C.o.V	Bounds
Surface chloride concentration C_s [%wt./c]	Truncated Normal	3.0	0.30	$C_s \geq 0$
Critical chloride concentrations C_{cr} [%wt./c]	Beta	0.60	$0.15/\mu$	$0.2 \leq C_{cr} \leq 2$
Reference diffusivity D_{ref} [10^{-12} m ² /s]	Truncated Normal	15.8	0.20	$D_c \geq 0$
Aging coefficient a [-]	Beta	0.30	$0.12/\mu$	$0 \leq a \leq 1$
Reference current density $i_{corr,ref}$ [μ A/cm ²]	Lognormal	2.586	0.67	$i_{corr} \geq 0$
Pitting factor R_f [-]	Gumbel	7.1	$0.17/\mu$	$R_f \geq 0$
Unconfined concrete strength f_c [MPa]	Lognormal	40.02	$5/\mu$	$f_c \geq 0$
Steel yielding strength f_y [MPa]	Lognormal	487.58	$30/\mu$	$f_y \geq 0$

4.2 Nominal structural analysis

Deterministic structural analyses are carried out for the two investigated cross-sections by assuming the mean values of the random variables as nominal values.

The bending moment M vs curvature χ diagrams in the vertical plane normal to the bridge axis (strong axis of the cross-sections) are shown in Figure 4a at the years 2000 (light gray line) and 2100 considering scenarios NCC (dark gray line) and RCP 8.5 (black line). Limit states are also reported over the capacity curves for concrete first cracking (star marker), concrete cover spalling (circle marker), and ultimate curvature (square marker). At the time 2100, cover spalling is not reported since it occurs earlier for corrosion products expansion. The results highlight that the effect of climate change significantly reduces the lifetime structural capacity of the bridge pier.

Figure 4b and Figure 4c show the axial force N vs bending moment M capacity curves associated with cracking and peak bending capacity limit states, respectively for cross-section A-A' (Figure 4b) and cross-section B-B' (Figure 4c). These results show that the detrimental impact

of climate change on the cracking limit state is exacerbated by the axial force level, while the effects on the peak bending capacity are almost independent on the axial force. Additional results related to multiple limit states of the cross-sections are available in Nava (2022).

Figure 4. (a) M - χ diagrams; M - N capacity curves of (b) cross-section A-A' and (c) cross-section B-B'.

4.3 Life-cycle structural reliability analysis

The results of a Monte Carlo simulation from a sample of 10^5 realizations are shown in Figure 5 in terms of bending moment M vs curvature χ diagrams of cross-section A-A'. Figure 5a compares median, 16% and 84% fractiles at years 2000 and 2100 under no climate change (NCC) and RCP 8.5. The results for the entire samples are also shown by strong transparency in Figure 5b (Year 2000) and Figure 5c (Year 2100 under RCP 8.5) to better highlight relevant statistical features of the M - χ diagrams, such as centrality, variability, and skewness.

Life-cycle structural reliability is assessed with a 10-year time step considering as limit state the attainment of a target peak bending strength $M_t=166$ MN. The sample size is adaptively selected to mitigate the computational effort and guarantee a sufficient level of estimate accuracy. The results in terms of time-variant reliability index $\beta(t)$ are reported in Figure 6a. The detrimental impact of climate change can be appreciated at the year 2100 by a larger reliability index decay, approximately of 20% for RCP 2.6 and 30% for RCP 8.5, with respect to NCC scenario. These results confirm the relevant effects of climate change on life-cycle structural reliability.

Figure 5. M - χ diagrams of cross-section A-A': (a) Median, 16% and 84% fractiles at years 2000 and 2100 under no climate change (NCC) and RCP 8.5; Results for the entire samples of 10^5 Monte Carlo realizations at years (b) 2000 and (c) 2100 under RCP 8.5.

Figure 6. Life-cycle reliability analysis of cross-section A-A' under no climate change (NCC) and two climate change scenarios (RCP 2.6 and RCP 8.5): (a) Time-variant reliability index $\beta(t)$; (b) Time lag ΔT between NCC and RCP scenarios vs target reliability index β_t .

An effective quantitative measure of the impact of a changing climate can also be achieved by computing the time lag associated with the attainment of a target reliability index β_t between two scenarios with and without climate change effects. Figure 6b shows the time lag ΔT vs the target reliability index β_t , normalized with respect to the initial reliability index β_0 (i.e., β_t/β_0). As an example, for $\beta_t=0.55\beta_0$ the time lag is approximately 30 years for the RCP 8.5 scenario and 25 years for the RCP 2.6 scenario. It is worth noting that the relevant time lag associated to the mitigation scenario RCP 2.6 is mainly due to the effects of the cyclic variation of temperature. Indeed, neglecting it, as highlighted in additional analyses reported in Nava (2022), the detrimental effects of climate change are reduced.

5 CONCLUSIONS

The effects of non-stationary climate conditions on life-cycle performance and reliability of RC structures under corrosion has been investigated. The deterioration model incorporates future projections of climate parameters leading to increase damage caused by corrosion. The results obtained for a RC bridge pier cross-section allowed to quantify the impact of climate change on long-term structural reliability and highlighted the importance of modeling degradation taking environmental exposure and climate evolution into account. Neglecting seasonal fluctuations and climate trends may lead to an underestimation of the reliability index over time and, in turn, an overestimation of times for inspections, maintenance, retrofit, and repair.

This paper focused on the impact of climate change on the life-cycle reliability of individual concrete structures under corrosion. Life-cycle maintenance and management of resilient infrastructure systems should also be investigated accounting for climate change effects on the interaction of an increasingly aggressive environment with multiple hazards and considering the harmful impact of loss of functionality in critical system components. Further research is hence necessary to incorporate the proposed framework into risk-based procedures for optimal mitigation and adaptation strategies with a systemic perspective.

ABSTRACT: The paper presents a risk assessment model, developed in the project oVER-FLOW and further implemented in the project CROSScade, for determining the direct and indirect impacts of flooding hazards. As a consequence of flooding, transport infrastructure and flood protection systems can be significantly damaged and cause cascading effects on other infrastructure. To achieve flood resilient infrastructure, it is necessary to assess the vulnerability of critical assets in the affected area. The model uses novel vulnerability assessment methods for embankments and bridges exposed to different flood hazard scenarios allowing the asset owners to understand risk and performance of their infrastructure. Scarce financial resources are allocated on the critical assets allowing significant cost savings and avoiding the waste of non-renewable resources in strengthening large sections which have sufficient resilience. The consequence analysis is based on an improved quantification model for direct and indirect impacts of different flood hazard scenarios used for risk mapping of the affected area.

1 INTRODUCTION

Climate change is leading to more extreme weather events in most parts of the world (EEA, 2016; World Economic Forum, 2019). High water levels caused by increased frequency of heavy rainfall are causing flooding hazards and higher impacts such as increased financial consequences and human losses. The complete life-cycle management for critical infrastructure needs to consider these new extreme loads by applying different climate change scenarios to prepare for future hazardous events. Infrastructure managers require tools to support decision-making and prioritize intervention measures, either during the response or during the prevention stage. A risk-based safety approach regarding flood events provides information by combining data about the chance of a flood event, vulnerability and exposure of community, property and infrastructure.

The overall objective of the oVERFLOW project (<https://projectoverflow.eu/>) is strengthening resilience to climate change impacts, with the specific objective being the development of climate-resilient infrastructure. The key step to achieving the project objective focuses around the refinement of the risk-based approach for vulnerability assessment of levees (Rijkswaterstaat VNK Project Office, 2012, 2014) and using physical (sensor-based) real-time condition data rather than periodic visual condition assessment. Data-driven enhanced knowledge about the vulnerability of the weakest links in the flood protection systems and bridges led to the reduction of uncertainties and improved numerical models. This serves as the basis for decision-making processes regarding the prioritization of strategic investments and to further develop civil protection protocols for flooding events as prevention and response measures. The methodology developed in the oVERFLOW project was validated in a flood-prone case study areas of South Holland Region in the Netherlands and the city of Karlovac in Croatia. This paper presents the methodology validation on Croatian case study area, shown in Figure 1.

Figure 1. Karlovac city center next to the Kupa river: a) <https://aktivirajkarlovac.net/>; 2014 flood in Karlovac, b) <https://www.jutarnji.hr/vijesti/hrvatska/>).

2 FLOOD RISK ASSESSMENT

The intersection of a flood scenario for a specific return period and the area impacted by the hazard, for which vulnerability or damage functions are developed, forms the basis of flood risk assessment methodology. Using the framework presented in Figure 2, the vulnerability analysis results are combined with potential flood effects to create the risk forecasting tool. The tool provides information on the possible financial cost of flood consequences, as well as the population at risk, critical infrastructure, and evacuation routes in the flood-affected area.

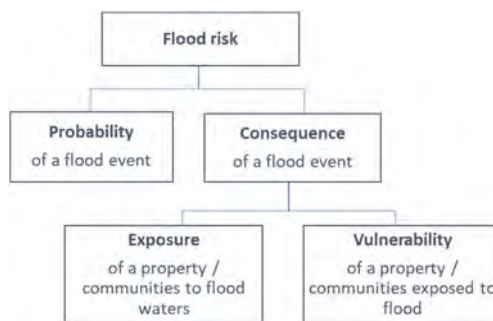

Figure 2. Risk assessment framework.

2.1 Flood hazard scenarios

Climate change is affecting the global mean temperature and the total amount of precipitation. However, the precipitation quantities are regionally significantly varying and have no clear trend compared to the temperature. Observations show that precipitation changes are occurring in the amount, intensity, frequency and type. Basic theory, climate model

simulations and empirical evidence all confirm that warmer climates, owing to increased water vapour, lead to more intense precipitation events even when the total annual precipitation is reduced slightly, with prospects for even stronger events when the overall precipitation amounts increase. The warmer climate, therefore, increases the risks of both drought and floods (IPCC, 2014). The effect of climate change on precipitation is similar to that of the river flows. Future changes in the mean and extreme river flow will show regional variety.

In the development of flood scenarios, historical and predicted climatological and hydrological parameters were analyzed for a period of one hundred years from 1970 to 2070 for the case study in Croatia. A machine learning technique was applied to predict changes in water flow and water level using an ensemble of temperature and precipitation data from the regional climate change model RegCM4 (MZOE, 2017). The model was used to calculate change (projections) for the future climate in two periods: 2011 - 2040 and 2041 - 2070, assuming the IPCC scenarios RCP4.5 and RCP8.5. The RCP4.5 scenario (moderate scenario) predicts the medium level of greenhouse gas concentrations while for the RCP8.5 scenario (extreme scenario) there is continuous increase of greenhouse gas concentrations. Simulations of water flow and water level show that climate change is likely to impact the Kupa river's future flows and water levels. Although the changes in annual average flows and water levels are expected to be small and not significant, models predict a significant increase in flow and water level in winter months and its decrease in summer months for both moderate and extreme scenarios, with bigger changes in the extreme scenario, shown in Figure 3. The climate change data and flood maps obtained with this analysis were further used for vulnerability analysis of critical infrastructure (Burić&Grgurić, 2020).

Figure 3. Modelled ensemble mean annual precipitation with RegCM4 for model point nearest to Karlovac 1970 – 2070; a) scenario RCP 4.5, b) scenario RCP 8.5. Data source: DHMZ (Burić&Grgurić, 2020).

2.2 Vulnerability analysis of embankments and bridges

Within the oVERFLOW project, the vulnerability analysis of critical assets focuses on the embankments and bridges, which are the most important components of the flood protection system and the transportation infrastructure as potential evacuation/emergency routes. The methodology is based on in-situ data collection and numerical models for bridges and embankments. The major outcomes of the proposed methodology are fragility curves for assessing the integrity of embankments and fragility surfaces for the serviceability and ultimate limit state for bridges. These data explicitly account for both material and loading uncertainty and can be used to interpret how likely a failure is, given a certain flood event.

The input data for the analysis of two bridges from the Karlovac case study area is obtained from archived projects, which were complemented with results of a drone and bathymetric survey and ambient vibration measurements (Kosić et al., 2021). The results of the drone and bathymetric surveys were used to define the geometry, whereas measurements of ambient vibration allowed the estimation of the bridge's modal properties. Due to specific hydraulic conditions, i.e. non-stationary flow (Burić&Grgurić, 2020), both velocity and water height are found to be necessary for precise estimation of the bridge performance, so the result of the vulnerability analysis is presented with fragility surfaces, which represents an extension of the classical fragility curve concept.

An advanced modelling approach for simulation of the bridge response considering soil-structure interaction is applied (Kosić et al. 2023a). The study examines different flood-loading scenarios, including hydrodynamic loads, debris and scour. Special attention is devoted to the

explicit simulation of the effect of scouring on the distribution of forces in the structure. Several failure mechanisms are considered, and the most unfavorable mechanism for the given flooding scenario is identified. The vulnerability analysis is performed separately for the serviceability (SLS) and ultimate limit state (ULS). The results of the analyses indicate that the SLS of the bridges is affected significantly by the accumulation of debris, which constricts the flow of the water and leads to an amplification of scour due to the local increase of the flow velocity (Kosič et al., 2023b). The fragility surfaces provide crucial input for developing the risk forecasting tool with the so-called traffic light indicators, representing a safe/unsafe evacuation route during the response.

The implementation of the methodology to the Karlovac case study area includes calculating the probability of failure of 3 km of riverbanks on the left and right side of river Kupa. Riverbank stability is assessed for both rapid drawdown and seismic loading scenarios, for which fragility curves were developed (Bačić et al, 2022). Characteristic riverbank sections are identified from a remote photogrammetric survey, geometry for different sections and probabilistic calculations are performed on each of them. Calculated values of probability of failure for different scenarios provide the basis for classifying the embankments and riverbanks based on their vulnerability and developing an inventory of critical flood protection infrastructure in the case study area.

To evaluate the vulnerability of the riverbank slopes, global stability is identified as the relevant failure mechanism. For each riverbank section, analysis is performed so that the water level external to the riverbank slope experienced a rapid reduction in level while residual water levels (RWL) in the riverbank remained at higher levels. For the seismic stability during the increase of the pseudo-static loads (acceleration), the probability of stability failure also increases. The maximum considered value of peak horizontal acceleration is selected as 0.3g, which is double the value of the 475-year return period in the city of Karlovac (<http://seizkarta.gfz.hr>). These analyses are performed by using drained parameters in the first step analyses and undrained parameters in the second step analyses, in which upper clay was modelled with undrained parameters. In further project developments, these results are incorporated into the risk forecasting tool for the purpose of classification of the embankments and riverbanks based on their vulnerability and development of an inventory of critical flood protection infrastructure (Gavin&Reale, 2021).

2.3 *Direct and indirect consequences*

Flood effects may be both direct, through the immediate interaction of flood water with built, natural and human environments, and indirect, through damage or disruption of transportation and economic activities that impact people's livelihoods. Damage to buildings, economic assets, loss in agriculture, loss of human life, immediate health impacts and loss of ecological goods are generally applied quantifiable parameters. Indirect flood damages are damages caused by disruption of physical and economic linkages and the extra costs of emergency and other actions taken to prevent flood damage and other losses. This includes, for example, the loss of production of companies affected by the flooding, induced production losses of their suppliers and customers, the costs of traffic disruption or the costs of emergency services. Indirect damage is often measured as a loss of flow values (WMO, 2015).

oVERFLOW methodology for quantification of different flood impact categories includes two approaches developed for different types of users:

- i. The quantification of impacts in monetary value to show direct flood damage to different assets can be used by infrastructure managers, owners or local authorities. This information can support decisions such as the prioritization of assets which need to be upgraded, identification of possible needed interventions and investments for flood protection systems, transport infrastructure or any other endangered asset. The model is used in the final risk assessment and can also be used for cost-benefit analysis (Bruijn et al., 2015).
- ii. Mapping of the vulnerability of critical infrastructure and population density gives the insights of direct impacts on humans, especially important for Civil Protection Agencies (CPAs) and first responders about the endangered population, areas with low rise buildings or buildings with people without self-sufficiency (preschools, schools, retirement homes etc.) where their immediate attention is needed in case of floods. It also provides information about safety evacuation routes so they can reach certain areas without delay or endangerment.

The main parameters for the risk evaluation and calculation of direct economic damage are the value of elements at risk and water depth-damage curves (Moel&Aerts, 2011; Klijn et al., 2007). In the oVERFLOW methodology, damages of industrial and residential buildings, businesses, infrastructure and land per different usage types are quantified in monetary terms, using literature and historical values from the case study area (Huizinga et al. JRC, 2017; Kok et al., 2005, Wagenaar et. al, 2016;). For the oVERFLOW project, mainly for the case study area of the city of Karlovac, different categories for residence and industrial buildings are taken into account with damage curves developed for the analyzed area, see Figure 4.

Special assets and areas, including vulnerable assets (critical infrastructure such as transport, healthcare, electricity, and water supply), cultural heritage, installations, and vulnerable nature areas, are identified and mapped. The flooding of these assets is of relevance for flood risk managers, infrastructure managers and evacuation services. Also, mapping buildings per number of stories, provides with the information needed to prioritize evacuation in certain areas. Higher buildings mean more space for people to evacuate themselves on higher floors which is why buildings are mapped according to the number of stories and number of residents.

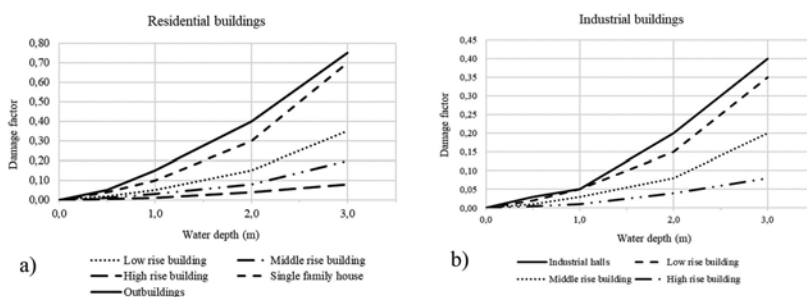

Figure 4. Proposed damage values for Croatian case study for a) Residential and b) Industrial buildings (Skaric&Stipanovic, 2022).

Safe evacuation routes and accessibility for first responders are determined by highlighting critical transport infrastructure. The safe evacuation routes are established based on reaching the nearest safe place within buildings, building blocks and city districts. Areas with higher buildings safer in case of a flood hazard can be highlighted. The main constraints associated with the emergency are structural vulnerabilities along escape routes (failure of bridges or flood protection structures), uncertain road conditions due to landslides, and parts of roads under the water, including traffic congestion, road blockage, etc. Optimal evacuation alternatives in the form of the safest and most efficient routes for evacuation of the population from the affected region are determined based on the results of the vulnerability assessment of bridges and embankments.

Losses to any business in the area affected by flood include loss of business value that would have been produced if a flood event had not occurred. Production is stopped due to the Material Damage (MD) of installations or disrupted supply chains. It could be that other businesses or productions, processes before or after, have also been stopped or delayed due to a hazardous flood event. These are indirect losses, defined as Loss due to Business Interruption (LBI), which do not include direct economic losses to a company caused directly by contact with water. Loss of business category implies the long-term economic effect of a flood due to business interruption. Indirect losses to a business are often expressed as a share of the material damage in flood (Vilier et.al, 2014). In the 1993 Netherlands flood, 75% of the damage to the industry was related to property, and 25% was related to productivity loss (Kok, 2001, Genovese, 2006).

Following the economic scenario that there is no income while the business is interrupted, but the expenditures remain, if the business is to be restored after the flood event, the economic loss due to business interruption (LBI) is calculated based on the following:

$$LBI = (I_{tot} + E_{tot}) \times Nr_{emp} \times T \quad (1)$$

where LBI = loss due to business interruption (€); I_{tot} = total income per employee per day; E_{tot} = total expenditure per employee per day; Nr_{emp} = a number of employees in the flood-affected area; T = time for the return of business to pre-flood conditions.

3 RISK MAPPING

Calculation of risk implies the combination of flood hazard scenarios with the exposed area, and the verification of direct and indirect consequences. The overall product is the spatial distribution of flood risks for selected areas. Direct impacts are quantified in monetary values, while indirect qualitative analysis with pre-designed risk classification and highlighting of different risk levels is proposed. The results are integrated into the existing GIS platforms as two different operational layers: for Infrastructure Managers (IMs) for future planning of investment measures and for CPAs in order to enhance the emergency response and ensure safe and efficient evacuation. Flood hazard maps, which show flood depths for different probabilities of occurrence of a flood, are overlapped with spatial data of area's exposure and vulnerability of critical assets.

3.1 Hazard maps

For the case study area in Croatia, the city of Karlovac, three different flood scenarios have been analyzed and compared. Flood scenarios are based on Croatian Waters flood hazard maps with three different return periods: high (HP), medium (MP) and low probability (LP) of occurrence, with return periods 25, 100 and 1000 years, respectively. Water depths are grouped into four categories: < 0.5 m, 0.5 – 1.5 m, 1.5 – 2.5 m and > 2.5 m (Croatian Waters, 2019).

3.2 Risk tool layers for Civil Protection Agencies

Based on the performed analysis, the following information is provided in the form of a GIS-based risk forecasting tool to be used by CPAs in a case of a flood event:

- Number of people to be evacuated, and their location in the affected area, see Figure 5;
- Crucial institutions affected by flood (hospitals, schools, retirement homes...);
- Available shelters for evacuation (flooded/not flooded);
- Safe and available evacuation routes (flooded roads; operating infrastructure – embankments and bridges that are safe or not safe for usage during flooding), see Figure 6.

Figure 5. Population flood risk map – Map of low rise buildings (red) and number of residents overlapped with a) Flood map HP and b) Flood map LP.

3.3 Risk tool layers for infrastructure managers

Based on the performed analysis, information about possible direct and indirect impacts is provided through a risk forecasting tool to be used by IMs for prioritization and strategic planning. Direct impacts to transport infrastructure and to industrial and residential buildings, businesses, infrastructure and land per type, all quantified in monetary terms. Indirect impacts regarding loss of business disrupted due to the flood event.

Figure 6. Results of the vulnerability analysis for embankments and bridges for a) HP of flood occurrence and b) LP of flood occurrence.

Figure 7 presents total estimated damage values (including direct and indirect damages) for different flood events for the City of Karlovac area. It can be seen from this graph that the total damage costs are increasing with the increase of the return period, or the extent of the flood event.

Figure 7. Graphical representation of economic damage (€) per category for three different flood probabilities for the city of Karlovac area.

4 CONCLUSIONS

Much effort is directed towards improving prevention and response measures for flood events to protect the population, their belongings, assets, businesses, and society at large. Experience has shown that, for the most part, consequences of flood hazard cannot be completely mitigated. As a result, the focus should be placed on reducing or avoiding adverse consequences on people, the environment, and property. Targeted data, which is frequently already available, can be used to extract relevant information from a range of users, including CPAs and IMs. This paper presents an overview of the risk assessment methodology developed within the oVERFLOW project and further implemented in the CROSScade project, which uses the improved vulnerability assessment of the critical infrastructure based on the actual monitoring data and consequence analysis of direct and indirect impacts using local exposure data. The main contribution of the methodology is a better prediction of the areas with the highest risk, which can be used to support decision-making during the response stage and to plan investments to strengthen most vulnerable parts of the critical infrastructure.

Equitable climate adaptation framework for levees

A. Mohammed & F. Vahedifard

Richard A. Rula School of Civil and Environmental Engineering, Mississippi State University, Starkville, Mississippi, USA

ABSTRACT: The evolving risk of floods significantly threatens the economy, safety, and well-being of several regions globally. In 2020, the average annual loss due to floods in the United States was over \$32 billion, projected to increase by over 26% by 2050 due to climate change. This calls for a critical need to proactively develop and implement climate adaptation strategies to ensure the integrity of earthen levees, which play a fundamental role in the nation's flood protection systems. The levees in the United States have an average age of 57 years, most of which are under marginal conditions. Approximately two-thirds of the American population lives in counties protected by levees where floods disproportionately affect disadvantaged communities. We present a risk-based equitable adaptation strategy for levees in a changing climate that concurrently considers changes in hazard levels, vulnerability, and exposure. Identifying new patterns of climatic extremes and natural hazards (i.e., hazard levels) that impact the performance of current and future levee systems is the first step in achieving a climate-ready levee system. The next step involves characterizing the vulnerability of levee systems while considering the influence of climate-adjusted hazard levels. Finally, the proposed adaptation framework suggests considering changes in the exposure of assets and communities in levee-protected areas due to various factors (e.g., climate change, urbanization, land use, and land cover changes). The proposed adaptation framework intertwines engineering factors and socio-demographic attributes toward achieving resilient, sustainable, and equitable levee systems in a warming climate.

1 INTRODUCTION

The evolving risk of floods significantly threatens the economy, safety, and well-being of several regions globally. In 2020, the average annual loss due to floods in the United States was over \$32 billion, projected to increase by over 26% by 2050 due to climate change (Wing et al. 2022). This calls for a critical need to proactively develop and implement climate adaptation strategies to ensure the integrity of earthen levees, which play a fundamental role in the nation's flood protection systems. The levees in the United States have an average age of 57 years, most of which are under marginal conditions. Approximately two-thirds of the American population lives in counties protected by levees where floods disproportionately affect disadvantaged communities (ASCE 2021).

We present a risk-based equitable adaptation strategy for levees in a changing climate that concurrently considers changes in hazard levels, vulnerability, and exposure. Identifying new patterns of climatic extremes and natural hazards (i.e., hazard levels) that impact the performance of current and future levee systems is the first step in achieving a climate-ready levee system. The next step involves characterizing the vulnerability of levee systems while considering the influence of climate-adjusted hazard levels. Finally, the proposed adaptation framework suggests considering changes in the exposure of assets and communities in levee-protected areas due to various factors (e.g., climate change, urbanization, land use, and land cover changes).

The proposed adaptation framework intertwines engineering factors and socio-demographic attributes toward achieving resilient, sustainable, and equitable levee systems in a warming climate.

2 LEVEE RISK

Risk is defined in this study as the likelihood of adverse effects on people and assets. (IPCC 2021). In climate change-related studies, the risk is identified as the result of the interaction of hazard, vulnerability, and exposure. Thus, levee risk in this study is defined as the product of evolving hazards, vulnerabilities, and rising exposure. This implies that there is no risk in areas where the hazard does not cause harm to communities or assets. Risk is found when there is an overlap of extreme events, people and assets, and vulnerability in the levee system. Here consider three scenarios i) Extreme event causing levee failure in a remote area with no people or assets. ii) Extreme events lowered levee performance in an urban area with adaptation measures in place. iii) Extreme event lowered levee performance in an urban area with no adaptation measures in place. The first option indicates the most significant hazard, while the third option indicates the highest risk. Delineating the evolving levee risk with climate change is critical to achieving a climate-ready levee system. Hence, the study considers these three components (hazard, vulnerability, and exposure) to constitute the key elements of a comprehensive risk assessment for levees (Figure 1).

Figure 1. Interaction between hazard, vulnerability, and exposure.

2.1 Hazard

The consequences of anthropogenic climate change are felt through the exacerbating intensity and frequency of extreme events in the form of rising water levels, particularly on levees (Milly et al. 2002; Buchanon et al. 2017; Vitousek et al. 2017; Taherkhani et al. 2020). The increase in the water level can be a result of storm surges, extreme precipitation, river discharge, increased surface runoff, and land subsidence. Changes in land use and urban developments in floodplains directly lead to a reduction in the storage capacity of natural storage systems. River channels are often confined within dikes or levees to accommodate new settlements. This can lead to higher river velocities increasing flood risk downstream. Measures to curtail flooding in one location may increase flood risk in different locations (Wang et al. 2018). Urban development also results in larger areas of impervious surfaces such as roads, pavements, and parking yielding increased surface water runoff. The failure of drainage systems can have severe impacts on the land side of the levee. Thus, it is critical to identify new patterns of climatic extremes and natural hazards (i.e., hazard levels) that affect the performance of existing and future levee systems.

Climate change can have an impact on individual extreme events as well as compounding and cascading hazards (e.g., co-occurrence of extreme precipitation and storm surge) (Moftakhari et al. 2017). Variations in the probabilities of storm surge, sea level rise, and even droughts can, either individually or combined can have a significant impact on levee performance in the short and long term. Levees are designed for rainfall through extreme precipitation estimates, which are derived from the assumption that the probability of extreme events does not change drastically over time. This assumption can lead to underestimation in the levee design (Vahedifard et al. 2017). Levees are also typically designed to withstand single or multiple extreme events. However, most design criteria, operating procedures, and levee maintenance and management practices do not consider the impact of compounding extremes, i.e., the simultaneous occurrence of multiple extreme events, or cascading impacts, i.e., successive extreme events contributing to the reduction in levee performance. Most often, the interdependencies of two or more hazards which may or may not be extreme events in and of themselves, are overlooked. This phenomenon is known as a compound event. The following scenarios provide examples of circumstances leading to compounding events i) two or more co-occurrences of extreme events (extreme rain and storm surge), ii) co-occurrence of extreme events with underlying conditions that amplify impact (earthquake and extreme rain) or iii) combination of events that are not themselves extreme but collectively lead to severe impacts (moderate rain and drainage failure).

2.2 *Vulnerability*

Vulnerability is defined as susceptibility in levee performance due to factors such as age and gaps in understanding the impacts of compounding events. Addressing vulnerability requires the development of frameworks that associate climate change data with physical performance measures (e.g., probability of failure) of levees. Levees were used to protect farmlands and livestock primarily. However, due to rapid urbanization, levee-protected areas now accommodate critical infrastructure. There is a growing number of studies into developing resilient levees; however, despite the advances in climate adaptation, there are several critical gaps in the current state-of-the-art, including i) uncertainties in changing hazard levels, particularly future extremes are often ignored. Typical levee performance studies consider one or a few sources of uncertainty, such as soil property. However, there are several sources of uncertainty including hydraulic loading scenarios, response thresholds, material properties, and uncertainties related to future representative concentration pathways (RCPs). ii) land vegetation atmosphere interactions, their impacts on the performance of levee systems, and their underlying uncertainties are typically overlooked. iii) interactions between different modes of failures, e.g., slope stability failure, under seepage, and over-topping failure under single and compound loading scenarios, need to be better understood and addressed in the design. iv) The changes in levee resilience over their service life are not well understood or modeled. Levees are subject to various hazards that may occur with non-stationary intervals and uncertain magnitudes throughout their service life. In addition, the residual effects of a hazard will affect levee performance in the subsequent hazard. Prolonged drought, for example, can cause desiccation cracks in earthen levees, leading to increased infiltration during extreme precipitation and eventual depreciation in levee performance. Awareness programs, monitoring, and mitigation efforts can all help to reduce vulnerability. A classic example is the \$500 million flood damage caused by levee failure in the Secchia river in northern Italy in January 2014 (Orlandini et al. 2015). In this incident, the failure of the levee raised awareness, which led to government agencies identifying a potential second breach. A quick mitigation response prevented a second levee failure and subsequent damage (Orlandini et al. 2015).

2.3 *Exposure*

The rising global population and encroachment in areas particularly close to natural water bodies constitute one of the main reasons that damages from extreme events have significantly increased in the past decade. Over half of the world's population lives within 3 kilometers of

a natural water body (Kummu et al. 2011). Despite covering less than 15% of the earth's total area, coastal regions susceptible to flooding accommodate a substantial proportion of the world's population. In the U.S., seventeen million people live behind a levee (ASCE 2021). The rising exposure to flood risk directly results from the growing population, assets, more frequent and severe extreme events due to anthropogenic climate change, and land-use/ land-cover changes. Most often, flood plains are attractive locations for new settlements due to the ease of access to water and the natural flat terrain for development. An example of increasing exposure is observed when the local public and decision-makers believe that the levee has controlled river flow and continues to develop flood-prone areas. Developed areas eventually become urban centers, where a levee breach can have serious consequences for people and assets. Therefore, a levee adaptation framework should account for the changes in the exposure of assets and communities.

Rising exposure increases the dependency and importance of other critical infrastructure systems, such as power grids, for a community's resilience. The uneven spread of post-flooding resilience can lead to pockets of areas with higher exposure. This is especially noticeable in areas with high concentrations of underserved and socially vulnerable communities. For example, people living below the poverty line have a lower capacity to recover from hazards than those who are affluent. This variability can be curbed by incorporating environmental justice into the adaptation strategy.

3 5-STEP FRAMEWORK FOR EQUITABLE LEVEE ADAPTATION

Broadly climate adaptation of infrastructure is viewed as a changing of the existing status quo and adopting new practices to enable the development of climate-resilient infrastructure. Here, we present a five-step framework for the equitable adaptation of levees. A comprehensive levee adaptation strategy requires concurrent consideration of both geotechnical and socioeconomic factors to achieve equitable risk. Despite rising interest in climate-resilient infrastructure, the state-of-the-art practice currently lacks in terms of ensuring equity in investments and adaptation. Historically underserved and vulnerable communities (HUSVCs) are considerably more vulnerable to flooding due to pre-existing conditions stemming from socioeconomic characteristics such as poverty, lack of education and awareness, health, and no vehicle access. Furthermore, these communities are ill-equipped to prepare for and respond to floods due to a limited understanding of forecast terminologies and the severity of floods. HUSVCs are found to disproportionately occupy levee-protected areas due to various factors such as segregation by race and ethnicity, low property value, language, employment status, and immigration status. Hence, any attempts to create a climate adaptation strategy should explicitly include considerations for environmental justice to ensure equitable adaptation outcomes. Such a framework should seamlessly integrate physical performance measures and socioeconomic characteristics.

This study proposes a five-step framework for equitable levee adaptation that considers rising flood risk and prioritizes HUSVCs (Figure 2). The framework is built to achieve equal flood risk for all communities, regardless of socioeconomic status. Moreover, the framework is designed to be iterative, meaning past shortfalls are identified and corrected for the next cycle. The five steps that constitute the adaptation framework is as follows.

- i) **Community assessment:** The main objective of the first step is to identify communities most in need of levee adaptation. This step entails geospatial analysis of levee-protected areas in conjunction with population characteristics. Two datasets used here include Levee-protected areas: regions protected from flooding by levees obtained from the national levee database (NLD 2022), and Census data: For levee-protected areas, the census bureau provides socioeconomic and demographic data such as African Americans, Asians, Native Americans, Hispanic or Latino, persons below poverty, persons with low education, households without access to a vehicle, and persons with disabilities at the tract level. The findings of the first step inform decision-makers about which areas require priority for adaptation and identify areas of higher exposure.

- ii) **Community engagement:** The second step is to broaden public participation to better understand their needs and priorities, knowledge gaps, and perceived risk. This step aims to identify stakeholders (public, political, environmental, and commercial) in the adaptation. Moreover, by engaging the community, knowledge disconnects between stakeholders can be evaluated and addressed through informal education (Collins and Ison, 2009). An effective strategy for improving hazard awareness in the general public is to provide a platform for discussions between the people, government, and researchers. A truly integrative approach can be reached when the local public, decision-makers, and researchers work together towards a common goal. Open discourse on preparedness, lack of awareness, response to the event, existing evacuation strategies, and funding available should take priority. The primary objective of this step is to establish a two-way dialogue with impacted communities and ensure their concerns are addressed during the adaptation process.
- iii) **Flood risk assessment:** Following community identification and engagement, this step entails the assessment of levee performance for different modes of failure under current and projected future climate conditions. Extensive research methods have been used to perform a risk assessment of levees (Zhang et al. 2013; Zimmaro et al. 2019; Lanzafame & Sitar, 2019; Vahedifard et al. 2020). These methods use fragility curves, which provide the relationship between the probability of failure and hydraulic loading. This step quantifies the impact of climate change by considering changes in hazard levels. Assessment should quantify the impact of worsening hydraulic loading on levees, individually or combined, which can severely impact levee performance. (Vahedifard et al. 2020). Furthermore, the assessment also provides guidelines and risk thresholds to initiate adaptation measures.
- iv) **Adaptation assessment:** The fourth step entails weighing feasible and practical adaptation options based on the outcomes of the previous three steps. The type of vulnerable communities, their needs, perceived risk, concerns, and the current state of the levee should all be used to determine the preferred adaptation option. Both soft and hard adaptation options can be proposed to determine the most practical approach in terms of funding availability, federal government support, and the viability of adapting the current levee system. Furthermore, it is necessary to estimate the financial resources required to implement adaptation measures and compare the potential cost savings from adaptation. It is also critical to

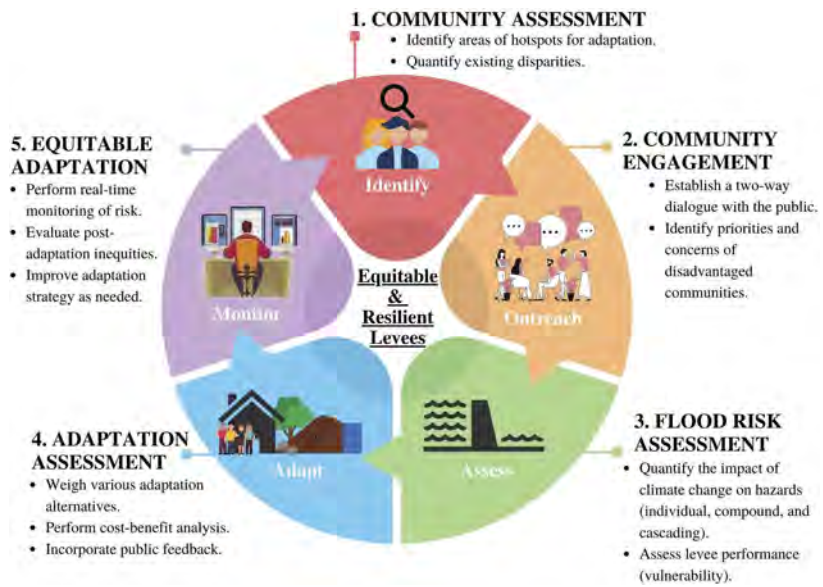

Figure 2. Five-step framework for equitable climate adaptation of levees that incorporates evolving flood risk and prioritizes disadvantaged communities.

debate the benefits and drawbacks of the proposed adaptation strategy at various stages of the framework and incorporate local public feedback into the design.

- v) Equitable adaptation: The final step is the implementation of a selected adaptation strategy. However, adaptation alone is not adequate; this step aims to establish long-term monitoring protocols to evaluate evolving risk. This step sets up protocols for long-term monitoring of evolving hazards, developing vulnerabilities, and rising exposure. This step also takes a look back at the adaptation process to identify room for improvement. For instance, an evaluation of how public participation influenced adaptation planning or tradeoffs between parties for reaching a consensus on adaptation strategy needs to be recorded. The proposed five-step framework is an iterative process that improves with each cycle by addressing shortcomings in the strategy for future adaptation efforts.

4 ADAPTATION STRATEGIES

Feasible levee design based on short and long-term hydraulic loading scenarios is required for levee adaptation. The uncertainties and intermodal variability in future climate extremes will elevate the probability of levee failure. As a result, developing resilient current and future levees requires accounting for the variability and uncertainty associated with a changing climate future. A viable approach is to have a risk-based adaptation strategy, which allows for the design to adapt to changes in hazard levels, vulnerability, and exposure. Levees can be built with a capacity for adaptation, allowing for adaptation measures to be implemented when water levels reach a particular threshold. This approach has a lower upfront cost but with the option of additional investment to respond to future extreme events (Hinkel et al. 2014). A risk-based adaptive strategy considers and identifies potential hazards and their likelihood of occurrence and prepares for the future decline in levee performance. However, rebuilding the nation's levee systems is prohibitively expensive. As a result, soft measures such as elevating levees, fail-safe options, land acquisition, flood warning systems, and land use regulations are frequently used in levee adaptation strategies.

To mitigate the effects of flooding, several adaptation options can be used. The list of possible soft measures is lengthy and frequently region/climate dependent. Some soft measures that can be implemented include i) complete mapping of levees across the U.S. as outlined in the national flood insurance reform bill. ii) Designate levees based on current conditions iii) Inspecting and bringing up to code current levee systems using updated loading scenarios. iv) Designate high-exposure zones to identify areas that require priority. v) Develop policies for maintenance and upgrading deteriorating levees. vi) Develop systems that reduce reliance on levees for flood protection, such as having safe-to-fail options. vii) Ensure adequate funding for the operation and routine maintenance of levees. viii) develop alternative water storage infrastructure or systems to route excess water. Finally, establish several funding streams to develop and maintain resilient levee systems that can withstand future climate change.

5 CONCLUSION

Despite the rising severity and magnitude of extreme events as a result of climate change, there are few studies that present a comprehensive framework that incorporates environmental justice into climate adaptation for levees. Here, we present a framework for climate-resilient levees that incorporates possible metrics to quantify progress and approaches that are grounded on environmental justice. In the proposed framework, First, we identify disparities in leveed protected areas, which serve to identify hotspots for equitable adaptation. Second, we approach at-risk communities to determine their needs, goals, and perceived risk. For an equitable outcome, it is critical that community feedback be incorporated into the adaptation process. The third step involves flood risk assessment, which entails detecting vulnerabilities in levee systems using physical performance measurements (probability of failure). The fourth

step is then used to evaluate adaption alternatives based on cost-benefit analysis and community feedback. The final step involves implementing adaptation and long-term monitoring of levee performance and social impacts. It is crucial that environmental justice is incorporated into each step of the framework. Finally, a robust five-step adaptation framework is proposed that incorporates both engineering and socioeconomic factors. Comprehensive studies are required to explore each step of the framework to develop a set of objectives, outcomes, and prerequisites for moving forward.

Maintaining levee resilience in a changing world while addressing existing inequities is a complicated and multidisciplinary problem. To address this issue, close collaborations between experts from various fields, including geotechnical engineering, climate science, social science, and hydrology, as well as decision-makers and authorities responsible for maintaining and operating levees, are required. Finally, climate adaptation of levees will fail to reach an equitable outcome unless the public is actively involved throughout the adaptation process to identify and recognize resilience and equity concerns.

Integration of information quality assessment in bridge resilience management

N. Makhoul & M.P. Limongelli
Politecnico di Milano, Milan, Italy

ABSTRACT: Bridge conditions assessment is increasingly relying on Structural Health Monitoring (SHM) which allows the continuous acquisition of information on the structural state and overcomes problems that affect visual inspection such as subjectivity of the assessment, and difficulty to access hidden damages. However, the quality of SHM data is scarcely considered when information extracted from data is used to support management decisions, even though it plays an important role in the optimization of the management strategy and relevant decision-making process. In this article, a proposal to integrate the assessment of SHM information quality into bridge condition assessment management is presented. Mainly are discussed a general bridge management assessment procedure, and a decision-making scheme based on the Value of Information analysis to quantify the Value of Information Quality Assessment (IQA), and the impact of SHM IQA on bridge performance indicators.

1 INTRODUCTION

Modern bridges, constructed primarily in the past century, are aging worldwide and require maintenance. It is a challenge to extend their lifetime due to population growth, and increased natural risks from climate change.

Transportation is a necessity for the economy, the appropriate operation of modern society, and its continuous welfare (Schroten et al. 2019). However, due to the scarcity of resources required for adequate maintenance, preserving the required functionality level of aging critical infrastructures such as bridges is problematic. The average annual loss on transport infrastructure due to floods during the years 2010 to 2015 (European Environment Agency 2019) represents an average annual loss of 13.3 billion euros, with a constant upward trend in the coming years. Therefore, one main objective of the European Union (EU) is to preserve transport infrastructures appropriately functional. This led the EU, for example, to invest solely €38 billion in maintenance (Schroten et al 2019). These figures call for the development of a strategy to optimize bridge integrity management accounting for our scarce capacity to precisely predict the occurrence, long-term evolution, and spatial distribution of disruptive events.

In the last 30 years, research efforts have been devoted to a change of perspective from a condition-based to a risk-based approach in pursuit of efficient bridge integrity management subject to limited budgets. This is demonstrated by the extensive literature on this theme resumed in (Makhoul & Argyroudis 2018) and by the several research projects funded by the EU, such as COST TU1406 (Casas & Matos 2021). However, risk-based approaches to bridge integrity management do not account for the need to improve the recovery phase after the disruption thereby reducing the indirect consequences related to its loss of functionality ((Bruneau et al 2003), (Faber 2007), (Cimellaro et al. 2009), (Linkov et al. 2014), (Sharma et al. 2018), (Faber 2018)). Furthermore, interconnections between networks and domains are neglected most of the time. This does not replicate the real world which is shaped by increasingly

interconnected technological, economical, sociological, and ecological networks (Havlin et al. 2012, Linkov et al. 2014). Thus, a systemic approach is needed to account for these interconnections allowing us to describe the resilience across and within these domains.

In (Faber 2018) a systemic approach was suggested for sustainable and resilient engineered systems. It allows for building decision support and management tools using an indicator-based approach, which was suggested for interconnected subsystems (i.e., physical, social, and economical). In (Turksezer et al 2020) the concept of resilience indicators was used to define the characteristics of the managed system in terms of physical, information, and organizational subsystems. In this framework, the management of the system operated by the organizational subsystem is supported by the information flow managed by the information subsystem. However, in this, as in many other approaches, information quality is not considered, implicitly assuming that the available information possesses the required quality to support decisions. Studies addressing information quality and discussing the role of information quality in resilience management are still absent (Makhoul & Argyroudis 2018, Makhoul & Argyroudis 2019, Faber 2018, NAP 2012s). The scope of this article is to propose a step toward this direction through the integration of information quality into a framework for managing the resilience of bridge infrastructure.

This article recalls in Section 2 indicators for data quality (DQ) assessment previously published (Makhoul 2022, Makhoul & Limongelli 2022) and in Section 3 their deterministic and probabilistic metrics (Makhoul 2022). In Section 4, which constitutes the core of the paper, a possible framework based on Value of Information (VoI) analysis is proposed to account for SHM information quality in the management of bridge condition assessment. Finally, the integration of SHM information quality assessment into VoI analysis and the impact of SHM information quality on bridge performance indicators are briefly discussed.

Table 1. Data quality indicators and sub-indicators.

Data management phase	Indicator	Definition
<i>Acquisition</i>	Correctness	data is accurate, precise, and consistent
	Accuracy	the measured value of data is close to the real-world
	Precision	the measured data values are close to each other
	Consistency	the measured data is free of internal contradictions with respect to a rule.
	Redundancy	the measured data is not unique (multiple sets of data exist).
<i>Processing and sharing</i>	Accessibility	the measured data is available and can be shared reliably
	Interoperability	the measured data is concise and interpretable by machines
	Security	the access to data can be restricted to other parties and kept secure.
	Traceability	the sources of data are known
<i>Supporting decisions</i>	Timeliness	the data is up-to-date when needed
	Completeness	all required data are available in the dataset
	Relevance	the data is useful for the task at hand

2 SELECTION OF INDICATORS FOR QUALITY ASSESSMENT OF SHM DATA

Data quality indicators for structural health monitoring were suggested in (Makhoul 2022) and (Makhoul & Limongelli 2022). Those indicators were clustered and assigned sub-indicators to describe their different aspects. Overall, six indicators, and five sub-indicators were designated as presented in Table 1 with their allocated definitions. The indicators were grouped into three phases of data management (i.e., acquisition, processing and sharing, and Supporting decisions). The classification aims to highlight proper data quality aspects for each one of the SHM data management phases.

3 METRIC FOR THE GLOBAL QUALITY INDICATOR INDICATORS

The data quality metrics were reviewed (Makhoul 2022), and two methods were suggested for assessing DQ metrics in SHM Context. Those methods are 1) A deterministic method, and a probabilistic method accounting for uncertainties.

3.1 Deterministic metrics

The deterministic method assigns data quality metrics using scales. Those scales range from 0 (i.e., the lowest quality) to 1 (i.e., the highest quality). Metrics are defined as discrete or continuous scales as follows.

The discrete scale, where the metric has at least two or more discrete values:

$$\text{metric} = \begin{cases} 1 & \text{yes} \\ 0 & \text{no} \end{cases} \quad (1)$$

$$\text{metric} = \begin{cases} 1 & \text{yes} \\ 0.5 & \text{partially} \\ 0 & \text{no} \end{cases} \quad (2)$$

where ‘yes’ and ‘no’ means that the data is accurate (for accuracy), or not, etc., and ‘partially’ means that the data partially possess the quality under consideration (e.g., 0.5).

The continuous scale, where the metric is defined as a percentage of the data having this quality (i.e., 50% of the data is accurate, etc.).

Then, (Makhoul 2022) introduced a global metric accounting for all quality attributes. This DQ is computed using the equation:

$$DQ = \sum_u \omega_u * DQ_u \quad (3)$$

where DQ_u is the metric for the u^{th} quality attribute and ω_u the relative normalized weight.

The normalized weights are calculated by:

$$\omega_u = \frac{S_u}{\sum_u S_u} \quad (4)$$

where S_u are the weights of the quality attributes which, for example, might be based on expert opinion. They enable us to distinguish between the importance levels of selected attributes. The decision-maker is required to allocate scales (S_u) to each quality indicator based on its assigned importance for the decision-making case at hand. The definition of the weights in equation (4) guarantees that the sum of all the weights equals 1:

$$\sum_u \omega_u = 1 \quad (5)$$

This global metric is used to assess the level of data quality by suggesting adequate thresholds.

3.2 Probabilistic metrics

Probabilistic metrics were proposed in (Makhoul 2022) in the form of probability distribution functions. They were offered for the cases of permanent and occasional monitoring to account for different data flows (Table 2). The probabilistic approach assigns an adequate probability distribution function to the indicator metrics. As discussed in (Makhoul 2022) probabilistic metrics varies based on the type of data and associated uncertainties. In SHM, the probability distribution function assigned is highly dependent on the flow of the SHM data. The flow is scarce in the case

Table 2. The probabilistic metrics for DQ for permanent and occasional SHM.

Indicators				
Measurement	Accuracy	Precision	Consistency	Completeness
Permanent	$A = R - M \sim N(\mu, \sigma)$	σ_d	$Co \sim N(\mu_{co}, \sigma_{co})$	$C \sim N(\mu_c, \sigma_c)$
Occasional	$A = R - M \sim B(n, p)$	σ_d	$Co \sim B(n_{co}, p_{co})$	$C \sim B(n_c, p_c)$
Indicators				
Measurement	Timeliness	Accessibility	Redundancy	Relevancy
Permanent	$Q_{Time} = 1$	$Ac \sim N(\mu_c, \sigma_c)$	$R \sim N(\mu_r, \sigma_r)$	$Re \sim N(\mu_{re}, \sigma_{re})$
Occasional	$Q_{Time}(T) = e^{-\lambda T}$	$Ac \sim B(n_c, p_c)$	$R \sim B(n_r, p_r)$	$Re \sim B(n_{re}, p_{re})$

of occasional SHM measurements, thus the data is discrete and the binomial distribution can be used (Faber 2012). The flow is abundant in the case of permanent SHM measurements, thus the data is continuous and the normal distribution can be used (Faber 2012).

4 ACCOUNTING FOR DATA QUALITY OF SHM IN THE LIFE CYCLE ASSESSMENT MANAGEMENT

In this section, the integration of SHM information quality assessment into bridge condition assessment is proposed. In Section 4.1, a general bridge management assessment procedure considering the SHM information quality is presented. Then in Section 4.2, the integration of SHM information assessment into the Value of Information analysis is presented. Finally, in Section 4.3, the impact of SHM information quality assessment on the estimation of bridge performance indicators is briefly discussed.

4.1 General bridge management assessment procedure considering the SHM data quality

A General Assessment Procedure (GAP) for the existing structure was presented in (ISO 13822 2010). Herein an Updated General Assessment Procedure (UGAP) that includes the assessment of SHM information quality in the process is introduced (Makhoul 2023). It is presented in Figure 1. This step was included after the inspection tests such as surveillance, visual, etc. The outcome of the VoI analysis may lead – or not – to perform an Information Quality Assessment (IQA). Two outcomes are possible i.e., whether the value of information equals zero, then the IQA is skipped, and GAP is followed straightforwardly. If the IQA leads to a value of information greater than zero, then IQA is performed on the collected information. The word ‘inspections’ is generically used herein to address the process of collecting information about the bridge condition. This process can be carried out through visual surveys, destructive and nondestructive testing, SHM, etc. The selection of the specific type of inspection can be carried out through a Value of Information analysis. However, herein the focus is on the integration of information quality assessment (IQA) into condition assessment thereby the selection of the inspection type will not be addressed. Without loss of generality, it will be assumed that the inspection process is carried out through SHM. The management actions considered in the flowchart in (Figure 1) can be operation actions (i.e., monitoring, and change in use) or construction actions (i.e., rehabilitation such as repair or upgrading, and demolition). In the following, they will be generically addressed as ‘interventions’.

4.2 Value of information analysis accounting for the SHM information quality assessment

The suggested decision-making framework to assess the benefit of performing SHM IQA is based on VoI analysis. The approach is based on pre-posterior Bayesian analysis and expected

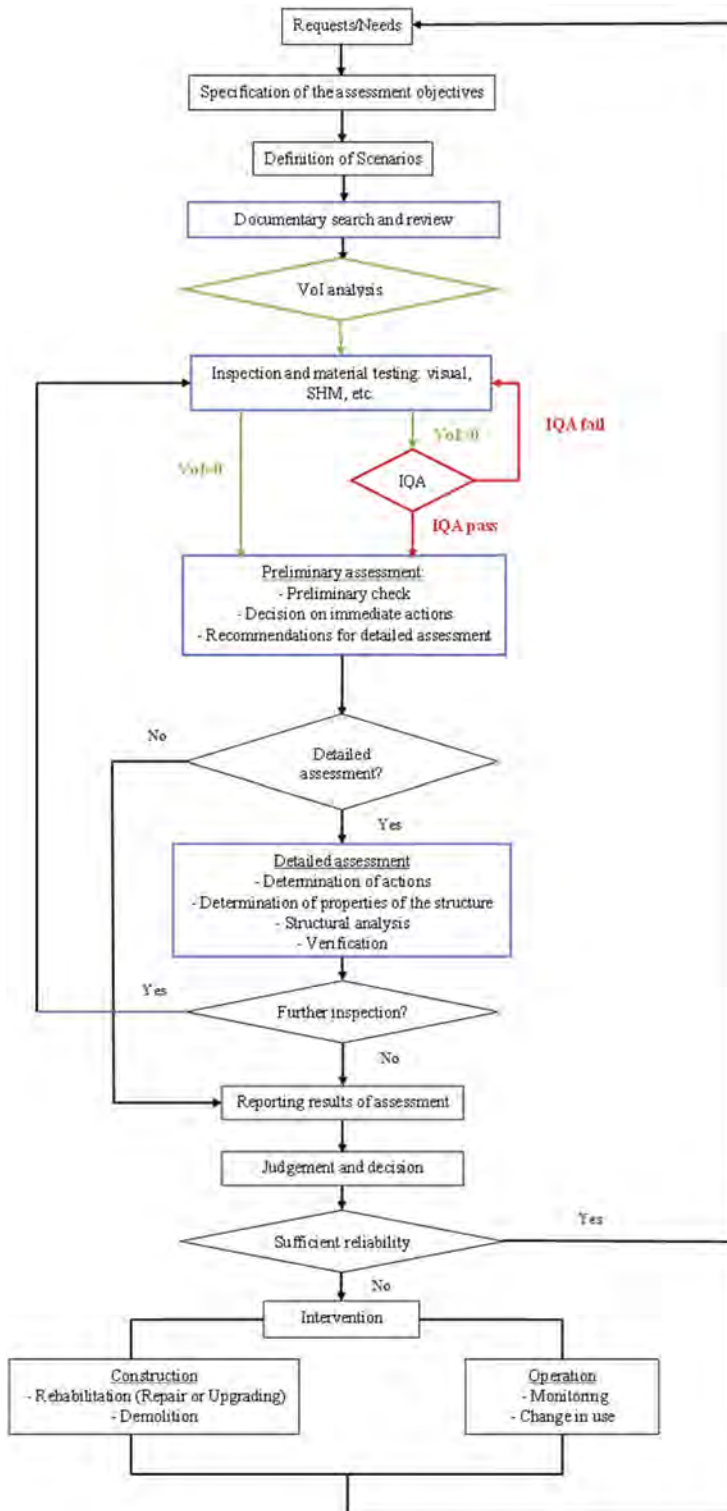

Figure 1. Flowchart for the updated general assessment procedure of existing structure considering the SHM IQA.

value theory (Schlaifer & Howard 1961, Benjamin & Cornell 1970, von Neumann & Morgenstern 2007).

In Figure 2 the process to quantify the VoI of IQA for information collected through inspections is represented through a decision tree. In reference (Giordano et al. 2023) the complete framework is described and applied using a machine-learning-based tool for the assessment of the information quality. Herein the decision tree that describes the VoI quantification is illustrated.

Decision nodes are depicted by a square, and chance nodes by a circle. Branches stemming from squares represent decision alternatives, and branches stemming from circles represent states of nature. Herein the decisions are about the implementation of the information quality assessment (IQA), and of the intervention action (a). The upper branch of the tree represents the prior decision analysis where the selection of the optimal intervention is carried out without performing IQA. The bottom branch is the pre-posterior decision analysis where the decision about the intervention is performed with the support of IQA. The difference between the expected consequences of the optimal actions (schematically reported in equation 6) selected with the two types of decision analyses (prior and pre-posterior) quantifies the values of IQA. The full processed equations are detailed further in (Makhoul 2023), and for utility counterpart and computations (Makhoul, 2019).

$$VoI = C_{preposterior} - C_{prior} \tag{6}$$

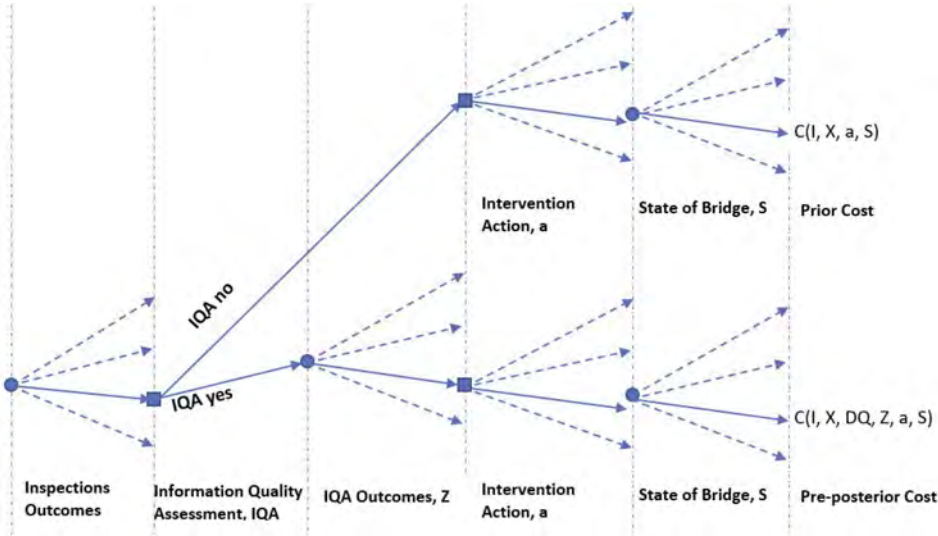

Figure 2. Decision tree for the quantification of the Value of Information Quality assessment (IQA).

4.3 System performance indicators accounting for SHM information quality

Bridge performance can be analyzed using several available performance indicators, such as for instance risk and resilience. Herein reference is made to a generic performance indicator.

The structural performance – and thereby its indicators – will generally decrease in time due, for instance, to deterioration associated with insufficient maintenance. The estimation of performance indicators can benefit from SHM information that provides an improved knowledge of the bridge condition (Bocchini et al. 2012) and (Capacci & Biondini 2020). If also SHM IQA is carried out, a further update of the performance indicator can be carried out, leading to a different estimation of the service life as shown in (Figures 3-4).

Figure 3. Performance indicator profile with and without SHM IQA: a) case of Service life longer with SHM and with SHM IQA, b) case of Service life greater with SHM but shorter without SHM IQA.

Figure 4. Resilience indicator profile with and without SHM IQA: a) case of Service life longer without SHM and longer with IQA than without IQA, b) case of Service life longer without SHM but shorter without IQA than with IQA.

5 CONCLUSIONS

Bridge conditions assessment is increasingly relying on Structural Health Monitoring (SHM). However, the quality of SHM information is rarely considered although it plays a vital role in management strategy optimization and relevant decision-making. To address this issue, this article suggests the integration of SHM information quality assessment on a Value of Information analysis base. The integration of SHM information quality assessment into VoI analysis and the quantification of resilience indicators and bridge service life are briefly discussed.

ABSTRACT: In the oil and gas industry, storage tanks play an important role, ensuring a continuous flow of the petroleum based products. Interruption in their performance due to unforeseen failure and subsequent repairs can result in losses running into millions of dollars. Even the prescribed inspection and maintenance regimes cause interruptions in their service resulting in monetary losses. Although such inspections are routine in the industry, information collected from non-destructive evaluations are rarely used in planning the life-cycle management of these structures. This work proposes a framework for planning the life-cycle management of steel oil and gas storage tanks by optimizing the inspection interval (or, minimizing the inspection cost and business losses). In this, a minimum reliability-based performance criterion is selected as the constraint. The time-varying probabilistic performance of the structure (considering uncertainty in loading, material and geometric parameters) is assessed through Bayesian updating of the deterioration model based on ultrasonic thickness measurements from past inspections. This framework is demonstrated on a “Horton sphere” liquefied petroleum gas storage tank subjected to corrosion deterioration.

1 INTRODUCTION

The oil and gas industry have a large number of metallic structures in their infrastructure asset portfolio. Steel storage tanks play a significant role in the storage of flammable and hazardous crude oil and its derivatives. A review of accidents of 242 storage tanks show that 74% of accidents occurred in petroleum refineries, oil terminals or storage (Chang & Lin 2006). A small accident may lead to property loss of million dollars and few days of production interruption. A large accident results in lawsuits, stock devaluation, or company bankruptcy. For example, a recent chemical spill in Charleston, West Virginia, USA resulted in more than 40,000 litres of toxic liquid from storage tank into a nearby river contaminating the drinking water of approximately 300,000 people for 12 days and resulting in the responsible company filing for bankruptcy shortly after (Larson 2014). An investigation into the disaster made by the US Chemical Safety and Hazard Investigation Board found that pitting corrosion on the tank degraded the thickness of the tank and was the direct cause of the incident (CSB 2014). Corrosion is one of the top factors responsible for such accidents (Esouilem, Bouzid, & Nadeau 2020).

Above-ground steel storage tanks are prone to atmospheric corrosion or interior corrosion or both, which causes reduction of shell thickness. The interior of a tank, that is in contact with the petroleum products, should not corrode since the hydrocarbons are not corrosive to metals and alloys. However, dissolved water and oxygen, hydrogen sulphide, certain organic sulphur and oxygen-containing compounds in petroleum products can cause corrosion (Groysman 2014b).

Annual report of economic losses from corrosion at a oil refinery near Haifa, Israel, with a capacity of 12 million ton crude per year had direct losses from corrosion of US\$ 4-8.5 million per year. The cost loss of production downtime (indirect losses) can sometimes be even more: US\$ 7.5-30.4 million per year. Thus, the total loss from corrosion amounts to US\$ 13.8-34.5 million per year (Groysman 2014a). It is no wonder that this cost of corrosion to our society is included in the price of many products that we buy, be it a car or everyday commodities like bread.

Conventionally, to keep the tank structural performance from deteriorating due to corrosion over the intended service-life, a corrosion allowance (CA) in terms of additional shell thickness is provided over the required thickness to bear the loads. CA is usually based on the expected deterministic corrosion rate for the service-life. However this deterministic method may be inadequate considering the uncertainties of the corrosion process over a long service life.

To track the life-cycle performance, an inspection interval of 5 years is usually prescribed, from 10 years after its commissioning. In this inspection the residual shell thickness of the tank is measured using ultrasonic thickness gauge. This prescriptive inspection interval approach may be either short or elongated with respect to the condition of the tank. When the interval is shortened, the cost of cleaning tanks (for inspection) and the temporary loss of storage volume or plant operating issues can be extremely costly. For elongated inspection intervals, there is the risk of environmental damage caused by leaking tanks and the high cost of environmental cleanup due to missed detection of corrosion. Therefore, tank owners have a keen interest in lengthening the service interval of their tanks to the extent that the safety of the tank is still maintained prior to the next scheduled inspection.

This work proposes a novel framework for planning the life-cycle management of Horton tanks (Figure 1) by optimizing the inspection interval. In this, a minimum reliability-based performance criterion is selected as the constraint. The time-varying probabilistic performance of the structure (considering uncertainty in loading, material and geometric parameters) is assessed through Bayesian updating of the deterioration model based on ultrasonic thickness measurements from past inspections. The next inspection is scheduled at the half remaining life computed (BIS 1969).

Figure 1. LPG Horton sphere tank.

2 TANK INFORMATION

In this paper a LPG/propane storage steel Horton sphere located in India is investigated (Figure 1). The sphere was designed following BS 5500 (BSI 1997) and SMPV rules (PESO 1981) with internal diameter $D_i = 18.0$ m for a design pressure $p = 21.2$ kg/cm² at top and design shell thickness of 50 mm. The grade of steel is A-537 CL-1. This tank was commissioned in 1999. The first set of measurements of shell thickness was taken in the year 2009 with a total of 734 measurements. The minimum shell thickness found in this survey was 49.4 mm. The second set of

thickness measurements was performed in 2014, with 684 measurements in total, with a minimum shell thickness of 49.7 mm. For these two sets, different agencies were involved in the measurements. It is inferred that in these measurements the locations of measurement were not identical, which is realistic considering that such locations are not marked for future usages.

The data along with a deterministic linear regression line is shown in Figure 2. As seen in this figure, there is a considerable scatter in the thickness data for every year of measurement. The most significant drawback in adopting a deterministic regression is that it ignores this scatter and results in (erroneous) point estimates of the model parameter and the estimation itself (actual corrosion level is above and below the regression curve as in Figure 2). Since failure of these tanks can be based on a local corrosion pit, any best-fit approach ignoring the scatter is not a suitable choice. Furthermore the absolute minimum thickness may not be captured during measurement. As a result, such deductions may also result in a misinformed decision making (Zheng & Ellingwood 1998).

Figure 2. Thickness data and deterministic regression corrosion model.

The A-537 CL-1 steel has a characteristic yield strength of $f_{yk} = 345$ MPa and tensile strength of $f_{uk} = 485$ MPa. As per BS 5500 (BSI 1997), the nominal design stress is $f = \min\left(\frac{f_{yk}}{1.5}, \frac{f_{uk}}{2.35}\right) = 206$ MPa = 2100kg/cm². Thus, the required thickness for design pressure is

$$\tau = \frac{pD_i}{4f - 1.2p} = \frac{21.2 \times 18000}{4 \times 2100 - 1.2 \times 21.2} = 45.56 \text{ mm} \quad (1)$$

The thickness provided was 50 mm.

3 BAYESIAN UPDATING OF SHELL THICKNESS

In oil and gas industry, a deterministic linear corrosion model is most widely used (API 2008). A probabilistic linear corrosion model is considered for this paper

$$\tau(t) = \tau_0 - Ct + \varepsilon \quad (2)$$

where τ_0 is the initial thickness of the shell i.e. at year 1999, $\tau(t)$ is the time-varying thickness of the shell, C is the corrosion rate and $\varepsilon \sim \mathcal{N}(0, \sigma)$ is the randomness.

It is assumed that the tank is effectively coated externally and the atmospheric corrosion is negligible. All corrosion occurs at the internal surface where there is no coating.

3.1 Prior distribution

The tolerance on thickness of plate for the present design is 50 ± 1.2 mm (BIS 2009), (BIS 2002). The corresponding lower thickness is adopted as the 2.5 percentile value and the upper thickness as the 97.5 percentile value of a normal distribution to form the prior distribution of τ_0 , given by

$$f(\tau_0) \sim \mathcal{N}(50, 0.61)(\text{mm}) \quad (3)$$

The minimum required thickness without corrosion allowance was 45.56 mm, and the provided thickness was 50 mm. Thus the effective corrosion allowance provided is 4.44 mm for a life of 50 years. Considering this information, an average corrosion rate of 0.09 mm/year is adopted a-priori as mean. Assuming a large coefficient of variation (CoV) of 50%, the lognormal distribution of C is

$$f(C) \sim \mathcal{LN}(-2.52, 0.47)(\text{mm/year}) \quad (4)$$

The lognormal distribution here is specified with the parameters of the lognormal distributions, i.e. the mean and the standard deviation of the logarithm of the lognormally distributed random variable.

In the absence of any specific data on σ , we assume it to be lognormally distributed with a mean of 1 and very large standard deviation of 5 (i.e., a CoV of 500%). Therefore, the prior distribution of σ is given by

$$f(\sigma) \sim \mathcal{LN}(-1.63, 1.81)(\text{mm}) \quad (5)$$

The joint prior distribution for the parameters $\theta = [\tau_0 \ C \ \sigma]$ is taken as the product of the densities of individual parameters, by considering each parameter to be independent of other:

$$f'(\theta) = f(\tau_0) \times f(C) \times f(\sigma) \quad (6)$$

3.2 Likelihood function

The parameter θ conditioned predictive distribution of remaining thickness based on Eq. 2 is

$$f(\tau|t, \theta) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left\{-\frac{[\tau - \tau(t)]^2}{2\sigma^2}\right\} \quad (7)$$

Eq. 7 is used to form the likelihood function for a thickness measurement τ_i at time t_j as $f(\tau_i|t_j, \theta)$. For m_j number of measurements at time t_j , $\mathcal{D} = \{\tau_{i=1:m_j}, t_j\}$, assuming each to be statistically independent of the other the overall likelihood function can be formed as

$$L(\theta, \mathcal{D}) = \prod_{i=1}^{m_j} f(\tau_i|t_j, \theta) \quad (8)$$

3.3 Parameter updating

The model parameters are updated to the posterior $f''(\theta)$ using Bayesian inference:

$$f''(\theta) \propto L(\theta, \mathcal{D})f'(\theta) \quad (9)$$

using the Markov chain Monte Carlo (MCMC) approach. For this Bayesian updating, we use a MATLAB toolbox for uncertainty quantification, UQLab (Marelli & Sudret 2014). We use the adaptive Metropolis algorithm for MCMC with 100 chains and 1×10^5 steps. The Markov chains indicate convergence and a 50% of the samples are discarded as burn-in. Three updating scenarios are considered:

1. data from year 2009 only
2. data from year 2014 only
3. data from year 2009 and 2014 combined

3.4 Results

Figures 3a, 3b, and 3c provide the posterior distributions of τ_0 , C , and ε , respectively. As the measurements indicated less corrosion, the impact of the data on corrosion model parameters

is found to be likewise. The posterior distribution of τ_0 indicates a higher value while the posterior distribution of C suggests a much lower rate of corrosion.

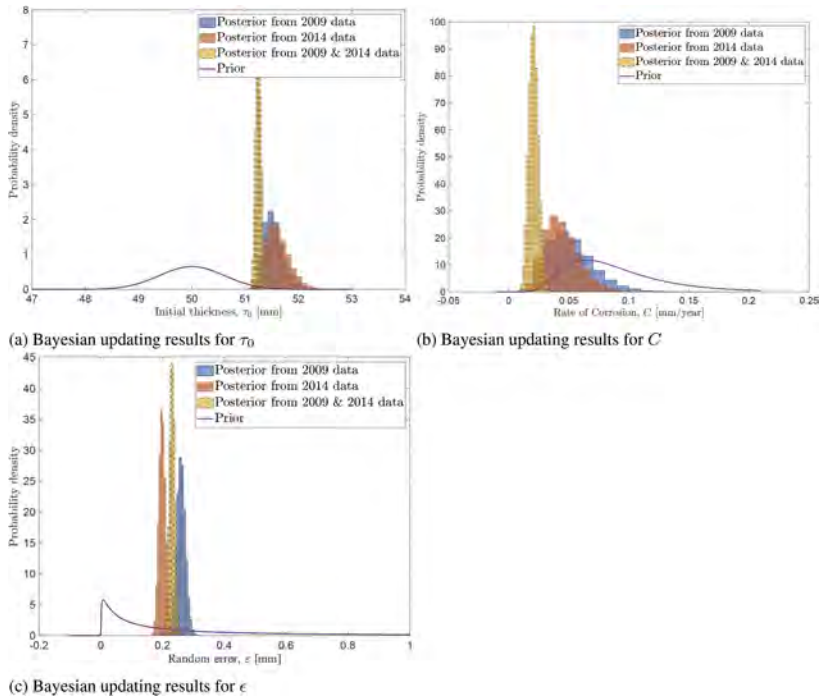

Figure 3. Bayesian updating results for different parameters.

3.5 Robust prediction of corrosion

θ -conditioned predictive distribution of the residual thickness (τ) for any time t is as per Eq. 7. Once the corrosion model is updated, the parameters θ are available in the form of sample values. In most of Bayesian inferences applied to model updating in engineering problems, either the sample mean or the sample median value is used for prediction (Faroz 2017). This ignores the parameter uncertainty. In the present work, a single parameter-unconditioned distribution of τ , which includes the variability due to the random samples of θ , is obtained using the total probability theorem for a robust predictive distribution for any time t (Faroz & Ghosh 2021)

$$f(\tau|t) = \int_{\Theta} f(\tau|t, \theta) f''(\theta) d\theta \quad (10)$$

4 REMAINING LIFE ANALYSIS

4.1 Uncertainty quantification

The remaining life analysis (RLA) is performed based on a minimum reliability-based performance criterion. The limit state for the reliability analysis is formulated as

$$G(t) = \tau(t) - \tau_{req} \quad (11)$$

where $\tau(t)$ is given by Equation 10, and τ_{req} is the thickness required as specified in the design standard (BSI 1997). τ_{req} is calculated by removing all safety factors from the equation specified in BSI 1997:

$$\tau_{req} = \frac{pD_i}{4f_y - p} \quad (12)$$

In Equation 12, it is assumed that fatigue strength for the steel is not critical. In this study, only the internal pressure is assumed as the governing load.

As per BIS (1969) the difference between the minimum and maximum values of D_i shall not exceed 1% of the nominal internal diameter (18000 mm) with a maximum of $\frac{D_i+1250}{200}$ (96.25 mm). Based on this, we assume D_i to be a uniformly distributed random variable:

$$f(D_i) \sim \mathcal{U}(17952, 18048) \text{ (mm)} \quad (13)$$

ASME CRTD-86 (2007) quantified statistical uncertainties in the yield strength of steels (f_y). For high strength carbon steel, a lognormally distributed yield strength with a bias of 1.2 and a COV of 0.09 are recommended. Therefore, for a nominal value of 345 MPa, the distribution of the yield strength is

$$f(f_y) \sim \mathcal{LN}(6.02, 0.09) \text{ (MPa)} \quad (14)$$

In the absence of statistical data on hydraulic pressures in spherical tanks, a normally distributed pressure with a bias of 0.91 and a COV of 0.25 are assumed. Therefore, for a design pressure of 21.2 kg/cm² we have

$$f(p) \sim \mathcal{N}(1.9, 0.47) \text{ (MPa)} \quad (15)$$

The samples obtained from MCMC simulations are used for reliability estimation using Monte Carlo simulation (MCS) with 5×10^6 samples.

4.2 Optimal next inspection

API (2008) provides ‘generic failure frequency’ (gff), a value representative of the refining and petrochemical industry’s failure data. In other words, gff is the average probability of failure in a large population of components. The gff is intended to be the failure frequency prior to any specific damage occurring from the operating exposure conditions. The accepted gff for tank shell course as per API (2008) is 1×10^{-4} . Helle (2012) demonstrated how this value of gff specified by API (2008) is too high. Therefore, in the present work we have adopted a lower value of gff , i.e. 1×10^{-5} , for a demonstration of the proposed methodology.

BIS (1969) specifies that the maximum period between inspections should not exceed one-half of the estimated remaining safe operating life of the vessel. Therefore, the maximum period between the inspections will be half of the time predicted by the model for the tank to reach a probability of failure equal to gff i.e. 1×10^{-5} .

4.3 Results and discussion

Figure 4 presents the resulting probability of failure (P_f) calculated from a MCS of the posterior distributions. The posterior distributions indicate very low corrosion of the tank consistent with the measurements, and consequently Figure 4 indicates a very slow progression of corrosion with the time elapsed in service. For the case with measurements only from year 2009, the gff is exceeded in the 74th year of service. Therefore, the resulting optimal next inspection is 32 years after 2009 or 42nd year of the service life. For the case with data only from 2014, the resulting optimal next inspection is $(95-15)/2 = 40$ years after 2015 or 55th year of the service life. For the case when data from both years are taken for updating (with corrosion measured very low), the estimated probability of failure crosses gff in the year 175 of the service life. Therefore, next optimal inspection as per this updating scenario should be on the 95th year of the service life.

Figure 5 presents a comparison of the thickness required as per the code with the thickness predicted by the updated model at a year far later in the service life of the tank, i.e. the

120th year of service. The relative lack of overlap between the histograms of model predicted thickness (with the required thickness), particularly for the case when both years data is used for updating, explains the highly safe condition of the structure estimated in Figure 4.

Taking a deterministic approach with the nominal thickness of 50 mm at year zero, the linear regression yields into thickness increasing with years, which cannot be realistic. If only the data from years 2009 and 2014 are used in linear regression (Figure 2), we find, $\tau(t) = 51.176 - 0.0149t$ (mm). Based on the minimum required thickness of 45.56 mm (Equation 1), the age to reach failure is 376.91 years. Thus, the next inspection will be on year $(376.91 - 15)/2 \approx 181$, which is almost double of the estimation based on the framework proposed here.

We note that the estimated tank performance and the consequent maximum interval between inspections is subject to the assumptions made in the study. Hierarchical probabilistic models and incorporation of correlation between the measurements can check for any potential Bayesian model over-fitting and lead to more accurate and practical results. This study has adopted a single linear corrosion model for Bayesian fitting. Other models such as an exponential model can also be adopted and a Bayesian model selection strategy can be used to choose the best model (Faroz & Ghosh 2021). A spatial model for nonlinear progression of corrosion could potentially lead to much different results. Similarly, this study adopted a non-hierarchical model while assuming statistically independent measurements.

Figure 4. Predicted probability of failure for various Bayesian updating scenarios.

Figure 5. Comparison of posterior model predicted thickness and required thickness as per code at year 120.

5 CONCLUSION

Conventional methods for performance based inspection planning of petroleum storage steel tanks rely on deterministic methods. Structural reliability methods can be used to incorporate the uncertainties that govern the performance of a steel storage tank. Bayesian statistics provides a conceptual framework to incorporate corrosion pit depth measurements into the existing models for corrosion progression. In this study, the authors propose a novel framework to determine the optimal next corrosion inspection of petroleum storage steel tanks. This framework is based on Bayesian statistics and structural reliability methods. It is expected to assist practicing engineers in conducting a reasonably thorough uncertainty quantification for the performance estimation of LPG storage steel tanks.

Tank shell thickness measurements are taken at two different time instances during the service life of the tank. Based on three different scenarios of data assimilation, a Markov chain Monte Carlo approach based on an adaptive Metropolis-Hastings algorithm is adopted for Bayesian updating. The study assumes a linear model for corrosion progression. The Bayesian updating results indicate a very slow progression of corrosion. The consequent probability of failure of the tank is very low and the performance indicates a highly safe structure. The optimal next inspection is found to be on the 42nd, 55th, and 95th year of the service life, for three different data considerations.

Future work along this line should incorporate combined load effects on the shell, nonlinear corrosion progression models, and spatial data analysis.

The role of life-cycle civil engineering practices in smart and sustainable cities

M.D. Lepech, A.S. Kiremidjian & K.H. Law

Department of Civil and Environmental Engineering, Stanford University, USA

ABSTRACT: Globally, civil infrastructure and our built environment is being embedded with dense sensing networks. These networks form the technological foundation of “smart cities” and enable a new, data-driven era of infrastructure engineering for increased lifecycle performance. But smart cities require more than simply embedding IT hardware into existing urban infrastructure, or the application of artificial intelligence to analyze municipal data streams. This paper discusses the set of physical infrastructures, digital technologies, regulations and policies, financing mechanisms, community outreach, businesses and business models, partnerships, institutions, and other engagement mechanisms that must be established in concert with each other to provide a high quality of life in smart and sustainable cities. Specifically, the role of infrastructure life-cycle evaluation is studied in the context of smart city traffic management systems. Results show that smart city traffic management can result in significant reductions in life cycle impacts associated with urban mobility and transportation.

1 INTRODUCTION

1.1 *The smart city paradigm and smart city models*

Around the world, civil engineering infrastructure and our built environment is being embedded with dense sensing networks. These networks form the technological and IT underpinnings of “smart cities” and are increasingly enabling a new, data-driven era of infrastructure engineering for increased lifecycle performance. This “smart city paradigm” was introduced out of a global need to respond to the challenges of increasing populations in megacities and significant growth in the demand for limited resources (Bačić et al. 2018). Today, smart city projects in many countries are being planned or implemented as a pathway toward greater urban sustainability in the face of global challenges such as climate change, as summarized by Kiremidjian & Lepech (2023).

To facilitate more successful implementation of the smart city paradigm, several models have been proposed to structure smart city services. These models include a theoretical foundation for the smart city concept by Harrison and Donnelly (2011), along with more detailed implementation models by Sánchez et al. (2013) and Li et al. (2015). A comprehensive summary of these models has been presented by Bačić et al. (2018). Some of the approaches to smart city development emphasize technological aspects (e.g., Park et al. 2018), while other approaches consider social and economic aspects that must also be addressed (e.g., Baraniewicz-Kotasińska 2022).

1.2 *Urban metastructure*

While dense sensing networks may form the technological foundation of smart cities, implementation requires much more than simply embedding information technology hardware into existing urban infrastructure systems or the application of artificial intelligence to analyze municipal data streams. Recognizing that large cities are complex systems of physical, environmental, social, economic, and financial systems, among others, smart city implementation requires a set of physical infrastructures, digital technologies, regulations and policies, financing mechanisms, community

outreach, businesses and business models, partnerships, institutions, and other engagement mechanisms that need to be established and operated in concert with each other to provide a high quality of life in smart and sustainable cities. This set of interconnected technologies, policies, and organizations, first applied to urban transportation systems (Rogers 2016), is referred to herein as urban metastructure (Lepech 2017, Lepech 2021, Kiremidjian & Lepech 2023)

This metastructure can be parsed into three critical elements. The foundational element is (I) a dense sensing and data collection network. This sensing and data collection network comprises the “set of physical infrastructures” within the urban metastructure. Such sensing networks can be constructed specifically for smart city purposes (i.e., CCTV cameras, traffic sensors) or leverage the increasing numbers and capabilities of smartphones. Built upon this sensing network is (II) a computational layer that translates the ever-growing stream of smart city data into information that can be used by residents, businesses, and visitors. This computational layer, which leverages advanced computational algorithms (i.e., machine learning, artificial intelligence) to efficiently and rapidly process incoming data streams, can provide the public with information via smartphone applications or direct alerts. These two basic layers of smart city metastructure, (I) sensing and (II) computation, are commonly associated with smart city research.

The final component of metastructure is (III) an engagement mechanism. This is a less commonly studied, yet critically important component. Effective engagement mechanisms comprise the “regulations and policies, financing mechanisms, community outreach, businesses and business models, partnerships, and other institutions” of urban metastructure and are necessary to substantially increase the quality of life for residents in smart and sustainable cities.

2 ELEMENTS OF URBAN METASTRUCTURE

2.1 *Physical infrastructure for smart and sustainable cities*

Sensors are a crucial component of any intelligent control system and a foundational component of smart city metastructure. The performance of an urban system can be improved via control systems that enhance awareness of its environment and its operational status, and therefore is equipped with an array of sensors (Bačić et al. 2018). Different types of sensors are typically deployed to collect a variety of data that are then synchronized and analyzed to extract information that enables robust decision making and control. In situ sensors, embedded on a structure, road, or other infrastructure system components, collect information locally (e.g., at traffic loops). Beyond local sensor networks, remote sensors (e.g., CCTV cameras, satellites) collect data from a distance. Data streams from smartphones are an increasingly critical component of smart city sensor networks. Today, an important part of this smartphone dataset are data from human-generated measurements which “include subjective observations on the environment, social media posts, mobile phone calls and text messages, and physiological measurements by wearable body sensors” (Bačić et al. 2018). Data and information transmission and storage are achieved through wired or wireless communications networks.

For illustration, the smart city of Songdo in South Korea has deployed a dense network of traffic loops and CCTV cameras. These systems are now generating terabytes of smart city vehicle traffic data for a complete network of intersections in Songdo and throughout the Incheon Free Economic Zone (IFEZ) in South Korea. In addition to traffic data, smart city physical infrastructure systems include air quality sensors that are dispersed in street lighting for pollution metering (Szarata et al. 2017, Vasiutina et al. 2022) and environmental monitoring systems that track air and water quality in buildings to identify airborne pathogens (e.g., Chew et al. 2022). Systems for tracking footsteps in buildings are being developed to optimize foot traffic flow and, in healthcare and assisted living facilities, monitor elderly occupants to prevent falls (e.g., Pan et al. 2017). Surely, these examples represent only a subset of the myriad types of physical infrastructure which comprises the first layer of metastructure; a dense sensing and data collection network.

2.2 *Smart city computational infrastructure*

A robust computational layer is necessary to support good decision making and infrastructure management. Data collected from the complex combination of sensors are meaningless until

information is extracted and used in the management and control of various urban systems. Computational and data science tools such as advanced statistical analysis, machine learning, and artificial intelligence have been under development for some time for these purposes and have greatly advanced over the past decade.

For example, a novel, adaptive traffic signal control algorithm has been developed for Songdo, South Korea that utilizes a new traffic signal control design relying on deep reinforcement learning (Gu et al. 2022). Unlike current approaches used in traffic signal design, the Songdo system is based on a multi-discrete soft-Q-networks (MD-SQN) algorithm and uses real-time traffic conditions (i.e., queue lengths, approaching traffic counts, presence of non-vehicle actors) to set traffic light durations. The MD-SQN algorithm results in traffic signal actions that are more practical than those devised by current traffic signal algorithms.

Embedding new forms of computational layers, like MD-SQN, into rapidly evolving digital twins is also key to the development of smart cities. These technologies can be used in many ways for managing critical systems in smart cities (Farsi et al. 2020). It is also important to link digital twins to the physical and functional properties of systems (Lepech et al. 2016) to map and study interdependencies and conflicts, thereby enhancing the ability to tackle difficult interactions.

2.3 *Smart city engagement mechanisms*

Engagement mechanisms are an important component of the metastructure, essential to the effective implementation of smart city systems. Engagement includes regulations and policies, financing mechanisms, community outreach, businesses and business models, partnerships, and other institutions. Without integration of these elements in smart city implementation, the value proposition of technologies remains ambiguous to residents and fails to achieve long-term goals.

There exist examples of successful engagement mechanisms around the world. For example, Virtual Singapore provides residents with “a geo-visualization, analytical tools and 3D semantics-embedded information platform to connect and create awareness and services that enrich their community.” Digital Dubai now has over 90 government services that are digitalized and accessible to citizens through its DubaiNow App.

Building upon the MD-SQN computational layer that is being implemented in Songdo, South Korea for integrated urban mobility management, Songdo city operations are controlled at a centralized command center that can enact smart mobility solutions in near real time. But it is important to recognize that smart city technologies must be implemented with people in mind to engage with citizens and create value for residents. Therefore, unlike other traffic optimization algorithms, the new MD-SQN traffic signal algorithm maintains the “cycle concept” (i.e., a recognizable repeating pattern of protected turns and free traffic flow) to account for human drivers’ preferences and habits (Gu et al. 2022). Using MD-SQN traffic signal timing, each agent (the traffic light) decides on the duration of its own phase, and multiple agents jointly control the duration of all phases in one cycle of intersection light timing and execute it in the next cycle. Additionally, MD-SQN explicitly considers non-vehicle travelers (e.g., pedestrians and bicyclists) and can deal with potential data transmission delays and interruptions, which are common in real-world traffic sensing conditions. Such engagement approaches that maintain the citizen-centered or user-centered focus of smart cities will be essential for their ultimate success.

3 SMART AND SUSTAINABLE CITIES

3.1 *Songdo, South Korea case study*

Songdo Smart City, located within Incheon Municipal City and near Seoul, South Korea is a purpose-built “ubiquitous city” constructed with sensors to track traffic conditions, feeding that information into traffic light timing routines to minimize traffic and local air pollution. Construction started with over US\$40 billion in investment from Gale International, POSCO E&C, Morgan-Stanley Real Estate, Asia Development Institute, Arup & Partners, and CISCO Services Korea.

The Stanford Center at the Incheon Global Campus (SCIGC) is currently conducting research in collaboration with Songdo Smart City on dynamic traffic management systems to

solve urban mobility issues along with urban sustainability challenges. SCIGC is an interdisciplinary research center located in Songdo and focusing on smart city technology implementation, sustainable urban systems and wellness, innovative smart city entrepreneurship and business models, and sustainable development and financing.

In this case study, the focus is a major traffic intersection in Songdo, South Korea. The intersection connects the major thoroughfares of Convensia Road and Incheon Tower Road in Songdo. The purpose of this study is to assess the impact of implementing the new MD-SQN traffic signal algorithm as compared to existing signal timing algorithms on the basis of social, environmental, and economic lifecycle impacts. The functional unit of measurement in this study is 1000 passenger vehicles traversing the intersection at Convensia Road and Incheon Tower Road.

To determine traffic conditions at the intersection, CCTV footage of traffic flow at the intersection was obtained in 5-minute-long videos taken at the start of each hour during a 24-hour period. Traffic counts for these intervals throughout the day are provided in Table 1. This results in a traffic mix of 95% automobiles, 2% busses, and 3% trucks. The collection of this type of data represents the sensing layer of the Songdo smart city metastructure.

Table 1. Extrapolated hourly traffic counts from 5-minute CCTV data for the convensia road and incheon tower road intersection.

Time	Auto	Bus	Truck	Time	Auto	Bus	Truck
00:00 – 03:00	276	12	0	13:00 – 17:00	2544	132	144
03:00 – 06:00	132	12	0	17:00 – 21:00	5220	78	30
06:00 – 09:00	3606	108	90	21:00 – 24:00	2058	42	6
09:00 – 13:00	2820	48	192				

3.2 Traffic signal control optimization using MD-SQN

A novel multi-discrete soft-Q-network (MD-SQN) approach is proposed for optimization of traffic signal actions at the Convensia Road and Incheon Tower Road intersection. In this case, MD-SQN is implemented to solve for the optimal traffic signal policy under a multi-discrete action space scenario. A complete description of the MD-SQN formulation, and a comparison of MD-SQN with other traffic signal control algorithms, can be found in Gu et al. (2022).

The traffic signal control problem is one with multiple agents jointly deciding an action plan. Such action design introduces a multi-discrete action space reinforcement learning (RL) problem, which is difficult for many existing RL methods to solve. One approach to this multi-discrete action space problem is multi-agent reinforcement learning (e.g., Foerster et al (2018), Sunehag et al. (2017)). Assuming that all agents are a part of the environment and do not interfere with each other, multi-agent reinforcement learning approaches can devise a rational policy, π , for traffic signal timing (i.e., red, yellow, and green light sequencing and timing in all directions). However, if interference between agents is ignored the result is that all agents compete for the limited resource (i.e., green duration). This creates more congestion and causes chaotic actions.

To solve this problem, instead of solving for π we can solve for a q-value, which is strongly correlated with π in value-function-based RL. The q-value can be determined by changing the policy from a base case and observing differences in performance. The optimization problem can then be solved with appropriate objective and constraint functions. Once again, a complete mathematical description of the MD-SQN algorithm can be found in Gu et al. (2022). The implementation of an optimal traffic signal timing algorithm represents the computational layer of the Songdo smart city metastructure.

Based on vehicle traffic counts, arrival times, and departure times determined from CCTV data, the time spent by vehicles currently traversing the Convensia Road and Incheon Tower Road intersection is determined. This is the base case traffic management scenario. Based on vehicle traffic counts and arrival times, and implementing MD-SQN as the signal timing algorithm, an alternative traffic management scenario is devised. The frequency of time spent (seconds) by 1000 vehicles waiting at the Convensia Road and Incheon Tower Road

intersection for the base case and MD-SQN traffic management scenarios are shown in Figure 1(left) and Figure 1(right), respectively. For each scenario, the idling time spent at the intersection was computed in two simulations, one during daytime (Simulation 1) conditions, and one during nighttime (Simulation 2) conditions.

Figure 1. The frequency of idling time spent (seconds) by 1000 vehicles in the Convensia Road and Incheon Tower Road intersection for the base traffic management scenario (left) and MD-SQN traffic management scenarios (right).

As seen in Figure 1, the number of vehicles experiencing shorter times idling at the intersection is much larger for the MD-SQN traffic management scenario. For those vehicles that do have to stop at the intersection, the MD-SQN traffic control scenario reduces the average total time a vehicle spends idling at the intersection from approximately 53 seconds to approximately 36 seconds. The reduction seen in average idling time spent at the intersection represents the engagement layer of the Songdo smart city metastructure.

3.3 Electrification of South Korean automobile fleet

South Korea has national goals for electrification of the national automobile vehicle fleet by 2030. In 2030, the South Korean automobile fleet is expected to be 33% electric vehicles (EV) and 67% internal combustion engine (ICE). For this study, three EV market penetration scenarios are assumed when comparing the potential sustainability impact of the new MD-SQN traffic signal algorithm with the base case for traffic management. Combining the 3 EV scenarios with the 2 traffic management scenarios, a total of 6 life cycle analysis scenarios are shown in Table 2.

Table 2. Vehicle fleet composition and traffic signal control algorithm for six life cycle analysis scenarios.

Scenario	ICE %	EV %	Signal Algorithm	Scenario	ICE %	EV %	Signal Algorithm
S1	100	0	Base Case	S2-MDSQN	90	10	MD-SQN
S1-MDSQN	100	0	MD-SQN	S3	67	33	Base Case
S2	90	10	Base Case	S3-MDSQN	67	33	MS-SQN

4 LIFE CYCLE ANALYSIS

4.1 Goal and scope of analysis

The goal of this analysis is to assess the impact of implementing an MD-SQN traffic signal management algorithm as compared to the base case (current) traffic signal management algorithm at the Convensia Road and Incheon Tower Road intersection in Songdo, South Korea. The functional unit of analysis is 1000 vehicles traversing the intersection. The boundaries of analysis include raw material acquisition, production, processing, transportation, use, and disposal for fossil fuels used in ICE vehicles and raw material acquisition, production, processing, transportation, use, and disposal for batteries used in EVs. The analysis excludes fuels and energy expended in vehicle acceleration or crossing the intersection, since these impacts are identical in both management scenarios. The analysis also excludes impacts associated with the manufacturing of ICE vehicles or EVs, along with exclusion of the impacts of tires, repair parts, and other maintenance.

4.2 Life cycle inventory and economic costs

The ICE vehicle fuel life cycle inventory analysis was split into two components. One component is raw material extraction, with the other being fuel processing, distribution, and combustion. The unit processes used in SimaPro databases were “crude oil inventory” and “light oil inventory”, respectively. For EV battery production, the unit process used in the SimaPro database was “rechargeable lithium-ion battery.” The impacts associated with this unit process were scaled to match the amount of wasted battery lifetime associated with waiting at the intersection. The assumed average EV battery lifetime is 10 years.

Idle time spent at the intersection was converted to cost per second based on ICE idling fuel costs and EV lost battery life. For ICE vehicles, average idling fuel consumption is 1.9 L/hr (South Carolina Dept. of Health 2022). The average price for gasoline in South Korea as of November 2022 was US\$1.16/L. Thus, the ICE vehicle idling cost is US\$6.1e-6/sec. The cost of an EV battery in South Korea is US\$15,300 with no cost for end-of-life disposal (Da-sol 2022). Based on the initial cost and expected lifetime of the battery, the EV idling cost is US\$4.9e-7/sec.

4.3 Life cycle impact assessment

Social, environmental, and economic indicators are reported for this analysis. These indicators, and their respective metrics, are summarized in Table 3.

Table 3. List of reported life cycle assessment indicators for the Songdo case study.

Indicator	Unit	Type
Idling Time	sec	Social
Global Warming Potential	kg CO ₂ -eq	Environmental
Ozone Depletion Potential	kg CFC11-eq	Environmental
Acidification Potential	kg SO ₂ -eq	Environmental
Eutrophication Potential	PO ₄ -eq	Environmental
Economic Cost	US\$	Economic

4.4 Interpretation and results

The impacts measured for each of the scenarios and indicators shown in Tables 2 and 3, respectively, are shown in Table 4. The results indicate that the reduction in idle time associated with implementation of the MD-SQN traffic signal control algorithm broadly reduces social, environmental, and economics indicators in each of the categories reported. Across the three EV penetration scenarios, implementation of MD-SQN traffic signal control algorithm generally results in consistent reductions in impacts, aside from eutrophication potential, which sees the benefits of MD-SQN implementation decrease with higher EV market penetration (Scenario S3). This is due to relatively high eutrophication potential emissions associated with battery production as compared to fossil fuel production.

Sensitivity analyses were carried to account for uncertainty in the assumptions that drive life cycle impact and cost calculations. Specifically, the idling fuel consumption of ICE vehicles and the battery lifetime of EVs batteries were varied. Uncertainties of $\pm 20\%$ on idling fuel consumption, battery lifetime, and fuel price were considered. This extent of sensitivity was selected as a likely magnitude of variation depending on vehicle age, manufacturer, and model. The analysis was performed for each scenario and impact category. A sample result of the sensitivity analysis for CO₂-eq emissions is shown in Figure 2. Results of all sensitivity analyses show that all impact categories, except eutrophication, are more sensitive to changes in the idling fuel consumption than to changes in the EV battery life. For each scenario, sensitivity is higher in the base case than in the MD-SQN case due to the larger absolute impacts associated with the base case. Across all scenarios and all variations, the conclusion that implementation of MD-SQN traffic signal control algorithm generally results in consistent reductions in impacts did not change.

Table 4. Life cycle indicators for Scenarios S1, S2 and S3 for each of the six indicators quantified.

Indicator	Scenario								
	S1	S1-MDSQN	Δ (%)	S2	S2-MDSQN	Δ (%)	S3	S3-MDSQN	Δ (%)
Idling Time (sec)	53.1	35.6	-33.0	53.1	35.6	-33.0	53.1	35.6	-33.0
Global Warming Potential (kg CO ₂ -eq)									
ICE	2.21E+01	1.48E+01		1.99E+01	1.34E+01		1.48E+01	9.95E+00	
EV	0	0		9.20E-02	6.20E-01		3.04E-01	2.04E-01	
Total	2.21E+01	1.48E+01	-32.9	2.00E+01	1.40E+01	-30.1	1.51E+01	1.01E+01	-33.0
Ozone Depletion Potential (kg CFC11-eq)									
ICE	6.75E-06	4.52E-06		6.07E-06	4.07E-06		4.52E-06	3.03E-06	
EV	0	0		3.89E-09	2.61E-09		1.28E-08	8.61E-09	
Total	6.75E-06	4.52E-06	-33.0	6.07E-06	4.07E-06	-32.9	4.53E-06	3.04E-06	-33.0
Acidification Potential (kg SO ₂ -eq)									
ICE	3.36E-02	2.26E-02		3.03E-02	2.03E-02		2.25E-02	1.51E-02

ICE	32.39	21.72		29.16	19.55		21.70	14.56	
EV	0.00	0.00		0.26	0.17		0.85	0.57	
Total	32.39	21.72	-32.9	29.42	19.72	-33.0	22.55	15.13	-32.9

Figure 2. Sensitivity in greenhouse gas potential emissions (kg CO₂-eq) by varying idling fuel consumption and EV battery lifetime by $\pm 20\%$ for Scenario S3 (left) and Scenario S3-MDSQN (right).

The results presented in Table 4 are calculated for a functional unit of 1000 vehicles traversing the intersection of Convensia Road and Incheon Tower Road. Summing the traffic counts provided in Table 1 for an entire day, over 60000 automobiles cross the intersection on a typical workday. Assuming 250 workdays annually, implementation of the MD-SQN traffic signal control algorithm can reduce greenhouse gas emissions by over 100 metric tons of CO₂-eq annually. Applied more broadly to traffic intersections throughout Songdo and other South Korean cities, the potential impact reductions associated with smart city implementations at scale can become a substantial part of meeting current sustainability challenges at a global scale.

5 CONCLUSION

This paper introduces the concept of urban metastructure as a transcendent set of physical, technological, and social infrastructure systems that must be built in concert with one another to increase the likelihood of smart and sustainable city success. Specifically, the three layers of urban metastructure - sensing, computation, and engagement – were discussed and examples from numerous smart city efforts around the world were presented. A specific case study, advanced traffic signal control management in the smart city of Songdo, South Korea, was used to illustrate all three of the layers and connect their results to life cycle assessment and life cycle engineering of smart city transportation systems. Results from this case study show that implementation of a newly developed MD-SQN traffic signal control algorithm at one intersection in Songdo smart city generally results in consistent reductions in social, environmental, and economic impacts over time.

The promise of future smart and sustainable cities is exciting. But there remain numerous challenges and obstacles to their successful implementation over the coming decades. These challenges include privacy concerns, data security, financial shortfalls, and instrumentation of legacy infrastructure with advanced sensors, among others (Kiremidjian & Lepech 2023). Therefore, as urban designers, municipal officials, IT specialists, civil engineers, and other disciplines we must

come together to deliver on this promise, and the concept of metastructure can increase the likelihood of smart and sustainable city success. Such success will ultimately result in smarter, more sustainable urban environments that offer high quality of life to city residents around the globe.

ABSTRACT: Value of Information (VoI) analysis provides a quantitative measure to justify the adoption of a structural health monitoring (SHM) strategy for civil infrastructure maintenance. The VoI analysis adopts predictive and measurement-based models to characterise the infrastructure state and monitoring quality. The uncertainties in such models have been explicitly considered in the current VoI framework and the decision maker is expected to choose the action maximizing the expected utility defined by a deterministic utility function. However, under the influence of some tangible or intangible factors like budget availability, bias, etc., the decision maker may end up choosing a sub-optimal action. The present study characterizes such decisions by introducing a concept of cost of decision and models such decisions by a random error, in addition to the predictive model and measurement errors, to assess their influence on the VoI. The results indicate the negative influence of such decisions on VoI.

1 INTRODUCTION

Civil infrastructure is crucial to the social and economic development of all communities worldwide (Calderón and Servén, 2004; Frangopol, 2011). This infrastructure, however, ages with time due to the effect of environmental stressors like corrosion, fatigue, etc. and therefore requires maintenance during its service life. The maintenance or repair needs to be carried out optimally both in terms of when (i.e., the point(s) in time) during the service life as well as the extent required. A decision maker, responsible for the maintenance, usually decides based on pre-defined degradation models or expert judgment (Konakli et al., 2016). However, the resulting maintenance may not be optimal for the specific structure as the actual degradation of the structure may deviate from the predicted one. Therefore, a decision maker faces the uncertainty regarding the actual state of the structure, wherein the decision may result in a conservative maintenance or a riskier one. A conservative maintenance leads to unnecessary costs resulting in the over-utilization of maintenance budget and in the presence of budget constraints, it would be highly undesirable. On the other hand, inadequate maintenance poses high risk of infrastructure failure leading to adverse consequences both in terms of direct costs including the loss of human life and an indirect effect on the country's economy.

Structural health monitoring (SHM) has the potential to aid a decision maker by providing additional information about the state of the system which may be a structure or a component, thus reducing the uncertainty and leading to relatively optimal maintenance decisions (Faber and Thons, 2014; Biondini and Frangopol, 2016). However, the cost saving obtained from a monitoring information must exceed the cost of monitoring strategy for its rational adoption. The value of information (VoI) analysis provides a metric to estimate the expected benefit from an information acquirement strategy (Schlaifer and Raiffa, 1961; Howard, 1962). For civil infrastructure

maintenance, VoI has the potential to assist the optimal utilization of additional information from monitoring (Pozzi and Der Kiureghian, 2011; Thöns, 2018; Khan et al., 2022). In this context, VoI is defined as the expected cost savings obtained by adopting a monitoring strategy for a given maintenance decision scenario consisting of (i) an action model, (ii) a cost model, and (iii) a probabilistic state degradation model (Pozzi and Der Kiureghian, 2011; Faber and Thöns, 2014; Thöns, 2018; Khan et al., 2022). VoI is obtained as the difference between the costs of prior optimal action and the optimal action after using the monitoring information. The conditional value of information (*CVoI*) is defined corresponding to a particular monitoring outcome and is estimated by posterior analysis of VoI framework (Thöns, 2019). Moreover, the expected value of information (*EVoI*) is obtained by pre-posterior analysis which involves taking the expectation over all the possible monitoring outcomes, thus giving the value metrics before implementation of the monitoring strategy (Thöns, 2019).

The VoI estimate is affected by the quality of information (Pozzi and Der Kiureghian, 2011; Srinivasan and Parlikad, 2013). Some studies (Khan et al., 2020; Zhang et al., 2023) have evaluated the effects of model and measurement errors on the value of information estimate. Consequently, these errors are being explicitly incorporated in a VoI based decision analysis. However, a common assumption in such an analysis is that the decision maker will always act rational and this behaviour is modelled as per the expected utility theory (EUT) (Cappello et al., 2016). Although the decision maker is expected to act rationally most of the time, chances are that the behaviour may deviate in some cases and a sub-optimal decision is preferred relative to the EUT frame of reference, for example, some studies have discussed the scenarios where a decision maker is affected by bias (Verzobio et al., 2021) or their preference may not align with the regulations (Li and Pozzi, 2021). Moreover, at times, social and political pressure may also play a role in such deviations from a rational or optimal decision making. Therefore, a number of factors, tangible as well as intangible, may influence the final decision and the actual benefit obtained from a monitoring strategy would be different from the predicted one. This may lead, in some cases, to an incorrect verdict on the monitoring adoption. The existing VoI framework lacks the robustness towards the realization of such random sub-optimal decisions and therefore, the resulting estimates are relatively ideal than the ones actually realized in the field.

The present study aims to incorporate the instances of sub-optimal decisions in a VoI framework by modelling them as generic random decision errors. The concept of the cost of decision is introduced to characterise a sub-optimal decision for a given knowledge about the state of the structure. Moreover, a parametric analysis is carried out to analyse the extent of effects on the VoI estimate by adopting a maintenance case study of a component and treating random model, measurement and decision errors as the parameters of interest.

2 SUB-OPTIMAL DECISIONS

In a maintenance decision problem, for a given level of knowledge regarding the actual state of the structure, the optimal action is the one incurring minimum expected cost. All other actions are sub-optimal relative to this action, that is, the expected costs of such actions is high. The posterior VoI analysis gives the optimal action for a given information and it is expected that a rational decision maker will choose the same action for maintenance. However, in reality, the decision maker may choose a sub-optimal action instead. The potential cause for this behaviour may include a random risk averse or risk seeking attitude of the decision maker. The word “random” is important here, as it is usually assumed that a properly elicited utility function would suffice for describing the decision maker’s risk attitude. However, an accurate calibration of the risk attitude is very difficult (Hey and Orme, 1994), if not impossible, and the risk attitude at any time may depend on various intangible factors if the decision maker’s judgment is influenced by some heuristics or bias (Tversky and Kahneman, 1987; Verzobio et al., 2021). Additionally, it has been observed that the decisions under risk vary with the choices available, and the way these choices are framed at the moment of decision-making (Stewart et al., 2019). The possibility of sub-optimal actions may be relatively high around the threshold outcomes, where the difference between the expected costs of two

actions is relatively less and the decision maker may decide to incur some extra cost and ends up with a sub-optimal decision to satisfy the intangible influencing factors like budget availability, social and political pressures, etc.

2.1 Cost of decision

For a given level of knowledge about the state of structure, a decision, whether optimal or sub-optimal, can be characterized by a quantity by which it offsets the potential cost saving corresponding to that level of knowledge. This quantity is defined here as the ‘cost of decision’. This cost is different from the actual expected cost incurred from doing an action and in fact forms an element of the incurred expected cost.

Figure 1. Cost of decision corresponding to different action choices for a given information z .

Let $C(a_j, z)$ denote the expected cost corresponding to an action a_j , for a given information z . Figure 1 depicts the concept of cost of decision. In a posterior analysis, the conditional value corresponding to a given information z is obtained as

$$CVoI(z) = C_{prior} - C(a_{opt}, z) \quad (1)$$

where, C_{prior} = expected cost for optimal maintenance action a_{prior} without information, and $C(a_j, z)$ = expected cost incurred by choosing the optimal action a_{opt} corresponding to the knowledge refinement due to an information z .

Therefore, a rational decision maker is expected to receive the benefit equal to $CVoI$. However, if the decision maker chooses a sub-optimal decision, it would decrease the benefit obtained from the information and may even bring the benefit to zero, if he ends up choosing the same decision as that without information, i.e., a_{prior} . The cost of decision is given as

$$\text{Cost of decision} = C(a_j, z) - C(a_{opt}, z) \quad (2)$$

where, $C(a_j, z)$ = the expected cost incurred from some chosen action a_j for a given information z .

The cost of a particular decision can be zero if it is an optimal decision or can have a positive value if it is a sub-optimal decision. This cost reduces the potential $CVoI$ that could be obtained from a given information.

2.2 Modelling sub-optimal decisions

The present study considers random occurrences of sub-optimal decisions; i.e., a cost utility function for a decision maker is available, however, the decision maker under some tangible or intangible scenario may deviate from the elicited behaviour. If $C(a_i, a_j)$ denotes the difference between the expected costs of action a_i and a_j , then

$$C(a_i, a_j) = C(a_i, z) - C(a_j, z) \quad (3a)$$

and as per EUT,

$$C(a_i, a_j) > 0 \Rightarrow a_j \text{ is chosen} \quad (3b)$$

In order to incorporate the possibility of a sub-optimal decision, a normally distributed error term is incorporated in the decision criteria as in Hey and Orme (1994) and Equation 3b becomes:

$$C(a_i, a_j) + \epsilon_d C_{ref} > 0 \Rightarrow a_j \text{ is chosen} \quad (4)$$

where, $\epsilon_d C_{ref}$ constitutes the decision error, $\epsilon_d \sim N(0, \sigma_d^2)$, and C_{ref} is a reference cost. If $\sigma_d^2 = 0$, the decision maker does not deviate from the expected rational behaviour and increase in the value of σ_d^2 results in higher chances of sub-optimal decisions.

3 CASE STUDY

A component case study, adopted originally from Konakli et al. (2016) which was further developed by Khan et al. (2020), is considered for the demonstration of sub-optimal decision making and its treatment. Khan et al. (2020) developed the VoI framework incorporating additive bias, multiplicative bias, and random errors in both the predictive model and measurements. However, the present study considers only the random model and measurement errors. The structural component is assumed to have a service life of $L = 30$ years. The component resistance at time t (years) is given as:

$$R(t) = R_0 G(t) \quad (5)$$

where R_0 = resistance at the start of service life at $t_0 = 0$ years, t = time discretized in years, and $G(t)$ is a degradation function:

$$G(t) = 1 - at^b \quad (6)$$

where, a and b are the degradation parameters characterizing the degradation mechanism (Mori and Ellingwood, 1993). a and b are assumed deterministic with values 0.01 and 1.0, respectively. R_0 is assumed as a lognormal random variable with mean = 2.5 units and coefficient of variation = 0.1. Load on the component S is also assumed to be a lognormal random variable with mean = 1.0 units and coefficient of variation = 0.3. It is assumed that the prediction model for the component performance estimates the lognormal resistance with the random error (ϵ_{M_o}). The predicted resistance $X(t)$ is therefore given as:

$$\ln X(t) = \ln R(t) + \epsilon_{M_o} \quad (7)$$

where, ϵ_{M_o} is a zero-mean normal random variable with variance $\sigma_{M_o}^2$. The limit state function at any year t is:

$$g(t) = X(t) - S \quad (8)$$

In terms of normal random variables, the limit state function can also be written as:

$$z(t) = \ln X(t) - \ln S \quad (9)$$

where, $z(t)$ is a normally distributed random variable

$$z(t) \sim \mathcal{N}(\mu_z, \sigma_z^2) \quad (10a)$$

where,

$$\mu_z = \mu_{\ln R_0} + \ln(1 - at^b) - \mu_{\ln S} \quad (10b)$$

$$\sigma_z^2 = \sigma_{R_0}^2 + \sigma_{M_o}^2 + \sigma_{\ln S}^2 \quad (10c)$$

and the annual probability of failure during year t is obtained as:

$$P_f(t) = \Phi_{z(t)}(0) \quad (11)$$

where, $\Phi_{z(t)}(\cdot)$ = cumulative distribution function of $z(t)$.

Two action choices are available to the decision maker; viz. (i) do nothing (a_0) and (ii) replacing the component (a_1) by a new component of similar type. The present cost of component replacement $c_r = 10$ cost units, and on the other hand, component failure cost $c_f = 1000$ cost units. The high cost of component failure is due to the resulting failure of the structure of which the component forms a critical part. For the present study, the utility function of the decision maker is assumed to be linear and the utility of a consequence is equal its negative costs. Therefore, the present analysis would express the utilities directly in terms of the costs. Moreover, the action decision is assumed to be taken at the start of any particular year. The discounted costs for the action decisions at any decision year t_a are obtained as:

$$c_{a_0} = c_f \sum_{t=t_a}^{L-1} \frac{P_f(t)}{(1+\lambda)^t} \quad (12)$$

$$c_{a_1} = \frac{c_r}{(1+\lambda)^{t_a}} + c_f \sum_{t=t_a}^{L-1} \frac{P_f(t-t_a)}{(1+\lambda)^t} \quad (13)$$

where, c_{a_0} and c_{a_1} = discounted cost corresponding to decisions a_0 and a_1 respectively, $L=30$ years, $t_a \in [0,30)$, λ = discount rate with due consideration to the inflation, and $\lambda = 0.02$ is assumed. Moreover, for the present study $t_a = 5$ years.

In addition, the decision maker has a choice to adopt monitoring strategy that measures the predicted lognormal resistance ($\ln X$). The measurements are not perfect and exhibit a zero-mean normally distributed random error ϵ_{M_x} with variance equal to σ_{Me}^2 . Therefore, a particular measurement at time t can be expressed as:

$$Y(t) = \ln X(t) + \epsilon_{Me} \quad (14)$$

The decision maker can use the information from these measurements to update the predicted lognormal resistance using Bayes theorem (Gelman et al., 2013). Consequently, an updated component failure probability could be obtained, which may change the cost of action decisions, resulting in different posterior costs of these actions. These costs are obtained using Equations 12 and 13, by replacing the prior probability of failure with the updated posterior probability of component failure.

3.1 Sub-optimal decision scenario

The adopted scenario considers a decision maker who behaves rationally during the prior decision making and the possibility of sub-optimal decision is present only after taking the measurements. For example, based on the established degradation models or maintenance guidelines, a decision maker is keen to adopt a particular action before taking the measurements, however, the measurements on a particular component in the field may suggest a different level of intervention compared to the prior one, but the decision maker may still follow prior regulations and may not modify his decision based on the measurement results. In such a scenario the prior and posterior decisions are obtained as:

$$\text{Prior decision} = \begin{cases} a_1 & \text{if } C_{prior}(a_0, a_1) > 0 \\ a_0 & \text{if } C_{prior}(a_0, a_1) < 0 \end{cases} \quad (15)$$

$$\text{Posterior decision} = \begin{cases} a_1 & \text{if } C_{post}(a_0, a_1) + \epsilon_d C_{ref} > 0 \\ a_0 & \text{if } C_{post}(a_0, a_1) + \epsilon_d C_{ref} < 0 \end{cases} \quad (16)$$

where, $\epsilon_d C_{ref} =$ decision error, $\epsilon_d \sim \mathcal{N}(0, \sigma_d^2)$, and $C_{ref} =$ reference cost. In the present study, the failure cost of component c_f is taken as the reference cost.

4 PARAMETRIC STUDY

A parametric study of the expected value of information, at the end of 5th year, is carried out considering the variation in random decision, model and measurement error parameters. The effect of each parameter on $EVoI$ is analysed individually. In addition, effects of different combinations of these error parameters is studied. The error combinations considered are shown in Table 1. The range of values considered for model error parameter is within the recommended bounds (Joint Committee on Structural Safety, 2001). However, due to a lack of such recommendations for decision errors in civil infrastructure literature, the range of values for decision error parameter have to be assumed. The sole aim of assuming these values is to analyse the magnitude of effect on $EVoI$. The actual expected values can be established by a survey of sub-optimal decisions encountered in civil infrastructure maintenance.

Table 1. Error combinations for parametric study.

Combination	σ_d	$\frac{\sigma_{Me}}{\mu_{in} R_0}$	$\frac{\sigma_{Mo}}{\mu_{in} R_0}$
EC1	0.0	0.0	0.0
EC2	0.05	0.1	0.0
EC3	0.05	0.0	0.15
EC4	0.0	0.1	0.15
EC5	0.05	0.1	0.15

Figure 2. Variation of $EVoI$ at the end of 5th year with change in (a) standard deviation of decision error, (b) normalized standard deviation of random measurement error, (c) normalized standard deviation of random model error, and (d) different error combinations (Table 1).

4.1 Results and discussion

Figure 2 shows the results from the parametric study. Figure 2a shows the variation of $EVoI$ with changes in the decision error parameter. $EVoI$ generally decreases with increase in the possibility of high cost decision errors. The effect is marginal for small decision errors with only 4.5% decrease in $EVoI$ at $\sigma_d = 0.02$. This is due to the fact that small magnitude errors lead to sub-optimal decisions having marginally higher costs compared to the optimal decisions. Consequently, the influence of small additional expected costs of sub-optimal decisions on resulting $EVoI$ is negligible. However, for large decision errors, the resulting sub-optimal

decisions have high expected costs, thereby decreasing the *EV_{oI}*. This can be observed through the rapid decrease in *EV_{oI}* value beyond $\sigma_d = 0.02$.

Figure 2b depicts the negative effect of measurement error on *EV_{oI}*, with 94% decrease in *EV_{oI}* at $\sigma_{Me} = 0.3\mu_{ln R_0}$. The more imperfect the information, the less is its value. This is in conformity with previous parametric studies conducted on *EV_{oI}* (Pozzi and Der Kiureghian, 2011; Konakli et al., 2016; Li and Pozzi, 2019). In fact, the concept of cost of decision is applicable in the case of imperfect information as well, and due to inaccuracy the decision maker in some cases may end up choosing sub-optimal decisions (Ali et al., 2022). Thus leading to expected costs that decrease the value of information relative to the perfect information case, i.e., at $\sigma_{Me} = 0$.

Figure 2c shows the effect of the model error on *EV_{oI}*. With increase in the model error, *EV_{oI}* increases – having a 152% increase at $\sigma_{Mo} = 0.3\mu_{ln R_0}$ with respect to the perfect scenario at $\sigma_{Mo} = 0$. The positive influence of model error is due to the increase in uncertainty at the prior analysis stage. Consequently, the information acquirement would be more beneficial under such scenario.

Figure 2d shows the effect of different error combinations on *EV_{oI}*. EC1 corresponds to a perfect model, perfect measurement and a perfectly rational decision maker. The presence of measurement and decision errors in EC2 results in a 68% decrease in *EV_{oI}* relative to EC1. For EC3 (i.e., with a model and decision error combination), the resulting *EV_{oI}* depends on the severity of each error, since the model error has a positive effect unlike the decision error, which negatively effects *EV_{oI}*. Consequently, for the error values adopted in EC3, the resulting *EV_{oI}* is 21% more than that corresponding to EC1. The negative effect of the measurement error is observed to be relatively large in the presence of the model error for EC4 resulting in *EV_{oI}* = 6.11 cost units, i.e., a 69% decrease compared to *EV_{oI}* = 10.82 cost units without any model error. In the presence of all these errors, the negative effect of decision and measurement errors overshadows the positive effect of model error as observed for EC5, where the resulting *EV_{oI}* is only 10% of that for the EC1 combination.

5 CONCLUSIONS

The existing VoI framework neglects the possibility of sub-optimal decisions and therefore gives relatively ideal VoI estimates that may lead to incorrect monitoring adoption. The present study considers random occurrences of sub-optimal decisions where the decision maker deviates from the elicited utility function. A quantity defined as the cost of decision is introduced to characterize a sub-optimal decision. Moreover, the occurrence of such decisions is modelled by incorporating a normally distributed random error in the conventional VoI framework. An attempt is made to evaluate the effect of incorporating such decision errors on the resulting *EV_{oI}* for civil infrastructure maintenance by considering the case study of a structural component.

It is observed that low magnitude decision errors result in marginal decrease in the information value. For the selected case, the decrease in *EV_{oI}* is found to be 4.5% at $\sigma_d = 0.02$. However, the effect is appreciable if the decision maker deviates significantly from the rational behaviour and chooses an action decision having large cost differences with the optimal decision for the given level of knowledge about the state of the structure. Therefore, it is recommended to include a reasonable level of uncertainty, specific to a particular decision maker, in the decision criteria for the purpose of carrying out a practical VoI analysis. The presence of measurement error, which is always present in different amounts in a practical measurement process, further brings down the value obtained from the information. The model error contributes to the uncertainty at prior stage and leads to more value in adopting the new information. However, in combination with measurement error, the overall effect is to decrease the *EV_{oI}*.

Finally, the VoI analysis is sensitive to the decision problem characterization and therefore the effect of different errors may vary, in quantitative terms, for different VoI decision problems. However, the general trend for the error influence on *EV_{oI}* is expected to remain the

same. Moreover, in this study, a range of decision errors is assumed, however, the incorporation of such decision errors in a practical VoI application requires the proper quantification of such errors in order to obtain a reasonable VoI estimate.

ABSTRACT: Lately, the need for adopting sensors in buildings and infrastructures for monitoring and inspection of the health state of those structures is increasing. This demand is due to the increasing age of the structural stock worldwide. Consequently, more economical ways of Structural Health Monitoring applications are getting huge attention. This paper presents and evaluates several low-cost electronics compatible with open-source digital technologies for static and dynamic Structural System Identification applications. Firstly, an open-source microcontroller (Arduino), the main programable logic controller, and a Raspberry pi, a small single-board computer, are introduced. Secondly, various economic sensors with diverse measurement applications, such as ultrasonic and laser ranging, acceleration, temperature, and humidity, are discussed. Thirdly, multiple experiments in different controlled ambients are applied to assess and compare their tolerances as well as advantages and disadvantages of their use, among their price. Some problems with the Arduino codes and sensor positions emerged during the installation of the sensors and the data collection process. Finally, to attain an effective manner of using these low-cost electronics, this article offers answers to the issues faced.

1 INTRODUCTION

Lately, the demand for adopting sensors in infrastructures and buildings is increasing. This need is due to the monitoring and inspection of the health state of those structures. Consequently, more economic ways of SHM applications are getting huge attention (Komarizadehasl et al. 2022). In this article, several models of low-cost sensors have been introduced. Furthermore, the features of each one of them have been explained. Each sensor could be applied in a particular circumstance. Every sensor has benefits as well as weaknesses in various conditions. To be able to work with them, firstly Arduino Uno (which is the main programable logic controller (PLC) in this project), and a Raspberry pi, a small single-board computer, are introduced. Secondly, diverse types of sensors along with their specifications have been introduced. Each type of sensor may use a different way to send its data. Thirdly, different ways of communicating with this PLC will be presented. Finally, the results of these sensors have been illustrated.

2 STATE OF THE ART

In this section the sensors and a microcontroller that has been used in the project will be reviewed along with their technical descriptions.

2.1 *Arduino Uno*

Arduino is an open-source electronics platform based on easy-to-use hardware and software. Aduino Uno is a microcontroller board based on the ATmega328P. It has 14 digital input/output pins, 6 analog inputs to measure and convert the voltage to a digital value. It facilitates numerous interfaces to communicate with other microcontrollers and computers such as Inter-Integrated Circuit (I2C), Serial Peripheral Interface (SPI) and Universal asynchronous receiver/transmitter (UARTA) (Pathak et al. 2019) (Komarizadehasl et al. 2022) (Mahyad Komary et al. 2023). Figure 1 is the schematic of the Arduino Uno circuit.

Figure 1. Schematic of the Arduino Uno (Pathak et al. 2019).

2.2 *Raspberry Pi*

Raspberry Pi is a low cost, small and portable size of computer board. It can be used to plug-in to computer monitor or television, keyboard, mouse, pen-drive etc. Raspberry Pi has built in software such as Scratch which enables users to program and design animation, game or interesting video. In addition, programmers can also develop script or program using Python language; it is main core language in Raspbian operating system (Komarizadehasl, Lozano Galant, et al. 2022b).

Figure 2. Schematic of the Raspberry pi.

2.3 *Ultrasonic sensor*

Ultrasonic ranging module HC - SR04 provides 2cm - 400cm non-contact measurement function which on Figure 3 its schematic has been presented. For this sensor, the ranging accuracy can reach to 3mm. The modules have transmitters, receiver and processing circuit. The basic concept of work is: firstly, using I/O trigger for at least 10uS (microsecond) high level signal. Secondly, The Module automatically sends frequency of 40 kHz and detect whether there is

a pulse signal back. Finally, the range can be calculated through the time interval between sending trigger signal and receiving echo signal. Test distance = (time × velocity of sound (340M/S)) (Kamal and Hemel 2019).

Figure 3. Schematic of an Ultrasonic ranging module HC-SR04 (Kamal and Hemel 2019).

2.3.1 Humidity sensor

As it has been written on section 2.3, for measuring the distance using that sensor the speed of sound is needed. The sound travels in different speeds in different temperatures and humidity (M. Komary et al. 2022). The schematic of this sensor has been shown on Figure 4. DHT22 has already been calibrated during production process and provides accurate information (Patil, Khedkar, and Jadhav 2019) (Liu 2013).

Figure 4. Schematic of a DHT22, digital temperature/humidity sensor.

2.4 The VL53L1X

The VL53L1X, which has been shown on Figure 5 is a state-of-the-art, Time-of-Flight (ToF), laser-ranging sensor, enhancing the ST FlightSense™ product family.

Figure 5. Schematic of a VL53L0X (Adafruit 2018).

It is the fastest miniature ToF sensor on the market with accurate ranging up to 4 m and fast ranging frequency up to 50 Hz. Housed in a miniature and reflowable package, it integrates a SPAD receiving array, a 940 nm invisible Class1 laser emitter, physical infrared filters, and optics to achieve the best ranging performance in various ambient lighting conditions with a range of cover window options. Unlike conventional IR sensors, the VL53L1X uses

ST's latest generation ToF technology which allows absolute distance measurement whatever the target color and reflectance. It is also possible to program the size of the ROI on the receiving array, allowing the sensor FoV to be reduced (Adafruit, 2018).

2.5 MPU 9250

The MPU-9250, delivered in a 3x3x1mm QFN package, is the world's smallest 9-axis Motion-Tracking device and incorporates the latest InvenSense design innovations, enabling dramatically reduced chip size and power consumption, while at the same time improving performance and cost. The MPU-9250 Motion-Tracking device sets a new benchmark for 9-axis performance with power consumption only 9.3μA and a size that is 44% smaller than the company's first-generation device. Gyro noise performance is 3 times better, and compass full-scale range is over 4 times better than competitive offerings(Mahyad Komary et al. 2022).

The MPU-9250 is a System in Package (SiP) that combines two chips: the MPU-6500, which contains a 3-axis gyroscope, a 3-axis accelerometer, and an onboard Digital Motion Processor™ (DMP™) capable of processing complex Motion-Fusion algorithms; and the AK8963, the market leading 3-axis digital compass (Komarizadehasl et al. 2022). Improvements include supporting the accelerometer low power mode with as little as 6.4μA of and it provides improved compass data resolution of 16-bits (0.15 μT per LSB) (InvenSense 2014). On Figure 6 schematic of this sensor can be seen.

Figure 6. Schematic of accelerometer sensor(InvenSense 2014).

3 COMMUNICATION WAYS

While many sensors use digital and analog ports for uploading the measured data to the microcontroller, some sensors use the inter-integrated circuit (i2c) protocol. This is a protocol that allows multiple “slave” digital integrated circuits (sensors) to communicate with one or more “master” chips (arduino). Like the serial peripheral interface (spi) which is only intended for short-distance communications within a single device. The ultrasonic sensor and dht22 have been connected to the arduino's digital ports. The laser and the accelerometer had to be connected to i2c port (scl, sda) on the board.

All the different types of ranging circuits have been connected and glued together, so data from all 3 of them would be measured almost simultaneously on the static experiment. A different circuit had to be made for the accelerometer, in order to perform the dynamic experiment. Finally, 2 different codes were written on the Arduino platform and uploaded to the board via a usb cable. In addition, a Raspberry Pi which is a small size Linux-based computer that can be connected to Arduino microcontrollers, was used as the wireless file server in this study (Komarizadehasl, Lozano Galant, et al. 2022b). This way, the operator can access the Arduino codes for modifying or upgrading purposes (Komarizadehasl, Lozano Galant, et al. 2022a). To save and acquire provided data of the accelerometers, a python code was written to save the acquisition data on the Raspberry Pi memory card. For getting the main characteristics of these sensors, a few dynamic and static tests have been carried on.

4 STATIC EXPERIMENT

The device was tested against for the purpose of same measurement against different materials. In the static experiment, tests with and without extreme ambient light has been done for getting the distance from the big book. For the one with the light bulb, the temperature sensor has been moved a bit far from the source of the light and heat. The reason was that the excruciating heat coming from the light bulb would not harm the sensor. standard deviations driven from the performed tests has been illustrated. On Table 1 ranging result of same experiment under different circumstances has been shown.

Table 1. Results of ranging experiments.

Sensors	Thick book	White paper	Black paper	Tissue	Transparent plastic cover	Extreme ambient light
Ultra	0.61	1.87	1	352	0.7	3.23
Laser	2.5	2.67	7.18	4.66	5.46	3607

It should be mentioned that the ultrasonic sensor which was the chipset sensor and the easiest one to install, had shown better performances compare to the laser ones. On down side, this sensor needs 5v interaction digital ports and needs at least 4 volts for its full functionality. The only problem with this sensor could be its data providing speed. Although the laser has a faster rate (50Hz data production), this sensor has a frequency of only 20Hz. In other words, this sensor can provide up to 20 data each second. The biggest problem with the ultrasonic sensors would be their dependence on the ambient temperature and humidity. Since the speed of sound changes from an environment to another. This sensor needs the accurate speed of sound for its calculations. The proposition of this paper would be using the ultrasonic sensor with a laser sensor if there was the probability of a changing temperature or of an extreme ambient light. Using the first laser sensor or the second one is due to what range and circumstances the experiment may experience.

5 DYNAMIC EXPERIMENT

For testing the accelerometer sensor and its reliability, an experiment has been implemented. With a dynamic jack, a sinus signal has been programed and the vibrations had been saved by the accelerometer. This jack can shake its bottom plate as was programmed. The instructions to the hydraulic jack was to make a wave with a fixed frequency 5 hertz (5 complete waves in one second). The movement of the jack was to go up to 0.1 millimeter up and -0.1 millimeter down from its null axis to make a sinus wave. With a very simple two time differential, the acceleration equation could be calculated.

$$y = d * \sin(\omega * t + \varphi) \quad (1)$$

$$\omega = 2 * \pi * f \quad (2)$$

In the above equation y is the displacement in time t, d is the maximum allowed movement of the jack in each cycle, ω is the angular frequency and f is the set frequency which equal to 5Hz and φ is the phase constant. On the equ.3, acceleration has been calculated from the equ.1 and equ.2. this was done by getting the second order derivative of the equ.1. By putting all the data in the equ.3 the maximum acceleration was calculated as $10.4352 \text{ g} * 10^{-3} \text{ m/s}^2$.

$$a = \frac{d^2 * y}{dt^2} = \ddot{y} = -d * \omega^2 * \sin(\omega * t + \varphi) \quad (3)$$

The very first faced problem in this experiment was that the sensor could not record data or if recorded, the data were messy. It was deduced that the sensor had to be glued to the bottom plate of the jack for getting accurate information. The second problem was that the written python code could save only 120 data per second while the sensor was reporting more than 300 data per second. Although by using a serial port commercial software on the computer it could have been possible to save data with the same speed of their production. Since here getting the accurate time of capture was vital, it was obligatory to use python to attach the provided data with their corresponding time. To tackle this problem, the speed of data capture had to be dialed down, so the python could get and save them. To be on the safe side the speed of capture had been set on 84Hz.

The other unexpected issue that this project faced was that, though this sensor had been calibrated in the company, it had a constant number added to all provided data which from now here it would be named as the white noise. As on the Figure 7a it has been illustrated, the averaged data is around -50milig while they had to fluctuate around zero. This -50milig was considered as the white noise of this sensor. In order to measure this correctly, the average of 10000 set of data in a vibration free test has been calculated. For this sensor the white noise had been calculated as -49.8535 milig. By removing this amount from the provided accelerations, the values had been pulled up where they needed to be. The data were clearer and more understandable when this white noise had been removed. This improvement can be seen on Figure 7b.

Figure 7. 7a shows Acceleration, Time diagram with white noise & 7b shows Acceleration, Time diagram without the white noise.

6 CONCLUSIONS

Notwithstanding that the laser sensors did not have as good results as the ultrasonic one, they can be useful as well. They are smaller, they are lighter and faster and have noise-free technology (no noise can enter from the wires). Moreover, they work independent of the temperature of their testing situation. Best results would only appear if an ultrasonic sensor (attached to its temperature and humidity sensor) be used alongside of a Laser sensor. They can cover the downsides of each other and provide accurate, useful set of data.

As on the Figure 7b it is visible the sinus wave conducted from the accelerometer is quite close with the expected behavior. As it is observable the sinus wave is fluctuating about 10.5 milig from its average. As it was calculated on the last section the graph should have had a 10.453 milig fluctuation. It is quite notable to see that they have worked out almost the same.

On the Figure 7b the filtered data from the 5Hz experiment has been shown. As it can be seen, the result is not so accurate, for the fluctuation has other unexpected data or noises as well. In the future works, filters must be applied to delete the unwanted data and ambient noises which may have entered in to this experiment unwantedly.

ABSTRACT: Recent years' publications have shown how valuable information can be in the integrity management of civil structures. Monitoring systems increase the knowledge about the structural state, improving the prioritization of the interventions, and the selection of optimal maintenance strategy and thereby allowing for budget optimization and risk minimization. This paper investigates the effect of multiple information on integrity management throughout a deteriorating structure's life cycle. Pre-posterior analysis and the concept of the Value of Information (VoI) are used to quantify the benefit multiple information provide in structural integrity management. Multiple information (e.g., local information about the condition state of the several components of a system) and actions are associated with an expected utility. Optimization is performed by determining the lowest total expected cost of the maintenance strategy for a given set of information.

1 INTRODUCTION

Decision-making is a crucial aspect of civil and infrastructure engineering due to the large social, economic, and structural consequences decisions can result in. Several factors may undermine the performance of civil structures as the deterioration effects, the intervention quality, the extreme load conditions, and environmental phenomena. Furthermore, these factors are affected by significant uncertainties and cannot be quantified effectively. Monitoring systems and techniques may reduce such uncertainties and increase the knowledge about the structural performance of a system. Collecting and analyzing information entails a cost that should be compensated by the benefit achieved by their use in integrity management. In this context, an optimization process may be performed by determining if, when, and which type of information is optimal to collect. This optimization process requires the utilization of the concept of Value of Information (VoI) from the Bayesian decision theory. Schlaifer and Raiffa (1961) formulated the VoI in the Bayesian context providing the base for the theoretical framework and many applications, see e.g., (Zhang *et al.*, 2021) for a review. The VoI provides a quantification of the expected benefit, e.g., in terms of saved expected budget, which information may provide in decision-making. Information may be obtained by destructive and non-destructive tests, inspections, and by deploying sensors on a structure. Multi-component deteriorating systems, multi-sensor information integration, and sensor arrangement optimization are investigated e.g., in (Long, Döhler and Thöns, 2020) and (Malings and Pozzi, 2016). However, in both papers, the

case studies only account for serial systems neglecting the system redundancy, the capacity to redistribute the loads, and the component behavior characteristics.

This paper extends the available VoI framework for engineering structures to account for multi-component measurements in the evaluation of the optimal maintenance strategy of a deteriorating structural system, accounting for its redundancy and the correlation among the components. A novel deterioration model is adapted from the literature and a new description for the information model is formulated and implemented. Furthermore, VoI is evaluated at several times during the service life of a deteriorating structure and accounting for different numbers of monitored components. The value of obtaining multi-component measurements rather than a single-component measurement is evaluated in terms of how it affects the selection of the optimal maintenance strategy. In Section 2, a generalized system state model is reported and discussed. The initial resistance, deterioration, load, and structural model are defined. Section 3 encompasses a novel description of the information model when multiple information on the structural state is obtained. Section 4 reports the decision scenario and utility model. Section 5 describes the analytical formulation which is later implemented in the case study in Section 6. Finally, the conclusions are drawn in Section 7.

2 SYSTEM STATE MODEL

A structural system is typically characterized by its capacity, i.e., initial resistance that decreases over time due to deterioration effects, and demand, i.e., effect of the load that will be herein addressed as load. Following the semi-probabilistic approach, the design resistance of a structure may be described as:

$$R_0 = \gamma_S \cdot \gamma_R \cdot A \cdot R_{mat} = \gamma \cdot A \cdot R_{mat} \quad (1)$$

where γ_S is the load safety factor for one dominating action, γ_R is the safety factor for the material, A represents the geometrical properties of the system (cross-section area, inertia etc.), and R_{mat} corresponds to the material strength (Thöns, 2022). The deterioration description accounts for degradation and damage. Degradation evolves gradually over time (e.g. due to corrosion, fatigue, crack growth, etc.) and damage corresponds to a shock deterioration process (e.g. due to earthquakes, floods, etc.). In reference (Mori and Ellingwood, 1993), the authors introduce a general modeling of deterioration proposing different parameters for the deterioration type and rate. Long, Döhler and Thöns (2020) apply this model in the analyses of an articulated structure and simulate different types of deterioration encompassing diffusion-controlled deterioration, corrosion, and fatigue as well as sulfate attack induced concrete deterioration. Furthermore, Kamariotis, Chatzi and Straub (2023) implement an empirical deterioration model to consider shock deterioration processes. In this study, the overtime resistance of a structure is defined as:

$$R(t) = R_0 \cdot (1 - \alpha(t - T_0)^\beta - \sum_{i=1}^{N(t)} D_i) \quad (2)$$

where the first term $\alpha(t - T_0)^\beta$ represents the gradual damage (Mori and Ellingwood, 1993), and the second term $\sum_{i=1}^{N(t)} D_i$ represents the shock deterioration processes modelled as a homogeneous Poisson process (Kamariotis, Chatzi and Straub, 2023). In the equation α is the annual deterioration rate, t is the time, T_0 is the deterioration initiating time, β indicates the deterioration type, $N(t)$ is the number of shock events in a year, and D_i is the amount of a shock deterioration. Herein two system states are considered: state X_1 indicating the failure and state X_2 indicating a safe state (Thöns, 2018). The limit state equation can be written as:

$$X_1: g_X = M_R \cdot R(t) - M_S \cdot S \leq 0 \quad (3)$$

$$X_2: g_X = M_R \cdot R(t) - M_S \cdot S > 0 \quad (4)$$

where M_R and M_S represent the resistance and load model uncertainties, $R(t)$ is the resistance defined by eq. (2) and S is the load considered constant in time. The load description, the resistance and the load model uncertainties are provided by the JCSS (JCSS, 2001). The probability of a failure event $P(X_1)$, and the probability of a safe state $P(X_2)$, i.e., the reliability, may be calculated with Eq. (3) and Eq. (4). When dealing with multi-components and multi-information systems, the structural system performance can be described through Daniels systems (DS) models. The DS enables the modeling of a structural system taking into consideration the system's redundancy, the capacity to redistribute loads, and the component behavior (ductile or brittle). The DS model is a parallel system representative of a wide range of redundant structures with an initial resistance R_0 , a current resistance $R(t)$ that depends on the deterioration level, and load S (Thöns, 2018). The initial resistance $R_0 = R(t=0)$ is fixed through a design iteration process, i.e., setting a target reliability $P_t = 10^{-5}$ and adjusting R_0 such that $P(X_2(R_0)) = P_t$. For a ductile DS with n components, the system reliability may be written as:

$$P(X_2): P\left(g_X = \sum_i^n M_{R_i} \cdot R_i(t) - \sum_i^n M_{S_i} \cdot S_i > 0\right) \quad (5)$$

where the resistance $R_i(t)$, the load S_i , and the model uncertainties M_R and M_S refer to the i -th structural component. For a brittle DS, system reliability can be written as:

$$P(X_2) = P\left(g_X = \max((n - i + 1) \cdot m_{R_i} \cdot r_i(t)) - \sum_i^n M_{S_i} \cdot S_i > 0\right) \quad (6)$$

with $m_{R_1} \cdot r_1(t) \leq \dots \leq m_{R_n} \cdot r_n(t)$

where m_{R_i} and $r_i(t)$ are individual realizations of the resistance model and resistance distributions and $R_i(t)$ and they are used for the maximization process, equivalent to an intersection set operator (Gollwitzer and Rackwitz, 1990). The structural properties, the deterioration, and the load on the single components of a multi-component system may be dependent, i.e., correlated. Indeed, the components' material resistance $R_{i,mat}$ is usually correlated since it depends on the material production and fabrication. Load on each component is fully correlated and depends on its structural properties, e.g., component stiffness. The annual degradation rate may not be correlated for localized degradation (e.g., degradation induced by fatigue) or may be fully correlated for system degradation (e.g., corrosion due to an aggressive environment). The damage due to shock events, e.g. earthquakes, floods, and fire, may be correlated if the event affects the whole structure or may not if it affects only some components (e.g. plastic hinges in seismically designed structures). Furthermore, model uncertainties' correlation is high in the case the same model for all the components is used.

3 INFORMATION MODEL

Information about the structural performance usually enhances the knowledge of the structural state thereby supporting integrity management and budget optimization. Information on the system or component resistance and load may be obtained directly or indirectly by measuring quantities that are related to them. For example, the load may be estimated indirectly from the measurement of the deflection it causes, when their relationship is known.

Taking basis in the definition and the determination process of model uncertainties (JCSS, 2001), measurements may be modeled as realizations of model uncertainties, i.e. normalized model-predictions, affected by measurement uncertainty. Furthermore, this modeling accounts for the fact that the structural probabilistic model cannot be usually completely determined with available measurement strategies (Thöns, 2018). For each component of a multi-component system, measurements can be modeled on the component model resistance and load uncertainty, i.e., with the realizations m_{R_i} and m_{S_i} , affected by the measurement uncertainty. When a measurement of the structural state has been obtained, the posterior probability of failure can be recalculated. The updated posterior probability of failure for a single component system is:

$$X_1|m_R: g_{X|m_R} = M_U \cdot m_R \cdot R(t) - M_S \cdot S \leq 0 \quad (7)$$

where m_R is the measurement obtained by the monitoring system and M_U is the measurement uncertainty. As indicated in the introduction, a contribution of this paper lies in the expansion of Eq. (7) to multi-component systems and multiple measurements. Measurements may be obtained on one or more components and the probability of failure of the system can be updated. For a redundant multi-component system, the posterior probability of failure can be written as in Eq. (8) for ductile component behavior, and as in Eq. (9) for brittle component behavior.

$$X_1|\mathbf{O}_R: g_{X|\mathbf{O}_R} = \sum_i^n O_{R_i} \cdot R_i(t) - \sum_i^n M_{S_i} \cdot S_i \leq 0 \quad (8)$$

$$X_1|\mathbf{O}_R: g_{X|\mathbf{O}_R} = \max((n - i + 1) \cdot o_{R_i} \cdot r_i(t)) - \sum_i^n M_{S_i} \cdot S_i \leq 0 \quad (9)$$

where \mathbf{O}_R includes the resistance model uncertainties M_{R_i} and measurements m_{R_i} (realizations of M_R) affected by a measurement uncertainty M_U . o_{R_i} is the individual realization of the i^{th} distribution in \mathbf{O}_R that are ordered as in Eq. (6), i.e. $o_{R_1} \cdot r_1(t) \leq \dots \leq o_{R_i} \cdot r_i(t) \leq \dots \leq o_{R_n} \cdot r_n(t)$. In the case a measurement is obtained only on the first component, the terms in Eq. (8) and (9) can be written as vectors as follows:

$$\mathbf{O}_R = \begin{Bmatrix} M_U \cdot m_R \\ M_{R_2} \\ M_{R_3} \\ \vdots \end{Bmatrix}, \quad \mathbf{R}(t) = \begin{Bmatrix} R_1(t) \\ R_2(t) \\ R_3(t) \\ \vdots \end{Bmatrix}, \quad \mathbf{M}_S = \begin{Bmatrix} M_{S_1} \\ M_{S_2} \\ M_{S_3} \\ \vdots \end{Bmatrix}, \quad \mathbf{S} = \begin{Bmatrix} S_1 \\ S_2 \\ S_3 \\ \vdots \end{Bmatrix}$$

4 DECISION SCENARIO AND UTILITY MODEL

The decision scenario adopted in the analysis accounts for five distinct actions, namely a_0 the do-nothing action, a_1 the strengthening action, a_2 the repair action, a_3 the load reduction action and a_4 the consequence reduction utility. Along with (Thöns, 2022), a_1 , a_2 and a_3 are system state actions, i.e. enhancing the structural state and reliability, whereas a_4 is a utility action, i.e. affecting consequences and functionality of the structural system. Each action is associated with an implementation uncertainty, which reflects the quality of the implemented intervention. Therefore, an implementation state, i.e., posterior to the action $X_1(t)|a_k, Y_k$, can be defined accounting for the full, partial or failed action implementation. Implementation uncertainty is exemplarily formulated in (Thöns, 2022). Table 1 illustrates the action types, effects, cost, and implementation uncertainty. The updated limit state equations are reported for the simple case of a single-component system. Information can be considered in these equations by substituting the model distribution M_R by its realization m_R and related measurement uncertainty M_U as in Eq. (7).

The strengthening action a_1 is representative of the case in which an action aiming to enhance the structural resistance is performed. The action effect is quantified to an increase of 50% of the resistance (e.g., Fiber Reinforced Polymers (FRP) strengthening on the resisting moment of a beam). The repair action a_2 results in the restoration of the initial resistance at the time of the action implementation (t_a). The load reduction action a_3 is assumed to result in a constraint of 50% of the acting load, e.g., by limitation of the traffic. The consequence reduction action a_4 is assumed to reduce the cost of failure by 15%. For simplicity reasons, the cost of failure c_F is set equal to 1. Action costs, information costs, and therefore, the utilities are calculated as a percentage of c_F . The cost of a single measurement, i.e., information, is set equal to 0.1 % c_F .

5 DECISION ANALYTICAL FORMULATION

The pre-posterior decision analysis is performed at different times to investigate how the VoI varies within the structure's service life. The posterior and pre-posterior utilities have been

Table 1. Action types, descriptions, effects, costs, and implementation uncertainties.

Action type	Description	Action effect	Cost (% C_F)	Implementation uncertainty
a_0	Do nothing	-	-	-
$g_{X_1(t) a_0} = M_R \cdot R(t) - M_S \cdot S \leq 0$				
a_1	Strengthening	$1.5 R$	2%	$Y_1 = Tr(0.95,1.05,1.10)$
$g_{X_1(t) a_1, Y_1} = M_R \cdot 1.5 \cdot R(t) \cdot Y_1 - M_S \cdot S \leq 0$				
a_2	Repair	$R(t = t_{a2}) = R_0$	10%	$Y_2 = Tr(0.90,0.95,1.00)$
$g_{X_1 a_2, Y_2} = M_R \cdot R_0 \cdot Y_2 - M_S \cdot S \leq 0$				
a_3	Load reduction	$S/2$	1.0%	$Y_3 = N(1,0.1)$
$g_{X_1(t) a_3, Y_3} = M_R \cdot R(t) - M_S \cdot S/2 \cdot Y_3 \leq 0$				
a_4	Consequence reduction	$c_{F,red} = 0,85$	1.0%	$Y_4 = Tr(0.85,0.95,1.05)$
$g_{X_1(t) a_4, Y_4} = M_R \cdot R(t) - M_S \cdot S \leq 0 c_{F,red} = 0,85 \cdot c_F \cdot Y_4$				

formulated to include the cost of the information as proportional to the number of measurements. Thereby, posterior and preposterior utilities can be compared in the evaluation. The extensive analytical formulation from (Schlaifer and Raiffa, 1961) is adopted in the analysis as allowing for the calculation of the posterior utilities and total expected costs which are later used in the exemplary case study. The consideration of system state actions and implementation uncertainties in the analysis led to an equivalence issue between the two decision analytical formulations from the literature, namely the normal and the extensive formulations. The analysis highlighted that the preposterior utility equivalence holds for utility actions but not for system-state actions. Therefore, an adjustment factor $r_E(X_l, Y_k, a_k)$ has been derived equal to $\frac{P(X_l|a_k, Y_k)}{P(X_l)}$. Eq. (12) includes such adjustment factor for the calculation of the preposterior utility. Table 2 reports the analytical formulation which is adopted in the analysis.

Table 2. Analytical formulation.

	Objective function
Prior	$U_{prior} = \max_{a_k} E_{X_l a_k, Y_k} [u(X_l, a_k, Y_k)] =$ $= \max_{a_k} \sum_{X_l} P(X_l a_k, Y_k) \cdot u(X_l, a_k, Y_k) - c_{a_k}$ (10)
Posterior	$U_{post}(O_{i,j}) = \max_{a_k} E_{X_l O_{i,j}, a_k, Y_k} [u(X_l, a_k, Y_k)] =$ $= \max_{a_k} \sum_{X_l} P(X_l O_{i,j}, a_k, Y_k) \cdot u(X_l, a_k, Y_k) - c_{a_k} - n_i \cdot c_i$ (11)
Pre-posterior	$U_{pre-post} = \max_{a_k, i_i} E_{oi,j} \left[\max_{a_k} E_{X_l O_{i,j}, a_k, Y_k} [u(X_l, a_k, Y_k)] \right] \cdot r_{E(X_l, Y_k, a_k)} =$ $\max_{i_i} \sum_{O_{i,j}} P(O_{i,j}) \cdot \max_{a_k} \sum_{X_l} \left(\frac{P(X_l a_k, Y_k)}{P(X_l)} \cdot P(X_l O_{i,j}, a_k, Y_k) \cdot u(X_l, a_k, Y_k) \right) - c_{a_k} - n_i \cdot c_i$ (12)

Where X_l indicates the structural states, a_k indicates the action k , Y_k is the implementation uncertainty, c_{a_k} indicate the action cost, i_i is the information strategy characterized by n_i , number of monitored components and c_i , cost of the measurement on a single component, $O_{i,j}$

corresponds to the information set (including the measurements) relative to an information strategy i_s , and u is utility associated to a state and, in the case of an utility action, to the action effect and its implementation uncertainty. According to (JCSS, 2001), durability needs to be taken into account by imposing the survival condition (X_2) of the structure at the time of analysis. Therefore, when calculating the $P(X_1(t))$ at the time t of analysis, the condition of survival in the previous time steps ($t-t_{step}$) is considered as:

$$P(X_1(t)|X_1(t-t_{step})) = \frac{P(X_1(t))}{1 - P(X_2(t-t_{step}))} \quad (13)$$

VoI is a quantification of the benefit that information provides in integrity management. The evaluation of such benefit over the structural service life is performed by calculating a pre-posterior and a prior utility at the different steps of analysis. VoI can be calculated as the difference between the pre-posterior and prior utilities at the time t .

$$VoI(t) = U_{prepost}(t) - U_{prior}(t) \quad (14)$$

6 EXEMPLARY STUDY

The calculation of the VoI is performed for an existing structure deteriorating over time due to degradation and damage effects. The structural system is modeled as a DS with five parallel components, e.g., a bridge with five piers, and the number of monitored components is made to vary from one to five. In the first case, information is obtained on a single component, in the second case, information is obtained on two components, etc. In the analysis, the current resistance of the components is monitored. Each measurement is local and provides information on the component state. Therefore, the system current resistance is estimated accounting for the components' brittle and ductile behaviors. Moreover, actions are assumed to be implemented simultaneously to the five elements of the structure. These hypotheses are made as herein the parallel components of the DS are modeled with the same initial resistance and being affected by the same deterioration phenomena. Further studies may concentrate on the study of component actions of more complex structures. The several decision options are compared by their total expected cost being the cheapest selected as the optimal. The probabilistic models assumed in the analysis are based on (Thöns, 2022) and here presented in Table 3.

Table 3. Probabilistic models.

Variable	Mean	Variance	Distribution	Reference
Load S	1.0	0.2	Gumbel	E.g., (JCSS, 2001)
Load model uncertainty M_S	1.0	0.1	Lognormal	JCSS Probabilistic Model Code Part 3.9 (2001) (JCSS, 2001)
Resistance R_{mat}	1.0	0.05	Lognormal	Generic, (JCSS, 2001)
Resistance model uncertainty M_R	1.0	0.05	Lognormal	(JCSS, 2001) Part 3.9
Measurement uncertainty M_U	1.0	0.3	Normal	(Thöns, 2022)
Annual degradation rate α	Medium $7.6 \cdot 10^{-5}$	0.001	Lognormal	(Kamariotis, Chatzi and Straub, 2023)
Jumps number $N(t)$	$0.04 t$	-	Poisson	(Kamariotis, Chatzi and Straub, 2023)
Shock deterioration D_i	$E(R_0)/50$	0.25	Lognormal	Generic
Deterioration type β	$\beta = 1$ corresponds to the most applied corrosion models			(Mori and Ellingwood, 1993)
Safety factor γ_S	1.5 for one dominating action			(EN 1990: Eurocode - Basis of structural design, 2002)
Safety factor γ_R	1.0 for steel			(EN 1990: Eurocode - Basis of structural design, 2002)

Several considerations on the components' properties, load conditions, and deterioration phenomena are made in the analysis. The components, the load S is fully correlated and distributes evenly to the parallel components.

The components' material resistance R_{mat} is assumed to be fully correlated as the parallel components are equal, degradation (α) and damage ($N(t)$, D_i) are assumed as fully correlated since in the analyzed parallel structure corrosion and shock events are assumed to affect equally. The correlation of the model uncertainties is modeled with 0 and 1 as hardly any such considerations can be found in the scientific literature. In this analysis measurement uncertainty is assumed not to be correlated for simplicity reasons. In the first part of the analysis, three times during the service life of a five non-correlated component structure are investigated, namely the construction year ($t = 0$), half of the service life ($t = 25$ years), and the end of the service life ($t = 50$ years). Figure 1(a), (b), and (c) present the total expected costs at the three times in the case a single sensor is installed whereas Figure 1(d) presents the case in which two measurements are obtained on the structure at $t = 25$ years. The optimal action given one or two resistance measurements is identified as the one with the lowest total expected cost and consequences. At time 0, for any measurement of one component resistance, the optimal action is a_0 (do nothing). This is because at the beginning of the service life and in the case component resistance measurements are not correlated, the other components can fully compensate the load demand maintaining a low system probability of failure. The other actions involve implementation costs, which are not compensated by their effect on risk reduction. When the service life approaches 25 years, the optimal action depends on the obtained resistance measurement varying from the load reduction action to the consequence reduction and do-nothing action when a high resistance value is measured. At $t = 50$ years, the repair action, and the consequence reduction action are found to be the optimal actions, respectively, for low and high resistance measurements. In Figure 1(d), the case of two monitored structural components (over five) is considered. The combination of two or more measurements may induce the selection of a different action with respect to the case when a single measurement is available.

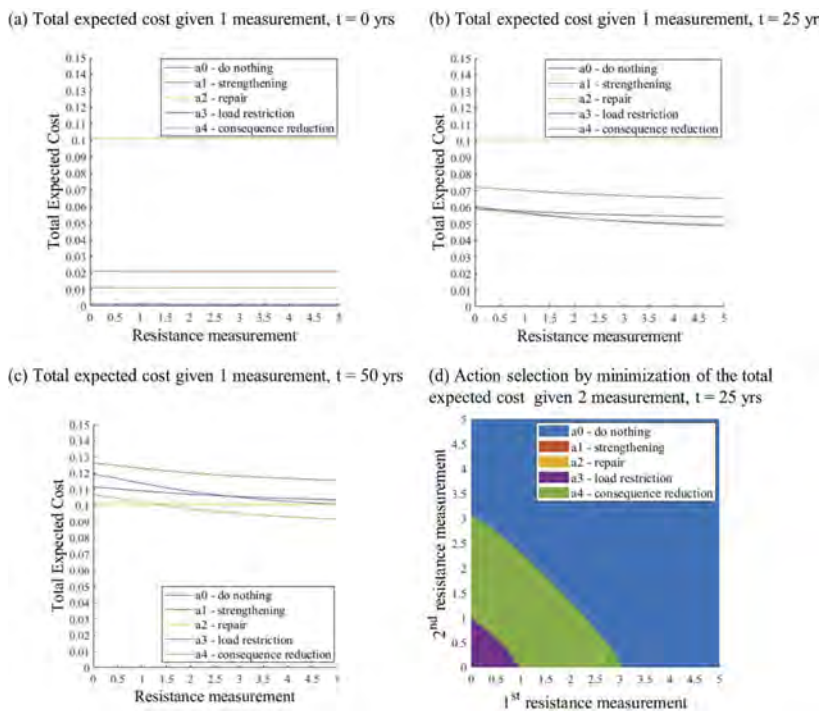

Figure 1. Total Expected cost given one measurement (a),(b),(c) and two measurements(d) at $t = 0$, 25, and 50 years.

This is the case where a low resistance measurement is obtained on the first component and a high one is obtained on the second component. The second measurement leads to the selection of a different action and thereby results in a higher VoI. The second part of this analysis aims to analyze VoI throughout the service life of a structure when different assumptions on the measurement's correlation, i.e., model uncertainty realization correlation, and DS component behaviors are made. This analysis aims to analyze how valuable information is throughout the structure's service life.

In Figure 2(a), a fully correlated ductile system is analyzed, i.e., resistance, deterioration, load, and the collected measurements are assumed to be fully correlated. In Figure 2(b), the same resistance, load, and damage characteristics are assumed for the DS whereas a non-correlated resistance model uncertainty is considered. Along with the deterioration processes and the decrease of the resistance in time, the VoI increases. It is found that at the very beginning of the structural service life (in this case before five years) measurements do not provide any support in the management. Later, in this case, after five years but before ten years, measurements do support the selection of the action, but their costs are not compensated by the risk reduction. Indeed, only after the first ten years, VoI has a positive value. Moreover, in the case of fully ductile and brittle correlated systems, it is found that monitoring a single component results more advantageous than monitoring several components accordingly to (Giordano *et al.*, 2020) . This is since the obtained measurements on the different components would reveal correlated measurements and therefore, the same action would be selected. On the contrary, when non-correlated components are assumed, a single component measurement provides optimal integrity management support in only a specific time interval. With the decrease of the structural capacity to due deterioration, a higher number of monitored components would provide optimal integrity management, e.g. in the case of the non-correlated brittle components the optimal management would be provided by no measurement in the first 10 years, 1 measurement in the range 10-13 years, 2 measurements in the range 13-17 years, 3 measurements in 17-20 years, 4 measurements in 20-25 years and successively by 5 measurements (one on each component).

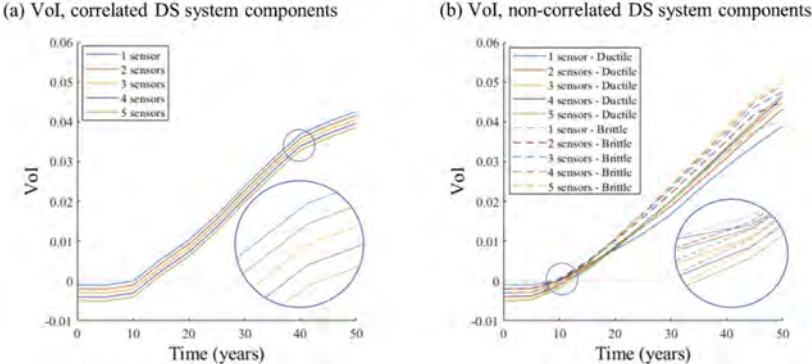

Figure 2. VoI for a full correlated DS (a), non-correlated DS with ductile or brittle components (b).

7 CONCLUSIONS

This paper presents the analysis of VoI throughout the service life of an idealized structural system. DSs are used to schematize a redundant structure with five components, e.g., a bridge with 5 piers, and a newly adapted deterioration model has been adopted in the analysis. Local information on one or more components of the structure is assumed to be obtained. The optimal action is selected by performing a minimization of the total expected cost. The decision scenario has been formulated for a wide range of actions including interventions enhancing the structural performance and interventions reducing the consequences of collapse. Information value analysis utilizing multiple measurements and system state actions in conjunction with a DS contributes to the novelty of the paper. Furthermore, the equivalence of the normal and extensive formulation has been stated. The results from the analysis show that the VoI increases throughout the service

life of the structure and that obtaining multiple information may not always be preferable. Indeed, in the case of fully correlated systems, a single measurement provides optimal management. On the contrary, in the case of non-correlated systems, it is found that a different number of measurements provide optimal management throughout the service life.

Recent progress developing a rating framework for evaluating SHM for bridge scour

P.J. Vardanega, G. Gavriel & M. Pregolato

University of Bristol, Bristol, UK

ABSTRACT: Scour is a complex phenomenon and one of the most frequent causes of riverine bridge failures. Detecting scouring effects is a complex geotechnical/structural/hydraulic engineering challenge. Incorporating more risk-based approaches into scour assessment frameworks may allow for enhancements over current processes which remain reliant on visual inspection to detect bridge scour. Scour detection and monitoring is inherently a ‘damage detection’ task. A wide range of technologies for scour monitoring are available which may partially replace or supplement visual inspection activities. Recently, a new rating framework has been presented to assist engineers to assess the relative merits of different sensor technology options on scour-prone bridges. In this paper, the development of this framework is reviewed and compared with other scour rating frameworks; suggestions for future development and calibration are proposed.

1 INTRODUCTION

1.1 *Bridge scour*

Scour is a complex phenomenon and a frequent reason for bridge failures across the world (e.g. Briaud *et al.* 2011, Maddison 2012, Prendergast & Gavin 2014, Dikanski *et al.* 2017, Ettema *et al.* 2017, Kerényi & Flora 2019). Scour effects on individual bridges may change with time due to changes in flows and flooding levels (cf. Dikanski *et al.* 2017). Detecting scouring effects is a complex forensic engineering challenge (see Vardanega *et al.* 2021 for a recent review). Incorporating more risk-based approaches into scour assessment frameworks may allow for enhancements over current processes which remain largely reliant on visual inspection to detect bridge scour (cf. Pregolato *et al.* 2021). Maroni *et al.* (2022) highlighted the need for probabilistic assessments of scour risk along with integration of ‘quasi-real-time’ monitoring data into scour risk management frameworks.

The categorization system for bridge Structural Health Monitoring (SHM) proposed by Webb *et al.* (2015) (summarized in Figure 1) includes the following five categories: (i) ‘Anomaly Detection’; (ii) ‘Sensor Deployment Studies’; (iii) ‘Model Validation’; (iv) ‘Threshold Check’ and (v) ‘Damage Detection’. These categories are presented in order of increasing complexity but arguably also of increasing value to the asset owner (Webb *et al.* 2015). Scour detection and monitoring is inherently a ‘damage detection’ task. Damage detection is a difficult challenge for many SHM systems, but it is necessary to prevent collapses of bridges over waterways in the case of scour.

1.2 *Rating systems*

Figure 2 shows some of the key considerations when specifying new SHM systems (Vardanega *et al.* 2016). Ahlborn *et al.* (2010a) and Vaghefi *et al.* (2012) offer a methodology to determine the efficiency of different remote sensing options for assessing bridge condition indicators (see also Ahlborn *et al.* (2010b) for a review of various remote sensing options for bridge condition detection). Vardanega *et al.* (2016) proposed a rating system to determine if a planned SHM system

would deliver value to a bridge asset owner. The framework from Vardanega *et al.* (2016) was in part inspired by the framework proposed to assign geotechnical reduction factors presented in Poulos (2004) and the system to assess the value of remote sensing technologies from Vaghefi *et al.* (2012) (see also Ahlborn *et al.* 2010a). The framework from Vardanega *et al.* (2016) was tested using information from five previous monitoring deployments (see Table 1, see also Nepomuceno *et al.* (2019, 2022) who used the framework for further case studies).

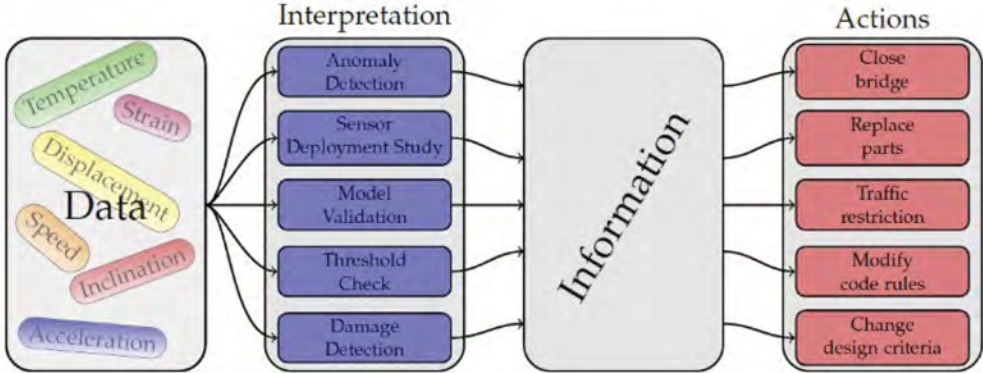

Figure 1. Categories of SHM systems (taken from Webb *et al.* (2015) and used under the terms of the cc by 4.0 license).

Table 1. Summary of Bridge Projects evaluated in Vardanega *et al.* (2016) using the framework (see also Nepomuceno *et al.* 2022).

Bridge Structure	References	Outcome from Vardanega <i>et al.</i> (2016) rating
Walton Bridge	Middleton <i>et al.</i> (2014) Webb (2014)	Project unlikely to yield value to asset owner/ manager
Nine Wells Bridge	Hoult <i>et al.</i> (2009) Schwamb (2010) Webb (2014) Webb <i>et al.</i> (2017)*	Project may yield value to the asset owner/manager
Humber Bridge (Hessle Anchorage)	Hoult <i>et al.</i> (2008) Fidler <i>et al.</i> (2021)*	Project likely to yield value to the asset owner/ manager
Ferriby Road Bridge	Hoult <i>et al.</i> (2010)	Project may yield value to the asset owner/manager
Hammersmith Flyover	Webb <i>et al.</i> (2014)	Project likely to yield value to the asset owner/ manager

* paper not published when Vardanega *et al.* (2016) framework first published

The framework from Vardanega *et al.* (2016) was further tested for a planned monitoring effort on a proposed footbridge (Nepomuceno *et al.* 2019) and has recently been examined in the context of prior monitoring efforts (Nepomuceno *et al.* 2022). Vardanega *et al.* (2021) have recently presented a new rating framework to assist engineers with answering the ‘Which sensor?’ question from Figure 2 in the context of bridge scour detection (see Gavriel (2019) for an early version of the rating framework for scour).

1.3 Paper aims

This paper briefly outlines some of the key monitoring devices used for scour monitoring and then discusses the new rating framework presented in Vardanega *et al.* (2021); it makes comparison of this framework with that discussed in Pregnotato *et al.* (2022) and the Scour Monitoring Decision Framework (SMDF) in Lueker *et al.* (2010). This comparison may allow the development of a new, comprehensive framework for planning and assessing scour monitoring efforts.

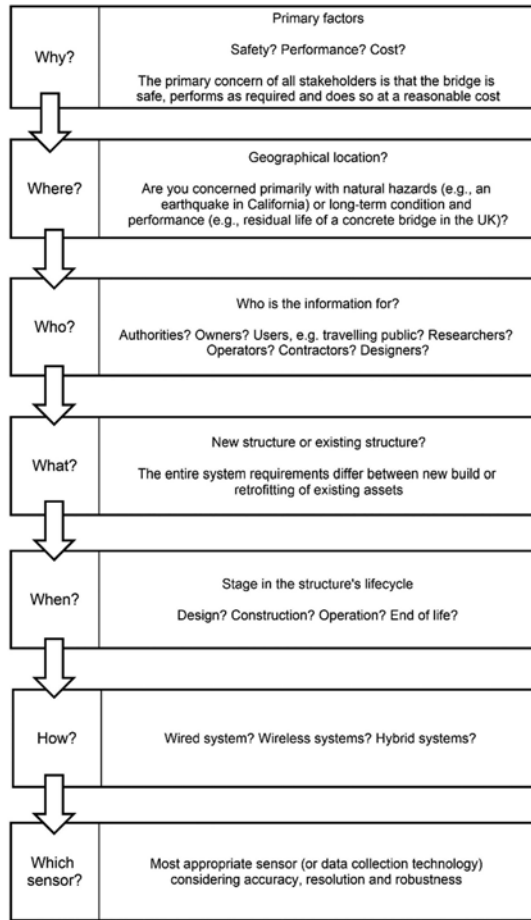

Figure 2. Key considerations when deciding whether to employ SHM (taken from Vardanega *et al.* 2016 and used under the terms of the cc by 4.0 license).

2 BRIDGE SCOUR MONITORING DEVICES

2.1 Scour monitoring technologies

A range of technologies for scour monitoring are available which may partially replace or supplement visual inspection activities (see Briaud *et al.* 2011, Prendergast & Gavin 2014, Wang *et al.* 2017 and Prendergast *et al.* 2018 for detailed reviews of scour monitoring devices). Sections 2.2 to 2.4 briefly outline the use of Accelerometers, Fiber-Bragg grating sensors and Sonar in some scour monitoring case studies. Further reviews on general bridge monitoring technologies can be found in Webb *et al.* (2015) and Middleton *et al.* (2016).

2.2 Accelerometers

Accelerometers are used to measure dynamic response of bridges subject to scour damage by detecting changes in the natural frequency (e.g. Prendergast & Gavin 2014, Bao & Liu 2016, Kariyawasam *et al.* 2019a, 2019b, 2020). The collected data can then be analysed using spectral analysis methods (e.g. Brincker *et al.* 2001, Briaud *et al.* 2011). Briaud *et al.* (2011) reported that based on studies of two bridges in Texas (USA) that draw-backs from accelerometers were 'lack of efficient excitation' from loading and high-power consumption (the latter may be mitigated with solar panels).

2.3 Fiber-Bragg grating sensors

Fiber-Bragg grating sensors can be installed on bridge piers to detect changes in soil levels during (and post) flood events (e.g. Lin *et al.* 2006, Prendergast & Gavin 2014 and Kong *et al.* 2017). According to the review of Prendergast & Gavin (2014, p.140) embedded rods that are “partially exposed due to scour will be subjected to hydrodynamic forces from the flow of water that induce bending in the exposed rod” and progression of scouring can be detected with an array of strain gauges installed along the rod (see the field studies of Lin *et al.* 2006 and Kong *et al.* 2017).

2.4 Sonar

Sonar devices can be mounted to vessels or on bridge piers to detect changes in riverbed conditions by sending out sound waves and measuring the time taken for the sound wave to return (e.g. De Falco & Mele 2002, Briaud *et al.* 2011, Prendergast & Gavin 2014 and Clubley *et al.* 2015). Briaud *et al.* (2011, p.15) explain that for sonar sensors: “The time taken for the signal to propagate from the emitter to the receiver in combination with the material properties gives an estimate of the distance from the emitter to the interface of the two mediums.” Briaud *et al.* (2011) also explain that fixed sonar devices can be damaged or destroyed due to the effects of debris.

3 SCOUR RATING FRAMEWORK

A preliminary version of a rating framework to compare various scour monitoring technologies was proposed by Gavriel (2019). Vardanega *et al.* (2021) further developed the framework and used it to evaluate seven monitoring deployments reported in the literature (see Table 2 for a summary of this recent work).

Table 2. Summary of the application of the scour monitoring rating framework to seven installed monitoring systems from Vardanega *et al.* (2021).

Bridge Structure(s)/Location	References	Score (/25)
Mezzana Corti & Borgoforte Bridges (River Po, Italy)	De Falco & Mele (2002)	16
Dadu Bridge (Wu River, Taiwan)	Lin <i>et al.</i> (2006)	17
Railway viaduct (River Hamble, England, UK)	Clubley <i>et al.</i> (2015)	14
Concrete bridge (Redwood Creek, Louisiana, USA)	Kong <i>et al.</i> (2017)	11
Tadcaster bridge (River Wharfe, England, UK)	Selvakumaran <i>et al.</i> (2018)	17
Baildon bridge (River Aire, England, UK)	Kariyawasam (2019a, 2019b)	17
A76 200 bridge (River Nith, Scotland UK)	Maroni <i>et al.</i> (2020)	19

When using the framework, it is important to understand how monitoring systems may be used to capture different aspects of scouring. For example, Highways England (BD 97/12: HA (2012): clause 7.14) considers three categories of scour monitoring techniques: “(i) those that seek to measure the maximum scour levels that have occurred at the bridge site; (ii) those that seek to measure the development of scour adjacent to the structure as it develops during a flood; (iii) systems based on monitoring analogues (conditions that may correlate with the development of scour) such as flow velocities, water level, or weather warnings.”

Monitoring devices may be used to capture data relevant to one or more of the aforementioned categories from HA (2012). The rating framework (Vardanega *et al.* 2021) includes five criteria (Q1 to 5) each of which are rated from 1 to 5, with a higher score given to a device with improved capability:

- “Q1 – Ease of installation”
- “Q2 – Ease of operation”
- “Q3 – Ease of data-logging/capture”
- “Q4 – Ease of data interpretation”
- “Q5 – Measurement frequency”.

Figure 3 shows a diagrammatic description of the scoring system (for a complete description of the rating system see Vardanega *et al.* 2021). The following classification is used to describe the level of applicability of devices scored using the rating framework (Vardanega *et al.* 2021):

- “Very high applicability” (score 23-25)
- “High applicability” (score of 18-22)
- “Moderate applicability” (score of 13-17)
- “Low applicability” (score of 8-12)
- “Very low applicability” (score of 5-7).

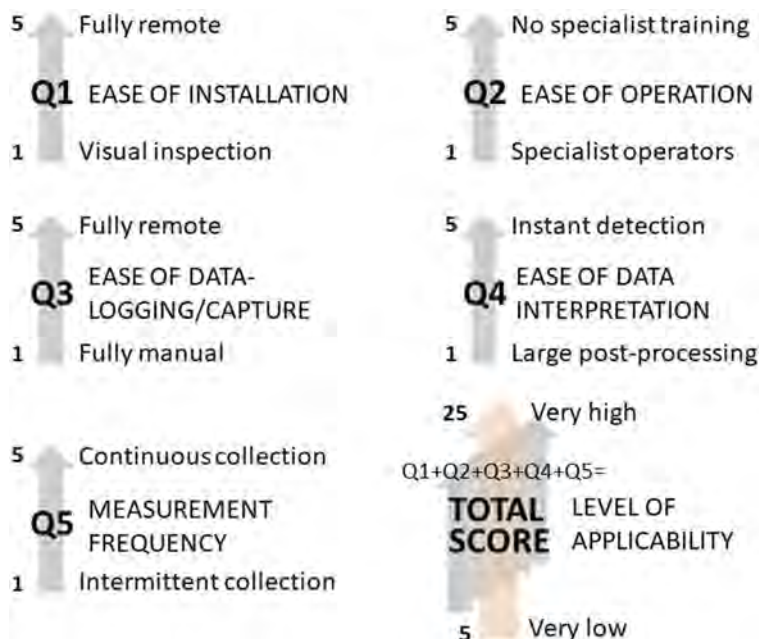

Figure 3. Schematic of the scour device rating system proposed in Vardanega *et al.* (2021).

4 COMPARISON WITH OTHER FRAMEWORKS

Pregolato *et al.* (2022) built on the framework presented in Vardanega *et al.* (2021) by introducing nine criteria versus the five criteria suggested by Vardanega *et al.* (2021). The updated framework by Pregolato *et al.* (2022) introduced two cost related criteria one related to the initial cost of the measuring apparatus and one related to the whole-life cost of the measuring apparatus. Pregolato *et al.* (2022) also considered the environmental limitations which are associated with the use of the examined apparatus as suggested by the original framework (Gavriel 2019). The updated framework from Pregolato *et al.* (2022) accounts for the robustness of the measuring apparatus. Pregolato *et al.* (2022) incorporated weighting factors for the criteria (albeit assigned by engineering judgement), such as those shown in Figure 3.

Lueker *et al.* (2010) applied the Minnesota ‘Scour Monitoring Decision Framework’ (SMDF) to five sites and demonstrated that a range of scour devices may be selected with sonar being the generally preferred option. The SMDF has many more criteria than Vardanega *et al.* (2021) with more details on the nature of the riverine conditions being considered, as well as e.g. the traffic levels on the bridge.

5 CONCLUSIONS

5.1 Summary

A rating framework (Vardanega *et al.* 2021) has been proposed to assist engineers to answer the ‘which sensor?’ question when considering SHM systems for scour monitoring and assessment. The framework has five key criteria which are rated from 1 to 5 depending on the capability of the technology in terms of “Ease of installation”, “Ease of operation”, “Ease of data logging/capture”, “Ease of data interpretation” and “Measurement frequency”. The framework can also be used to assess a full scour SHM deployment, which may involve multiple technologies which form a more complex SHM system. Finally, the comparison with other frameworks (Pregolato *et al.* 2022 and Lueker *et al.* 2010) highlighted the possibility to include other criteria, such as sensor cost or traffic levels.

5.2 Further work

The framework should also be tested for proposed monitoring efforts on new projects to see its use in both selecting and comparing different sensing device options and to evaluate the designed monitoring specification on such projects. As previously stated, the possibility of adding further criteria or weightings for different criteria depending on the situation should also be explored. In addition, the rating-frameworks of Vardanega *et al.* (2021) (with the additions proposed by Pregolato *et al.* 2022) along with other methods such as the ‘Scour Monitoring Decision Framework’ (Lueker *et al.* 2010) should be applied to a wider range of past case-studies to improve calibration and determine the minimum number of criteria needed for successful specification of scour monitoring systems. While the cost of the initial deployment and operation of the monitoring system should be added to the framework a consideration of the cost of data-interpretation and processing should also be considered to supplement the ‘Ease of data interpretation’ criterion. This would allow for better consideration of the life-cycle costs of the specified monitoring system.

Predicting the usefulness of monitoring information for structural evaluations of bridges

N. Bertola & E. Brühwiler

Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland

ABSTRACT: With economic, environmental, and material resources becoming increasingly scarce, more sustainable solutions for the management of civil infrastructure are required. Accurately evaluating the structural capacity is primordial to avoid unnecessary replacement of existing bridges. The assessment of existing structures is currently made based on construction drawings, recorded information on the materials used, and visual inspection. The remaining uncertainties on the structural behavior are compensated by conservatism assumptions. Monitoring data collected through bridge load testing, structural performance monitoring, and non-destructive tests provide additional information on the structural behavior leading to decision regarding bridge safety and reducing considerably the costs and environmental impacts of management. Nonetheless, collecting this information is often costly as the sensor deployment and the data management are expensive. The monitoring costs may not always be justified by the benefits in terms of information gain. This paper proposes a methodology to evaluate the potential impact of monitoring activities on the evaluation of structural performance. A full-scale bridge in Switzerland is used to assess the usefulness of several monitoring techniques. Results show that the monitoring leads to more accurate evaluations of structural verifications, and each method provides complementary information.

1 INTRODUCTION

Civil structures are designed using conservative assumptions and simple design models. Existing structures have thus untapped reserve capacity, and monitoring the structural behavior can unlock this potential (Smith, 2016). A better knowledge of the behavior and properties of a complex structure through monitoring may be then leveraged to optimize structural rehabilitation, focus inspection, and extend service durations (Frangopol et al., 2008).

Monitoring of structural behavior can be separated into two activity subsets depending on the monitoring goal: the evaluation of the structural capacity at a given time, called structural performance monitoring (SPM) (Feng et al., 2004), and the evolution of the structural behavior over time, called structural health monitoring (SHM) (Farrar & Worden, 2010). These two uses of monitoring data have different implications for infrastructure management. SPM provides information for structural-capacity evaluations (Proverbio et al., 2018) and the structural behavior in its environment (i.e., traffic loading and environmental actions) (Sawicki & Brühwiler, 2022). SHM aims to detect current and future damage in structures (J. M. Brownjohn, 2007), improving their maintenance and safety assessments in the future (Orcesi & Frangopol, 2011). Despite the undeniable potential of structural monitoring, both SHM and SPM are still rarely put into practice by asset managers (Ye et al., 2022). Several reasons explain this reluctance: the lack of time, the lack of resources, and missing related courses in curricula (Große et al., 2019).

The assessment of existing structures is made based on construction drawings (if they are recorded), and visual inspection. The remaining missing information is compensated by conservative assumptions following new-design principles (Brühwiler et al., 2012). Several

methods have been proposed to assess existing-structure performance (Ghosn et al., 2016a; Ghosn et al., 2016b). In Switzerland, structural safety is evaluated based on the indicator of the degree of compliance n calculated using Equation (1). A value of n exceeding 1.0 means that structural safety is ensured and that there is reserve capacity (Swiss Society of Engineers and Architects, 2011). This generic metric has the advantage that it can be applied to any structural verification for ultimate limit states (ULS), fatigue limit states (FLS), and service limit states (SLS). Analytical or numerical models are required to compute structural capacity and load effects. Typically, several structural verifications are made for each limit state.

$$n = \text{Capacity} / \text{Demand} \quad (1)$$

SPM aims to update the evaluations of the degrees of compliance using field measurements. Several monitoring techniques are possible for this task, such as non-destructive tests (NDT) (Helal et al., 2015), bridge load testing using static and/or dynamic excitations (Brownjohn et al., 2011), and continuous monitoring to measure the real bridge condition (i.e., through a bridge weight in motion process) (Lydon et al., 2016). Evaluation of structural behavior based on monitoring data may require an inverse analysis (Pasquier & Smith, 2016). Sensor data do not directly support the structural-property evaluation, meaning that the data interpretation is complex (Catbas et al., 2013). Conventional residual-minimization approaches have provided unsafe parameter estimates and population-based methodologies (i.e., Bayesian model updating, error-domain model-falsification) are recommended (Pai & Smith, 2022).

The choice of the monitoring system significantly influences the success of SPM (Ercan & Papadimitriou, 2021). Studies have developed strategies to predict the information gain of monitoring systems, for instance, based on information entropy (Bertola et al., 2017; Papadimitriou, 2004). Recently, efforts have been made to quantify the value of information by comparing maintenance intervention with and without including expected information gain (Bertola et al., 2020; Kamariotis et al., 2022). Nonetheless, the first choice of engineers is to select the appropriate monitoring techniques rather than sensor configuration. This paper proposes a methodology to evaluate the usefulness of several monitoring systems in terms of their potential influence on the degrees-of-compliance evaluations.

2 METHODOLOGY

In this section, the methodology to predict the benefit of monitoring data on the evaluation of bridge structural capacity. This methodology is shown in Figure 1 and involves four main phases.

Figure 1. Methodology predicting the usefulness of monitoring techniques for structural-performance evaluation.

The first phase involves evaluating structural performance without monitoring information. After a visual inspection, the main structural characteristics (i.e., material properties) and load levels are estimated. These estimations are based on recorded information (such as structural drawings) and conservative bridge-parameter values on missing information.

Several structural verifications are made for serviceability, fatigue, and ultimate limit states. The results are expressed in terms of degrees of compliance (Equation 1). Typically, a finite-element model is built to improve the accuracy of structural verifications. At this stage, the first evaluation of bridge potential deficiencies is made, and potential uncertainties on the structural behavior are assessed.

The second stage involves defining the potential monitoring techniques that could be applied. Estimations of sensor types, the number of devices, and the duration of monitoring are made. Additionally, it must be evaluated which bridge parameters can be more precisely estimated using monitoring data from each technique.

The third stage involves assessing the usefulness of each monitoring technique independently and is performed using three steps. First, the prior distribution of each bridge parameter (i.e., material properties, boundary conditions, load levels) is estimated. Then, based on monitoring-technique accuracy, the expected identification range is defined. The identification range may sometimes be complex to estimate, especially when monitoring involves updating multiple parameters using inverse analysis. Nonetheless, studies on sensor placement have shown that it is possible to predict expected parameter ranges after monitoring (Bertola et al., 2017, 2020). As measurements are unpredictable, this step only involves defining possible ranges of parameter identification rather than a predicted value. For instance, bridge load testing will enable the identification of the bridge girder stiffness from which concrete elastic modulus with a precision range of 5 GPa, called the identification range. Let's assumed that the elastic modulus has an expected value defined between 20 and 50 GPa with a mean value of 35 GPa. Expected parameter values after monitoring are evaluated based on the most conservative value when centering the identification range on the mean value of the prior distribution. In the previous, the expected identification value is equal to $35 - 5/2 = 32.5 \text{ GPa}$. The third step is to reevaluate the degrees of compliance based on expected identification values for each monitoring technique. It may happen that the re-evaluations of the degrees of compliance may not vary if the parameter is not influencing the structural verification. In this example, the elastic modulus will have influence on the SLS verifications but no impacts on the ULS verifications. Each method may provide information on a subset of bridge parameters, and the expected influence on structural verification can vary significantly.

The last step is selecting the appropriate combination of monitoring techniques that maximize the information gain for all limit states. As each monitoring technique provides different information, the best technique will often differ between structural verifications of limit states. A combination of monitoring techniques is thus often recommended to maximize the information gain. Another strategy would be to pick only monitoring techniques that may significantly influence structural verifications with a degree of compliance smaller than 1.0.

3 CASE STUDY

3.1 *Bridge presentation*

In this section, the methodology proposed in Section 2 is implemented on a full-scale case study in Switzerland. This eight-span viaduct was built in 1959 is an eight-span viaduct (Figure 2) and is one of the first steel-concrete composite bridges built in Switzerland. The superstructure involves a reinforced concrete (RC) slab fixed to two steel box girders. The spans vary between 12 and 25.6 m, and the bridge width is 12.7 m. The RC slab has a varying thickness between 0.17 and 0.24 m, while the two steel girders have a constant height of 1.30 m. The structure was subject to an intervention in 2002, where longitudinal stiffeners on the steel girders and bolts at the Gerber joints between the spans were added.

3.2 *Monitoring systems*

This bridge was monitored between 2016 and 2019. Strain gauges and thermocouples were installed to monitor traffic effects and temperature variations directly on rebars in both longitudinal and transverse directions with potential fatigue issues (see Section 3.3). These sensors were also used for bridge weight-in-motion and calibrated using load tests. Several static load tests were performed on the fourth span in 2016. The sensor network during these tests involved five LVDTs at mid-span, and five strain gauges both in the transverse and longitudinal directions near midspan were mounted (Bayane et al., 2021). Two non-destructive tests were performed: rebound hammer and sound-velocity measurements on the RC slab on the same span.

Figure 2. Composite steel-concrete bridge case study in Switzerland and the finite-element model.

3.3 Prior evaluation of bridge capacity

The bridge performance before monitoring was assessed following the rules given in Swiss standards for existing structures (Brühwiler et al., 2012), using construction and intervention drawings, and visual inspections. A numerical model was built using SCIA software, and the model involves 1D and 2D elements. The entire bridge is modeled (including bridge piers) to improve the accuracy of the predictions at the monitored span (Figure 2). The bridge deck geometry has been modeled accurately, especially the complex shape of the RC slab. The size of the finite elements is set to 400 mm, except for the monitored span, where it is reduced to 100 mm to improve the quality of the predictions.

Several structural verifications have been made: 13 for ULS, 10 for FLS, and 2 for SLS. Of these 25 structural verifications, only two have degrees of compliance smaller than 1.0, and both involve FLS on longitudinal and transverse rebars in the RC deck (Figure 4).

3.4 Expected information gain

3.4.1 Step 1 – Prior distribution and potential information gain

In this section, the usefulness of information gain is made. First, the main bridge parameters that can be identified using the three monitoring techniques (bridge load testing, B-WIM, and continuous monitoring) are defined. These parameters involved: the deck stiffness (approximated as the elastic modulus of concrete), the rotational stiffness at the Gerber joints, the daily maximum stress differences in rebars due to traffic loading, the ULS load level (in terms of maximum axle force), and the concrete compressive strength. The prior distribution of each distribution is shown in Figure 3. Value ranges and distributions of these parameters are selected based on engineering judgment.

Figure 2 also qualitatively presents the potential information gain of each monitoring technique on these parameters. Rebound hammer and sound-velocity measurements provide information on the uncracked elastic modulus and compressive strength of concrete. Static load testing helps update concrete elastic moduli and the rotational stiffness at boundary conditions, but these estimates may not be precise enough to provide reliable safety verifications. The continuous monitoring provides accurate estimations of maximum stress differences necessary for fatigue safety verification, while B-WIM helps to define more accurate load models for ULS. These monitoring techniques thus provide complementary information.

3.4.2 Step 2 – precision of monitoring output

The second step involves estimating the precision of monitoring outputs. For each parameter that can be updated by a monitoring technique, an identification range is estimated (Table 1). For NDTs, these identification ranges mostly depend on the sensor precision and the number of tests performed. The continuous monitoring and B-WIM have precisely measured the traffic on the bridge for three years. Nonetheless, these techniques require estimating tails of distributions to

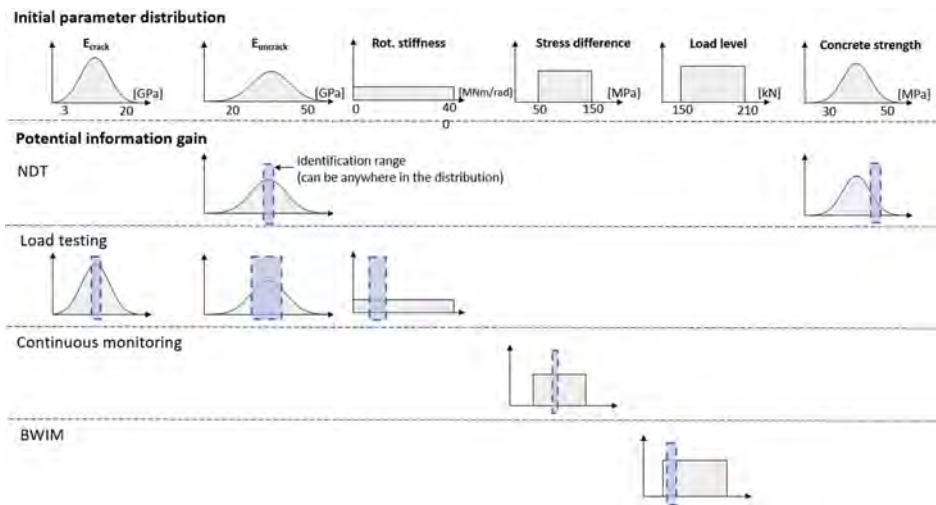

Figure 3. Prior bridge-parameter distributions and potential information gain of each monitoring technique on these parameter distributions.

Figure 4. Degrees of compliance prior to and after monitoring for each structural verification.

define accurate evaluations of maximal stress differences and axle load levels which may have some extrapolation errors. Bridge load testing provides simultaneous information on three bridge parameters based on an inverse analysis. The precision of identification ranges is determined using the hierarchical algorithm based on the sensor configuration and performed load test. More information on this information gain can be found in (Bertola et al., 2022).

3.4.3 Step 3 – Influence on degrees of compliance

Based on the results in Steps 2 and 3, the expected values used for structural verification after monitoring are obtained. These values are calculated as the mean value in the prior distribution (Figure 1) minus half of the precision range (Table 1), and the results are shown in Table 2. Each monitoring technique helps increase a subset of bridge parameter values.

For each monitoring technique, the influence of expected monitoring outputs on the degrees of compliance is evaluated (Table 3). Except for the NDT (only updating and E_{ncr}), all monitoring techniques provide useful information for the bridge structural verifications. Nonetheless, only load testing provides useful information for SLS verifications, while FLS verifications are mostly influenced by continuous monitoring and ULS verifications by the BWIM data. When all techniques are combined, an average increase of degrees of compliance of 19 % over the 25 structural verifications is obtained, showing that monitoring can provide

Table 1. Estimates of value-range identification for each parameter and each monitoring technique.

Bridge parameter	Precision of identification range of monitoring technique			
	NDT	Load testing	Cont. Monitoring	B-WIM
Cracked RC section E_{cr} [GPa]	-	6	-	-
Uncracked RC section E_{ncr} [GPa]	5	15	-	-
Rot. Stiffness [MNm/rad]	-	100	-	-
Stress difference [MPa]	-	-	2	-
Load level [kN]	-	-	-	5
Concrete strength [MPa]	2	-	-	-

Table 2. Expected parameter values obtained after monitoring.

Bridge parameter	Mean expected values after monitoring			
	NDT	Load testing	Cont. Monitoring	BWIM
Cracked RC section E_{crack} [GPa]	6	10	6	6
Uncracked RC section E_{ncr} [GPa]	30	28	20	20
Rot. Stiffness [MNm/rad]	0	100	0	0
Stress difference in steel rebar [MPa]	150	150	73	150
Maximum axle load [kN]	210	210	180	210
Concrete compressive strength [MPa]	38	30	30	30

significant information for bridge performance evaluation. Nonetheless, in a value of information perspective (only measuring when it can change the safety assessment of the bridge), only the continuous monitoring is justified.

Table 3. Expected influence of monitoring information on structural-verification degrees of compliance.

Structural verification	Mean degrees of compliance before monitoring	Expected mean degrees of compliance after monitoring				
		NDT	Load testing	Cont. Monitoring	BWIM	Combined
SLS	2.84	2.91 (+3%)	3.23 (+14%)	2.84 (+0%)	2.84 (+0%)	3.23 (+14%)
FLS	1.45	1.45 (+0%)	1.45 (+0%)	1.76 (+21%)	1.45 (+0%)	1.76 (+21%)
ULS	1.82	1.88 (+2%)	1.82 (+0%)	1.82 (+0%)	2.12 (17%)	2.1 (+18%)
Combined	1.75	1.79 (+2%)	1.79 (+2%)	1.88 (+7%)	1.91 (+9%)	2.08 (+19%)

3.5 Result validation

In this Section, predictions in terms of monitoring usefulness are compared to observed information gain based on field measurements. Details of the data interpretation and evaluations of degrees of compliance after monitoring can be found in (Bertola et al., 2022).

In the previous section, it was concluded that each monitoring technique (except NDT) provides useful information, and their combination should improve degrees of compliance by a mean average of 19 %. The results of the information gain after monitoring are shown in Figure 4. On average, the monitoring data increases degrees of compliance by 36 %. As predictions were evaluated as mean values, both prediction and observed results can be evaluated as similar.

It is also worth looking at information-gain predictions in terms of the performance of each monitoring technique individually. For SLS verifications, it was predicted that the most useful technique is static load testing, and this result is validated by field measurement. The prediction for ULS verifications showed that only the B-WIM could provide significant information, and this result is also validated by field measurements. Continuous monitoring is the

most useful monitoring technique for FLS verifications, and this prediction is verified using monitoring data. These results confirm that the proposed methodology can provide accurate estimations of the usefulness of monitoring techniques.

Thanks to monitoring data, the bridge safety is now verified as FLS verifications that had a degree of compliance smaller than one has updated values larger than 1.0. This result confirms that structural performance monitoring can lead to untap reserve capacity of bridges.

4 CONCLUSIONS

In this study, a methodology is provided to estimate the usefulness of serval monitoring techniques for bridge performance evaluations. This methodology supports engineers and bridge owners by selecting the optimal combination of monitoring techniques to maximize the information gain in terms of increasing the metric for structural-safety assessments. A bridge case study in Switzerland, where four monitoring techniques were performed, showed that most monitoring techniques provide useful and unique information. Additionally, the predictions in terms of expected information gain for each technique and their combinations are in agreement with results based on monitoring data. In the next step, this methodology will be extended for a comprehensive value-of-information framework to select the optimal combination of monitoring techniques.

ABSTRACT: For the appropriate decision-making on maintenance and safety of existing infrastructure, obtaining accurate monitoring information is of crucial importance. Both at a European and national level, current standards and monitoring practice lack standardized approaches to monitoring and this could be partially attributed to the high diversity of the transport infrastructure assets and their environments that increases the complexity of this matter. The new *fib* Model Code 2020 (MC2020) paves the way to new European standards for monitoring and maintenance of structures. Furthermore, MC2020 aims to improve the rules in the structural design codes by bridging the gaps in the current knowledge in theory and practice regarding the monitoring of structures. The main objectives of MC2020 should facilitate and support the various standardization bodies to prepare new standards in monitoring, maintenance, and safety of transport infrastructure. In addition to MC2020, the EU Horizon 2020 IM-SAFE project suggests a respective methodology that tries to be in line with classical engineering procedures, presented in the form of a flow chart. Based on these multi-level condition assessment processes, which are briefly presented in the current paper, an Austrian bridge is used as a case study. The Seitenhafenbridge in Vienna has been monitored over the past 10 years and the acquired data with respect to the condition assessment of the bridge are used for the implementation of the IM-SAFE flow chart aiming to increase the service life for the structure.

1 INTRODUCTION

In the last decades, codes and standards focused mainly on the documentation of guidelines and recommendations for the design of new structures, aiming to ensure the safety and serviceability. At the same time, another goal was to provide the designers with a set of recommendations that are simple, transparent and that avoid potential critical errors. The relative simplicity of those rules includes some conservatism. For new structures this has hardly any influence on the cost, whereas, conversely, this conservatism may turn out to be favourable in the future, if new unforeseen conditions develop, different to the initial design assumptions and criteria adopted.

More recently, as the existing road and railway infrastructure in Europe and worldwide has aged significantly, many existing structures, after having functioned satisfactorily for decades, no longer meet the demands placed upon them for structural safety. Partially, this can be due to a change in the loads which may be larger than envisaged in the stage of design, like the traffic loads on many bridges. Another reason can be that the structures have experienced deterioration, leading to a reduction of the bearing capacity as a result of diminished mechanical properties, and loss of cross-sectional area of concrete and steel. Furthermore, it is possible that it turns out that structures have been designed on basis of design rules from the past, which are actually not accepted anymore.

Therefore, there is an urgent need to provide the engineering community with standards on monitoring and maintenance of existing structures, in an effort to address the question of how the condition of an existing structure can be assessed and how potential deteriorations affect its remaining service.

At this moment *fib* TG 10.1 works to develop a new *fib* Model Code for Concrete Structures (*fib* MC2020, 2023), which should integrate rules for both the design of new and the assessment of existing structures. The behaviour of existing structures is, therefore, an important new component to be considered. This contribution is developed as a part of a collaboration between *fib* TG 10.1 and *fib* Commission 3 “Existing Structures” that consists of several Task Groups. Particularly TG 3.3: Existing Concrete Structures: Life Management, Testing and Structural Health Monitoring has produced a state-of-the-art Bulletin (under publication) that serves an accompanying document to the MC2020 and summarises available scientific information on the subject (*fib* TG 3.3 Bulletin, 2023).

Furthermore, the ongoing European Horizon 2020 project IM-SAFE (<https://im-safe-project.eu/>) also deals with the same thematic and has managed to gather valuable number of case studies and monitoring data information that will serve a new and harmonized European standard for monitoring, maintenance and safety of transport infrastructure in a standardized digitalization approach. The aim of this contribution is to briefly mention the performance condition assessment methods proposed by *fib* (and are also in line with IM-SAFE), including monitoring and data informed approaches and to present a case study of an existing bridge in Vienna, Austria, which was equipped with a certain monitoring setup right after its erecting, where this specific multi-level performance assessment finds application up to date, helping the continuous assessment of the present and future behaviour of this structure.

2 PERFORMANCE ASSESSMENT OF EXISTING STRUCTURES

2.1 *Data informed approaches for the assessment*

Based on practical experience, the performance assessment of a structure is reasonable to break down into a minimum of three levels to support the decision-making process with regards to performance assessment and maintenance optimization. These levels are: Level I - Visual Inspections, Level II - Detailed Inspections, Testing and Monitoring and Level III – Structural Health Monitoring (SHM) & Modelling.

This multi-level performance assessment approach has been reflected in the decision-making flow developed as part of the IM-SAFE Project objectives, a framework of the data-informed safety assessment (H2020 CSA IM-SAFE, 2022a and 2022b) highly interrelated with the life-cycle management of the transport infrastructure. The proposed flow describes the different stages of the assessment of new and existing structures, focusing on various levels (network, system and component) and taking into account the available data during the lifespan and maintenance process of the structure. The same proposed flow is also adopted and can be found in the (*fib* MC2020, 2023) and (*fib* TG 3.3 Bulletin, 2023).

Very briefly, the purpose of Level I is to remove existing doubts about the performance using simple methods, which must, however, be adequate. The preliminary evaluation consists of an approximate assessment based on inspection, an accompanying study of the available documents, and a simplified check on structural safety. An added value can be achieved by using drone-based inspections with AI controlled cameras (Bergmeister et al., 2022). In this first level, it makes sense to distinguish between key performance indicators, which allow an initial assessment, and performance indicators for detailed inspection and to define performance targets and performance thresholds. The performance evaluation based on detection of visible anomalies can either lead to Key Performance Requirements (KPR) level or, in case of an insufficient condition, to a Level II evaluation.

Structural investigations and updating of information are typical of Level II – it comprises detailed inspection, testing and monitoring, among other activities. The additional information gained e.g., from the performance indicators of these investigations can be introduced into confirmatory calculations with the aim of finally dispelling or confirming any doubts as to whether the structure is safe. A detailed inspection of the structure or structural part in question is

extremely important, especially the recognition of typical hazard scenarios that could endanger the structure's residual service life. Further any defects and damage process due to excessive loading or some fragility of important structural members must be detected e.g., by using the visual inspection associated observations and/or performance indicators. As in the first level, it is recommended to distinguish between key performance indicators, which allow an assessment based on a minimum of detailed inspection, testing or monitoring related observations, and performance indicators associated with detailed testing and monitoring. The results of Level II must be summarised in a report. In particular, the report must give information on the structural safety based on the performance indicator findings of Levels I and II and must contain the information about the Performance Requirement Indexes (PRIs) for e.g., network assessment purposes as in Level I.

For important structural members or important structures and for problems with substantial consequences, an advanced analysis (including material and geometry nonlinearity) for performance assessment and performance prediction should be planned to check carefully the proposal for the pending decision that results from Level I and II evaluations. This advanced analysis that includes SHM and FE Modelling with the data acquired by the first ideally updating the second, constitute Level III of the performance assessment methodology.

2.2 *Data informed associated performance indicators*

A particular challenge is the utilisation of measurement data and its use in the performance assessment processes. This topic is already partly addressed in MC2020 (*fib* MC2020, 2023), also to a greater extent in the associated background Bulletin documents (*fib* TG 3.3 Bulletin, 2023) and in further literature sources (Strauss et al. 2017; Strauss et al. 2021). However, some differentiation is also required, associated with informed performance indicators, as will be shown below. A performance indicator can be considered as a measurable/testable parameter that quantitatively describes a property of a structure. The multi-level methodology presented above mainly involves the concept of gathering information through observations/inspection/monitoring that leads to the potential identification of e.g., a degradation mechanism affecting structure. These observations or damage indicators (DIs) can be further defined as performance indicators (PIs), that can interact with one or all levels of bridge management, which are: a) the network, b) the system and the component.

2.2.1 *Performance indicators at the network level*

At the network level, based on bridge condition assessment gained through standard inspection and evaluation procedures with additional evaluation of bridge importance in the network, the primary goal to be reached is supporting the maintenance management and asset management decision process. Priority repair ranking is an example of the essential indicator for the final goal: optimal management plan of road-/railway bridges, which is to be evaluated through decision ranking by power and weakness of decisions. While the bridge structural performance assessment is based on four criteria: structural safety, serviceability, durability and robustness related to the (general) condition of the structure, the bridge importance in the network is based on five criteria: road or corridor category, annual average daily traffic, detour distance, largest span and total length. Such criteria are usually reduced to comparable values with the help of preference functions and with the help of an adequate thresholds of indifference and preference for each criterion. Indicators for the key performance requirements are determined at this level.

2.2.2 *Performance indicators at the system level*

A qualitative assessment can show how the collapse of a particular element would affect the individual Structural Performance Requirements. Structural performance assessment at the system level will require an adequate knowledge level on particular PIs and DIs with related properties, such as stiffness changes and traffic load characteristics, which may require investment in additional inspection, testing or monitoring methods, advanced modelling techniques and updating data on resistance and loads. Besides technical indicators, at this level sustainability and socio-economic indicators will be an essential component of the set of the performance requirements. Additionally, indicators related to scientific achievements in, for example, testing and monitoring, dynamic behaviour and reliability of structures, should be elaborated at this level, as well.

2.2.3 Performance indicators at the component level

Inspections of structures are generally carried out at the level of components. For bridges, three main subsystems can be distinguished: substructure, superstructure and road-/railway, with specific bridge components associated with these systems, including constitutive materials. For tunnel systems, a similar decomposition is possible, distinguishing e.g., ridge, callous, abutment and base area, or inner shell, outer shell and sealing level. At the component level, one of the important goals to be reached (or task to be performed) is the damage assessment. This implies the detection of damages but also the identification and evaluation of damage within the set thresholds. The categorization of damage as a primary performance indicator at the component level, requires considering related detection methods, performance thresholds and evaluation methods. PIs, DIs, damage processes, surveying technologies and performance assessment levels can be correlated.

3 THE CASE STUDY OF THE SEITENHAFENBRIDGE IN VIENNA, AUSTRIA

In the framework of the performance condition assessment presented in section 2, the Seitenhafen-bridge is used as a case study to partially apply this methodology, highlighting the three levels of assessment for a newly constructed structure. The bridge, shown in Figure 1(a), is part of a new road connection in the city of Vienna, crossing the Danube Channel. It is a concrete/steel composite bridge, constructed in 2011, and it was designed for road, pedestrian and bicycle traffic. The total length of the bridge is 128,69 m, divided in 5 fields, and a width of 15 m. The road deck is a solid reinforced concrete structure, and its support was realized through steel columns, arranged in pairs

Figure 1. The Seitenhafenbridge crossing the Danube Channel in Vienna, Austria. (a) General overview and (b) Longitudinal section (Geier et al., 2009).

next to the bearings. The abutments are not aligned at right angles with the road axis, as it can be seen in the longitudinal section of Figure 1(b) (Geier et al., 2009).

The Seitenhafenbridge in Vienna is currently the longest integral bridge in Austria and due to its significance, the infrastructure manager requested and installed a complex system for the monitoring of the movements of the construction. This step leads to a more detailed inspection level (Level II) and the infrastructure manager along with the consulting company defined performance and key indicators and their thresholds that go hand in hand with the monitoring setup.

The monitoring set up is shown in Figure 2 and it was designed to serve the particularities of this integral bridge, constantly measuring temperature and the movements of the construction, like for example deflection, inclination, length variation and ground pressure at the abutment. The data are continuously assessed and summed up in intermediary reports showing the actual behaviour of the structure.

Figure 2. Monitoring setup at the Seitenhafenbridge crossing the Danube Chanel in Vienna, Austria (Geier et al., 2009).

In parallel to the application of the monitoring system, a detailed finite element (FE) model of the structure was created, going into level II of the performance assessment process. After monitoring the structure for a significant period of time, important information on its behaviour in terms of temperature, deformations and overall movement of the structure could be extracted. The monitoring data was used to update the FE model and verify the performance of the critical details of the structure. In Figure 3, within a period of 3 years (12.2011 to 12.2014), the variation of the measured vertical deformations (Figure 3(a)) and temperature (Figure 3(b)) is documented. It can be noticed that at the middle of the structure a maximal vertical deformation of $\sim +30\text{mm}$ was measured during the summertime, while during the winter months a vertical deformation of $\sim -10\text{mm}$ was documented.

In the following Figure 4, the generic framework and process flow for risk management proposed by the IM-SAFE project is applied step by step for the Seitenhafenbridge, highlighting the 8 most important points for this particular structure. In this flowchart, one can also see on the left side of each step which levels in terms of bridge management (e.g., component, system, network) should be considered for the PI definition. The exact elaboration of the process steps is described in detail in the (H2020 CSA IM-SAFE. 2022a) and (H2020 CSA IM-SAFE. 2022a).

In more detail, for the Seitenhafenbridge the following main points of the risk management flow are listed below, showing the flow indicated by the blue arrows in Figure 4:

1. Classification and Prioritization: This new bridge is currently the longest integral bridge in Austria. Due to the total length of approx. 130 meters, an in-depth performance analysis and risk assessment was requested, classifying this structure as medium to high priority structure.

2. Detailed investigation (Yes/No): In this context, the monitoring of the movements of the structure was required.
3. Condition survey at level II: Performance and key indicators and their thresholds were defined in order to reach condition survey level II.
4. Level II Performance monitoring: The monitoring system continuously measures temperatures and movements of the structure, such as deflection, inclination, length change, and soil pressure at the abutment.
5. Detailed structural assessment: A detailed digital twin model was developed using the monitoring data to verify the performance of the critical details, reaching condition survey level III.
6. Condition survey at level II: The digital twin models were updated, and the functionality of the critical details was verified.
7. Level III Performance monitoring: Thresholds were set for the monitored performance indicators using the digital twin models.
8. Alert level assessment: An alarm system was set up in combination with the monitoring system and the client.
9. Continuous monitoring and diagnostics are active since 2011, on all the 5 spans of the bridge, with a real-time alerting system active to support proactive maintenance intervention figure.

Figure 3. Measured data within a period of 3 years for (a) vertical deformations at the location of sensors S1 to S6 and (b) temperatures at the location of sensors T1 and T2 (Geier et al., 2009).

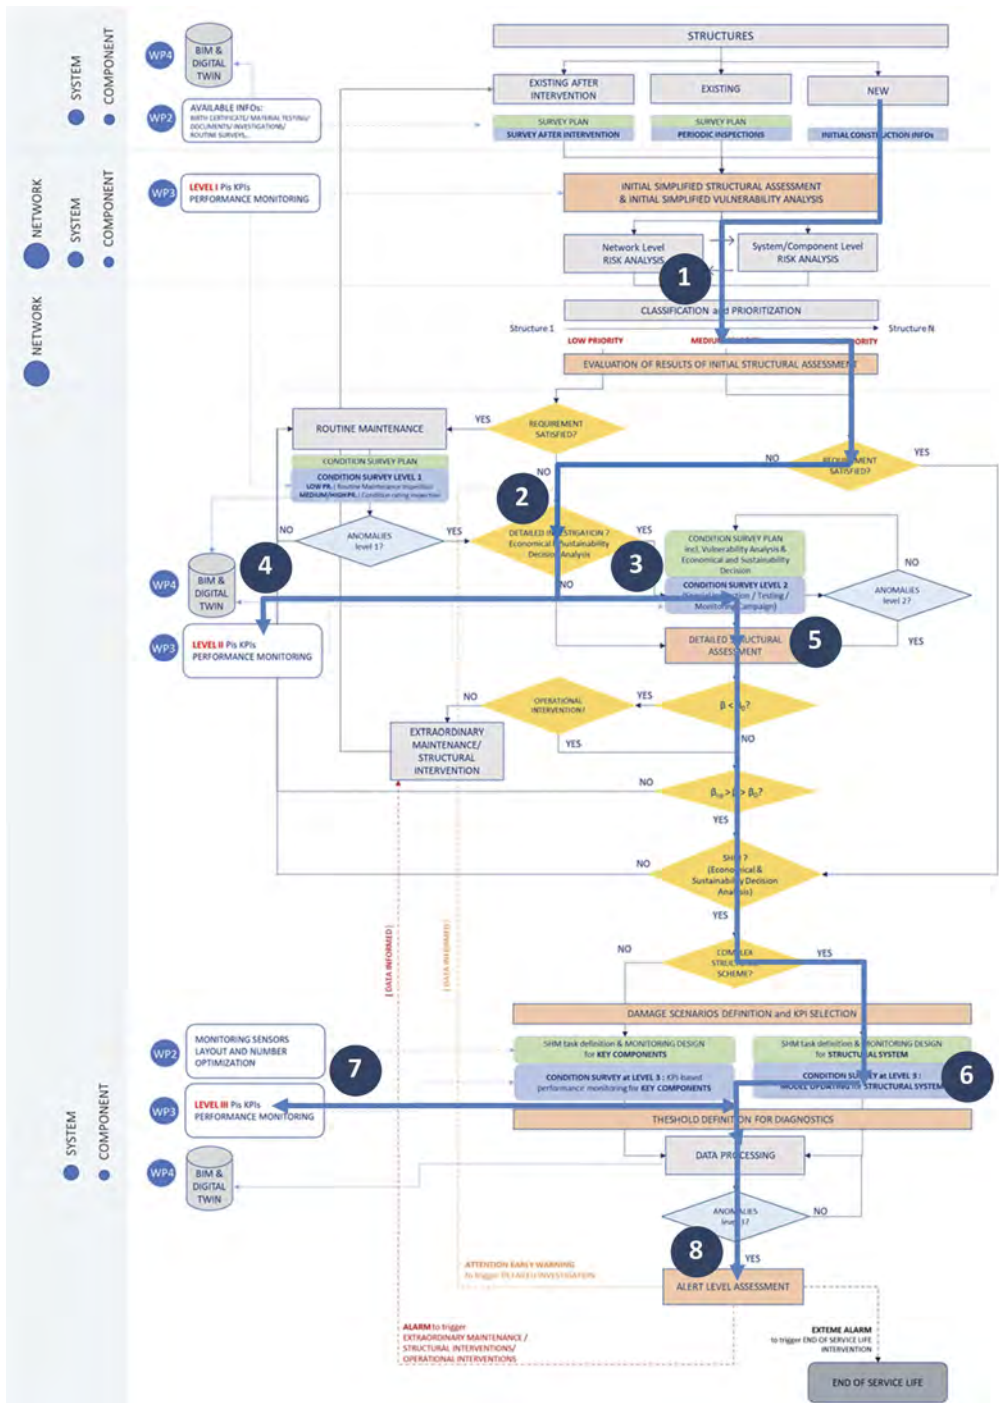

Figure 4. Generic framework and process flow for risk management, from IM-SAFE project report D3.1, particularly adjusted for the Seitenhafenbrücke in Vienna, Austria (H2020 CSA IM-SAFE. 2022a).

4 CONCLUSIONS

In the current paper, a brief overview of the framework for the data-informed safety assessment and its high interrelation with the through-life management of the transport infrastructure is presented. The relevant performance assessment methodologies developed by the *fib* MC 2020 and the IM-SAFE project are briefly presented. Through the application in a specific bridge structure, the Seitenhafenbridge in Vienna, of the generic framework and process flow for risk management adopted by the IM-SAFE project, an assessment process more in line with the classical engineering procedure is verified. This framework assists the more organized and systematic assessment of the structure throughout its lifetime, enabling a better understanding and communication of its condition not only to the owners and the involved engineers, but also to other related disciplines. Furthermore, it assists the systematic definition of PIs based on the different levels of assessment targeting a longer service life of infrastructure.

ABSTRACT: The fundamental purpose of structural health monitoring (SHM) is to examine the accuracy of the structural health state and predict its future strength. Lately, researchers have been paying close attention to the structural damage detection process employing inclinometers. However, this technique can only be used with unique structures with a sizable Structural Health Monitoring (SHM) budget due to the high cost of inclinometers. Therefore, the use of low-cost sensors by implementing various techniques to improve their accuracy compared to high-cost precision sensors has attracted much attention for structural assessment. This paper introduces a novel, low-cost inclinometer that measures inclination by fusion technology combining gyroscopes and accelerometers. The microcontroller technology used in this gadget is an open-source Internet of Things (IoT) based platform, allowing for wireless data streaming and free commercial software for data collecting. Not only are the coding and placement issues of these sensors thoroughly explained, but detailed answers to the problems mentioned above are also provided, as well as an efficient way to assemble and prepare the sensors.

1 INTRODUCTION

Structural Health Monitoring (SHM) has attracted the attention of engineers over the past decades as a control system to measure the structural response of structural elements to prevent future potential failures in civil infrastructures. A number of factors and situations such as construction defects, fatigue and environmental factors might decrease the structure's serviceability and safety over time (Kaloop et al., 2022), (Mahyad Komary et al., 2022), (Seyedmilad Komarizadehasl et al., 2022). Therefore, monitoring and assessing structures' health state throughout their life cycle are essential to minimize the future reparation costs and to confirm the Structural safety and serviceability (Proske, 2020), (Farré-Checa et al., 2022). SHM applications provide vital information about the actual structural response of infrastructures, the condition of the structures and their performance (Mahyad Komary et al., 2023).

For measuring static and dynamic responses, sensors are widely used in SHM systems (S. Komarizadehasl et al., 2022). Accelerometers are commonly used for monitoring the dynamic response of the structures, while the most common sensors for static measurements include strain gauges, inclinometers and thermometers (Lei et al., 2021), (M. Komary et al., 2022).

Even though accelerometers can detect global structural damages to a structure, they traditionally fail to detect the damage location and its severity (Hester et al., 2019). Displacement

sensors such as Laser Displacement Sensors (LDS) can be used in load tests to help to locate the damage and its extension as long as a particular reference point exists (Raghuwanshi & Parey, 2018), (Yao et al., 2022). Unfortunately, a number of limitations on-site can make the proper definition of the required reference points difficult (Park et al., 2013). Alternative strain-type sensors can be used to evaluate the extent of the damage and its location. In fact, this type of sensor has shown remarkable accuracy and applicability in the literature (Li et al., 2020), (Iriarte et al., 2021), (Copertaro, 2022). However, a large number of this type of sensor might be needed to monitor the structure's structural properties entirely.

In order to overcome the drawback of the aforementioned sensors, inclinometers can be used. Angular sensors (inclinometers, tilt sensors) are manufactured to estimate the angular rotation of a target object respected to an artificial horizon (Hester et al., 2019), (Seyedmilad Komarizadehasl et al., 2022). Most inclinometers follow the principle of measuring responses induced by pendulum behaviour due to gravity (Huseynov et al., 2020). Furthermore, this slope can be used to calculate the drift of vertical members and vertical deflection of the horizontal elements (Ha et al., 2013).

Table 1 illustrates the characteristics of some of the commercially available inclinometers and is sorted by the price of the sensors. It should be noted that prices are based on the recent producer declaration and are VAT excluded.

Table 1. Characteristics of some of the commercially available inclinometers.

Model	Sampling Rate (Hz)	Resolution (Degrees)	Measurement Range (Degrees)	Price (€)
ZEROTR ONIC	10	$100 \times 10^{-5} \text{ }^\circ$	$\pm 0.5^\circ$	3950
ACA2200	20	$10 \times 10^{-5} \text{ }^\circ$	$\pm 0.5^\circ$	710
HI-INC	100	$100 \times 10^{-5} \text{ }^\circ$	$\pm 15.0^\circ$	650
ZCT-CX09	8	$100 \times 10^{-5} \text{ }^\circ$	$\pm 15.0^\circ$	350
DNS	100	$300 \times 10^{-5} \text{ }^\circ$	$\pm 85.0^\circ$	348

Analysis of Table 1 shows a wide range of prices (varying between 350€ up to 3950 €) and measurement ranges (varying between 0.5 and 85.0 degrees). It can be seen that inclinometers with a lower range have a higher resolution and price. Furthermore, inclinometers with higher resolution typically have higher costs and lower sampling frequencies.

On the contrary to the benefits of using inclinometers (Hester et al., 2019), this monitoring system presents limited precedents in the literature of SHM of bridges (Erdenebat et al., 2018), (Alten et al., 2017). Among the reasons given by Huseynov (Huseynov et al., 2020) to explain the lack of the use of the inclinometers is to highlight the lack of sensor technology, low-frequency sampling, and the cost of the current inclinometers.

To solve the aforementioned drawback of inclinometers, low-cost sensors can be used. In fact, Micro-Electro-Mechanical Systems (MEMS) accelerometers have revolutionized the measuring applications with reduced size and price (Seyedmilad Komarizadehasl, Lozano Galant, et al., 2022a). It should be noted that other low-cost MEMS accelerometers were already published for SHM applications in the literature.

MEMS sensors are typically coupled with gyroscopes. MEMS Gyroscopes measure the angular rate by Coriolis acceleration, enabling the rotational speed measurement. The main drawback of the gyroscopes is bias instability or Flicker noise (Hiller et al., 2019).

Almost all current MEMS inclinometers use sensor fusion capability to improve the individual drawbacks of the accelerometer and the gyroscope. In addition, the negative impacts of a sudden movement of the accelerometer estimations are controlled with the gyroscope measurements (Ghasemi-Moghadam & Homaeinezhad, 2018).

The literature review shows no accurate, low-cost inclinometers based on the Arduino or NodeMCU technology that could be used in SHM of bridges due to the special peculiarities of this type of monitoring (Huseynov et al., 2020). To fill these gaps, this paper presents, for the first time in the literature, a Low-cost Adaptable Reliable Angle-meter (LARA) system for SHM of bridges. LARA is a low-cost wireless inclinometer based on an IoT-based microcontroller (NodeMCU) technology with an accuracy of 0.003 degrees based on the performed experiments of this paper.

LARA is based on MEMS technology and uses the complementary filter to couple the outputs of its accelerometer and gyroscope calculated angles.

In addition, to build an inclinometer with higher accuracy, better resolution and lower noise density, this paper develops a custom-designed Printed Circuit Board (PCB) containing five low-cost aligned MEMS MPU9250 chipsets, each of one incorporating a gyroscope, an accelerometer and a magnetometer (Seyedmilad Komarizadehasl, Lozano Galant, et al., 2022b).

2 THE PROPOSED INCLINOMETER

2.1 Low-cost Adaptable Reliable Angle-meter (LARA) system

2.1.1 Hardware architecture of LARA

This paper proposes multiple combinations of gyroscopes and accelerometers for producing a more accurate inclinometer. To this end, five chipsets of MPU9250 are engineered together on a single PCB and synchronized using a multiplexor (TCA9548A). To avoid the problems of a manual fabrication (such as nonalignment of the circuits, time-consuming process of aligning, soldering and sensor quality control and size), the PCB of LARA was designed and produced to satisfy the delicacy of current project measurements. In addition, the required components of LARA are soldered to the PCB using machine assembly. The cost of a LARA made by connecting five MPU9250 and TCA9548A and a bulk company-produced PCB with assembled components is around 37 and 51 €, respectively.

As shown in Figure 1.a, LARA has four output ports. These wires should be connected to a microcontroller to power up the sensors, acquire the sampled data, and convert the gyroscope and the accelerometer to tilt and pitch inclination. The used microcontroller of this paper is NodeMCU and shown in Figure 1.b. This low-cost open-source Internet of Things (IoT) platform runs on the ESP8266 chipset. ESP8266 is a low-cost WiFi microchip with the Internet protocol suite (also known as TCP/IP) capability (Chiesa et al. 2020).

Figure 1. Illustration of LARA: (a) The produced product, and (b) NODE MCU microcontroller.

2.1.2 Software architecture of LARA

In this section, the used software for this project is presented in the following:

Arduino platform: NodeMCU is first programmed using the Arduino platform. This program first estimates the angle in real-time from each of the individual MPU9250 chipsets. Then, the formulas for calculating the rotation using a triaxial accelerometer for X and Y axes are presented in Eq.1 and Eq.2, respectively.

$$\text{angle}_{accX} = \tan^{-1} \left(\frac{\text{acc}Y}{\sqrt{\text{acc}Z^2 + \text{acc}X^2}} \right) \times \left(\frac{360}{2\pi} \right) \quad (1)$$

$$\text{angle}accY = \tan^{-1}\left(\frac{accX}{\sqrt{accZ^2 + accY^2}}\right) \times \left(\frac{360}{2\pi}\right) \quad (2)$$

In Eq.1 and Eq.2, where, $\text{angle}accX$ and $\text{angle}accY$ are the calculated angles from the acquired data of a MPU9250 accelerometer around the X-axis and Y-axis, respectively. The $accX$, $accY$ and $accZ$ represent the obtained acceleration data of X, Y and Z axes. Eq.3 and Eq.4 present the used complementary equation for the fusion of the gyroscope and the accelerometer results for measuring the rotation around X and Y axes, respectively.

$$\text{angle}X = (0.96 \times (\text{angle}X_0 + \text{gyro}X \times \text{time})) + 0.04 \times \text{angle}accX \quad (3)$$

$$\text{angle}Y = (0.96 \times (\text{angle}Y_0 + \text{gyro}Y \times \text{time})) + 0.04 \times \text{angle}accY \quad (4)$$

In Eq.3 and Eq.4, where, $\text{angle}X$ and $\text{angle}Y$ are the final calculated rotations around X and Y-axes, respectively. The $\text{angle}X_0$ and $\text{angle}Y_0$ are the estimated angle of the system from the previous measurement. The $GyroX$ and $GyroY$ represent the measured angular speed of the gyroscope for X and Y axes, respectively. The time presents the interval time between two measurements. Further analysis of these equations shows that the angle calculated from the accelerometer is multiplied by a smaller coefficient than that of the gyroscope (Yi et al., 2018). This low coefficient factor of $\text{angle}acc$ is for mitigating the impact of environmental vibrations (also known as cross-talk of vibration) and can vary between 0.02 and 0.05 (Shen et al., 2012).

Data acquisition: Unlike the Arduino platform, free commercial software like SerialPlot can represent the sampled data in real-time in a graphical interface and save the data with the date and timestamp of data acquisition.

3 STATISTICAL REPRESENTATION OF COMBINING DYNAMIC-SENSOR THEORY

3.1 Noise reduction of Inclinometers

It was noticed that the average value of outputs of several aligned synchronized inclinometers has lower noise density than the those of a single one. The standard deviation of up to five combined inclinometers is presented in Figure 2.

The analysis of Figure 2 shows that the higher the number of sensors considered the lower the noise density of their averaged measurements that the more combined inclinometers have a lower noise density. The reason behind the beneficial behaviour of combined inclinometers is within the inherent dynamic noises of the produced accelerometers and gyroscopes chipsets.

These results led to investigating the beneficial impact of dynamic sensor combinations. Analysing the individual outputs, the five used MPU9250 sensors showed that every single sensor has unique dynamic noises.

By improving the noise density, the inclinations that in the first place were smaller than the noise density of the sensor can now be detected due to the improved noise level.

Figure 2. Representation of the noise ratio of a single and up to five combined inclinometers using standard deviation.

4 LABORATORY EXPERIMENTS

4.1 LARA resolution and accuracy verification using a beam model

In order to present the resolution and accuracy of LARA more clearly, a load test is performed on a small-scale beam with a length of 1.24m. This section compares the slope estimation of two sensors (LARA and HI-INC) located on the support of a simply supported aluminium beam model under a point load of 467 gr (4.58 kN) with hand calculation of slope at the beam edges.

This test is carried out using a U-shaped aluminium profile with section dimensions of 25×25×3×3 mm. The effective length of the beam model, which is the distance between the null axis of its support, is fixed as 1080 mm.

The test aim was to read the maximum slope of the beam model deck under a known applied load on the mid-span. The maximum slope at the supports can be calculated by Equation 5. Therefore, LARA and HI-INC were attached to achieve this objective on top of the beam model support. First, LARA and HI-INC worked for a while without any loads and their estimations were acquired. Next, the point load was set on the mid-span of the beam model (Figure 3) and then another data acquisition process was carried out to measure the slope of the beam by LARA and HI-INC. It is essential to mention that this test was repeated three times.

Figure 3. Load test of a beam model.

The used formula for calculating the slope of a simply supported beam with a load located on its midspan by hand is presented in Eq.5 (Hibbeler, 2017).

$$\Delta\theta_1 = \frac{P \times L^2}{16 \times E \times I} \quad (5)$$

In Eq.5, where, $\Delta\theta_1$ (Radians) is the maximum slope at the supports, P is the value of the applied load at the mid-span, L is the effective beam length, E (69637.05 MPa) is the beam elasticity module, and I (12853.08 mm⁴) is the beam moment of inertia.

Table 2. Comparing the inclination estimation of LARA and HI-INC.

Number of the experiments	Hand calculation slope (degrees)	LARA Difference (degrees)	LARA (degrees)	HI-INC difference (degrees)	HI-INC (degrees)
1	0.021372	0.001613	0.022985	0.002447	0.018925
2	0.021372	0.002316	0.023688	0.000853	0.020519

The analysis of Table 2 shows that the accuracy of LARA based on these experiments is less than 0.002 degrees. Further study of Table 2 illustrates that the accuracy of HI-INC is around 0.005 degrees. In fact, this is very close to accuracy value detailed in its datasheet ($\pm 0.003^\circ$ for $\pm 15^\circ$ version).

Another experimental test was carried out on this beam model using a heavier weight (21.942 N). In this experiment, instead of putting the weight only on the midspan, the weight was set on various beam locations.

Figure 4 presents the slope measurement comparison of HI-INC and LARA with the hand calculation values. It is vital to mention that this experiment is carried out on the same beam model presented in Figure 3. As showed in this figure, the inclinometer is mounted on a pinned support.

Figure 4. Support slope of a simply supported beam under a point load located on various spots.

Analysis of Figure 4 shows that LARA has a maximum measured difference of 0.003 degrees from the hand calculation slope. In addition, it can be seen that LARA has a closer trend to the hand calculation values compared to those of HI-INC.

It can be seen from Table 1 that HI-INC, ZCT-CX09 and DNS have a resolution of 0.003 degrees. Therefore, LARA can be compared with them. Figure 5 presents the price comparison of these inclinometers.

Analysis of Figure 5 shows a significant difference between the price of LARA and inclinometers with the same resolution. LARA is 12, 6 and 6 times cheaper than HI-INC, ZTC-CX09 and DNS inclinometers, respectively. Also, it does not need extra paid commercial software for data acquisition, and it is based on open-source software and hardware.

Figure 5. Price comparison of LARA with traditional commercial inclinometers with a resolution of 0.003 degrees.

5 CONCLUSION

Lately, the implantation of inclinometers for SHM of bridges is receiving a lot of attention from engineers and researchers. In fact, unlike accelerometers, inclinometers can enable easily the evaluation of both the location and severity of the structural damage. This characteristic makes them suitable for long-term Structural Health Monitoring (SHM) of bridges. However, the current inclinometers' high price has limited their use. There is gap in the literature with the development of a low-cost inclinometer for long term SHM of bridges with a low budget for their health assessments.

To fill these gaps, in this paper, a Low-cost Adaptable Reliable Angle-meter (LARA) system is presented. LARA is a low-cost wireless IoT-based inclinometer with a sampling frequency of 250 Hz. The main novelty of LARA is combining the results of five aligned inclinometers for reducing the inherent noise density of individual accelerometers and gyroscopes of LARA.

In order to validate the assumption of noise reduction and signal improvement of inclination measurements using the averaged results of several aligned inclinometers, four laboratory experiments were carried out. The results of tests show that averaging the values of

a number of aligned accelerometers reduces the noise density of the frequency domain representation of a vibration acquisition experiment.

In addition, in order to compare the accuracy of the used commercial inclinometer and LARA a load test is performed on a beam. In this test, the reported values of the commercial inclinometer are compared with LARA's. It is shown that LARA estimated the theoretical slope with less than 0.003 degrees of difference from the hand calculated values. However, HI-INC showed an accuracy higher than its datasheet data with a magnitude of $\pm 0.005^\circ$.

ABSTRACT: The validation of behaviour of existing structures and its materials characteristics requires the application of tests and monitoring to gather information about the actual response. The comparison of the actual performance and the designed performance enables the validation of the design assumptions in terms of implied loads and materials resistance. In case of non-compliance of the design with the current performance, the design assumptions need to be updated. The application of prescribed loads to a structure to check its load carrying capacity is a powerful tool for evaluating existing structures. In particular, in this research, different types of load tests are employed on a tunnel profile. The system responses to validate the structural performance is recorded with innovative monitoring in tunnel systems, such as accelerometer arrays, fibre optic sensors, and laser distance sensors. Special attention is paid to the capabilities of digital image correlation and nonlinear finite element analysis.

1 INTRODUCTION

Austrian railway infrastructure operator maintains and operates about 150 tunnels with an age of more than 100 years. Most of these are masonry tunnels whose lining can be made of different materials, e.g. rubble masonry, brick masonry, bricks. Damages in such tunnels, e.g. due to ageing and operational influences as well as requirements for current clearance profiles, sometimes require extensive repair or renewal measures on the existing masonry. These measures, which are partly carried out during ongoing railway operations, are usually accompanied by a temporary weakening of the existing tunnel. Measurement systems that have become established in conventional tunnel construction, such as 3D displacement measurements, are not always suitable for carrying out construction measures in masonry tunnels, or are only suitable as an additional aid. In order to select an appropriate monitoring system, the prevailing boundary conditions in the tunnel are crucial. These include operational boundary conditions, e.g. during installation, and on the boundary conditions during continuous monitoring. Typical parameters/conditions to be considered for tunnel monitoring are: (a) condition of the masonry (e.g. geometry, roughness), (b) overhead power supply line (e.g. electromagnetic field), (c) temperature or temperature fluctuations, (d) humidity, (e) aerodynamic effects due to passing trains, (f) dust (e.g. due to passing

trains, construction work), (g) impacts/vibrations (e.g. due to train travel or construction work), and (f) lightning conditions. Beyond that, experience shows that when monitoring the load-bearing capacity of masonry tunnels, the displacements resulting from the construction measures have very low levels and these can be detected in form of local spalling, brittle fracture of masonry or detachment (Zimmermann et al., 2010, 2011). Locally, these can occur even at extremely low displacement values and cannot be detected with conventional monitoring methods (Spyridis and Strauss, 2020). Therefore, when selecting the monitoring instruments, it is important to consider which phenomena are to be recorded during the monitoring (e.g. displacements, spalling, strains, skewing) associated with short and longer reaction times. The aim of this research project was therefore to analyse classic and innovative monitoring systems that can be used reliably and economically in the reconstruction of old masonry tunnels under tunnel conditions.

2 FIELD TEST

2.1 Preliminary studies

The preliminary studies were carried out together with the Austrian Federal Railways, the Vienna University of Technology and the University of Natural Resources and Life Sciences to analyse modern measuring systems for recording deformations in tunnel structures. Tachymeters and laser trackers were used as reference systems, which have been in use for many years and can be compared with newer innovations in terms of accuracy and manageability. With these systems, horizontal and vertical angles as well as the oblique distance from the measuring device to the measuring point are recorded, usually by means of a standardised mirror prism. The recorded measuring points can also be easily integrated into higher-level coordinate systems. The systems to be analysed were profile laser scanners, which use a reflectorless distance measurement principle, an inclinometer chain system mounted along the ring in the inner wall of the tunnel, a fibre optic system and a Digital Image Correlation system. Special attention is given in this paper to the analysis of the Digital Image Correlation System and its suitability for the monitoring of masonry tunnels in the process of retrofitting (Neuner et al., 2022).

2.2 Demonstrator and monitoring systems

As a demonstrator for the experimental investigations, the HABA reinforced concrete mouth profile 3600/2250, manufactured according to ÖNORM EN 1916 and ÖNORM B5074, was used (see Figure 1). As can also be seen in Figure 2, the profile was designed with 30 cm deep and 20 cm wide slots in the crown area, in the upper and lower strut area in order to reduce the bending stiffness of the mouth profile and thus to generate significant 3D deformations which can occur in real tunnel shells. The loading processes has been applied via tie rods, shown in the illustrations.

Figure 1. Data sheet of the HABA mouth profile (Strauss et al., 2022c) and 3D NLFEA drawing of the mouth profile.

The HABA mouth profile is a reinforced concrete profile C25/30 with a 4 cm concrete cover and 36 pieces of $d = 8$ mm longitudinal reinforcement on the inner and outer circumference of the profile as well as $d = 9$ mm ring reinforcement every 8 cm on the outside and 6 cm on the inside, see Figure 2(b) and 2(c) (top view) and Figure 2(d) (front view) show the arrangement of the operated monitoring systems. In particular, the following systems were operated in the profile shown in these figures: (1) Longitudinal inclinometer from HBK, (2) Fibre optic sensor system from HBK, (3) Profile laser scanners from TripleIn, (4) Digital Image Correlations System DIC from DANTEC, and (5) SAA inclinometer system from Measurand. In addition, a laser tracker and a tachymeter – both from Leica - were operated from outside the profile.

The *Digital image correlation* captures the surface of the object being measured and correlates the images from different cameras or viewing angles to create a 3D model. By comparing the model at different load levels, pixel displacements and subsequently strains, in-plane and out-of-plane displacements can be determined. Since not only individual measuring points but the entire surface is recorded, the subsequent evaluation with the help of modern software is very versatile. For example, a line element can be defined and the strain calculated over time. In this project, the focus was on the evaluation of the local strain determination and the evaluation of the out-of-plane displacements - profile deformation.

The *SAA inclinometer* is a chain of 41 accelerometer triads connected sequentially by rigid rods with a length of 125 mm. It enables the measurement of inclination angles in 3D-space by sensing the components of the gravity vector. By means of an initial zero measurement followed by repeated measurement cycles, the SAA inclinometer can be used to derive displacements and deformations along the chain and thus of the deformations of the mouth profile due to the applied loads. The measurement interval was 10 minutes and the starting point of the system was monitored by laser tracker or a tachymeter respectively.

The *fibre-optic inclinometer* system HBK records the strains, i.e. the changes in length between the fixation points on the tunnel profile. The geometric deformations of the tunnel profile can only be determined indirectly via the strain changes along the FOS inclinometer band.

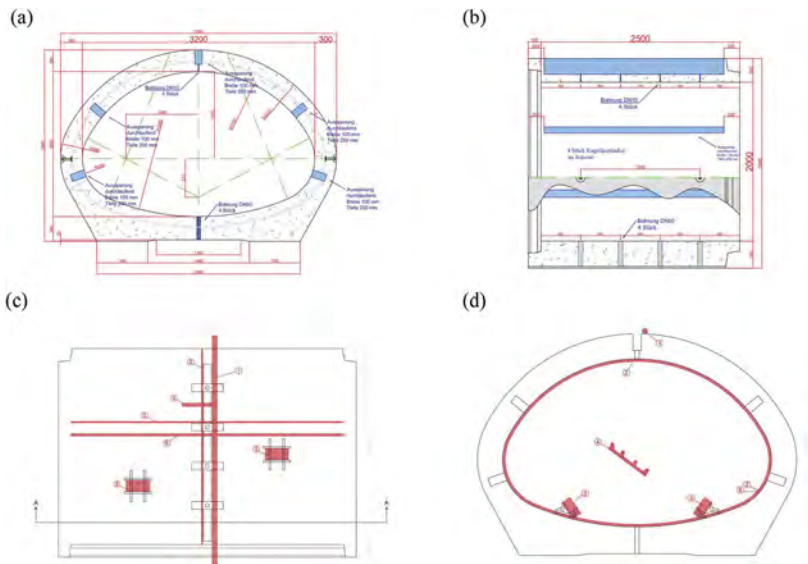

Figure 2. Modified HABA mouth profile and the location of the monitoring systems (a) mouth profile cross-section, (b) reinforcement plan, (c) profile floor plan with measuring system arrangement and (d) mouth profile cross-section with measuring system arrangement. Monitoring systems: (1) Longitudinal inclinometer by HBK, (2) Fibre optic sensor system by HBK, (3) Profile laser scanners, (4) Digital Image Correlations System DIC by DANTEC (5) SAA – inclinometer by Measurand. In addition, a laser tracker and a total station were operated, which were located outside the profile.

Profile laser scanner and laser tracker are polar measurement devices and basically deliver coordinates of measured points related to an instrument specific coordinate system. While the laser tracker measures the distances on corner cube reflectors using the interferometric principle, the laser scanner uses reflectorless distance measurements based on Time-of-Flight principle. The distance, the alignment angle and thus the position of the measured point are recorded. Occurring displacements result from coordinate difference of points.

Table 1 gives an overview of the measured variables that have been recorded (+) or derived (~) on the mouth profile (Beigel, 2023).

Figure 3. Load transmission by means of strain-controlled bars: (a) bar arrangement in the symmetry plane of the mouth profile, (b) load transmission by means of hydraulic cylinders beneath the profile (Neuner et al., 2022).

Table 1. Measured parameters of the monitoring systems applied to the tunnel/mouth profile (Beigel, 2023).

2.3 Loading procedures and processes

The HABA Mouthprofil on the factory grounds of HABA GmbH was subjected to a temporally rapid load regime in predefined load steps. The load was applied in static, uniform load steps in the vertical symmetry plane of the profile. The uniform load application by means of hydraulic cylinders was achieved by four rods (diameter M24), which were guided through holes in the apex and in the base plate to the outside of the profile and anchored accordingly on the outer sides, see Figure 3. The tests on the demonstrator were carried out on 7th, 9th and 23rd February 2022. During the entire loading procedures, see Figure 4, the deformations were continuously recorded with SAA. The increase or decrease of the load was always done gradually with a step size of 40 kN. On 7th February 2022, a load of 0 to 80 kN (4 x 20 kN thread force) had been applied. The test was used to record the elastic system response and profile stiffness information for the creation of the digital twin. The digital twin was then used to obtain a numerical prediction of the maximum load, which was set at 400 kN (4 x 100 kN). Visible cracks on the inner surface of the mouth profile and also on the outside of the profile first appeared at about 120 kN.

The tests on February 9th, 2022, were used to obtain a non-elastic system response and to initiate cracks in order to verify the suitability of the monitoring system for crack detection and plastic deformations. As shown in Figure 4, the load level of 80kN (from February 7th, 2022), at which the digital imaging correlation (DIC) system was set up, was gradually reduced to 0 kN. Thereafter, the load was twice gradually increased up to a maximum load of 200kN.

Figure 4. Loading process on 9th February 2022.

3 DIGITAL IMAGE CORRELATION AS MONITORING SYSTEM IN TUNNELS

Dantec's Q-400 system was used as a digital monitoring system for the mouth profile. Details of the system setup and system can be found in Beigel, 2023. Of particular interest in these analyses was the monitoring of the entire displacement and strain field of the inner surface of a defined profile section near the ridge, see Figure 2(d). As shown in Figure 5, the z-deformations in the ridge area (blue) and the flank area (red) were analysed at different load levels (stages 1 to 6), see Figures 4 and 6, as well as the crack development. The complete deformation curves of the individual stages are shown in the upper right graph. As can be seen from these images, the vertical deformations in the range $\leq 1/10$ mm can be clearly detected and followed. Up to a load of 200kN, a ridge deformation of 3mm was detected.

Figure 5. Z displacement | loading process 0 → 200 kN → 80 kN (9th February 2022) Stage 1 to 6.

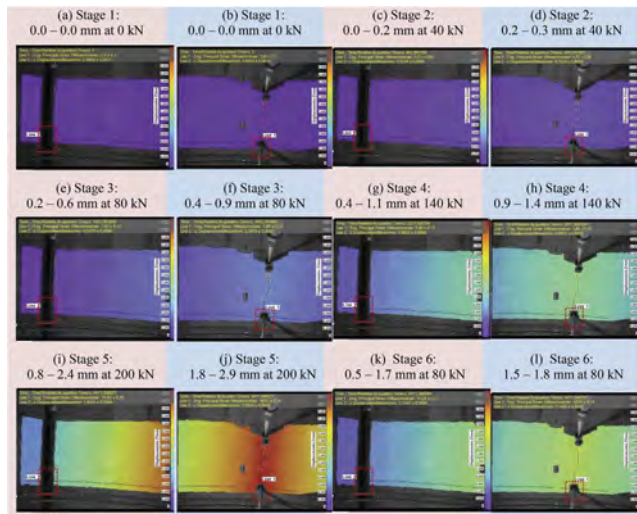

Figure 6. DIC z displacement | loading process 0 → 200 kN → 80 kN (9th February 2022) Stage 1 to 6.

As shown in Figure 7, in addition to the vertical displacements z of the profile, the horizontal movements of the entire profile as well as the local horizontal movements of e.g. cracks and crack surfaces as well as localizations were of particular interest. As can be seen in Figure 8(b), (d), (j) and (l), a crack has developed in the ridge area and the two crack surfaces move in opposite directions according to the applied load level. These deformations and crack pattern development can also be seen in the graphs in the upper right area of the figure, especially the non-linear and partly opposite movements are of high interest. These observations show the high potential of this monitoring technique. The general strain and principal strain developments are also analysed with a non-linear analysis method in Beigel (2023). Details on the monitoring procedures are provided in Polt (2023).

Figure 7. X displacement | loading process 0 → 200 kN → 80 kN (9th February 2022) Stage 1 to 6.

Figure 8. DIC x displacement | loading process 0 → 200 kN → 80 kN (9th February 2022) Stage 1 to 6.

4 DIC VS. OTHER INVESTIGATED MONITORING SYSTEMS

The aim of this research was not only to analyse the capabilities and strengths of innovative monitoring systems in tunnel systems that are renewed, such as the digital image correlation, the SAA inclinometer, the fibre-optic system, the laser distance measurement and laser tracker measurement (see also Neuner et al., 2022, Beigel, 2023) but also to assess the accuracy and measurement reliability as well as the stability of the monitoring systems and their installation possibilities in tunnels under renovation. Figure 9 shows one of these analyses from these

investigations, in which the measurement accuracies of the vertical and horizontal displacements of the DIC were compared with the results of the SAA measurements and the laser tracker reference measurements. As can be seen from this diagram, the differences between the observed monitoring systems are in the range of 1/100 for the displacements both vertically and horizontally.

Figure 9. Measurement accuracies of the vertical and horizontal displacements of the DIC vs. SAA and Tracker measurements.

The digital image correlations system can be classified as an innovative system based on these analyses, which can provide exact results for local monitoring of e.g. strains as well as very precise solutions for the global monitoring of the profile geometry. However, the investigations also showed that site conditions such as dust, humidity and vibrations can limit the applicability of the system. Nevertheless, it should also be noted that systems, like the DIC, provide an excellent basis for the development of digital twins which subsequently allow evaluation and prediction models for degradation, deterioration processes and the detection of service life changes as well as for in-depth probabilistic simulations, as shown for example in (Canestro et al., 2021, Slowik et al., 2021, Spyridis and Strauss et al. 2020, Strauss et. al. 2004, 2006, 2010, 2018, 2020, 2022).

5 CONCLUSIONS

In this research project, several innovative monitoring systems were investigated for their suitability for use in tunnel retrofitting processes in controlled field experiments. The studies have shown that modern innovative systems such as the Digital Image Correlation (DIC) system provide very comprehensive detailed results at the different levels of monitoring (micro-strain analysis and global profile deformation). However, the use of the DIC systems is still sometimes limited by site conditions.

ABSTRACT: Bridges are essential transport infrastructure components that are subjected to degradation due to dynamic loads and environmental impacts. Continuous condition monitoring is essential to ensure the safe and economical use of the structures until the end of their life cycle. Predictive maintenance can be implemented using modern information and communication technologies such as the digital twin (DT) combined with structural health monitoring methods. DTs are virtual real-time representations of structures that collect, evaluate, and provide data for informed decision-making. However, a unified approach still needs to be developed for application in the civil engineering domain. This paper proposes a concept to implement modular DT for bridge structures based on the linked data approach. Modularity is realized by use cases that integrate existing heterogeneous data sources providing a closed view of an aspect. An exemplary implementation of one use case is realized using a container-based approach.

1 INTRODUCTION

Bridges are an integral part of an efficient transport infrastructure. Therefore, ensuring their safety, reliability, and availability is a very high priority for authorities and operators. Due to the aging of structures, increasing traffic loads, and climate change influences, considerable measures must be taken to maintain and modernize structures. Meeting these challenges is one of the most urgent future tasks in transport infrastructure. For this reason, new innovative approaches for information delivery and assessment will be integrated and further developed to provide the basis for an optimized predictive life cycle management. This includes, among other things, the minimization of life cycle costs, optimized structure inspection, and improved availability, safety, and reliability of engineering structures.

The digital twin (DT), as a virtual representation of a real asset or structures, is an essential component for the collecting, evaluating, and providing data and information along all life cycle phases. It provides the basis for smart services and other artificial intelligence based methods for condition prediction, maintenance planning, or traffic control. The Federal Highway Research Institute in Germany has initiated the research project “concept study for the

unification of digital twin bridge components”, which focuses on developing a modular concept for DTs of bridges.

This paper provides a basis for the future realization of modular DTs of bridge structures on a conceptual and technical level. The modular concept ensures the expandability and future viability. The concept is validated in a case study in which the technical implementation of the use case of interval-based condition inspection (structure inspection) is demonstrated.

2 STATE OF THE ART

A DT is commonly understood as a formal virtual representation of a physical object, process, or system that captures the properties and behaviors of the respective entity and enables context-specific communication, data storage, interpretation, and evaluation (Industrial Internet Consortium 2020). Since its introduction as the conceptual ideal of product life cycle management (PLM), many industries have recognized the potential the DTs. As a result, the DT is becoming a key concept for digital transformation in many industries, each with its definition that considers individual industry-specific requirements so that no uniform understanding of the concept exists (Kritzinger et al. 2018).

The term DT is often used synonymously with other concepts. Kritzinger et al. (Kritzinger et al. 2018) distinguish the DT based on the degree of integration, making it differentiable from concepts like the digital shadow and digital model. They define the DT as a digital representation with an automatic bidirectional data flow. In contrast, they define the digital shadow as a digital representation with unidirectional and a digital model as a representation without any form of automatic data exchange. In construction, the adoption of the DT is still in its infancy. It is seen as an extension, complementary to, or completely independent of existing Building Information Modeling (BIM) approaches (Shahzad et al. 2022). For Delgado et al. (Delgado et al. 2021), BIM and the DT serve different industry needs. According to Boje et al. (Boje et al. 2020) the DT is a virtual representation of components or structures that goes beyond a BIM model by exploiting the bidirectional data connection enabling an ever-updated representation of a building.

The DT for bridges is mostly discussed in the context of structural health monitoring for continuous condition monitoring. The DT captures the data measured by the structural sensors and can predict about the structural behavior of the structures in conjunction with structural reliability techniques to deal with uncertainties (Bittencourt et al. 2021). The main features and capabilities of a DT for structural health monitoring of bridge structures are essentially a digital representation consisting of geometry and other relevant metadata, a connection to the structure, for example, through sensors, and a common data environment for data access as well as for the integration of visualization and simulation tools (Ye et al. 2019).

In their work, Shim et al. (Shim et al. 2019) present a DT framework for bridge structure maintenance. Their solution consists of a maintenance information management system based on a 3D information model combined with a digital inspection system with image processing. A major challenge in modeling DTs of bridge structures is the creation of basic geometrical models, especially for existing structures. Lu et al. (Lu et al. 2019) propose an object-matching method for existing reinforced concrete bridges in IFC format using four types of point clusters to create geometric twins based on point clouds. Their method generates a geometric twin with LOD 250 to LOD 300.

AR & VR methods can be used to make the results of structural inspection accessible. Omer et al. (Omer et al. 2019) propose a novel bridge inspection method in which bridges are digitized using LIDAR (light detection and ranging) so that they can later be inspected in a virtual reality (VR) environment. Their approach enables access to critical areas and increases the safety of inspectors. Furthermore, Wenner et al. (Wenner et al. 2022) present the realization of a DT of the Köhlbrand Bridge, which can detect damage and changes in condition by collecting data in real-time. The real-time data, as well as the collected data history, are used as the basis for predictive maintenance. Lazoglu et al. (Lazoglu et al. 2023) present

a concept of a DT, which is realized for the Filstal bridges. This includes integrating, processing, and aggregating of data from bridge inspections and calculated structural safety verifications, as well as monitoring and diagnostic data to display the bridge condition continuously.

3 CONCEPT

The prerequisite for the transition from reactive to predictive life cycle management of bridges is the DT for the acquisition, evaluation, and provision of data enabling informed decision-making using, among others, current engineering models and methods from the field of artificial intelligence. The high fragmentation and complexity of the construction industry require the development of a flexible DT concept that facilitates the integration of heterogeneous data sources. As life cycle phases change, so do the requirements for bridges and new functionality consisting of data and processes must be continuously integrated into DT. A modular approach to implementing the DT is one way to ensure the necessary flexibility.

The following sections present a modular DT concept for bridges, which considers modularity separately regarding the business processes and software-technical implementation. Modularization generally means dividing a whole into largely independent, exchangeable, and modifiable modules, forming a closed functional unit. Interaction between the individual modules takes place via standardized interfaces (Balzert, 2010).

The present concept is based on a top-down approach in which the objectives of DT have been defined first. Based on these objectives, the associated business processes and use cases required for implementation were identified. The business processes and use cases form the process modularity and are based on existing regulations. Each use case consists of any number of process steps. For example, the use case of continuous condition monitoring is divided into data acquisition, evaluation, and information generation and uses context-specific methods, software tools, and data. A deep understanding of the corresponding processes and their input and output data is essential for a modular implementation. In order to develop suitable data structures and identify data exchange and interaction needs, it is recommended to develop a detailed use case description.

The software-technical implementation must integrate the modules described at the process level into modules that contain all relevant data, methods, tools, and models. In addition, the technical requirements placed on the digital twin regarding information modeling, compilation, synchronization, interfaces, connectivity, and interoperability must be met by the software-technical implementation (cp. Industrial Internet Consortium 2020).

Figure 1. Top-down approach for the development of the complete modular concept.

3.1 Process modularity

Process modules are use cases that provide specific services or specific data as a self-contained functional unit with clearly defined input and output data. A distinction is made between mandatory and optional use cases. Mandatory use cases create a data baseline, while optional use cases provide additional services that can be individually integrated into the DT. For example, a mandatory use case is of interval-based condition inspection (bridge inspection), while visualization of traffic restrictions is optional.

Process modularity is divided into different levels. The use case level and subordinate process levels of the individual use cases are modular. The various use cases describe the

superordinate level of process modularity. The subordinate level of process modularity represents the detailing of the individual use cases into different process steps. Depending on the requirements profile and the level of detail of the use case within DT, the individual process steps are exchanged, transformed, or extended. In particular, the implementation of the use case and the associated process steps can change significantly as the level of digitization progresses. Despite the variable methodical implementation of the use case, the required input data and the defined output data remain unchanged.

3.2 Description of the use cases

Some general conditions have to be defined to identify and describe the individual use cases. An essential aspect is the structure of the bridge. It has to be ensured that each bridge can be implemented by the modular concept of the DT regardless of its design. Furthermore, the superordinate structure of a use case within the virtual representation has to be described.

A bridge structure is composed of several components, so the DT is also formed by several DTs on the component level. This structure corresponds to the classification systems used in civil engineering, such as ASB-ING (BMVBS 2013). This decomposition of the DT also makes it possible to understand components or hotspots as subsystems and, thus, to compose the overall bridge system from individual components.

The general structure of a virtual use case representation can also be divided into four levels, see Figure 2. At the lowest level, various data can be used, e.g., a BIM model enriched with data from the building database, measurement data, or user data. Depending on the data type, these data can be collected once, cyclically, or continuously. Different evaluation methods can generate information for different business processes on the second level from the various data sources. Business processes representing the third level can be divided into methods for monitoring, analyzing, or predicting the state of the physical object. Finally, the information can thus be obtained and converted into knowledge at the top level by making it available to the user in a suitable manner. In this way, the use cases serve as decision support for the user.

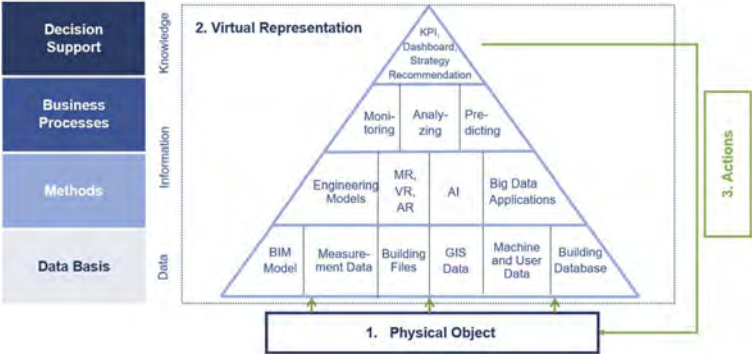

Figure 2. Layer concept of the virtual representation.

Within the underlying project, 21 use cases were identified which can be divided into three areas of operational processes, maintenance planning and execution, and strategic life cycle management. Each area serves different business processes in the use phase. The goal of the operational processes area is the optimal execution of structural maintenance and ensuring operational processes. The use cases of this area focus on a short-term time horizon of 1 to 3 months and relate to the entire roadway, such as winter maintenance or car accident management. The maintenance planning and implementation area aims to maintain the required condition of the structure, including, for example, the use cases of interval-based condition

inspection (structure inspection), continuous condition monitoring, or traffic data acquisition. These use cases cover a time horizon of 1 to 5 years and only consider components at the structure and component level. The third area of use cases covers strategic life cycle management with a time horizon of 3 to 50 years. Examples mentioned here are degradation analyses, the formulation of maintenance strategies, and EU-taxonomy analyses. In the future, this area will ensure the application of predictive management for the operation and maintenance of bridges at the structure, component, and portfolio levels.

3.3 Software modularity

A modular implementation of a DT must allow access to existing and established heterogeneous data sources, such as digital building databases, for running the business processes embedded in the use cases. Access is granted utilizing queries and web interfaces that differ from database to database. The different data sources, therefore, form data islands that must be software-technically integrated into the modular DT concept. Additionally, the data must be provided in a uniquely identifiable and machine-readable way. Linked data enables the linking of building-related databases to relevant data sources so that information can be related in a partially automated way. An update of interconnected data sets enables processes to adapt by automatically processing specialized inquiries, enabling reactions to new and changed contents. With linked data, access to data is provided via standardized interfaces.

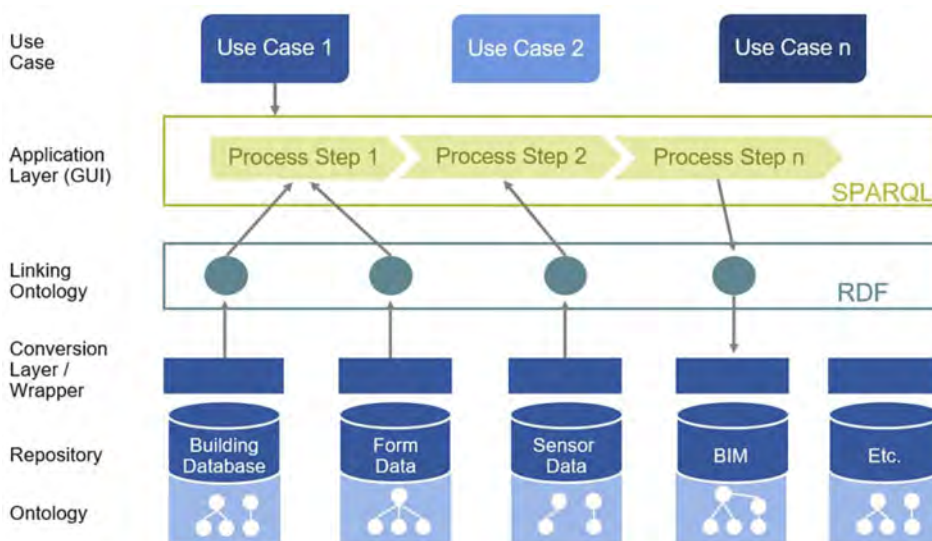

Figure 3. Framework of software modularity.

Figure 3 shows a layer-based framework for implementing a linked data-based modular DT. The framework is based on an ontology-based description of linked resources to uniquely associate data. For this purpose, data are formalized in a graph-based manner using the resource description framework (RDF). RDF defines data in subject-predicate-object triples emerging as a directed graph representation. Ontologies are used to model RDF-based data sources on a schema level and connect them to business processes invoked by use cases. For this purpose, existing ontologies must be reused, or new ontologies must be developed for each data source providing corresponding class and properties definitions.

Uniform resource identifiers (URI) enable unique identification and mapping of RDF entities. Various conversion tools and wrappers convert existing databases into RDF format, thus ensuring data access via uniform interfaces. Semantic searches and queries can be

performed using the SPARQL protocol and RDF query language (SPARQL) in conjunction with the used ontologies. Semantic information from data sources of other use cases can be systematically defined and linked to existing data sets using appropriate ontologies. Data sources can be automatically converted to RDF format using conversion tools and wrappers as mentioned above in conjunction with ontology definitions and added to the module with an ontology for a formal schematic description of the data.

4 CASE STUDY

Information containers for linked document delivery (ICDD) are suitable for implementing modular DTs based on linked data. ICDD containers integrate heterogeneous data sources to enable context-specific simplified information delivery. All data relevant to an aspect or use case can be stored in the container or linked externally. In addition, it is possible to express links and relationships between the various data, making them an ideal foundation for implementing the presented concept. Besides the usage as an exchange format, due to the employment of semantic web technologies, the ICDD schema is suited to be implemented in web applications, such as common data environments (CDE) or asset management applications (Hagedorn et al. 2023).

The structure of ICDD containers is specified by ISO 21597-1:2020 (ISO 2020). The file format with the extension `.icdd` complies with the ZIP64 standard defined by ISO/IEC 21320. Essentially, the data structure of an ICDD container consists of an index file and the three folders ontology resources, payload documents, and payload triplets. The index file describes the data content and identifies the container. The folder ontology resources contains the container ontology and linkset ontologies. The container ontology specifies classes and properties to describe the container contents associated with the index dataset. Linkset ontologies specify classes and properties for describing links and relationships between the data contents of the container. All ontologies are available as RDF(s)/OWL files. The payload documents folder contains all data and documents relevant to the use case. Through the link datasets in the payload triples folder, relationships and links between the data contents can be specified in conjunction with the corresponding linkset ontologies.

In this paper, ICDD containers are created per use case to implement a modular DT. The federation of all container modules forms the DT. As part of a proof of concept, an ICDD container has been equipped for the interval-based condition inspection use case. The container has been created using the web platform developed in the work of Hagedorn et al. (Hagedorn et al. 2023). The use case of interval-based condition inspection is utilized for data collection and damage assessment as part of structural inspections based on existing regulations and codes such as DIN 1076 or ASB ING. The data collected during the structural inspection must be structured to create a basis for other use cases based on interval-based condition monitoring. Therefore, the ICDD container for representing the interval-based condition recording must contain, among other things, a digital building model and digital images, plans, and structural documents. Furthermore, an interface for building databases, such as digital ones, must be ensured.

Figure 4 shows the ICDD container for the interval-based condition recording comprised of the ICDD ontologies, a folder with located damage images, a bridge IFC 2x3 model, and an “ExternalBridgeDatabase” entry in the payload documents folder, and a linkset file “DamageLocalization.rdf” interconnecting the damage images and the results from the interval-based condition inspection to their matching elements in the IFC model in the payload triples folder. The “ExternalBridgeDatabase” is an instance of the ICDD extension class “ExternalDatabase” provided in an extension ontology. It acts as a connector between the container and the relational database storing the condition data. The connector applies the RDB to RDF Mapping Language (R2RML) for generating RDF triples from the condition database, which can be linked and queried in the container context. In addition, the used software implementation supports direct mapping and custom R2RML mapping files stored within the container. In this use case, the R2RML direct mapping is employed to retrieve all

unfiltered database entries and in their relational structure. RDF triples are generated to the “ExternalBridgeDatabase.instances.ttl” file in the payload triples folder whenever the procedure is triggered manually or via a webhook request.

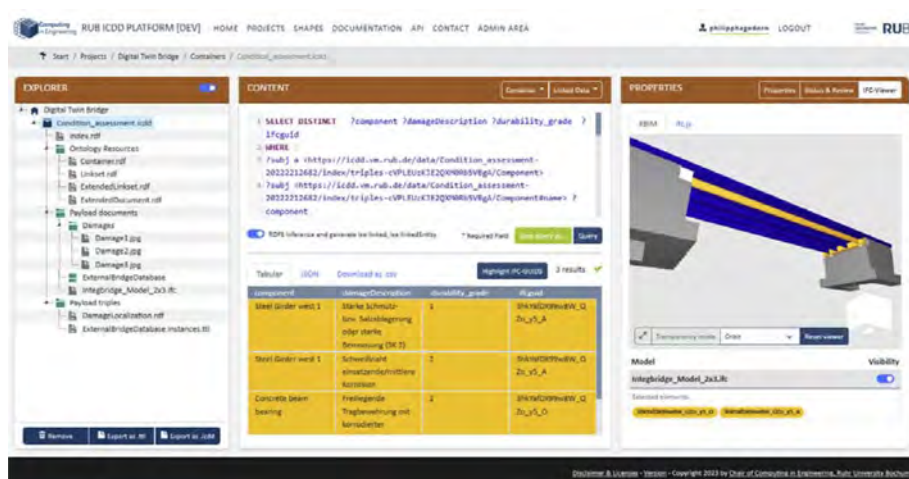

Figure 4. Querying and visualizing recorded conditions from database registered in the ICDD container.

In the context of the ICDD container, the retrieved condition data can be queried using SPARQL, resulting in textual damage descriptions, damaged components and their interconnections to IFC elements, and the assessment of durability, stability, and safety. The interconnection between the damaged IFC elements and the respective on-site damage images is shown in Figure 4.

Further use cases of this dynamic integration of bridge condition and maintenance data can be found in Hagedorn et al. (Hagedorn et al. 2023). The present case study shows the feasibility to deploy a modular DT using ICDD and Linked Data.

5 CONCLUSIONS

In this paper, a concept of a modular DT based on linked data has been developed. Modules are use cases consisting of data, methods, business processes, and decision support, each providing a closed view of a single aspect. A container-based implementation demonstrates the functionality of the presented concept. The following findings and can be summarized:

- The division into the process and software modularity enables the overall design of a modular concept for DT of bridges.
- Use cases are suitable as modules of process modularity because they each form a self-contained functional unit that provides specific services or data for business processes.
- The implementation of the individual process steps of the corresponding use cases is realized within the software modularity using various methods tools, utilities, and input and output data.
- Linked data enables a modular software-technical implementation through which all data sources belonging to a use case are linked, uniquely identifiable, and accessible via standardized interfaces.
- ICDD containers are ideal for implementing modular linked data-based DTs. For each use case, an ICDD container can be created that contains all relevant data sources and provides methods for the semantic description of the data and standardized access to the data. The individual containers together form the DT.

In future research, the developed concept will be validated by implementing a pilot project. On this basis, further digital services enable optimization and expansion of DT processes.

ACKNOWLEDGMENT

Sustainability-informed intelligent management of aging civil infrastructure systems with emphasis on bridge networks

Xiaoming Lei & You Dong

Department of Civil and Environmental Engineering, The Hong Kong Polytechnic University, Hong Kong, China

Dan M. Frangopol

Department of Civil and Environmental Engineering, ATLSS Engineering Research Center, Lehigh University, PA, USA

ABSTRACT: Infrastructure systems are subjected to deterioration throughout the duration of their life-cycle from exposure to the environment. The bridge network systems play a crucial role in urban, and their safety are highly related to the carbon emissions within the construction field. This study suggests a deep reinforcement learning (DRL) approach for the sustainability-informed life-cycle management of aging infrastructure systems to meet the goal of dropping the global carbon emissions. The management of aging structures completely considers the environmental, economic, and safety impacts. The management optimization with Markov decision process is achieved with the DRL approach. The effectiveness and efficiency of the approach are validated with a bridge network. The proposed DRL-based management approach maximizes structural conditions while minimizing overall carbon emissions and economic expenses. The proposed approach could also assist stakeholders in efficiently allocating funds to maintain aging structures and understanding the performance, risk, sustainability, and life-cycle of infrastructure assets.

1 INTRODUCTION

With the expansion of human civilization, the number of infrastructure systems has unavoidably increased, causing a significant daily CO₂ footprint on the environment (Bianchi and Biondini 2022, Biondini and Frangopol 2015). Recently, the idea of carbon neutrality has been promoted with the aim of achieving zero net worldwide CO₂ emissions. Therefore, it is urgent to improve civil infrastructure management and operation processes in order to reduce carbon emissions over the course of a civil infrastructure's life and encourage the creation of a low-carbon smart world.

The sustainable policy-making process typically includes a number of factors, such as the effects on the environment, economy, society, and safety (Capacci and Biondini 2020, Capacci et al. 2020). In previous research projects, risk assessments for network-level bridges under service loads or multi-hazard scenarios were completed empirically, qualitatively, and quantitatively (Lei et al. 2022a). Dong et al. (2014) calculated the sustainable metrics for a transportation network in the USA under a seismic scenario. Abdelkader et al. (Abdelkader et al. 2022) developed a multi-stage policy-making approach to involve a neural network model and an optimization model for predicting sustainable resource allocation. These studies mainly used the Markov decision processes (MDPs) to simulate the deterioration and maintenance progress. Genetic algorithms are often employed to give good policies for optimizing infrastructure system management.

Deep reinforcement learning (DRL) is an effective deep learning method to optimize complicated infrastructure systems. Cheng and Frangopol (2021) proposed a DRL-based approach for load rating projects of network-level bridges. Andriotis and Papakonstantinou (2021) presented a management optimization method with a decentralized multi-agent DRL model. This study efficiently formulated the plans, considering the life-cycle risks and budget constraints. Zhang and Si (2020) advanced the conventional condition-based management plans for infrastructure systems based on DRL. Lei et al. (2022b) proposed the DRL life-cycle maintenance framework for network-level bridges, and the proposed method effectively improved the regional safety of bridge structures and reduced the management cost simultaneously. Very few studies have been performed on aging infrastructure systems with life-cycle management optimization using DRL methods and taking sustainable metrics and risk attitudes into account.

This study develops a DRL-based sustainable life-cycle maintenance policy-making system for aging infrastructure systems. The environmental, economic, and safety metrics are transformed into multi-utility models to construct the reward function for DRL. The time-variant structural failure probability is developed based on the measured data. Within the employed structural features, system topology, and sustainable metrics in the DRL environment, the CNN-based policy-making agent could suggest optimal life-cycle management policies. An existing highway bridge network in China is used to validate the suggested approach.

2 DRL-BASED MANAGEMENT POLICY OPTIMIZATION FRAMEWORK

2.1 Sustainable life-cycle management framework

Figure 1 shows the DRL-based management policy-making framework, which consists of a CNN-based management policy-making agent, service environment, state and sustainable reward, and management outputs. The CNN-based agent gives the management actions for the infrastructure. The service environment contains structural deterioration and management effects, which could be obtained from theory, inspection, and monitoring. The state and reward represent the service condition of infrastructure, and the sustainable reward feeds back to the agent to evaluate the policies. The DRL method enables the policy-making agent to learn better management actions in an interactive environment to maximize cumulative rewards.

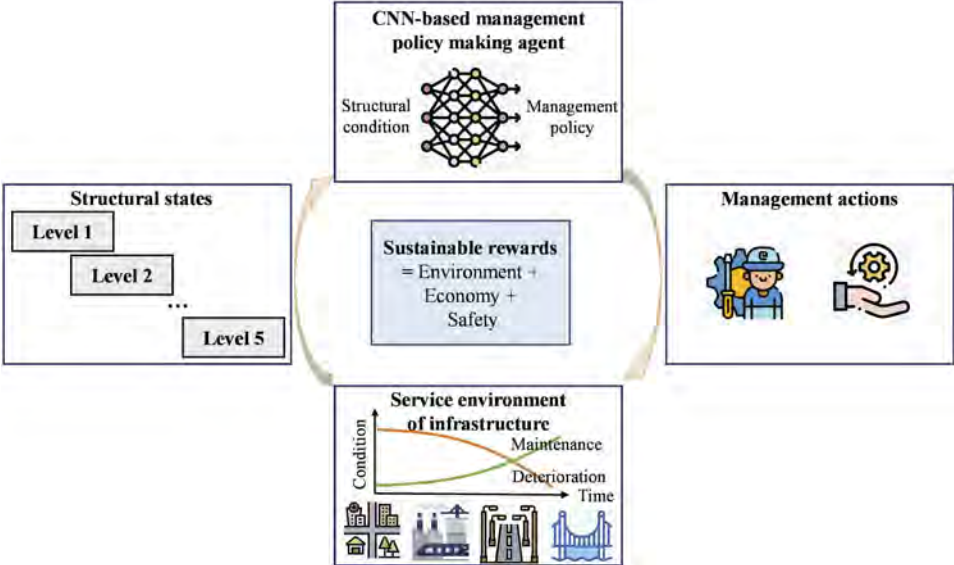

Figure 1. DRL framework considering multi-attribute utilities.

2.2 Convolutional neural network-based policy-making agent

Normally, the MDPs method assumes offline information of detailed stochastic models for the whole environment and provides optimum management policies. DRL uses domain information and learns to perform efficiently by engaging directly with environments. Figure 2 illustrates the Convolutional neural network (CNN) -based policy-making agent with Q learning. It is a model-free technique that uses a CNN model to output the value function. In Q learning of Figure 2, grey blocks are the main parts of the algorithm. The hollow blocks are the outputs of estimated states, actions, and rewards. Some primary operations are illustrated beside the arrow lines, and the blue arrows are the updating of the model parameters.

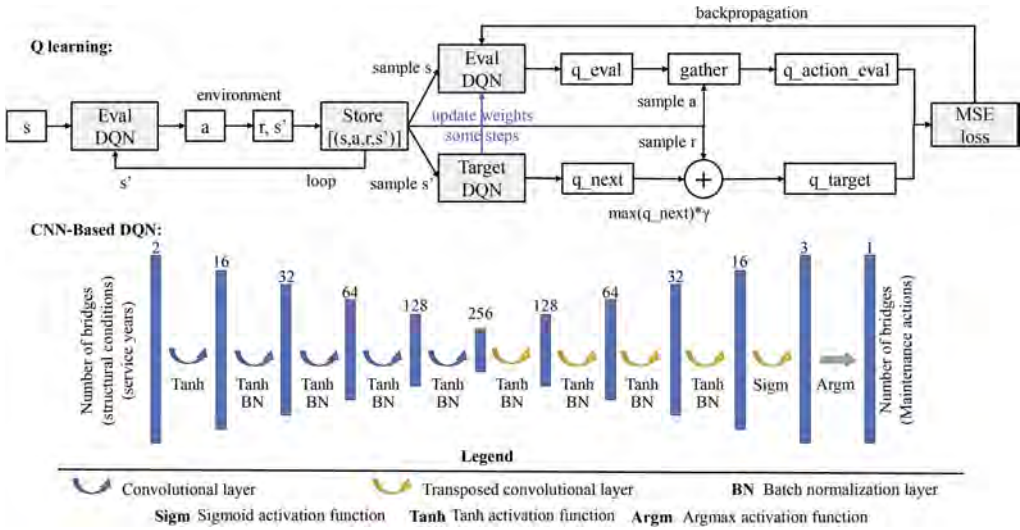

Figure 2. The CNN-based policy-making agent with Q learning.

The DRL agent observes the structural state s_t , recommends a management action a_t , and outputs a reward r_t at each step. The output management policy $\pi(a|s)$ links structural states with management procedures (Lei and Dong 2022). The agent receives feedback to evaluate the action. The purpose of the DRL agent is to maximize its predicted total reward, which is weighted by $\gamma \in [0, 1]$ at each step to express their value to the current state. At the same time, the return is $R_t = \sum_{t'=t}^T \gamma^{t'-t} r_{t'}$ where T is the step taken after the episode ends. The predicted return after monitoring the structural state and conducting a management action under a management policy is the action-value function $Q^\pi(s, a) = E[R_t | s_t = s, a_t = a, \pi]$. With the help of the greedy algorithm, the Q value is determined by

$$Y_t^{DQN} = R_{t+1} + \gamma \max_a Q(S_{t+1}, a; \theta_t) \quad (1)$$

The Q-learning has two critical advantages (Busoniu et al. 2008): 1) Experience replay could take random samples from the replay memory and break the data correlation. 2) Two separate Q-networks contain the current parameters θ and the old parameters θ^- , respectively. At every update iteration i the current parameters θ are updated to minimize the mean-squared error concerning old parameters θ^- by optimizing the following DQN loss function:

$$L_i(\theta_i) = E \left[\left(r + \gamma \max_{a'} Q(s', a'; \theta_i^-) - Q(s, a; \theta_i) \right)^2 \right] \quad (2)$$

The CNN-based agent is used as the policy-making agent, as shown in Figure 2. The CNN-based agent receives the measured data of civil infrastructure and extracts their hidden features. The inputs contain the spatial-temporal structural condition data of civil infrastructure. The CNN model gives the management actions of infrastructures with compressed features. The obtained high-level abstracts are unsampled and decompressed into valuable information using the transposed convolutional layers. Up until the targets are reached, the feature extracted by the convolutional layers is sampled nonlinearly with weights. The recommended management action for civil infrastructure is the output of the CNN-based agent.

2.3 Multi-attribute utility model with sustainability metrics

The utility model defines management costs taking the policy maker’s perspective into account. To reduce the impact of different ranges, utility models normalize cost values from 0 to 1. The risk attitude of the policy maker also can be taken into account in the model. The single-attribute utility model is

$$u(t) = \frac{1}{1 - \exp(-\gamma)} \left[1 - \exp\left(-\gamma \frac{C_{max} - C(t)}{C_{max}}\right) \right] \quad (3)$$

where, C_{max} denotes the maximum single-attribute sustainable metric; γ denotes the risk attitude, where $\gamma > 0$ and $\gamma < 0$ represent risk aversion and acceptance attitudes, respectively; and $C(t)$ denotes the time-variant single-attribute sustainable metric.

Along with the aforementioned single-attribute utility model, the sustainable multi-attribute utility model also incorporates the contribution of economic, environmental, and safety metrics. The sum of all the weights equals 1. The sustainable multi-attribute utility model is shown in Figure 3, and is formed as

$$u_f = w_c u_c + w_m u_m + w_s u_s \quad (4)$$

where, u_f is the sustainable multi-attribute utility model; w_c , w_m , and w_s are the weights for the environmental, economy, and safety single-attribute utility in the sustainability perspective.

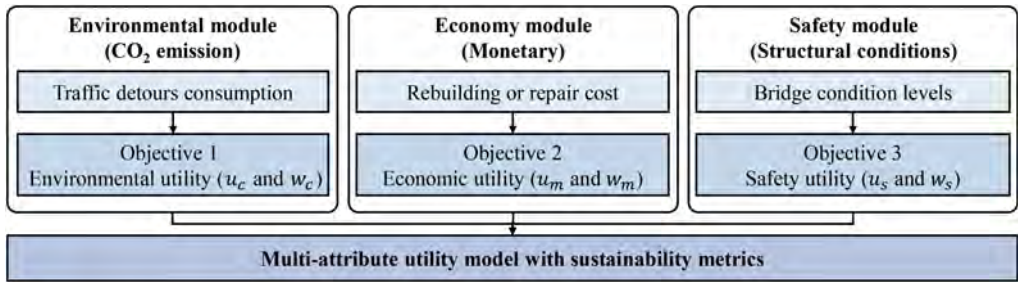

Figure 3. Sustainable multi-attribute utility model for infrastructure system.

3 CASE STUDY FOR LOCAL BRIDGE NETWORK

3.1 Bridge network descriptions

The proposed sustainable intelligent management of aging civil infrastructure systems is implemented on an existing highway bridge network in China. Eight roads link the six cities together, which is depicted in Figure 4. The network contains a total of 308 middle- and small-span RC bridges. This study aims to optimize the 100-year maintenance policy.

In this case, the failure of network elements other than bridges is regarded as insignificant in comparison to those of bridges.

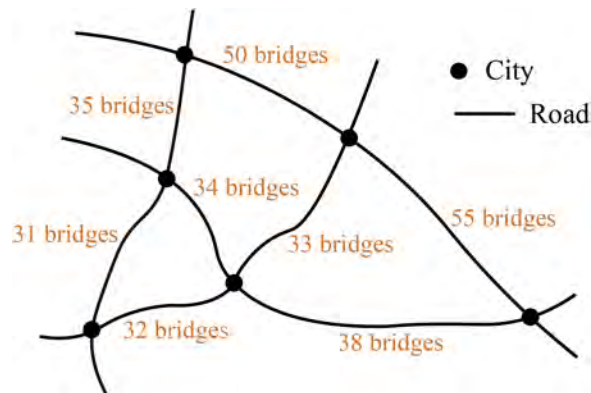

Figure 4. Bridge network layout.

These bridges range in width from 5 to 20 meters. The largest proportion is found in bridges with a width of roughly 20 meters and 5 to 10 meters. Although the span length of these bridges ranges from 5 to 96 meters, most of them have a length of less than 50 meters. The sustainable maintenance policy takes traffic volume into account when calculating CO₂ emissions from traffic detours. The CO₂ emission per kilometer for each type of vehicle is defined by a survey in 2016.

3.2 Structural deteriorations

The actual structural deterioration features can be extracted from the measured data, such as inspection reports and structural health monitoring systems. The failure probabilities of constructed bridges and the network links are essential for managing the bridge. Generally, the bridge condition and safety levels comprehensively determine the structural failure probability.

The structural condition level, which ranges from 1 to 5, describes the general structural condition of the bridge structure. Level 1 denotes the best structural conditions for the bridge, while Level 5 denotes the worst conditions. Considering the impacts of material and load uncertainties, the life-cycle time-variant structure failure probability distribution of this network is shown in Figure 5. It can be shown that the probability of failure in later phases of operation is vast, indicating a significant need for optimal management to improve structural performance. The maintenance effects also could be determined in similar approaches.

The deterioration model for each bridge in the network is sampled from this distribution. Without maintenance, the average value of environmental, economic, and safety metrics are 9174.07, 2537.93, and 981.0, respectively, in the 100th year. They could also be used as the maximum value of each metric to form the multi-attribute utility model.

3.3 Model setting and training

To fully retrieve the high-dimensional features and generate optimal policies in practice, the training epoch is set at 1000. In order to allow agents to remember and reuse previous experiences, the memory capacity is set to 50. The weights are updated during training at a rate of 0.001, which is the learning rate. The value of the discount factor is set to 0.05. It could be used to gauge how motivated the agents are by rewards and provide evidence of the convergence of some techniques.

Figure 5. Probability density distributions of life-cycle failure probability under no maintenance.

The coordinate value of each point in Figure 6 denotes the life-cycle accumulated values of the economic, environmental, and safety of network-level bridges. Figure 6 also contains the optimized policy for each training epoch. The smaller the metric (coordinate) value, the better the management policy. The output management policies become more efficient at maximizing sustainable metrics as the number of epochs rises. The optimal management policies in terms of environmental, economic, and safety metrics are 3443.8, 5248405.3, and 2612.0, respectively, as shown by the green point with projection lines. The trained optimal policy outperforms the most successful conventional policy in terms of environmental, economic, and safety metrics by 32.12%, 47.52%, and 41.96%, respectively.

Figure 6. Optimized management policies during model training.

3.4 Optimal life-cycle management policies

The annual changes in network-level bridge conditions and management actions are displayed in Figure 7 from the regional view. Figure 7 (a) displays that most bridges are in condition Level 1 during the life-cycle. Bridges with condition Level 2 are around 7%, and bridges with condition Level 3 are less than 1%. The optimal management policy keeps the network-level

bridges in better service performance. Figure 7 (b) shows that the optimal management policy employs a small number of efficient management actions to ensure the good condition of network-level bridges. Among all the management actions, the repair action is mostly selected as preventative.

Figure 7. Annual changes in structural conditions and maintenance actions of the optimal policy.

From the individual view, Figure 8 displays the condition level of each bridge in four typical years. Each bridge holds a distinct structural condition variation and maintenance scheme. In the four subfigures, only seven bridges (one in the 20th, 40th, and 60th year and four in the 80th year) deteriorated to condition Level 3. The additional CO₂ emissions are 37.42, 31.52, 34.35, and 37.53 tons in these four years. The available budgetary resources maintain a balance between regional structural safety and environmental impact.

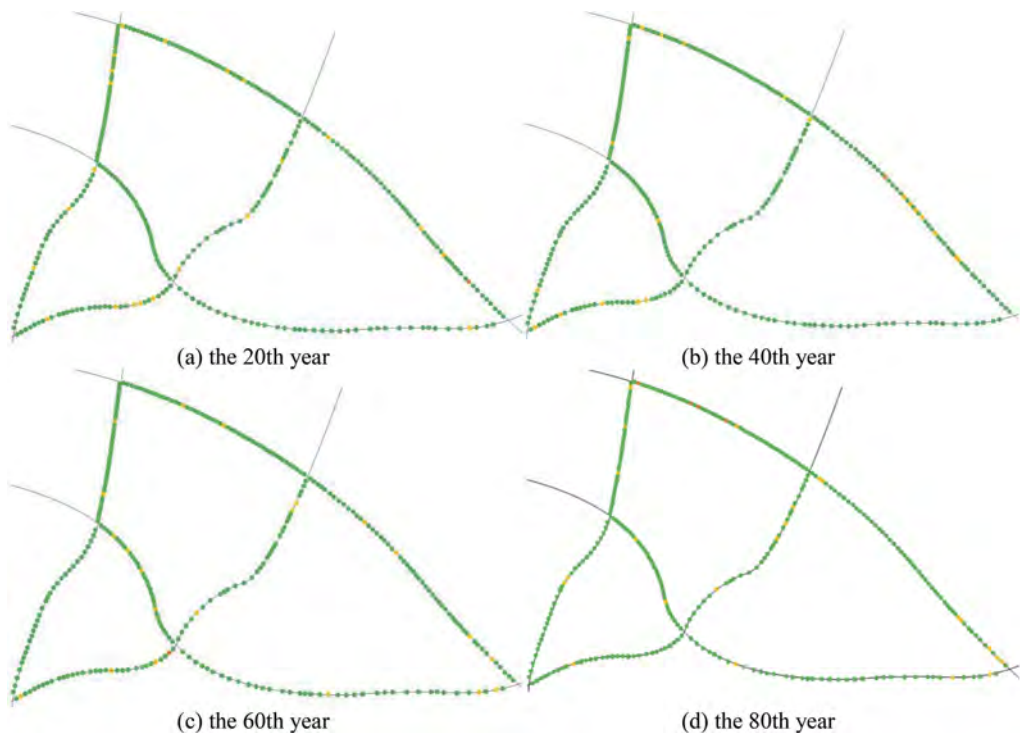

Figure 8. Individual bridge conditions in four typical years.

4 CONCLUSIONS

This study provides a DRL-based framework to determine life-cycle sustainable management policies for aging infrastructure systems. The following are the main conclusions:

- 1) The sustainability metrics are transformed into utility models to construct the reward function for DRL. DRL could output more efficient and sustainable life-cycle management policies than traditional condition-based methods. It also proved to have a better trade-off between the three main objectives of the infrastructure system.
- 2) The optimal management policy keeps the network-level bridges in better service performance. It employs a small number of efficient management actions to ensure the good condition of network-level bridges. Among all the management actions, the repair is mostly selected as preventative.
- 3) From an individual perspective, each bridge holds a distinct structural condition variation and management scheme. Very few bridges that deteriorated to condition Level 3. The available budgetary resources maintain a balance between sustainable regional impact.

ABSTRACT: Time-variant reliability analysis is an essential computational procedure to quantify the failure probability and risk throughout the life-cycle of structures. A major challenge of time-variant reliability analysis is the computational effort and expense, especially when sampling-based methods are involved. Artificial Intelligence inspires a new perspective for developing advanced life-cycle computational tools in this field. This paper presents a meta-learning method to provide an alternative computational scheme that can achieve higher efficiency in terms of utilizing the evaluations from earlier point-in-time reliability analysis. The proposed meta-learning method uses the deep neural network (DNN) as the surrogate for reliability analysis. The model-agnostic meta-learning (MAML) method is adopted as the meta-learning algorithm to learn a set of adaptable parameters for subsequent DNN training. A corrosion problem is used to illustrate the applicability and efficiency of the proposed method.

1 INTRODUCTION

Civil and marine structures are often exposed to severe environment that can cause deterioration of structural performance. A rational assessment of deteriorating structural performance during life-cycle is critical for effective intervention strategies. In this regard, time-variant reliability analysis (Liu & Frangopol 2018; Gong & Frangopol 2019) became an essential computational tool for life-cycle management of aging structures (Frangopol 2011). Reliability analysis usually adopts sampling techniques to quantify the failure probability accurately. As a result, the required number of simulations is considerably high, especially when dealing with low failure probability events. The computational efficiency problem remains a key challenge for reliability tools as decision-makers demand rapid solutions for life-cycle management.

Machine learning methods can be used to address the computational expensive problem associated with reliability analysis (Saraygord Afshari et al. 2022). The trained DNN model can approximate the limit state function, therefore, helping to accelerate the computation process. A series of machine learning methods are successful in the structural reliability analysis domain such as Kriging (Yi et al. 2021) and Artificial Neural Network (Chojaczyk et al. 2015). DNN modeling research also concerns with the refinement of models for computational accuracy. An extensive review of adaptive DNN model methods for reliability analysis can be referred to Teixeira et al.(2021). The application of deep neural networks (Bao et al. 2021) in this field has shown an enlarged capability to deal with more complex reliability problems. However, the training of deep neural

networks is non-trivial as a large number of episodes are required for convergence. In addition, refinement samples are often needed to ensure the quality of DNN predictions (Xiang et al. 2020; Zhang et al. 2022).

Despite the improvement of structural reliability analysis with machine learning methods, time-variant reliability analysis still lack an appropriate surrogate method. The DNN modeling process has to repeat from scratch in each point-in-time reliability assessment. The traditional way of training and tuning a large number of DNNs is not considered an ideal solution for time-variant analysis. A key aspect of artificial intelligence is the capability to utilize experience and knowledge. Meta-learning is the concept of learning a model that can generalize and adapt to new tasks with prior knowledge from learned tasks (Finn et al. 2017). Cheng et al. (2022) proposed a meta-learning framework for DNN modeling with reduced sampling data. A similar idea of utilizing prior data for Gaussian process modeling is presented in the work of Pfingstl and Zimmermann (2022). The concept of meta-learning is appealing to address the computational problem with time-variant reliability analysis.

This paper proposed a meta-learning framework for time-variant reliability analysis in a way to significantly reduce the computational effort for surrogate training. Time-variant surrogate-assisted reliability problem is treated as a series of similar training tasks. The goal of the proposed meta-learning is to learn the prior knowledge that can generalize across the various training tasks, thereby accelerate the subsequent training process. This computational scheme can achieve higher efficiency in terms of utilizing the deep neural network training from earlier point-in-time reliability analysis. In other words, the computational scheme “learned” to improve the efficiency of reliability analysis as time evolves. The proposed method is illustrated with a simple corrosive beam problem.

2 META-LEARNING FRAMEWORK FOR TIME-VARIANT RELIABILITY ANALYSIS

2.1 Time-variant reliability analysis

It is considered that a time-variant reliability problem can be defined with a limit state function, $G(t) = g(X(t))$, where $X(t) = [X_1(t); X_2(t), \dots, X_n(t)]$ is an n-dimensional time-variant random variable vector. If $G(t) \leq 0$, the structure is considered to be in the failure domain, otherwise it is safe. The probability failure over time is expressed as:

$$P_f(T) = P(G(t) \leq 0), \exists t \in [0, T] \quad (1)$$

where T is the point in time during the life cycle; $P_f(\cdot)$ denotes the probability of failure.

2.2 Deep neural network for limit state function approximation

A reliability analysis framework based on the DNN model can be used to approximate the limit state function in order to improve efficiency. The DNN model transforms the feature representation of the sample from the original space to a new feature space to make classification or prediction easier. The typical structure of the DNN is shown in Figure 1. It consists of the input layer, several hidden layers, and the output layer. In this work, the input is the time-variant random variable $X(t)$ of specific problems, and the output is the predicted value of the limit state equation $G(t)$.

2.3 Model-agnostic meta-learning algorithm

This work proposes a meta-learning method for time-variant reliability analysis. The reliability analysis framework has a meta-training phase and a learning phase as shown in Figure 2. For the meta-training phase, Model-agnostic meta-learning algorithm (MAML) (Finn et al.

2017) is used to obtain the meta-trained model, which represents the knowledge learned from the earlier time DNN training tasks. For the learning phase, DNN models are adapted from the meta-trained model to accelerate training for subsequent tasks.

The meta-trained model parameterized by θ'_{mt} and the DNN model for new task T_w parameterized by θ'_w are denoted as f'_{mt} and f'_w . The goals of the meta-training phase and the learning phase are to find the optimal neural networks parameters θ'_{mt} and θ'_w .

To obtain the optimal θ'_{mt} , each epoch of MAML consists of the following steps.

- (a) Sample N_s tasks $(T_{s1}, T_{s2}, \dots, T_{sn})$ from the earlier time tasks.
- (b) For $T_{si} \in (T_{s1}, T_{s2}, \dots, T_{sn})$, the DNN model f'_{mt} is adapted from θ'_{mt} by using data points from T_{si} . The specific process is as follows, θ'_{si} is updating using one gradient descent

$$\theta'_{si} = \theta'_{mt} - \alpha \nabla_{\theta'_{mt}} \mathcal{L}_{T_{si}}(f'_{\theta'_{mt}}) \quad (2)$$

where α is the learning rate of the inner loop, and $\mathcal{L}_{T_{si}}$ is the loss function associated with T_{si} .

Figure 1. The construction of the DNN model.

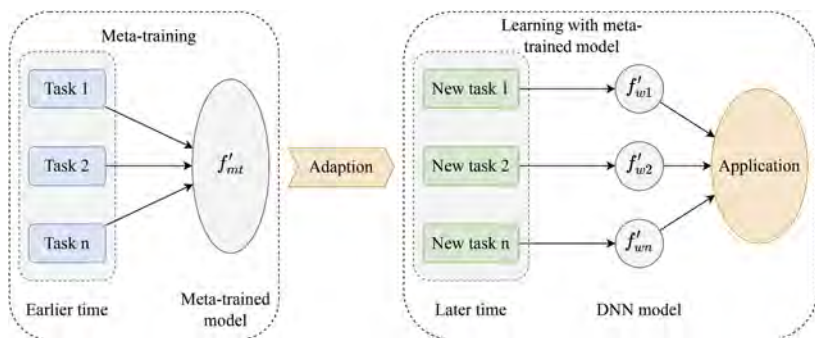

Figure 2. Meta-learning-based DNN modelling framework(Adapted from (Cheng et al. 2022)).

- (c) The DNN model θ'_w is adapted from θ'_{mt} by using new data points from all tasks. θ'_w is updated using gradient descent

$$\theta'_{mt} \leftarrow \theta'_{mt} - \beta \nabla_{\theta'_{mt}} \sum_{T_{si}} \mathcal{L}_{T_{si}}(f'_{\theta'_{si}}) \quad (3)$$

where β is the learning rate of the main loop. The purpose of meta-training is to find θ'_{mt} that minimizes \mathcal{L}_{T_m} . The procedure is shown in Algorithm 1.

Once the meta-trained model is available, the next step is to update the DNN model from the meta-trained model on specific tasks. When optimizing θ'_w , the first update is an update from θ'_{mt} , which represents the adaptation from the meta-trained model:

$$\theta'_w = \theta'_{mt} - \alpha \nabla_{\theta'_{mt}} \mathcal{L}_{T_w}(f'_{\theta'_{mt}}) \quad (4)$$

while later updates using the same data points are

$$\theta'_w = \theta'_w - \alpha \nabla_{\theta'_w} \mathcal{L}_{T_w}(f'_{\theta'_w}) \quad (5)$$

In this paper, stochastic gradient descent is used for Eq.(2), while the Adam optimizer (Kingma & Ba 2014) is used for other updates.

Algorithm 1 MAML for the meta-training phase (adopted from (Finn et al. 2017))

Require: α, β : step size hyperparameters
1: Randomly initialize θ'_{mt}
2: **while** not done **do**
3: Sample N_s tasks $(T_{s1}, T_{s2}, \dots, T_{sn})$;
4: **for** all T_i **do**
5: Sampling data points from existing data points;
6: Evaluate $\nabla_{\theta'_{mt}} \mathcal{L}_{T_{si}}(f'_{\theta'_{mt}})$;
7: Compute adapted parameters with gradient descent: $\theta'_{si} = \theta'_{mt} - \alpha \nabla_{\theta'_{mt}} \mathcal{L}_{T_{si}}(f'_{\theta'_{mt}})$;
8: **end**
9: Update $\theta'_{mt} \leftarrow \theta'_{mt} - \beta \nabla_{\theta'_{mt}} \sum_{T_{si}} \mathcal{L}_{T_{si}}(f'_{\theta'_{si}})$;
10: **end**

2.4 Meta learning for time-variant reliability analysis

For time-variant reliability analysis, the meta-training set is obtained by selecting the time interval. As shown in Figure 3, tasks in the earlier time interval are sampled as the meta-training set, and DNN models are adapted from the meta-trained model by training on data points from the later time interval.

Figure 3. Division for meta-training and meta-learning tasks.

To implement the framework for specific problems, it is important to know what can be categorized as meta-training tasks. In this work, tasks within a time interval have a certain degree of similarity. In the meta-training phase, when using tasks in an appropriate time interval as the meta-trained model training set, the meta-trained model will show better performance in predicting tasks at later time, and it can reduce the number of epochs required for the learning phase. In contrast, if an inappropriate meta-training set is selected, the trained meta-trained model may not be effective. In the learning phase, the converged meta-trained model is used to predict tasks at later time points. As the time point moves away from the time interval which is used to construct the meta-trained model training set, the performance of the meta-trained model gradually degrades. In this case, it is possible that the meta-trained model is less effective than a randomly initialized DNN.

3 ILLUSTRATIVE EXAMPLE

3.1 Corrosion beam problem

For illustrative purposes, a simple-supported beam corrosion problem is used here. The cross-section shape of the beam is shown in Figure 4. The size of the cross-section decreases with time due to the corrosion.

Considering the material properties and manufacturing errors, the yield strength of the material σ (MPa) and the length of corroded beam L (m) are treated as random variables that follow normal distributions, where $\sigma \sim N(200, 20^2)$ and $L \sim N(8.5, 0.2^2)$. The material mass density, ρ (kN/m³), the height $h(t)$ and the beam breadth $b(t)$ (m) are assumed to be uniform distributed variables listed in Table 1. An stochastic load F (kN) is applied on the middle point of the beam, which follows normal distribution, where $F \sim N(5000, 700^2)$.

Figure 4. Corroded beam under midspan load.

Table 1. Uniform random variables in the corroded beam problem.

Variable	Distribution	Mean	Radius
ρ (kN/m ³)	uniform	78	0.5
$b(t)$ (m)	uniform	$0.3-5 \times 10^{-4}t$	0.015
$h(t)$ (m)	uniform	$0.05-4 \times 10^{-4}t$	0.004

According to the mechanical analysis, the failure event occurs when the maximum stress exceeds the yielding limit of the beam, and the limit state function associated with the failure is expressed as:

$$G(\sigma, L, \rho, F, b(t), h(t)) = \frac{b(t)h(t)^2}{4} \sigma - \left(\frac{FL}{4} + \frac{\rho b(t)h(t)L^2}{8} \right) \quad (6)$$

3.2 Results

The considered time period is given as [20, 30] month in this problem. For the DNN architecture, the hidden layer number is set to two. The first hidden layer has 128 neurons and the second has 64 neurons. For meta-training, t varies from time t_1 to time t_2 , where t_1 and t_2 belong to [1, 30] and t_1 is less than t_2 . For task after time t_2 , the surrogate $\hat{G}(\sigma, L, \rho, F, b(t), h(t))$ is adapted from the meta-trained model. As a comparison, a randomly initialized DNN is used to solve the same task. The following concrete example can illustrate the performance of MAML.

In this illustrative example, t_1 and t_2 are set to 20, and 25 in meta-training, respectively. The number of Monte Carlo simulations is 10^6 . For new tasks, the DNN training is adapted from a meta-trained model or randomly initialized DNN. As shown in Figure 5, the time-variant failure probability in the time interval [20, 30] is illustrated. For the randomly initialized neural network and meta-trained model, when updating the model, the number of data points and convergence epochs are the same. The specific improvement of efficiency is shown in Table 2 and Figure 6. The difference between the predicted failure probabilities and those obtained by Monte Carlo sampling is less than 3%, which represents the model has converged. In this example, it is found that randomly initialized DNN models cannot converge to the

Figure 5. Time-variant probability failure of the corroded beam.

target value when using a small number of data points. Therefore, the number of sampling data points is selected to be 5000 to ensure that both MAML and DNN can meet the requirements. The DNN model based on the meta-trained model converges with fewer epochs, and the failure probability curve varies smoothly. As the time point of a new task becomes farther away from the time interval set in the meta-training phase, the efficiency of the meta-trained model will decrease, and it may be worse than a randomly initialized DNN. This problem can be solved by changing the time interval set in the meta-training phase.

Figure 6. Task 1, 2, 3 and 4, comparison of results on the same data points.

4 CONCLUSIONS

This paper presents an initial study of applying the meta-learning method for time-variant reliability analysis. Time-variant reliability analysis is an essential computational procedure to

Table 2. Comparison results of the proposed method with randomly initialized DNN on the same data points.

* Each value in Epoch column is the average of 5 runs.

quantify the failure probability and risk over the life-cycle of deteriorating structures. Based on the model-agnostic meta-learning algorithm, the meta-trained model is obtained by using data points from an earlier time as the meta-training set. The DNN model is adopted from a DNN initialized with meta-trained model parameters. This method can speed up the training process and achieve higher efficiency for life-cycle analysis.

Optimization of sewer flushing programs: A deep reinforcement learning approach

A. Keshvari Fard & X.-X. Yuan

Department of Civil Engineering, Toronto Metropolitan University, Toronto, ON, Canada

ABSTRACT: Flushing programs are critical for managing municipal sewer assets and require efficient planning and funding. The multi-year flushing program planning decision is a complex and challenging problem involving a vast number of decision alternatives and dependencies among asset components. This paper presents a deep reinforcement learning (DRL) approach to solve this problem. The sewer network is divided into catchments and flushing decisions are made at the catchment level. The problem is formulated as a Markov decision process with the goal of maximizing the expected cumulative flushing effectiveness reward. The annual budget has a lower and upper bound, and unused budget can be saved for future years. The results show that the DRL approach performs better than a conventional genetic algorithm and is close to the Pareto frontier, particularly for longer planning horizons.

1 OVERVIEW

Sanitary sewer systems are an important class of municipal infrastructure assets. As the service age of these infrastructure assets accumulates, they deteriorate in both functional capacity and structural integrity (Yuan, 2016). Obstructions in the sewer network, such as tree roots, solidified grease, and illegally dumped waste, can impede the flow of water and decrease the system's overall capacity, which is considered an operational failure. If this capacity falls below the amount of water being discharged into the system, it can lead to overflowing, which poses risks to properties, the environment, and public health (Phillips et al., 2012). Municipalities are therefore responsible for developing proactive maintenance interventions, such as flushing, for maintaining the networks at the desired level of service and reducing the risk of blockages and overflows (Weatherly et al., 2017; Halfawy et al., 2009).

Municipalities need optimization tools to prioritize sewer segments for flushing at the network level due to their limited workforce and budgets allocated for maintenance activities. In most flushing programs, the flushing cycle is designed for a finite horizon, thus ensuring that every pipe segment is flushed at least once during the cycle. This requires determining which sewer segments need to be flushed each year so as to achieve maximum network performance while remaining within budget constraints. To reach an optimal solution, this problem requires integrated planning for the entire period since each sewer segment may degrade at different rates, and its condition at a specific time depends on the flushing decisions taken in previous years. For multi-year planning, the problem is traditionally formulated as integer programming. However, due to the nonlinear relationship between the network performance and the decision variables, this is a challenging optimization problem to solve. Moreover, when the annual budget is allowed to be transferred between years, this budget variation allowance adds another layer of complexity to the problem. All of these call for more effective solution strategies.

Recently, researchers have explored various approaches for optimizing sewer system maintenance. Abraham et al. (1998) proposed an optimization model for sewer management using a Markovian approach and dynamic programming. Elmasry et al. (2019) used mixed integer linear programming for multi-objective optimization of sewer inspection scheduling. Fontecha et al. (2020) employed linear programming for short-term maintenance scheduling. Many studies have also used evolutionary optimization methods, such as genetic algorithms, but

they have limitations in reaching the optimal solution (Tack and J. Chou, 2002; Altarabsheh et al., 2018; Chan et al., 1994; Fwa et al., 1994; Liu et al., 1997).

Markov Decision Processes (MDP) is a mathematical framework for making decisions in systems where the future state of the system depends only on the current state and the action taken rather than the entire history of states and actions. MDPs are often used to model and optimize the long-term behaviour of engineering systems, such as infrastructures (Golabi et al., 1982; Madanat, 1993), through the use of dynamic programming (Bellman, 1966). Machine learning techniques, particularly deep reinforcement learning, have been applied to optimize maintenance and renewal plans modelled by MDP. Mohammadi and He (2022) used deep reinforcement learning to optimize rail maintenance, with a reward function based on cost-effectiveness and hazard improvement. Cheng et al. (2022) compared two reinforcement learning methods for optimizing dynamic inspection policies in condition-based maintenance. Du and Ghavidel (2022) developed a deep reinforcement learning framework for maintenance decision-making in a highway bridge portfolio, and Cheng and Frangopol (2021) used deep reinforcement learning for load rating planning of bridges.

Overall, it is clear that there are a variety of approaches that have been proposed for optimizing the maintenance of sewer systems. While traditional optimization methods have been widely used for maintenance planning, there is also a growing interest in the use of machine learning techniques, such as deep reinforcement learning to improve the decision-making process. However, more research is needed to evaluate the effectiveness of these approaches in real-world scenarios and to identify the best practices for implementing them in practice. The objectives of the paper are twofold: First, develop a deep reinforcement learning approach for sewer network maintenance planning problem, and second, evaluate the performance of the proposed algorithm by comparing its optimality with genetic algorithm results.

2 PROBLEM STATEMENT

The optimization of sewer flushing programs is a complex problem for municipalities to enhance network performance while utilizing limited resources efficiently. The flushing program is usually optimized for a defined horizon to determine which sewer segments should be flushed every year to achieve maximum network performance while maintaining budget constraints. The flushing program usually starts in the summer and covers a certain percentage of the network each year. The annual budget can be flexible and may include a predefined level of variation tolerance. A sewer network is typically divided into catchment areas to account for the operational and spatial dependencies between sewer segments. All segments within a catchment must be flushed together to maximize the flushing effectiveness. This means that all segments within a catchment are considered as a single unit in the decision-making process, and asset managers must determine which catchments to flush in each year of the planning horizon.

2.1 Deterioration model

Markov chain models are frequently used to represent the deterioration of sewer conditions (Baik et al., 2006; Altarabsheh, Kandil, and Ventresca, Altarabsheh et al.). Protocols like WRC-MSCC and NASSCO-PACP categorize sewer condition data into five levels, where 1 represents excellent condition, and 5 represents the worst. The deterioration transition probability matrix for each sewer segment, represented by \mathbf{P} , is a 5×5 matrix, where each element, p_{ij} , is the probability of transitioning from state i to state j in one year. The maintenance effectiveness matrix, \mathbf{M} , models the improvement in sewer condition after flushing.

Considering all the segments in a catchment as a single unit simplifies the problem. This allows the overall condition of catchments to be considered instead of the condition of each segment. The catchment state vector represents the percent of the total length at each state. The initial state vector is determined by averaging the initial states of all sewer segments within the catchment. The equivalent transition probability matrix of the catchment is a weighted average of its sewer segments' matrices. The equivalent maintenance effectiveness matrix is also derived with the same method. The expected catchment condition is predicted following the Kologmorov-Chapman equation once the initial state vector and the catchment deterioration transition matrix are determined.

2.2 Problem formulation

The objective of this optimization problem is to minimize the overall average condition of a sewer network, which is made up of n catchments, over a h -year planning period. This objective function can be represented mathematically as:

$$\text{Minimize } \frac{1}{Lh} \sum_{j=1}^h \sum_{i=1}^n l_i \mu_{ij} \quad (1)$$

where l_i is the length of catchment i ; L is the total length of the network ($L = \sum_{i=1}^n l_i$); and μ_{ij} is the average condition of catchment i at the end of year j , which can be calculated by $\mu_{ij} = s_{i,j}v'$, where v is the state space vector (1,2,3,4,5) and $s_{i,j}$ is the state probability vector represents the probabilities that the catchment i is being in each state, at the end of year j .

The change in the condition of each catchment over time is affected by both the natural deterioration process and the flushing decisions made. This is modelled using Equation 2, where x_{ij} is a binary variable representing the decision to flush catchment i in year j . If flushing is done, the variable is set to 1, and 0 otherwise. The equation states that without flushing, the condition follows the natural deterioration process described by the matrix P_i , but with flushing at the end of the decision year, the condition is updated by the maintenance effectiveness matrix M_i .

$$s_{ij} = (1 - x_{ij})s_{i,j-1}P_i + x_{ij}s_{i,j-1}P_iM_i \quad (2)$$

The flushing program is subject to the following constraints:

$$\sum_{j=1}^h \sum_{i=1}^n c_F l_i x_{ij} \leq B \quad (3)$$

$$\left| \sum_{i=1}^n c_F l_i x_{ij} - \frac{B}{h} \right| \leq \frac{B}{h} \tau, \forall j \in (1, 2, \dots, h) \quad (4)$$

$$\sum_{j=1}^h x_{ij} \geq 1, \forall i \in (1, 2, \dots, n) \quad (5)$$

Constraint (3) limits the total program cost with respect to the total available budget (B). In this constraint, c_F is the cost of flushing per unit length of the sewer. According to constraint (4), annual budget variations, with regards to the average annual budget (B/h), must not exceed the allowable tolerance (τ). Also, constraint (5) guarantees that every catchment will be flushed at least once within the planning horizon.

The condition of each catchment at a specific year is determined by all the decisions made in previous years. Therefore, the overall condition of each catchment, represented by μ_{ij} , is a function (Equation 6) of the initial condition vector of the catchment, $s_{i,0}$, the transition probability matrix, P_i , the flushing effectiveness matrix, M_i , and decision variables (x_{ij}), from year one (x_{i1}) up year j (x_{ij}). Therefore, the objective function is not a linear function of the decision variables for planning horizons greater than one year ($h > 1$).

$$\mu_{ij} = f(s_{i,0}, P_i, M_i, x_{i1}, x_{i2}, \dots, x_{ij}) \quad (6)$$

3 PROPOSED RL METHODOLOGY

An MDP environment is defined by a set of discrete states, S , a finite set of actions, A , a stochastic transition model, P , and a reward function, r . At each decision step, the agent observes the current state, s_t , takes action a_t , and receives a reward r_t based on the reward function. The agent then proceeds to the next state, s_{t+1} , according to a known stochastic model with transition probability $p(s_{t+1}|s_t, a_t)$.

In this framework, a policy, π , is defined as a state-dependent sequence of actions. It is a mapping from states to actions. The decision-maker's goal is to maximize the total return, R_t , it receives in the long run from any time step, t , to the end of the planning horizon, and this criterion is the primary basis of altering a policy. The total return, from time t to the end of the planning horizon, is calculated as follows:

$$G_t = r(s_t, a_t) + \gamma r(s_{t+1}, a_{t+1}) + \dots + \gamma^{T-t} r(s_t, a_t) = \sum_{i=t}^T \gamma^{i-t} r(s_i, a_i) \quad (7)$$

where γ is a discount factor, $0 \leq \gamma \leq 1$, that determines the present value of future rewards. The total return can be conditioned on the current state and action pair, called *action-value function* $Q^\pi(s_t, a_t)$, and denoted the value of taking action a_t in state s_t under a policy π . In other words, $Q^\pi(s_t, a_t)$ is the expected return starting from s_t , taking action a_t , and thereafter following policy π :

$$Q_\pi(s_t, a_t) = \mathbb{E}_{s_t > r, a_t > r} [G_t | s_t, a_t] \quad (8)$$

and using Equation 7, the action-value function can be formulated recursively as follows:

$$Q_\pi(s_t, a_t) = r(s_t, a_t) + \gamma \mathbb{E}_{s_{t+1}, a_{t+1}} [Q_\pi(s_{t+1}, a_{t+1})] \quad (9)$$

The best action at each given state s is determined by selecting the action that maximizes the expected return starting from s . By having optimal action-value function, Q^* , we can directly find the optimal action by $a^*(s) = \arg \max_a Q^*(s, a)$. It can be proven that for an MDP with a discount factor less than 1, there exists at least one optimal deterministic policy (Sutton and Barto, 2018). The optimal action-value function $q^*(s_t, a_t)$, follows the Bellman equation and can be recursively formulated by Equation 10:

$$Q^*(s_t, a_t) = r(s_t, a_t) + \gamma \sum_{s_{t+1} \in S} p(s_{t+1} | s_t, a_t) \left[\max_{a_{t+1} \in A} Q^*(s_{t+1}, a_{t+1}) \right] \quad (10)$$

3.1 Deep reinforcement learning

Reinforcement learning can be viewed as a broad class of learning problems in which an agent interacts with a dynamic, stochastic, and incompletely known environment to find a decision-making strategy (policy) for taking actions in order to optimize a measure of its long-term performance (Sutton and Barto, 2018). The Q-learning algorithm (Watkins and Dayan, 1992) is a popular method for solving RL problems using a value-based approach. It aims to find the optimal action-value function, $Q^*(s, a)$. The Q-learning algorithm uses a Q-table to store the estimated action-value function and updates the Q-values iteratively using the temporal difference (TD) error, which measures the difference between the current estimate and the expected future return. The Q-table is updated according to the following update rule:

$$Q(s_t, a_t) \leftarrow Q(s_t, a_t) + \alpha (r + \gamma \max_{a_{t+1} \in A} Q(s_{t+1}, a_{t+1}) - Q(s_t, a_t)) \quad (11)$$

where α is the learning rate. The Q-learning algorithm converges to the optimal action-value function as the number of iterations increases.

The conventional Q-learning method uses a tabular form to represent the action-value function. However, this method becomes intractable for systems with a large number of states and actions. To overcome this problem, deep reinforcement learning (DRL) utilizes deep neural networks as a function approximator to provide an accurate representation of the value function in large state-action spaces. This allows for the problem of determining the action-value function for every point in the state-action space to be reduced to determining the optimal value of the parameters of the neural network function approximator. One popular DRL method is using deep Q-learning (DQL), which was first introduced by Mnih et al. (2013) and allows for the estimation of the value of an action using a function approximator, $Q(s, a; \theta) \approx Q^*(s, a)$, instead of using a Q-table. As a function approximator for Q-values, a simple deep neural network called deep Q-network (DQN) is used under the principle of

Q-learning. This deep neural network gets the states as input and estimates the Q-values for all possible actions in the output layer. Therefore, the number of nodes in the input layer and output layer equals the size of the state space and action space, respectively. At time step t , the approximate target value of an action is calculated as follows:

$$y_t = r(s_t, a_t) + \gamma \max_{a_{t+1} \in A} Q(s_{t+1}, a_{t+1}, \theta) \quad (12)$$

where θ represents the parameters of DQN, which are updated by minimizing the mean squared error (MSE) between the approximated and the target Q-value. The parameters of DQN are updated using stochastic gradient descent through the back-propagation process according to Equation 13:

$$\theta_{i+1} = \theta_i + \alpha [y_t - Q(s_t, a_t; \theta_i)] \nabla_{\theta} Q(s_t, a_t; \theta_i) \quad (13)$$

3.2 DQN configuration for sewer flushing program

Figure 1 presents the DQN designed to optimize the flushing program for a sewer network. The state space includes the overall condition of the network, current decision year, remaining budget, and each catchment's condition. The action space consists of all possible binary decisions for all catchments, making it a combinatorial space of 2^n possible actions. The DQN architecture includes two hidden layers with 64 neurons each, with input and output layers. The reward function is the effectiveness of the annual flushing plan and is calculated as $1 - s_{t+1}$, where s_{t+1} is the normalized overall condition of the network at the beginning of the next year. The annual budget and one-flush constraints are also considered in the reward function, with penalties applied if violated.

Figure 1. Neural network architecture of the proposed methodology.

4 RESULTS

The case study is based on a real-world example of a town's sewer network in Ontario. The studied network is composed of 531 sewer segments, which are grouped into seven catchments. The planning horizon for this study is seven years, with a time interval of one year. The transition probability matrix for each sewer segment is calculated using a regression equation that takes into account the pipe attributes of length, diameter, and slope (Lin et al., 2019). It is assumed that the flushing procedure is perfect maintenance, meaning that after flushing a segment, its condition is immediately changed to excellent. The cost of flushing per unit length of sewer is \$1.38, and the available budget for the whole period is \$70,000. Therefore, the average available budget for each year is \$10,000. The allowable tolerance for annual budget variation with regard to the average budget is 15 percent, meaning that the allowable range for the annual budget is [\$8,500, \$11,500].

In this study, a DQL agent was trained¹ to optimize the flushing program for a 7-year period in the case study. The training involved 20,000 simulations (episodes), each representing a simulation

1. <https://github.com/amirkfard/Deep-Q-Learning-Infrastructure-network-planning>

of seven years using Markov decision processes. The agent’s goal is to select the optimal catchments to flush each year in order to achieve the highest possible flushing effectiveness over the 7-year horizon. All the results are obtained on a desktop computer operating 64-bit Microsoft Windows with a Xeon(R) W-2155 processor at 3.3 GHz and 32GB RAM. During the learning process, the DQN learning rate (α) is 0.0005, the discount factor (γ) is 0.99, and the epsilon decay rate is 0.9995.

The result of the training process is shown in Figure 2. Each point represents one simulation and the associated total reward. Through repeated training episodes, the DQL agent was able to learn and improve its decision-making strategies, ultimately leading to the selection of a flushing plan that achieved high flushing effectiveness (minimizing overall network condition). The outcome of the optimized policy is presented in Table 1. The objective value (seven-year average network condition) of this plan is 2.412. Each column in the table provides the annual flushing plan and specifies the catchments which must be flushed that year. The last row of the table presents the cost of the plan for each year, and the total program cost is \$69,494.9.

Figure 2. The performance of DQL during training for 7-year plan.

Table 1. Optimized flushing program.

Catchment	Year 1	Year 2	Year 3	Year 4	Year 5	Year 6	Year 7
1		✓				✓	
2		✓			✓		✓
3	✓		✓		✓		✓
4		✓				✓	
5				✓			
6			✓		✓		
7	✓					✓	
Annual cost	9,471.9	9,564.0	9,836.5	10,155.7	11,430.9	9,552.2	9,483.7

The OR-Tools library (Perron and Furnon, 2019) was used to find feasible solutions using a constraint programming method based on considering all possible decision sequences for each catchment. The total number of feasible solutions found was 10,571,631. The results are presented in Figure 3, which shows the distribution of feasible solutions in terms of the flushing program cost and the performance of the program. The best solution found is highlighted in green, with an objective value of 2.400 and a total cost of \$69,814.0.

The performance of a proposed methodology is also compared with Genetic Algorithm, which is a commonly used method in the literature. The python library Deep (Fortin et al., 2012) was used to implement GA. The initial population consisted of 300 random individuals, each having 49 binary genes representing a seven-year flushing plan for seven catchments. The two-point crossover and mutation probabilities were set at 0.9 and 0.1, respectively. The Hall of Fame method was also used to improve performance. For each optimization round, the number of generations was set at 1000, which took about 508.7 seconds on average to complete. This computation time is roughly the same as the 20,000 episodes in the DQL algorithm (which took 507.8 seconds to complete), making the comparison fair in terms of optimization time.

The solutions obtained from two different methods, GA and DQL (100 results each), are highlighted in blue and red, respectively. The graph shows that the solutions found by DQL are more consistent and lie on the Pareto frontier, while the solutions found by GA are more scattered with lower flushing program performance.

Figure 3. Feasible solution region and distribution of DQL and GA results.

The results presented in Table 2 provide insight into how the length of the planning horizon affects the performance of two different approaches for solving the problem of sewer network flushing optimization. The average performance of plans generated by DQL and GA are compared for different planning horizon lengths of 7, 14, 21, and 28 years. The results show that as the planning horizon increases, the performance of GA decreases, while the performance of the DQL approach remains relatively consistent. The numbers in the parenthesis show the portion of infeasible outcomes of each method at different planning horizons, which demonstrates, e.g., for 28-year planning horizon, the GA method cannot reach a feasible plan in 57% of the solution outcomes. This suggests that the GA may not be an effective algorithm for longer planning horizons. On the other hand, the DQL approach appears to be less affected by the length of the planning horizon, and it is a more suitable approach for longer planning horizons.

Table 2. The effect of planning horizon on the performance of DQL and GA.

Horizon	7 years	14 years	21 years	28 years
GA	2.564 (0.02)	2.732 (0.09)	2.791 (0.38)	2.823 (0.57)
DQL	2.423 (0.00)	2.491 (0.00)	2.496 (0.00)	2.493 (0.00)

5 CONCLUSION

In this paper, we proposed a DQL approach to solve the flushing program optimization problem for sewer networks. Results showed that the DQL approach produces plans with a higher overall performance than the GA approach, particularly for longer planning horizons. DQL’s solution landscape is also closer to the Pareto frontier, which represents the set of optimal solutions. However, the limitations of DQL in dealing with combinatorial action spaces need further research. To address this, solutions such as multi-agent RL, hierarchical RL, or changing the decision variables to continuous ones have been proposed. Overall, the DQL approach is a promising solution for infrastructure network maintenance planning and a valuable addition to existing methods for solving sewer network flushing program planning.

Carbon emission reduction in railway maintenance using reinforcement learning

J. Sresakoolchai & S. Kaewunruen

School of Civil Engineering, University of Birmingham, Birmingham, UK

ABSTRACT: At present, the effect of global warming becomes more severe due to carbon emissions. This negative effect attracts the interest of the international community to minimize it. The railway industry is an industry in which carbon emission cannot be neglected due to the sizes of projects, long operation and maintenance stages in the service life, including sources of energy that might not be clean in some areas. This study aims to minimize the negative effect of the railway industry on the maintenance aspect by using reinforcement learning to optimize maintenance activities. The maintenance in the railway industry is a complicated task and might not be optimized in terms of cost efficiency, serviceability, and environmental impact. The use of reinforcement learning can improve the overall efficiency of railway maintenance as it has been proven in many tasks in the railway industry and other industries. Data used to develop the machine learning model are based on field data collected during 2016-019. The length of the studies section is 30 km. Sources of data are from track geometry cars, maintenance reports, defect reports, and maintenance manuals of the sampled railway operator. The methodology used in the study is Proximal Policy Optimization (PPO). The results show that the use of reinforcement learning can reduce the carbon emission from railway maintenance activities by 48% which causes a significant amount of carbon emission while the railway defects are reduced by 68% which improved maintenance efficiency.

1 INTRODUCTION

Carbon emission is one of the causes of severe global warming and climate change nowadays. Therefore, carbon emission attracts more attention. The international community then tries to reduce it to minimize the negative effect on the environment. Although someones claim that railway transportation is one of the transportation modes that are environmentally friendly. However, it cannot be denied that many activities in the railway industry also create carbon emissions. For example, the construction of a railway project needs a lot of construction materials their production processes emit carbon or the sources of energy that are used to operate the railway may not totally clean. In addition, railway projects have long service life so the operation and maintenance phase also cause carbon. Therefore, minimizing carbon emissions in railway activities will be able to significantly minimize the negative effect on the environment.

This study aims to reduce carbon emissions from railway maintenance activities using reinforcement learning (RL). A technique used to develop a deep RL model is Proximal Policy Optimization (PPO). Data used to develop the RL model is collected from field data. The samples section is 30 km long. The duration of data collection is 2016-2019. Sources of data are from track geometry parameters collected using track geometry cars, track inspection reports showing track component defects, and maintenance reports showing performed maintenance activities during the interesting duration. Data from different sources are processed and combined together to feed into the RL model. Then, a maintenance manual of the sampled authority will be used to compare and define thresholds to create the customized RL

environment which will be used to define rewards for the RL's agent in the RL model training process. The expected contributions of the study are the developed RL model can be used by railway operators to plan railway maintenance activities more efficiently when carbon emission from maintenance activities is reduced as well as the number of railway defects. These will result in the improvement of an environmentally friendly railway system, and better serviceability, reliability, and safety in the railway system due to few defects occurring in railway networks. In addition, the developed RL model can be used to support decision-making for railway maintenance if railway operators are not ready to use a data-driven scheme in which decision-making completely relies on data and the RL model.

2 LITERATURE REVIEW

RL was first introduced in the early 1980s. It was developed to solve problems about how to react or what to do when we are in different situations (Sutton and Barto, 2018). The purposes of different reactions are to maximize rewards or outcomes from actions. As a representative, an agent is used and trained to know how to respond to different situations. The agent is not told how to do but it has to explore by itself how to maximize rewards at the latest stage. A challenge is each action not only affects the immediate rewards but also what happens next (stage). All of these are the important characteristic of RL that other types of machine learning techniques do not have and cannot resolve.

Examples of popular RL applications are chess and other game players, robots in industries, or pilot assistance in passenger cars (Sutton and Barto, 2018). Many methods are used to solve RL problems. One of the first methods is Tabular Solution Method which is the simplest. Then, other techniques were developed to be used with RL such as Markov Decision Processes, Dynamic Programming, or Monte Carlo Methods. During the last decade, many techniques have been developed to extend the potential of RL and other recent RL models have been developed and proven that the performance is better.

RL is one of the main categories of machine learning among supervised and unsupervised learning. RL becomes more popular because it has a capability that supervised and unsupervised have not. RL can react to specific environments and be trained to respond to environments that optimize rewards. Therefore, RL can be used to solve problems by finding the best responses or actions under specific situations. The interaction of the RL model is done through an agent over time or stage. The agent will use the process of trial and error to find the optimum policy under different situations.

In each timestep or stage, two components continuously interact which are the agent and the environment. The environment will provide information to the agent through stages and rewards. Then, the agent will react to the environment by taking action. After that, new stages and rewards will be provided by the environment to the agent again. This process will repeat until the end of the training. A simple flowchart of this process is shown in Figure 1. In every stage, a reward is provided to the agent based on how well the agent reacts to the environment. This will be used to find the best policy for the agent.

Reinforcement learning (RL) has been more popular in the last few years. It has been applied in many fields (Li, 2019) such as communication and networking (Luong et al., 2019), biology (Mahmud et al., 2018), electrical systems (Zhang et al., 2019), robotics (Kormushev et al., 2013), transportation (Abdulhai and Kattan, 2003), medical (Zhou et al., 2021), finance (Kolm and Ritter, 2020), or engineering (Andriotis and Papakonstantinou, 2019). Shaker et al. (2010) proposed a technique applying RL to assist in the landing of unmanned aerial vehicles. In that study, it was found that the RL agent could learn very fast and achieve the goal. Sun et al. (2017) applied RL to control and improve water use or agricultural irrigation. They found that RL could increase productivity while decreasing water use.

RL has been applied in the railway industry in different aspects. Šemrov et al. (2016) applied Q-Learning for rescheduling single-track trains. The action spaces of the agent consisted of two actions which were stop and go. Rewards were calculated based on delay. The model was tried with a three-station scenario. It was found that using RL could reduce delays

Figure 1. Simple flowchart of RL model.

in train schedules. This finding was also confirmed by Khadilkar (2018), Cui et al. (2016), Zhu et al. (2020b), and Cui et al. (2020). Other applications of RL in the railway industry were alignment optimization (Gao et al., 2022), power management (Xu and Ai, 2021, Zhu et al., 2020a, Deng et al., 2022), inspection (Zhong et al., 2021), and control (Wang et al., 2022).

For the environmental aspect, RL was used to manage the building energy (Yu et al., 2020) which showed that efficiency was improved by up to 30%. Cao and Wang (2022) applied RL to schedule the carbon emission of electric vehicles. They found that the use of RL could reduce carbon emissions by up to 20%.

From the literature review, there has never been a study applying RL for railway maintenance and carbon emission reduction. This research gap is interesting and is possible to be fulfilled using RL. Therefore, this study aims to apply RL to reduce carbon emissions generated from railway maintenance activities.

3 METHODOLOGY

3.1 *RL model*

This study applied PPO to develop the RL model. Referring to OpenAI (2017), PPO provides a better result than the state-of-the-art approaches while it is simple and easy to use and tune. PPO includes the supervised learning technique to implement a cost function. A concept is the RL model will try to minimize the cost function in each stage while keeping the deviation from the previous policy small. This creates less variance during the training process. As a result, the training will be smoother and prevent the agent from unreasonably reacting to the environment.

PPO applies the Actor-Critic scheme for the RL agent. The RL model comprises two parts which are the Deep Neural Nets of the Actor and the Critic. For the actor part, the model learns what action to take in specific situations. In other words, the agent will receive information from the environment. Information can be images or numerical data in the form of features like supervised learning. For the critic part, the model will receive information about actions and observe the next stage to evaluate how well those actions are. The positive and negative outcomes will be evaluated and updated by the critic part. In conclusion, the actor part has the function to select actions and the critic part has the function to tell whether those actions are good or bad. From this process, the agent will have the ability to learn which actions are good. If the new policy is better than the current one, the agent will update its policy. If not, the agent will keep the current policy.

3.2 Data characteristics and preparation

Data are obtained from a selected section of the 30-km track during 2016-2019. Sources of data are track geometry measurements, defect inspection reports, and maintenance records.

Track geometry measurement contained data of superelevation, longitudinal level (10m chord), longitudinal level (20m chord), alignment (10m chord), alignment (20m chord), gauge, and twist (20m chord).

Defect inspection reports contain data on different track component defects. To simplify the defects, defects are categorized using types of track components consisting of ballast, fastener, rail, sleeper, and switch and crossing. Track geometry parameters and component defects will be used as states of the RL model. Therefore, there are 12 features used as states to determine whether track sections have defects. For component defects, it is straightforward. However, for track geometry parameters, defective sections will be considered using thresholds defined by the railway authority. If track geometry parameters exceed the thresholds, they will be considered defective. The thresholds are shown in Figure 2.

Maintenance records collect data on performed maintenance activities on each track section. There are seven maintenance activities which are tamping, rail grinding, ballast cleaning, sleeper replacement, rail replacement, fastening components replacement, and ballast unloading.

Every source of data is combined to process and analyze the characteristic of data. These data will be used to develop the custom RL environment. Maintenance activities can be considered seven binary action spaces. In each stage, different maintenance activities can be combined and it will create a lot of diversity in performed maintenance activities. However, the data sources are rich enough to be numerically processed to support this diverse action space. In other words, the size of the data is big enough to tell how much track geometry parameters will improve or deteriorate when any maintenance activities are performed. At the same time, how much the probability of each track component defect will increase or decrease when different maintenance activities are performed. More detail will be described in the following section.

Figure 2. Track geometry thresholds.

3.3 Problem description

In the RL model, there are five components consisting of agent, environment, states, actions, and rewards.

In this study, the agent will learn how to perform maintenance activities according to 12 states which are seven track geometry parameters and five track component defects. There are five maintenance activities which are tamping, rail grinding, ballast cleaning, sleeper replacement, rail replacement, fastening components replacement, and ballast unloading that can be independently combined. Therefore, there are possible 128 combinations of maintenance activities. Different combinations of maintenance activities result in different improved and deteriorated track geometry parameters and the probability of track component defect occurrence that is obtained from the analysis of collected field data. The RL agent aims to minimize the maintenance activities to minimize the carbon emission while keeping tracks free from defects. Non-defective track means every track geometry parameter does not exceed defined thresholds and there is no track component defect.

The first stage of the RL model will have states or features as the field data. Then, the agent will randomly take actions that generate a new stage. This process will repeat 100 times which is the defined number for the agent to learn. Then, the reward will evaluate based on the actions. Rewards are defined by setting negative values of maintenance activities creating carbon emissions and penalties when tracks are defective. The penalties are set relatively high because maintenance aims to keep track in good conditions or defect-free. In a study done by Kaewunruen et al. (2021), they found that the maintenance activities of a 2.45 km track caused carbon emissions of 3,017 tCO₂e. In this study, the length of a section is 1 foot or 0.3 m. Form the calculation, the average carbon emissions per maintenance activity in a section is 0.37 tCO₂e. The agent is trained until the loss converges which demonstrates that the policy is optimized.

Then, results from field data and the RL model will be compared to evaluate the carbon emissions and the number of defects.

4 RESULTS AND DISCUSSION

The RL model is set to train for 100,000 epochs or training times. The RL model is developed using Python language. The technique used to develop the RL model is PPO as mentioned. The loss of the training is shown in Figure 3. It can be seen that after the model is trained for 30,000 epochs, the loss is equal or close to 0 which means the RL model is optimized and the training is done.

Figure 3. Training loss.

Figure 4 presents the differences between the number of performed maintenance activities and defects from field data and the RL model. From the field data, the number of performed maintenance activities and defects are about 963k and 520k respectively. However, the results from the RL model are 503k and 164k respectively. Therefore, the use of the RL model can reduce the number of performed maintenance activities by 48% and the number of defects by 68% which significantly improves the overall maintenance efficiency.

In terms of carbon emissions, assume that one maintenance activity causes a carbon emission of 0.37 tCO₂e. Therefore, the maintenance activities from the field data will create a carbon emission of 356,404 tCO₂e while the carbon emission from the maintenance when the RL model is applied is only 186,154 tCO₂e which is only 52% of the current carbon emission. Therefore, it can be concluded that the developed RL model can significantly reduce carbon emissions from the maintenance activities in the railway industry which conforms to the aim of the study.

Figure 4. Differences in the number of performed maintenance activities and defects from field data and the RL model.

5 CONCLUSION

This study aims to apply the RL model to reduce carbon emissions from railway maintenance. The technique used to develop the RL model is PPO. States used to train the agent consist of 12 parameters from track geometry parameters and track component defects. Combinations of seven maintenance activities are used to create the action spaces for the RL agent. Rewards are based on the number of performed maintenance activities and defects found in track sections. Therefore, the RL agent is trained to minimize the maintenance activities to reduce carbon emissions while keeping railway tracks defect-free. Data used to develop the RL model are from field data collected from the 30km track in 2016-2019.

The developed RL model can fulfill the aim of the study. It demonstrates the potential in reducing carbon emissions from railway maintenance by minimizing maintenance activities while limiting occurred defects. Compared to field data, the results from the RL model shows that it can reduce carbon emission by 48% and the number of defects by 68%.

Contributions of the study are the railway operators can use the concept from this study to develop their own RL model to support decision-making and plan the maintenance using their data. More states can be added to meet different requirements such as setting a limited budget for maintenance or time constraints to perform maintenance activities.

ACKNOWLEDGMENT

The authors also wish to thank the European Commission for the financial sponsorship of the H2020-RISE Project no.691135 “RISEN: Rail Infrastructure Systems Engineering Network”, which enables a global research network that addresses the grand challenge of railway infrastructure resilience and advanced sensing in extreme environments (www.risen2rail.eu).

ABSTRACT: Relying on the Science and Technology Demonstration Project of the Ministry of Transport for the safe and intelligent construction of the Fengjian Expressway in the Three Gorges Reservoir Area, this paper focuses on the long-term performance evolution and construction and operation safety of Daxihe Bridge, a steel-concrete composite beam cable-stayed bridge with a main span of 650m, and carries out the research and application of intelligent monitoring and fine construction control technology throughout the entire bridge construction and operation life cycle. Based on BIM and GIS, an intelligent monitoring and early warning system is constructed that incorporates monitoring of bridge construction, completed bridge load test, and operation-related health monitoring. This system realizes intelligent bridge construction monitoring and measurement, online monitoring of incremental and full data of completed bridge load test and health monitoring during operation, and guarantees the data continuity of construction monitoring and health monitoring, seamlessly connects the whole process of bridge construction, management, maintenance, and operation, and realize online perception, monitoring, identification, evaluation, and real-time warning of the effects of the environment and load on the bridge as well as the structural response, performance, state, and safety level.

1 INSTRUCTIONS

Bridge projects have high complexity, long periodicity, and numerous construction phases (Shang 2007), bridge workers suggest an intelligent whole-life design to address the flaws in bridge engineering, and the approach improves the basic framework and design methodologies in the design phase (Zhang et al. 2019), requiring that the comprehensive costs of operation, maintenance, management, and demolition after completion should be fully considered in bridge design to achieve long-term service levels with minimal input (Gu 2008), utilizing BIM technology in tandem with the most recent computer, information, and management technology to fundamentally address deficiencies in intelligent bridge construction (Chen et al. 2009 & Zou 2014).

The intelligent bridge structure consists of three parts: monitoring subsystem, diagnostic subsystem, and assessment subsystem (Zhou et al. 2019). Sensors are used in bridge health monitoring research to monitor key bridge parameters and thus predict structural degradation and damage mechanisms (Shan 2010, Hawk et al.1998, Söderqvist et al. 1998 & Thompsonet 1998). Cable-stayed bridges, as a cable-stayed load-bearing system, have greater spanning capacity than girder bridges, as well as good mechanical properties and economic indicators, are widely used in the construction of various types of bridges (Wu 2015, Wu 2015 & Jiang 2013). The bridge health monitoring team has conducted health monitoring studies on structures such as marine platforms and proposed a system design for construction monitoring, bridge

completion testing, operational health monitoring, and maintenance management of cable-stayed bridges (Zhang 2010, Li 2006 & Li 2006). The application of intelligent construction and control technology for cable-stayed bridges is gradually gaining attention (Tan 2006, Jiang et al. 2021, China J. Highw. Transp. 2021 & Lai et al. 2021).

In view of the long-term performance evolution of cable-stayed bridges and construction and operation safety issues, the intelligent construction and refined monitoring and control technology demonstration application is carried out during the construction-operation period based on the Daxihe Bridge, and an intelligent monitoring system considering bridge construction monitoring, bridge load test and operation health monitoring is built. The bridge construction monitoring and measurement is intelligent, and the online monitoring of the incremental and full data of the bridge load test and operation health monitoring ensures the continuity of the data of the construction monitoring and measurement and operation health monitoring, and the real-time monitoring and warning of the bridge structural status and safety level.

2 WHOLE LIFE-CYCLE INTELLIGENT MONITORING AND CONTROL SYSTEM SCHEME

2.1 *Project overview*

The Fengjian Expressway is located in Fengjie and Wushan counties in the hinterland of the Three Gorges Reservoir Area, with a total length of 48.752km. It has 20 bridges totaling 10533 m, including 5 extra-large bridges that are 6898m long and 13 great bridges that are 3483m long, for an 88.2% bridge to tunnel ratio. The project has a high ratio of bridges and tunnels, complex terrain, and difficult construction. Construction and operation safety is the focus of this project, and the durability and reliability of the bridges and their appurtenances need to be enhanced, as well as the use of advanced monitoring and control technologies to ensure construction safety and improve the quality of construction.

The Daxihe Bridge, a representative mega-span cable-stayed bridge in the project, adopts a double-tower, double-cable deck fan-shaped arrangement of cable-stayed wires, and the main bridge is a 650m steel-hybrid combination girder with a full-width of 27.6m. The main tower is a reinforced concrete structure with a diamond-shaped shape, and the tower pier is a single-box, three-compartment section. The diagonal cables are anchored by external steel anchor tubes at the ends of the girders, 208 diagonal cables with 1860MPa epoxy-coated steel strands are used throughout the bridge. The diagonal cables use a double corrosion protection system to ensure that they are corrosion-free throughout their design life (Yu et al. 2021). Because of the long cable and low self-vibration frequency, vibrations are extremely easy to happen under the excitation of wind load or vehicle load (Zhou et al. 2014, Zhang et al. 2016 & Sun 2020), which needs to be monitored and controlled to keep the amplitude of cable vibrations within an acceptable range. The effect of the whole bridge after the completion of the construction is shown in Figure 1.

Figure 1. Rendering of Daxihe Bridge, a mega-span cable-stayed bridge.

2.2 Program design

With 5G communication, cloud computing, big data, the Internet of Things, and intelligent control as the basic core technologies, the demonstration application of intelligent monitoring and refined construction control technology during the construction and operation of large cable bridges is carried out for the long-term performance evolution, construction and operation safety of bridges with large cable structure systems such as cable-stayed bridges and suspension bridges, and a comprehensive bridge construction monitoring, bridge load test, and operation health monitoring system is built on the Daxihe Bridge. The intelligent monitoring and early warning system (Figure 2), which integrates bridge construction, management, maintenance, and transportation, can sense, monitor, identify, evaluate, and warn about the effects of the environment and the load on the bridge as well as the structural response, performance, status, and safety level in real-time.

During the construction of the bridge, long-life maintenance-free intelligent sensors are buried to avoid damage to the bridge structure at a later stage of deployment and to provide instantaneous and cumulative monitoring of environmental parameters such as temperature, humidity, wind field, load effects such as automobile, ship impact, earthquake, structural mechanical responses including steel structure and concrete stress and cracks, main girder deformation, main cable and deck alignment, cable force, tower deflection, foundation settlement and dynamic characteristic parameters such as vibration and damping. It provides flawless structural response data to understand the long-term performance evolution of the bridge, uses 5G communication to wirelessly transmit stored data, images, and videos, and combines with IOT technology to realize bridge safety assessment and real-time warning on the BIM integrated management platform, records and responds to disasters promptly, and generates analysis reports quickly. It can effectively enhance the quality of bridge projects and guarantee the safety of construction and operation while also enhancing the scientific nature of bridge-bearing capacity assessment and safety warning. It can also significantly improve the quality of large cable-stayed bridge construction and operation management.

Figure 2. Design of the whole life-cycle intelligent monitoring and control system of Daxihe Bridge.

3 INTELLIGENT MONITORING AND CONTROL OF BRIDGE PROJECTS DURING THE CONSTRUCTION PERIOD

3.1 Monitoring and control of bridge structure

Intelligent monitoring and control of bridge structure during the construction period is an important part of the construction quality control system, which is a macro regulation of bridge construction quality and a supplement and prerequisite for bridge construction quality control. The stress of the main stress sections, the deformation of the main measurement points, and the stress of the main components are measured during the bridge construction process to apply the structural testing technology and field analysis technology to the construction and combined with the actual construction process to form a complete system of structural calculation and analysis, monitoring and feedback control, its importance is self-

evident. The general arrangement of monitoring during the construction period of the bridge is shown in Figure 3.

The cable-stayed bridge is a high-order statically indeterminate structure, and the construction method and installation sequence used are closely related to the alignment and internal force state of the main girders after the bridge is finished, and the structural system and loading conditions change continuously during the construction phase (Li 2020), monitoring the stress state of the key parts of the piers and towers during the construction period can control the stress state and geometric deflection of the piers and towers. Considering the need for later monitoring or bridge load tests, buried steels and concrete strain gauges are used on both sides of the tower column, and the test section is chosen to be the control section against the bottom of the tower and the section near the anchorage area of the cable tower, with a total of 32 sensors arranged. During construction, the major girders will experience the combined effect of axial pressure and shifting bending moment, therefore, 98 sets of external affixed stress transducers are installed in the key control sections of the main girders for stress monitoring, and the concrete girders use embedded steel string strain gauges and the steel girders use external affixed steel string strain gauges. The main girder elevation measurement is carried out by precision level, and the main tower deformation measurement is carried out by distance measurement method and high precision total station.

Figure 3. General arrangement of monitoring during the construction period of Daxihe Bridge.

During the construction of cable-stayed bridges, the cables not only bear the self-weight and construction load of the girders, but also control the alignment of the girders by adjusting the cable force, which is critical to the smooth progress of the main span closure. Usually, after the tensioning of each construction stage, the cable force of 2-3 pairs of cables in the vicinity needs to be checked, and the control of the cable force includes the adjustment of the tensioning force of the cable at the current stage after the completion of each construction stage of the main girder and the adjustment of the multi-cable force at the stage. The bridge primarily employs the frequency method to monitor the cable force, using the highly sensitive sensor attached to the cable to pick up the vibration signal of the cable under the environmental excitation vibration, after filtering and analysis, amplification and spectrum analysis, determine the cable's self-oscillation frequency according to the spectrum graph, and then determine the cable force according to the relationship between the self-oscillation frequency and the cable force.

The main structure of the cable-stayed bridge, diagonal cable and tower girder are spatially non-linear structures, and the temperature difference will have an important impact on the internal force and alignment of the structure, so the temperature field of the cable-stayed girder and tower need to be measured for a long time during the construction period, and the temperature impact will be adjusted at every step of construction to avoid the alignment and internal force of the bridge deviating from the design target value. Temperature sensors are arranged in designated sections of the tower, span, tower pillar, and cable, and the temperature sensor system adopts an analog and digital hybrid semiconductor temperature sensor system, with a total of 168 temperature sensors required to be deployed during the bridge's construction period.

3.2 Monitoring and control of large construction equipment

The intelligent hydraulic climbing formwork monitoring system of Daxihe Bridge adopts the technical route of *intelligent control* and *safety monitoring*, deploying strain sensors on the key stress parts of the climbing formwork system such as formwork, frame, track, etc. The main implementation contents include:

- (1) Hydraulic climbing formwork Programmable logic controller (PLC) closed-loop intelligent control system. PLC closed-loop control system is adopted to realize intelligent control of climbing, real-time monitoring, and automatic control of the load at each position of the climbing device by microcomputer, real-time display of the load value at each position, with the functions of over and loss of load warning and automatic shutdown.
- (2) Hydraulic climbing formwork safety monitoring system. Stress sensors are positioned in critical areas of the formwork to automatically, wirelessly and in real-time monitor the formwork's stress, compare the measured and theoretical values of the formwork's stress and deformation in real-time, assess the safety level of the hydraulic climbing formwork's stress, and implement early warning.
- (3) Real-time monitoring data display and analysis system. The system mainly displays the monitoring data in real-time, and the site staff can clarify the real-time height, plane position information, and force deformation of the hydraulic climbing device.

The monitoring system of intelligent cable hoisting system is similar to the intelligent hydraulic climbing formwork monitoring system, which also adopts the technical route of *intelligent control* and *safety monitoring*. It adopts sensor integration technology and video monitoring technology and establishes an intelligent control platform to realize digital control and management of the hoisting system, which greatly reduces manual operation in the process of hoisting and abnormal risk. Strain sensors and cable force sensors are deployed on key stress parts of the hoisting system, such as the main truss, flat beam, and cable, and the data is connected to the bridge construction intelligent monitoring and control system to perform online intelligent monitoring and safety warnings on the stress and deformation of key parts of the hoisting system.

4 BRIDGE STRUCTURE LOAD TEST INSPECTION AFTER BRIDGE COMPLETION

After bridge completion, the bridge structure load test inspection mainly includes the tower and pier displacement, the stress and strain of the bridge body, and the cable force of the cable-stayed bridge under load (Shi et al. 2022). The stability of the cable-stayed bridge body, pier tower, and cable-stayed bridge state is the prerequisite for ensuring its safe operation throughout its life. Bridge load test detection points are laid out as shown in Figure 4.

Figure 4. Daxihe Bridge load test measurement point arrangement.

Under the static load test, the pier tower displacement monitoring points are laid at the top of the bridge tower or the pier position at the junction of the bridge deck and the pier, the bridge body stress-strain detection points are laid in the key section of the main beam at the middle

and both sides of the top and bottom, the section is laid out in the main span's 1/2 and 1/4 position, through the stress-strain monitoring of the key sections of the main beam, the stress of the bridge in the load test can be understood and the disease can be diagnosed in time. The frequency, vibration type, damping, vibration intensity, and amplitude of the cable-stayed bridge are the signs of the bridge's overall safety, and the change of the material strength on the dynamic characteristics of the bridge should be given special attention in the early stages of bridge formation. The change in the self-vibration frequency or local mode shape of the bridge may indicate local structural damage, and the vibration monitoring measurement point is arranged at the bottom of the span beam with more obvious vibration, attempting to be in the same position as the strain monitoring section, and cooperating with the accelerometer to detect the dynamic characteristics and vibration level of the tower beam structure under the dynamic load test, the dynamic monitoring state of the bridge strain and the measurement results of the accelerometer can effectively evaluate the safety of the bridge function.

After completion of the bridge, each pair of cables is measured once to provide a basis for subsequent cable force control, and the cable force data under constant load is used to further fine-tune the bridge alignment and adjust the cable force to the optimum cable force to achieve or approach the design value. The cable force under dynamic and static load is measured and compared to the design value during the load test to ensure that the dynamic and static characteristics of the cable meet the specifications and design requirements. The measurement points are usually placed at the longest and shortest diagonal cables, and a flux sensor is placed every few cables according to the density of the cables in the bridge design, with the flux acquisition system used for data collection.

5 INTELLIGENT MONITORING AND SAFETY WARNING OF BRIDGE STRUCTURE DURING OPERATION

According to the idea of whole-life monitoring and safety warning for cable-stayed bridges, intelligent monitoring and safety warning are required for the traffic volume, wind load, ambient temperature and humidity, and micro-cracks under different service states and service environments during the operation period, in addition to the conventional stress-strain monitoring for each structure of the bridge. A video monitoring system is used to monitor bridge traffic and structural status, while a dynamic weighing system provides load data support for assessing bridge safety status, and an inspection and maintenance system conducts electronic inspections to collect, process, and analyze bridge management and maintenance data. The health monitoring system monitors the bridge's overall, local, environmental, and load response, whereas the electromechanical monitoring system is mainly responsible for monitoring and maintaining electromechanical equipment such as dehumidifiers.

To evaluate the traffic flow during bridge operation, the load cell and other equipment are set up near the approach bridge. According to the structural characteristics of the Daxihe Bridge, the wind speed and direction meter (Figure 5a) is positioned at the top of the bridge tower or the open area of the bridge deck, by monitoring wind speed and direction. The ambient temperature and humidity monitoring use temperature sensors and moisture-sensitive

Figure 5. Monitoring instruments during operation: a). ambient temperature and humidity sensor; b). ultrasonic wind speed and direction meter; c). crack meter.

elements (Figure 5b), and the measurement points are placed at the bottom of the span at the same location of the section as vibration or strain. Microcracks are monitored by a high-precision crack meter (Figure 5c), and the measurement points are placed at the expansion joints and the bottom of the bridge, the location of easy cracks is determined by calculation analysis and engineering experience.

In terms of safety warning, it is mainly divided into stress warning and displacement warning. The stresses in the main beam, main tower, diagonal cable, and subsidiary members are monitored in areas where model calculations indicate that stresses may be exceeded. At the beginning of the service phase, the frequency of stress monitoring of key sections is increased to keep abreast of the stress state of the main beam. In addition, it is also necessary to analyze and deal with the tower top offset and bridge deck elevation monitoring results in time, when the load and environmental effects of the bridge alignment deviation trend, or displacement abnormalities exceed the warning value, the early warning system provides timely warnings through intelligent control platforms and all units to consult and find countermeasures to solve the problem.

6 CONCLUSIONS

The Fengjian high-speed bridge project uses information technology synergy, sensor integration technology, and video monitoring technology to establish a digital intelligent control platform, achieve online intelligent monitoring and safety warning of large construction equipment, protect the bridge structure and construction equipment safety, and improve engineering quality. Long-life maintenance-free intelligent sensors are buried during bridge construction to prevent later deployment from causing damage to the structure. These sensors monitor in real-time the instantaneous incremental and cumulative full amount of structural mechanical response and dynamic characteristic parameters, such as pier and tower displacement, bridge stress and strain, and cable force, to provide perfect structural response raw data for mastering the long-term performance evolution of the bridge. It will significantly raise the standard of large cable-stayed bridge girder construction and operation management, as well as the scientific nature of bridge capacity assessment and safety warning, all of which have important promotion and application value and industry-leading significance for the building of mountain bridges.

Integrating unstructured data analytics and BIM to support predictive maintenance

S. Sobhkhiz & T. El-Diraby

Centre for Information Systems in Infrastructure and Construction, Department of Civil & Mineral Engineering, University of Toronto, Toronto, Canada

ABSTRACT: Maintenance resource prediction is difficult because it is influenced by a multitude of factors such as the rate of system deterioration, operational effectiveness, and the efficiency of the asset management program. Work orders (WO) can provide useful insights to account for such factors, but they come in unstructured non-standardized forms that is difficult to analyze. This paper proposes an approach that leverages semantic networks for WO text analytics to support predictive maintenance. The proposed system pulls the basic facility attributes from BIM and historical work orders. This is primarily done by transferring the text of WOs into semantic networks. Using network-based machine learning, clusters of WO typical concepts are extracted. The clusters are categorized to act as prototypes for future WOs. Along with BIM features, these clusters help match the scope of work to previous similar WOs, which are used to estimate the required resources for a new WO.

1 INTRODUCTION

While predicting future maintenance budgets is essential to any life cycle analysis (LCA), enhancing the quality of asset management (AM) is the key to reducing LCA. If assets are well-managed, the speed of deterioration can be reduced; and we can decide more accurately on timely proactive maintenance, which optimizes the life cycle performance of buildings. One key aspect in optimizing maintenance strategies is resource allocation. Facility managers need to have accurate estimates of how much resources each maintenance task requires. Otherwise, they may end up spending a significant amount of their limited resources on tasks that have less priority. Depending on the size and number of the buildings, a facility manager needs to make such estimates for a large number of work orders on a daily basis. For instance, in the institutional building sector, a significant number of work orders are issued every year. As an example, the University of Toronto has around 40,000 work orders per year for its 150 buildings.

However, facility managers do not usually have access to the right information to make such estimates. For instance, consider a problem/failure that has occurred with a mechanical part of an HVAC system. Such issues are usually submitted to building managers using work orders by building engineers or inspectors. A building manager has to use her domain knowledge to estimate how much this problem is going to cost, how long it's going to take to resolve, and how many people are going to be engaged in resolving it. Furthermore, it is very likely that a maintenance task will trigger a few other tasks as well. For instance, if the asset is located in a sensitive and secure area, then for an engineer to access it, a number of security access requests are needed as well. Or if the asset is part of a larger more complex system, then maybe more than one expertise is needed for resolving the issue. A facility manager has to consider all such issues in her decision-making processes. With the existing practices, most of the decisions are made without the needed data and solely based on the manager's experience and expertise.

Most of the required information for FM decisions can be found in the text of the current and previous work orders. However, work orders come in unstructured non-standardized

forms, which makes it very challenging to extract knowledge from. Work orders can be submitted by a wide range of users (e.g., occupants, engineers, managers) which use different terms and ways to describe a wide range of issues. With the recent advances in natural language processing (NLP), there has been a number of ongoing lines of research which focus on resolving the challenges of work order analytics. For instance, some studies used text mining to extract performance metrics from work order data (Gunay et al. 2019; Dutta et al. 2020; Yang et al. 2018). More complex studies used text mining to extract keywords and topics which can help profile/classify issues (McArthur et al. 2018; Yang et al. 2022; Hong et al. 2022). Finally, some researchers have focused on linking work orders (and other FM documents) to BIM.

One common trend in these studies is the use of standardization and structured analytics. In other words, studies often tend to transform the unstructured work order data into structured forms to make them easier for training predictive models, or extracting key performance indicators (KPIs). For instance, using ontological approaches or developing static templates is very common. The purpose of this study is to investigate a different approach which considers the unstructured and non-parametric nature of work orders (and unstructured data in general). Mainly, we will investigate the use of network theory for work order analytics and linking work orders text data to IFC concepts.

2 BACKGROUND

Work orders contain valuable knowledge which is directly relevant to a building's performance. Gunay et al. (2019) recognize this potential as an untapped opportunity, and propose a method where fault frequencies of different building systems are calculated based on work order text analytics. Similarly, Dutta et al. (2020) proposed a method which used text mining on four different classes of work orders (Lighting, thermal & air quality, janitorial, and maintenance) to develop performance metrics. In another study, Yang et al. (2018) developed a method for analyzing the failure modes of HVAC equipment using work order data.

One key area of focus has been work order profile classification. The purpose in these studies is to automatically classify a record into a set of predefined classes such as mechanical or electrical. It can be argued that if work orders are automatically classified into such topics, it facilitates processes such as resource allocation (Mukhopadhyay et al. 2020). For instance, the work order would be sent to its pertinent division much faster, if its topic is known. To this end, Naqvi et al. (2022) developed a work order classifier for a manufacturing company that classified work orders into four groups of mechanical, electrical, electronic, and miscellaneous, and achieved an accuracy of 82%. Such studies are recently being conducted in the domain of building maintenance as well. The work of Yang et al. (2022) is a good example. In their study, Yang et al. developed a classifier that considers several aspects of work orders such as location, associated element, and defect type. Their classifier used 11 defect classes and achieved an f-1 score of 0.93. In another study, Hong et al. (2022) used work orders submitted regarding HVAC issues and developed a SVM classifier that achieved an accuracy of 85% over 25 classes.

Linking work orders to BIM has also been investigated in several studies. For instance, Lee et al. (2016) proposed an ontological approach where a defect ontology was developed that included concepts from BIM and defective issues. The ontology was used to model a given work order by including the relevant BIM concepts as well as the relevant defect concepts. Given that the concepts are linked before-hand (when developing the ontology) a link between the defect and corresponding BIM concepts is established. In another similar study, Kim et al. (2018) proposed a method using semantic web technologies. Their proposed ontology was more comprehensive in the sense that in addition to BIM and work order concepts, they included COBie concepts. As a result, their proposed method covered asset information as well as BIM and defect information. Designing ontologies with the purpose of adding BIM to the AM process is an ongoing line of research.

Farghaly et al. (2019) also proposed the use of semantic web technologies to support BIM-based asset management. The study develops an ontology that integrates concepts from three domains of IFC, maintenance scheduling, and procurement documents. The approach employed a participatory action research in which focus groups and interviews were

conducted to determine key concepts and their relationships for building the ontology. Next, a framework is presented where asset maintenance data as well as data extracted from BIM is converted to RDF according to the proposed ontology. The ontology uses encoding systems from standards such as Uniclass2 and requires maintenance data to be generated according to the same standards as well.

These methods mostly rely on using standardized processes to add some sort of a structure to the unstructured work order data. For instance, all the studies on linking work orders to BIM either require the user to use a coding mechanism (such as using object IDs when submitting work orders) or static mapping mechanisms where the links are predefined in an ontology or a relational schema. Even when developing work order classifiers, the common practice is to define a set of generic classes (such as mechanical, electrical, and so on), then label work orders according to these classes and train a classifier. This approach implies that work orders will always be submitted within the scope of the predefined classes, which is not necessarily true. Given that the work orders are unstructured text, they may very likely include concepts and classes that do not fit with the predefined set of classes the classifier is trained on. In such cases, the classifier will push the work order into one of its classes, nonetheless.

3 SEMANTIC NETWORKS AS AN ALTERNATIVE

It can be argued that one of the key challenges in working with an unstructured data source such as work orders is the data modeling approach that is chosen. Currently, studies tend to restructure the data into relational or ontological forms (Sobhkhiz et al. 2021). This process usually requires defining the structure, either in the form of an ontology or a relational schema, in advance. Here, we aim to investigate an alternative approach where instead of pre-modeling the data, we use techniques for extracting patterns from the unstructured data in an unsupervised process. Semantic networks can be a potential candidate. Semantic networks allow us to formally represent the concepts in a graph structure without parametrizing it. It extracts the knowledge inductively as opposed to the traditional top-down methods where knowledge is deducted (Yun and Park 2018; Shi et al. 2018).

The purpose of this study is to investigate the potentials of network analytics and concept networks in resolving the challenges discussed in the previous sections. The motivation behind using concept networks is that they are obtained in an unsupervised manner without the need of using top-down modeling. In other words, we do not need to define the concepts and relationships in the data, rather they are extracted in a bottom-up manner from the data. This can be viewed as a way of formalized representation of the data which can be used for a variety of purposes such as work order classification or linking work orders to structured schemas such as that of IFC (Sobhkhiz and El-Diraby 2022). Another advantage of network modeling is that it can easily adapt to the changes in the data. If a new concept or relationship appears or an existing relationship changes, the network can adapt itself to represent those changes. In the following we will examine the usability of these features in two contexts of 1) work order modeling, and 2) linking work orders to BIM.

To generate a semantic network, we need to identify the concepts and their relationships in the data. This can be done through data mining techniques such as association rule mining. Figure 1 shows the overall step-by-step process for extracting a semantic network. After text preprocessing, the method employs association rule mining in order to identify association relationships between different concepts. Namely, we will be using the 'lift' measure to define how strongly connected two different concepts are. In association rule mining, the lift value determines how the probability of appearance of one concept changes when another is present. If the lift value is 1, then it indicates that there is no dependency between the two. Values greater than 1 indicate that the presence of one concept increases the presence probability of the other. Once the lift measures are calculated, the rules can be represented in a graph structure where the concepts are the nodes, and lift measures the weight of the edges between them.

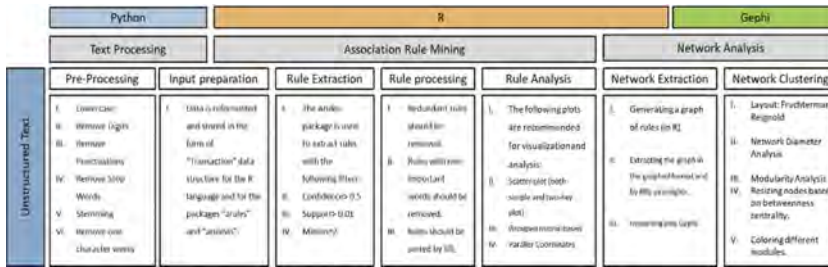

Figure 1. Extracting semantic networks from text sources.

3.1 Use case 1 - Extracting AM-related concepts using network analytics

As discussed in the literature review, one of the challenges in the studies related to work order analytics is to develop classification systems. The common trend so far has been to use expert defined top-down classes for modeling AM concepts. But the problem is that these classes do not necessarily represent the specific AM trends that are occurring within an organization. An alternative approach would be to use data-driven solutions that extract the key topics and classes from the data. Here, we propose using a semantic network that is extracted from the work orders and algorithms such as network modularization and topic modeling for extracting the work order classes. Figure 2 shows a proposed algorithm for this purpose. More details will be published in a subsequent paper.

The proposed method works by extracting the classes level by level from high-level generic classes in the highest layer to more detailed classes in the lowest ones. The high-level classes would be the by-the-book classes that are common across all organizations. Mechanical or electrical classes are examples of such high-level classes. As the layers increase, the classes become more AM relevant. For instance, mechanical systems in a hospital are not the same as the ones in an institutional building. These differences start to emerge when the classes become more detailed in lower levels.

3.2 Use Case 2- Linking work orders to BIM using semantic networks

The use of non-standardized language makes it difficult to link a given work order to its corresponding element/s in a BIM model. Consider a work order that is discussing an issue regarding a door located on the second floor of a building. Linking the work order to the 'door' object of the building's BIM model would not be a very straightforward process. This cannot be done using simple keyword matching. An issue with a door could include its different systems such as lock, fob, key, cylinder (for controlling its closing and opening), shafts, handle, or different functions such as closing, opening, being noisy, and so on. And all of these are just for a simple door. How would we match other systems and issues? Back to using structured approaches, some studies suggest using standardized mechanisms such as adding a BIM object code to the work order which is not really feasible in practice. Not everyone knows these codes and IDs. Also, many times the user does not know which element the issue is originating from (for instance, a burning smell with unknown source).

Semantic networks can also help here. When we extract a semantic network from work order data, we are essentially providing a semantic representation for different concepts based on their co-occurrence with other concepts. As such, when the term 'door' appears with concepts such as 'entrance' and 'access' it will be indirectly connected to concepts such as 'fob' which itself will be connected to the same concepts ('entrance' and 'access'). If we use the same network representation for the BIM concepts, we will be able to link the two networks using logical relationships. For instance, linking 'IfcDoor' to 'Door' is a logical link. But since 'Door' is itself connected to other concepts such as 'fob' we are essentially linking 'IfcDoor' to 'fob' as well. We can use these connections and train a classifier that will determine whether the concepts in a work order text are close enough to a given IFC concept. If so, the work

order will be linked to its associated IFC concept. We can extract a semantic network for BIM concepts from the text sources such as buildingSmart Data Dictionary (bSDD). Figure 3 shows the general idea behind the approach. More details will be published in another subsequent paper.

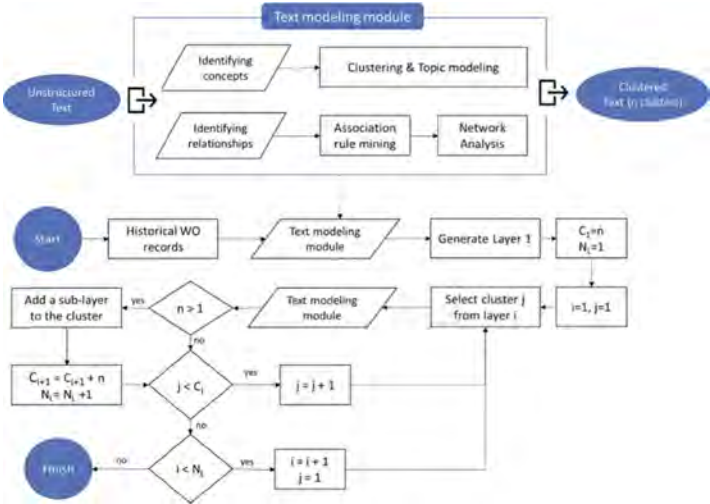

Figure 2. An algorithm for extracting a hierarchical class from work order texts.

4 CASE STUDY

In this study, we used the database of a facilities and services department responsible for the operation and maintenance of institutional buildings in the city of Toronto. The department uses its in-house developed CMMS solution for managing service orders where a digital form is used for work order submission. The dataset contains 36 columns including the information of the people involved with the work order (e.g., who requested the work order, who is supervising it, and who is directly solving it), the date and time of when the work order was submitted and closed, status code, building, location, description, and so on. We used a dataset of 1055 work orders that was collected for an institutional building over a period of 8 months.

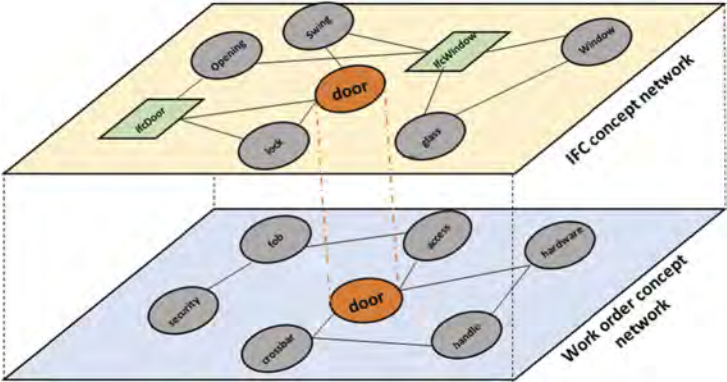

Figure 3. Linking work order semantic network to IFC semantic network.

4.1 Work order modeling

In this section, we employ the algorithm proposed in the first use case to develop a classification model for the work orders that can be used for a variety of purposes such as KPI development or automated work order classification. In the first step, a semantic network needs to be extracted. Figure 4 shows the modularized semantic network that was extracted from the work order sample database. Next, we perform topic modeling to extract the probabilistic features of similar documents. By employing the proposed algorithm, the hierarchical classification system can be extracted from the work order data. In the first step, the high-level classes are determined according to the results of network modularization. Figure 5 shows the 9 classes that were identified as follows: mechanical, electrical, plumbing, janitorial, event management, access & security, space comfort, carpentry, and elevator.

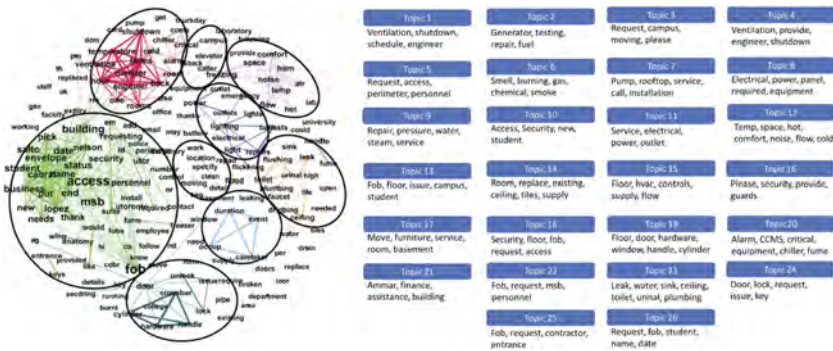

Figure 4. Extracting work order semantic network and topic models.

As can be seen, these classes are generic (or by-the-book) classes that are common across all organizations. Next, we start adding details to the model and extract low-level classes. These classes represent the specific AM practices of an organization. Given the limited size of the database, this can be done for a few classes that have large enough samples. For instance, the class mechanical is broken down into four more sub-classes of failure alarm, HVAC services, generic repair, planned maintenance, and contractor administrative. The access and security class also included a large number of samples and could be further broken down into two sub-classes of fob/key request and door/window hardware services. In a future study, we will use these classes to develop a dynamic hierarchical classifier for work order data.

4.2 Linking work orders to BIM

In this section, we use semantic networks to link work order documents to IFC concepts. This would be the essential first step to link a document to its associated BIM object/s. To this end, we first need to extract a similar concept network for the IFC concepts from the records in the bSDD database. Figure 6 shows a snapshot of such a network for the two classes of IfcDoor and IfcWindow. Once the IFC network is constructed, we can link the two networks through their common nodes. For instance, the node 'door' is common between the two networks, and will be one of the nodes that connects the two networks. Now, we can calculate the distance between a given concept, say 'fob', to a given IfcClass such as 'IfcDoor'.

In the next step, we label 80% of the documents with their associated IFC classes. For instance, a work order requesting a service to fix a door would have a label of Ifcdoor. Work orders may include more than one class. The dataset in this study included 28 IFC classes. Next, for each pair of work order and IfcClass, we extract the distance features from the networks. For instance, consider the work order 'please fix the closing cylinder in room gb229'. For each concept in the work order, we calculate the distance of the concept to a given IFC

class (28 classes in this study). Next, if the instance is related to the IFC class, it will have a label of 1, if not, a label of 0. Now we can train a classifier that can learn whether the distances of the concepts in a work order represent relatedness to a given IFC class based on the semantic networks. Our initial analysis on the remaining 20% of the work orders achieved an average f-score of 0.97 over all classes which is very promising. More detailed analyses will be published in a subsequent paper.

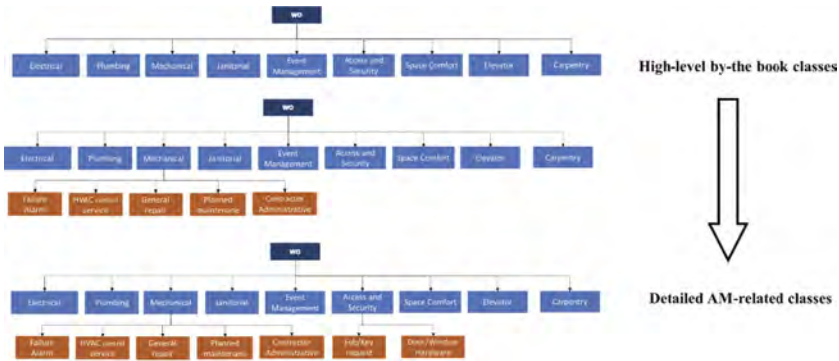

Figure 5. Developing a hierarchical work order model.

Figure 6. IFC semantic network.

5 CONCLUSIONS

The majority of building data is unstructured in the form of inspection forms, specifications, communications (e.g., emails), complaints, feedback and so on. Unstructured data is the most valuable source for capturing business and operational knowledge and is central to developing business intelligence applications. Considerably, studies focus on the structured side with applications that aim to develop real-time digitized models of physical entities for services such as monitoring and prediction. For instance, a well-studied subject on this matter is using

building asset data (e.g., HVAC systems) for predicting asset failure and developing maintenance strategies. These types of studies require using predefined data models to make data machine-readable and usable for applications such as predictive analysis. Although top-down model-based analysis is reasonable for data coming from sensors, this is not the case for unstructured data such as texts. Unstructured data, inherently, does not follow a specific form or standard, and pushing it into any predefined standard will limit the analysis to the extent of that standard. Nevertheless, many studies use top-down modeling approaches for analyzing unstructured data. Pre-defined data models that are developed heuristically and by experts can cause critical limitations for unstructured data analytics.

As such in this study, we investigate an alternative approach where a structure is not imposed on the data, rather, it is extracted in a bottom-up unsupervised process. We narrowed down the scope to using semantic networks and the domain of work order data analytics. Obviously, other techniques and domains are yet to be explored. Hypothetically, such approaches should broaden the opportunities for analytics. For instance, semantic networks can be easily updated according to the changes in the data. If more classes and relationships emerge (which is likely in the case of unstructured sources) semantic networks have the capacity to accommodate those changes. This allows for developing dynamic and self-updating solutions for cases such as classification. This particular issue will be investigated in a follow-up study.

Ultrasonic monitoring of large-scale structures - input to engineering assessment

N. Eppe, C.A. Sanchez-Trujillo & E. Niederleithinger
Bundesanstalt für Materialforschung und -prüfung, Berlin, Germany

ABSTRACT: Ultrasonic coda wave interferometry can detect small changes in scattering materials like concrete. We embedded ultrasonic transducers in the Gänstorbrücke Ulm, a monitored road bridge in Germany, to test the methodology. Since fall 2020, we've been monitoring parts of the bridge and comparing the results to commercial monitoring systems. We calculate signal and volumetric velocity changes using coda waves, and long-term measurements show that the influence of temperature on strains and ultrasound velocity changes can be monitored. Velocity change maps indicate that different parts of the bridge react differently to environmental temperature changes, revealing local material property differences. A load experiment with trucks allows calibration to improve detectability of possibly damaging events. Our work focuses on measurement reliability, potential use of and distinction from temperature effects, combination with complementary sensing systems, and converting measured values to information for damage and life cycle assessment.

1 INTRODUCTION

Monitoring concrete bridges is necessary to ensure a safe and reliable transport infrastructure. Bridges require monitoring, maintenance, and, if needed, restoration of damage, especially when they were built some decades ago and started suffering from aging effects. Damage can include discontinuities, like the formation of new fractures, deformation, or deterioration, like corrosion of the rebar and pre-stressing systems. Some of this damage is visible on the exterior. But what happens when it isn't? Then, the need for a reliable Structure Health Monitoring (SHM) system arises.

Ultrasonic (US) monitoring with coda waves is an SHM technique that has been highlighted as particularly sensitive to the effects of stress, temperature, moisture, and cracking of scattering materials like concrete (Snieder et al. 2002). These effects are encrypted in the velocity variation of ultrasonic waves. Coda Wave Interferometry, CWI, is a technique to measure velocity variations. This method has been widely applied by seismologists to measure and localize wave velocity changes in the interior of the earth (Sens-Schönfelder & Wegler 2006). With the right adjustments, it can be used for civil engineering structures (Zhang et al. 2016). This method has been tested in small concrete samples but it must be adapted to larger structures. This is part of the goal of the DFG research unit CoDA. This unit aims for an integral development of the application of CWI on concrete specimens and real structures. It's supported by simulations and experiments designed by experts in diverse domains from signal processing, structural engineering, material science, and numerical modeling. The Gänstorbrücke is the first large-scale structure to be equipped with a measuring system monitored with this technique by the research unit. In this paper, we will show results from permanent monitoring as well as a load experiment after a brief introduction to CWI. It is followed by an outlook on the possible integration into existing bridge monitoring frameworks and the benefits towards engineering assessment.

2 METHODOLOGY

Concrete is a peculiar material for ultrasonic testing, as it is composed of aggregates of varying sizes and a fine matrix around them. Elastic waves propagating through the structure will encounter these aggregates and get scattered if the wavelength is about the size of the aggregate. For classical non-destructive testing, looking at reflections from backwalls and delaminations this is reducing the resolution power. In Ultrasonic Monitoring with coda waves, on the other hand, we take advantage of this property. Let's suppose two sensors are installed and active on a bridge. When one of the transducers sends a pulse, a certain part of the energy might go through a straight path, without scattering, from the transmitter to the receiver. Nevertheless, some waves will be inevitably scattered by the aggregates of the medium. The path these scattered waves take is longer than the direct one and makes them "sensitive" to a larger area than the direct ones. The scattered waves are recorded later in time by the receiver. If a small change in the medium occurs, the direct waves might not show any change but the scattered waves will, as shown in Figure 1. This late part of the recorded waveform corresponds to the so-called coda. The ultrasonic methods have been proven effective to monitor concrete structures (Zhang et al. 2016, Clauß et al. 2020, Epple et al. 2022). Ultrasonic sensors can be embedded directly into the structure either during construction or later on when the necessity to monitor the structure arises (Wang et al. 2022). The transducers used in the study act as transmitters but also as receivers. This property allows switching sources and receivers to create different sensor arrangements with different spatial sensitivities and therefore to acquire more information without having to replace the sensors. Additionally, the measurements can be stored in the cloud almost in real time making the data accessible from remote places and monitoring a much easier task for engineers.

2.1 Ultrasonic monitoring

2.1.1 Correlation coefficient

The objective of this parameter is to provide a value for the similarity of the waveforms of a pair of signals. The first signal recorded $u_o(t)$ is taken as the reference. If the medium is subjected to a small change, the second signal $u_c(t)$, recorded after the perturbation, is supposed to have the small change encoded in its coda. With a similarity measure, one can estimate the magnitude of the medium change. The similarity between these pairs of signals is measured by a simple correlation coefficient, CC , ranging from -1 to 1:

$$CC = \frac{\int_{t_1}^{t_2} u_o(t)u_c(t)dt}{\sqrt{\int_{t_1}^{t_2} u_o^2(t)dt \int_{t_1}^{t_2} u_c^2(t)dt}} \quad (1)$$

The two signals are compared on a finite time interval between t_1 and t_2 . A correlation coefficient approaching zero means that the waveforms are dissimilar and when it approaches 1 it means that there's no change at all between the reference, $u_o(t)$, and the later waveform, $u_c(t)$. In the rare case of a complete phase shift, the correlation coefficient would approach -1.

To monitor, many signals must be acquired through time and all of them are then directly compared with the reference. Therefore, is very important to choose the reference carefully. In case of small changes in the material, it is sufficient to choose the first measurement as a baseline corresponding to the potential undamaged state. When the damage level continuously increases with time, if there's not enough recovery of the structure, the waveforms acquired later can change so much that the reference becomes obsolete in the long run. Therefore, using a step-wise reference is advised to asses relative changes over time (Zotz-Wilson et al. 2019). The correlation coefficient method does not provide a direct quantitative measure of the change induced by strain or environmental factors like temperature. It is not suitable for distinguishing between global velocity changes and changes in local scattering behavior, nor the kind of damage that the medium suffered. Therefore, to extract information valuable for structural engineers, we need to apply a more advanced method.

2.1.2 Stretching method

When the properties or condition of the medium changes, the waves are expected to propagate either a little bit faster or slower than before. The longer their travel path, the more head start or delay they'll have compared to the reference measurement. If one can measure how much a signal apparently dilates or compresses by this effect, it would be possible to determine the average velocity change in the medium. The stretching method (Lobkis & Weaver 2003, Sens-Schönfelder & Wegler 2006, Hadzioannou et al. 2009) is used to detect subtle dilation or compression of the waveform with respect to a reference initial state and link- it to a relative velocity change $\Delta v/v$. To do this, the reference trace, $u_o(t)$, is stretched and compressed by a series of epsilon factors, ϵ , creating a series of stretched references $u_o(t + \epsilon t)$. The measured waveform, $u_c(t)$, is then correlated to all the traces in the series:

Figure 1. Two signals recorded with the same source and receiver. Emphasis is on the first arrival of the signal and the coda. The waveforms of both recordings are similar in the first arrival but on the coda, it's possible to appreciate a phase shift between the two signals. Figure adapted from Epple et al. (2022).

$$CC(\epsilon) = \frac{\int_{t_1}^{t_2} u_o(t + \epsilon t)u_c(t)dt}{\sqrt{\int_{t_1}^{t_2} u_o^2(t + \epsilon t)dt \int_{t_1}^{t_2} u_c^2(t)dt}} \quad (2)$$

The epsilon corresponding to the highest correlation value, $CC(\epsilon)$, corresponds to the representative velocity change due to the disturbance in the medium. When this method is applied to waveforms acquired at different times, it provides information on the temporal evolution of the medium. The method can be applied to different parts of the coda. It is possible to select the whole coda, the early part, or even the later part, resulting in a slightly different spatial sensitivity. Both, the stretching method and the correlation coefficient provide a temporal evolution of the medium but both lack the ability to locate the area of the changes and the type of damage encountered by the structure. In this case, advanced inversion algorithms are needed.

2.2 Experiment

The Gänstorbrücke (Figure 2) is one of the many bridges that traverse the river Danube and connects the cities of Ulm and Neu-Ulm in Germany. The 96m reinforced concrete bridge was constructed in 1950. Since damage has been detected in the form of corrosion and subsequent fractures of prestressing wires, the bridge is currently monitored with acoustic emission and strain sensors until its dismantled and rebuilt. This base monitoring makes it the perfect structure to test ultrasonic monitoring. Therefore, in 2020 the bridge was equipped with 24 embedded ultrasonic sensors as well as several external transducers. These transducers have a center frequency of 60 kHz (ACS and 25 kHz (ACS S0205), respectively. Thus, we have unscattered energy as well as

Figure 2. Photo of the Gänstorbrücke bridge with the location of the sensors indicated by red dots on the schematics of the bridge.

scattered coda in the recordings. 20 of these embedded transducers are located in the center of the bridge (Figure 2, schematics) to perform active ultrasonic measurements with an array for monitoring and imaging applications. The measurement device is a raspberry-pi based instrument for permanent ultrasonic monitoring developed at BAM (Barroso et al. 2021), especially for this kind of data acquisition. In December 2021, a load test was carried out during the night. This decision was made to calibrate the system and compare the changes induced by load and the effects of temperature to determine if the detection of cracks is in fact possible. In the experiment, two trucks of 15 and 32 tons were placed in 5 different positions over the bridge while ultrasonic consecutive measurements were taken. To reduce the acquisition time, a commercial device similar to the raspberry-pi-based was used for the acquisition (Wang et al. 2022).

3 RESULTS

All data were bandpass filtered to remove low and high-frequency noise. In Section 3.1 the relative velocity change is multiplied by negative one to indicate the correlation of velocity change and temperature change.

3.1 Long term analysis

The monitoring system at Gänstorbrücke has been running since installation in late 2020 with some downtime due to device maintenance. For most transducers, the signal quality has remained comparable. Comparisons of signals re We have identified in previous experiments (Epple et al. 2021) that the environmental temperature change has a significant influence on the signal, and can lead to strong decorrelations during a single day. While this is a reversible structural change, it is important to quantify it to determine thresholds and possible overshadowing of damage events. Figure 3 shows the CWI results from December 2021, the same month the load experiment was conducted. It is important to note that in this graph we have the sign for the velocity change reversed. Positive numbers refer to a decrease, to emphasize the correlation with temperature. A comparison of strain (gray), temperature (black), and three exemplary source-receiver combinations evaluated with the stretching technique using a fixed reference show that temperature

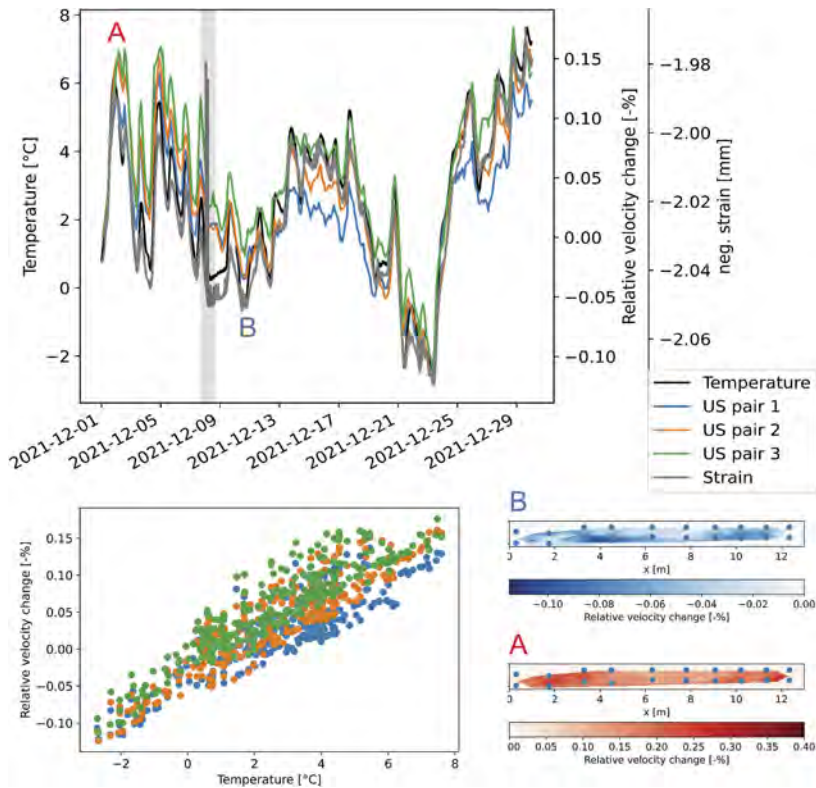

Figure 3. The results of a fixed reference analysis in Dec. 2021 show a strong correlation between temperature, strain, and negative velocity change (top). The time of the load experiment is marked in gray. The relationship between relative velocity change and temperature is linear (bottom left). An analysis of the sensor array at a warm (A) and cold (B) time shows an increased reaction to temperature change in two distinct areas of the array.

influences both strain and ultrasound velocity in a similar manner, while the strain measurements have a better temporal resolution. An increase in temperature reduces the stiffness of the material (and leads to material expansion) and therefore increases strain and decreases the velocity. Here, the relationship between temperature and velocity change is almost linear with $\approx 0.025 \frac{\%}{\text{C}}$ which is about the same magnitude as found in the aforementioned studies. With the focus on damage detection, we have plotted an areal map of velocity change from measurement during the day (A, warm) and during the night (B, cold) to evaluate if there are areas significantly reacting to temperature changes. The areal plots are created in accordance to Niederleithinger et al. (2018) where we attribute the calculated value for every transducer pair to their respective midpoint and interpolate between the results. In both cases, we see that the velocity decrease/increase is larger at the edges of the array compared to the center of the array. The anomalies on the left side of the array we mainly attribute to the separation of tendon ducts (see Figure 2). For the increased velocity change in the very center of the bridge, we are lacking an obvious interpretation and need to consult numerical simulations of the bridge strain fields under changing environmental conditions.

3.2 Load test

Figure 4 shows the result and setup of the load test. After data evaluation, we detected bad data quality in two combinations (8-9 and 17-18). The long-term analysis has shown that these two combinations are having some consistency issues from time to time, which might be caused by issues with transducer coupling. The experiment was conducted at night and temperature data shows a constant temperature during the entire experiment. Therefore, we do not

need to correct or account for any influence of temperature. As the influence of trucks on positions 1 and 5 was minimal, we focus on analyzing the influence of both trucks on measurements recorded with horizontal source-receiver combinations and both trucks at positions 2,3, and 4. The results are attributed to the midpoint between the source and receiver and shown over the distance in the sensor array. We separated the analysis for both trucks and plotted the results of the transducer combinations at the bottom of the array separately from the results from the top combinations. With these results, we see how our measurements are reacting to the load, which on the one hand induces compression and bending in the beam in the upper part and on the other hand opens existing cracks in the bottom, altering our ultrasonic signal.

The maximum changes in the load experiment exceed the influences of temperature variations below 10°C. Unsurprisingly, the 32 T truck induces a larger velocity change, the biggest change occurs in both cases when the truck is at position 3 directly above the array. When comparing the bottom and top zone with the truck at position 3, we see that velocity changes in the lower area are exceeding the changes on the top. These results are in accordance with bending experiments (Clauß et al. 2020) where the tensile forces are larger on the bottom, which decreases the ultrasonic velocity. In general, the velocity decreases even on the top zones, where numerical models suggest compression and therefore a velocity increase. We assume that the strong tensile forces, combined with the areal analysis of CWI will always lead to velocity reduction below a strong load on a bridge.

At positions 2 and 4 mainly sensors 1-3 and 11-13 are influenced. While this position 2 is close to these sensor positions (5 m), we would expect almost no influence from the load at position 4 due to the large distance to sensors 10 and 20 (15 m). Furthermore, in these cases, the velocity increases, indicating compression instead of tension. Also, this is the only scenario where the velocity change in the top part exceeds the change in the bottom part. We attribute this to the tendon duct layout. As shown in Figure 2, the tendon ducts are split in this region re-distributing strain. While this effect is most prominent with load at position 4, it can also be observed for sensor combinations 11-12 and 1-2 with load at position 3.

4 CONCLUSIONS

We have instrumented the Gänstorbrücke with a reliable ultrasonic monitoring system that can be used for permanent monitoring and short-time experiments. During monitoring operations, daily temperature changes can change the velocity by about 0.25% with a mostly linear relation between

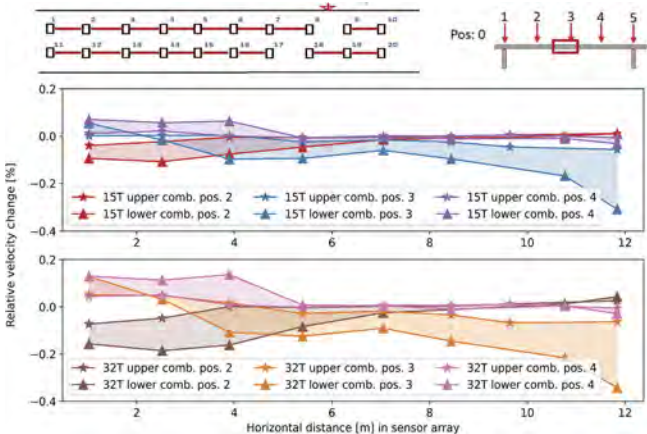

Figure 4. The results of the load test: For both trucks (15T and 32T) we analyze the relative velocity change throughout the array for horizontal combinations with load at positions 2,3 and 4 (schematics top). In the areas directly affected by load, the tensile forces induced by the bridge bending cause a strong velocity change predominantly in the bottom part of the array. The influence of load at positions further away is more complex and can lead to velocity increase caused by compression.

temperature and velocity change. Correction of these influences is complicated because it is not fully linear. Therefore, for the evaluation of material changes, we suggest choosing the reference measurement at the same ambient temperature and time of day instead of attempting a correction. The temperature changes can also be seen in the localized strain measurements installed for commercial bridge monitoring. Strain data has a better temporal resolution but no spatial resolution. The benefit of active ultrasonic monitoring lies in the areal analysis where we can identify parts of the bridge more influenced by temperature change than others. This can for example indicate cracks or other material damages reacting to temperature change. Furthermore, there is a nonlinear portion in the temperature-velocity relation. This non-linear part might be more sensitive to damages (Sun & Zhu 2019), so we hope to analyze and use this effect in future works.

The observations made in the load experiment show that load influences are stronger than influences of temperature change but of similar dimensions. This might cause problems in damage detection if no additional devices are available, e.g. acoustic emission. For damage detection, we advise using data collected at similar temperatures, preferably during the night time to minimize temperature gradients in the material. The array monitoring system helps localize the origin of changes, which opens possibilities for advanced damage localization algorithms based on inverse calculations. This has already been applied on several occasions (e.g. Zhang et al. (2016)) but not in an operational bridge with embedded 60 kHz transducers. Research on this topic will show the added value of a coda-based active ultrasonic monitoring system. It is not meant to replace but complement other monitoring technologies. A combination with AE is straightforward. It can be implemented at a relatively low cost and help to improve maintenance and repair strategies as well as general LCA/LCC analysis.

A new technique to detect altered stresses in tendons early

N. Sträter, F. Clauß, M.A. Ahrens & P. Mark

Institute of Concrete Structures, Ruhr University Bochum, Bochum, Germany

ABSTRACT: Prestressing is the decisive component for achieving large spans with concrete bridges. For the long-term preservation of prestressed concrete bridges, the early detection of damage to tendons is particularly important. As tendons are often located within the concrete, the assessment of their condition is difficult with conventional methods. Ultrasonic measurements with sensors embedded in the concrete and evaluated with coda wave interferometry offer a promising new approach for assessing the internal health of concrete structures. To demonstrate the detection of tendon failures, two experiments—one with pre-tensioning and one with post-tensioning—were carried out at Ruhr University Bochum, Germany. By simulating a tendon failure, the prestressing force drops abruptly. The experimental results prove that the coda technique detects such tendon failures unambiguously, although no external changes seem to have appeared.

1 INTRODUCTION

Prestressing is the key technique to economically bridge large spans with concrete structures (Fischer et al. 2014, Sanio et al. 2014). In contrast to ordinary reinforced concrete (RC), the prestressing enables to reduce deformations, closes cracks and utilizes the high compressive strength of concrete. Typically, tendons used to apply prestress to the concrete are embedded in it, which renders visual inspection impossible. If failures of individual tendons occur, for example due to fatigue (Sanio et al. 2018) or stress-corrosion cracking (Nürnberger 2002), the concrete remains under compression. Only progressive damage and further tendon failures lead to visible cracks on the surface, resulting in the risk that the entire structure may collapse.

Nowadays, techniques such as strain gauges, fiber optics (Konertz et al. 2019, Clauß et al. 2021) or acoustic emission (Tonelli et al. 2020) exist for assessing the health of reinforced and prestressed concrete structures. It is the nature of the beast that many of them have disadvantages, as they either only provide local information, are not suitable for permanent monitoring or are of uneconomical use.

A promising approach for the condition assessment of concrete structures lies in coda waves. Coda is the late part of an ultrasonic (US) signal sent from a transmitter to a receiver. The corresponding coda waves are scattered many times in the concrete and pass through a large volume. The waves react sensitively to influences from strain (Clauß et al. 2020, 2022, Diewald et al. 2022), temperature (Epple et al. 2021), moisture (Ju et al. 2015, Legland et al. 2018) and structural changes like cracks (Finger et al. 2021, Grabke et al. 2021, Grabke et al. 2022). The ultrasonic signals are evaluated using coda wave interferometry (CWI) originating from the field of seismology. In the past, the method was transferred to the health assessment of concrete structures (Larose & Hall 2009, Planès & Larose 2013).

This contribution aims at how tendon failures can be detected with coda waves. As a method for their evaluation, the CWI is first introduced briefly. Afterwards, the experiment of an unbonded post-tensioned beam is presented, where the prestressing can be adjusted and

changed in a controlled manner. Here, a tendon failure is simulated by a gradual release of the prestressing. Furthermore, a more complex test of a pre-tensioned beam was carried out, in which tendons are in bond with the concrete. In this test, a tendon rupture was initiated by drilling from the outside. The results collected in both tests for the artificial generation of tendon failures are discussed and compared with each other.

2 METHODS

2.1 Principles of coda wave interferometry

Conventional US methods from the field of non-destructive testing mainly avail the arrival of a ballistic wave for evaluation. In contrast, CWI is based on the coda part, i.e., the rear part of an US signal (Snieder 2006). The associated waves spend a longer time in the medium, are scattered several times and thus repeatedly record information in a large volume. When using CWI, knowledge is not gained from individual US measurements, but rather two signals before and after an event are compared with each other to obtain measure of changes happened.

Coda waves are known to be very sensitive to changes in strain (Clauß et al. 2020, 2022, Diewald et al. 2022), temperature (Epple et al. 2021), moisture (Ju et al. 2015, Legland et al. 2018) and structural changes such as cracks (Finger et al. 2021, Grabke et al. 2021, Grabke et al. 2022). Figure 1 depicts an example of two US signals measured before and after a small event. In the direct part (at the beginning of the signals), hardly any differences are notable, whereas in the later coda part, which is enlarged here, a clear change is apparent.

In mathematical terms, the CWI compares two signals u_1 and u_2 within a time window t_1 to t_2 . The correlation coefficient CC is determined as a measure of similarity of the two signals in the given time window. If the signals are identical, CC reaches the value 1. If the signals are completely different, it approaches 0.

Figure 1. Ultrasonic measurement for the same source-receiver combination before and after a small event on a test specimen.

From the wave shift of both coda signals, another quantity the relative velocity change dv/v can be derived. To this end, the stretching technique (Niederleithinger et al. 2018) is used here, which compares the signal u_2 to a stretched version of u_1 being the reference signal. The

stretching factor ε maximizing the correlation coefficient CC corresponds to the negative relative velocity change dv/v . An increase in the velocity of the signal u_2 compared to u_1 causes a positive value of the relative velocity change and vice versa.

$$-\frac{dv}{v} = \arg \max_{\varepsilon \in \mathbb{R}} CC(t, \varepsilon) = \arg \max_{\varepsilon \in \mathbb{R}} \frac{\int_{t_1}^{t_2} u_1(t(1-\varepsilon)) u_2(t) dt}{\sqrt{\int_{t_1}^{t_2} u_1^2(t(1-\varepsilon)) dt \int_{t_1}^{t_2} u_2^2(t) dt}} \quad (1)$$

2.2 Experiments

To investigate the detection of tendon failure by the application of coda waves, a stepped series of experiments was conducted in the labs of Ruhr University Bochum, Germany. Therefore, two externally identical test specimens ($w/d/l = 200/200/1500$ [mm]) were manufactured. In the first step, an internal bondless prestressing (test 1: post-tensioned beam) is explored. Possible influences from the bond between tendons (in this case threaded rods) and the concrete are completely excluded. In this way, the focus lays on the pure effect of the prestressing force within the concrete and its effect on the coda waves. In the ensuing step (test 2: pre-tensioned beam), the tendons (still threaded rods) are completely embedded in the concrete, i.e., as an additional effect, only the bond between concrete and tendons is added. The results reveal the detection of externally invisible tendon failure.

Figure 2. Test specimen of an unbonded post-tensioned beam before (left) and after (right) concreting.

Figure 3. Test specimen of a pre-tensioned beam before concreting: formwork (left) and prestressing bed (right).

Three threaded rods ($\varnothing 16 \text{ mm}$) pass through the first test specimen. The threaded rods run in ducts, which were concreted in beforehand. The rods are prestressed by tightening nuts against anchor plates on both sides of the hardened specimen (cf. Figure 2, right). Via the anchor plates, the intended total force of 100 kN is transferred directly to the concrete. Guiding the tendons bondless in the ducts renders it possible to apply and release prestress in a controlled manner in order to set altered tendon stresses. As there is no bond to the concrete, tendon failure—in other words, a drop in force—can be simulated by loosening the nuts. In the experiment, the application of the prestress is monitored via the strain of the threaded rods measured with strain gauges. The post-tensioned beam was reinforced with longitudinal bars ($4 \varnothing 12 \text{ mm}$) and stirrups ($\varnothing 10 \text{ mm}/250 \text{ mm}/2$). An additional stirrup was inserted at load application.

Also the second specimen is passed through by three threaded rods (now $\varnothing 12 \text{ mm}$, cf. Figure 3, left). Before concreting, the rods are prestressed in the casting bed. They protrude from the formwork and can be prestressed by tightening nuts, which is again monitored by measuring the steel strains (Figure 3, right). To compensate for possible losses due to slip, prestressing was slightly above the target level of 100 kN (cf. Figure 6). After concreting and during hardening, the force is carried by the prestressing bed for another 12 days until it is transferred to the concrete. The nuts are loosened gradually to apply the stress evenly. Due to the bond between the concrete and the threaded rods, the test specimen is set under compression.

To create an artificial tendon failure on the pre-tensioned beam, a rod had to be drilled from the outside. Drilling into the concrete would lead to its damage, to which the coda waves react sensitively. To obtain comparable results before and after tendon rupture, the concrete is not allowed to be damaged by the drilling. For this purpose, a plastic tube was inserted during concreting to provide free access from the outside to the tendon later.

3 RESULTS AND DISCUSSION

3.1 Post-tensioning

The post-tensioned beam was prestressed in 10 uniform steps up to 100 kN. Figure 4 ($t = 0$ to 3000 s) reveals the successive increase of the measured strains in the threaded rods in increments of $125 \mu\text{m}/\text{m}$. Afterwards, to simulate tendon failure, the middle bar is gradually released. For this reason, the strain profile of the central rod decreases in steps of $125 \mu\text{m}/\text{m}$ (3000 to 4600 s), whereas the steel strains of the other two tendons rise negligibly from 1250 to 1280 $\mu\text{m}/\text{m}$.

Figure 4. Measurement results of the strain gauges for the post-tensioned beam during prestressing and loosening.

Figure 5. Comparison of the ultrasonic measurements and the strains in the rods for the post-tensioned beam.

Accompanying these strain measurements, US measurements were performed on each prestressing level. Figure 5 compares both the relative velocity changes for an inner and outer transducer pair (in black) and the measured strains of the threaded rods (in grey) for each prestress level (cf. Samples). The elevation in prestress is evident from the nearly linear increase in strain in all three threaded rods ($n = 0$ to 10). With the increasing prestress of the threaded rods comes—the actual goal of prestressing—the increase of concrete’s compressive stress. In accordance to the acoustoelastic effect (Lillamand et al. 2010), the relative velocity change becomes positive, thus indicates a speeding up of the coda waves. For both transducer pairs, there is an almost linear increase in the velocity change, which is in line with the uniformly applied prestress. The larger spacing of the outer US transducers leads to a greater rise in the relative velocity change (max. 0.98%) with increasing load than it is the case for the inner pair (max. 0.18%).

After reaching the maximum force, the prestressing of the central threaded rod is released by loosening the nut in 10 even steps ($n = 10$ to 20) to simulate the failure of a tendon. The measured strain in the middle bar therefore drops linearly, whereas again a slight increase in strain can be observed in the other two tendons. With the gradual failure of a tendon and the resulting decrease in the total prestressing force in the concrete, the relative velocity changes also fall approximately linearly. After the total failure of the middle rod ($n = 20$), the relative velocity changes decrease by 26% (outer pair) and 39% (inner pair). Therefore, the failure of the tendon becomes visible in an evident reduction of the relative velocity change.

3.2 Pre-tensioning

In the case of the pre-tensioned beam, the threaded rods were prestressed in the casting bed before concreting. Figure 6 left illustrates the gradual increase in steel strains in all three tendons and elucidates the exceeding prestressing beyond the target of 100 kN to compensate for effects from slip (relative displacement between the concrete and the threaded rods). After concreting and curing, the load is transferred to the concrete by releasing the prestressing bed (Figure 5, right). Between 0 and 4000 s, the steel strains decrease slightly, which can be attributed to the slip mentioned.

From 4000 s on, the cutting of the central tendon begins. Since the drill bit tends to slip of the threaded rod during drilling, several attempts had to be made and the cutting succeeds only gradually. This results in the stepwise decrease of strain in the middle bar. Due to the bond to the concrete, the tendon is anchored again with increasing distance from the cutting location. Thus, even at the location of the strain gauges, a residual strain of about 500 $\mu\text{m/m}$ remains in the central threaded rod. During tendon failure, the strains in the undamaged bars stay constant.

Figure 6. Measurement results of the strain gauges for the pre-tensioned beam during prestressing, load transfer and cutting.

Figure 7. Comparison of the ultrasonic measurements and the strain in the central rod for the pre-tensioned beam.

Again, accompanying US measurements were carried out several times during the load transfer to the concrete (loosening of the prestressing bed) and the cutting of the tendon. Figure 7 highlights the measured relative velocity changes dv/v again for an inner and outer transducer pair as well as the strains of the middle tendon (left: load transfer, right: cutting). The force transfer to the concrete was not measured directly, but the slight decrease in strain in the tension rods due to slip ($n = 1$ to 15) allows it to be traced. As the load transfer progresses, the measured relative velocity changes for both pairs of transducers are also altered.

Cutting the threaded rod at center triggers a significant drop in the relative velocity change of 50% for the outer and 25% for the inner transducer pair. The damage to the tendon can be clearly recognized by the change in the ultrasonic signals.

3.3 Comparison

In contrast to the post-tensioned beam, all measured relative velocity changes in the pre-tensioned beam have a negative sign. According to the acoustoelastic effect, positive relative velocity changes dv/v would have been expected here since both beams are prestressed. It is assumed that local tensile stresses and cracks occur due to the bond between concrete and threaded bars, which cause a reduction of the ultrasonic velocity. These side effects seem to dominate the measurements, so that the results do not indicate any compressive stresses as a result of the prestressing. Since there is no bond in the post-tensioned beam, these side effects do not appear, making it possible to measure positive values for dv/v there.

4 CONCLUSIONS

A post-tensioned and a pre-tensioned beam were experimentally investigated to detect tendon failures using coda wave interferometry. On both beams, the transmission of the prestressing force as well as the artificial generation of a tendon failure were monitored with ultrasonic and strain measurements.

Provided there is no bond between the concrete and the tendon, as is the case with the post-tensioned beam, the ultrasonic results indicate compressive stresses in the beam. For the pre-tensioned beam, the results are overlaid by local effects—in the form of cracks and tensile stresses—of the bond, so that negative relative velocity changes are measured despite the applied compressive force. Nevertheless, for both types of prestressing, tendon failures could be clearly identified by distinct changes in the ultrasonic signal. The results underline the potential of using the coda wave technique as a permanent measuring instrument to monitor tendons.

In the future, the investigations will be extended to a post-tensioned beam, whose tendons are grouted so that there will be bonding to the concrete. Subsequently, larger prestressed structures will be investigated that are additionally subjected to bending.

Comparison of structural analysis results with coda wave interferometry measurements

S. Grabke & K.-U. Bletzinger

Chair of Structural Analysis, Technical University Munich, Germany

ABSTRACT: Coda wave interferometry is an ultrasound-based technology for structural health monitoring of concrete structures that is based on a correlation evaluation of two ultrasonic signals. To detect damage locations, sensitivities of the coda waves are used. These sensitivities are derived from wave propagation approximations that are computed with the finite element method applied on a diffusion problem. So far, the actual value of localized damage has little meaning in real experiments. This study compares results from structural analysis to the actual measurements. The analysis results should be used as the basis of a measurement classification that in the end should identify damage with a threshold. The comparison is performed at a real four-point bending test of a reinforced concrete specimen.

1 INTRODUCTION

Coda wave interferometry (CWI) is an ultrasound-based structural health monitoring technology for concrete structures. With increasing age of build infrastructure combined with heavier traffic loads, monitoring structures is essential for an evaluation and lifetime extension. The non-destructive CWI is an ideal candidate for a permanent monitoring. Due to a high sensitivity to changes in the medium it can detect cracks at very early stages. Several studies (Niederleithinger et al. (2018); Wang & Niederleithinger (2018); Wang et al. (2019, 2020); Zhan et al. (2020)) have shown the immense potential of damage detection with CWI in large scale field experiments. With a measurement network even a damage localization is possible. In general, the authors refer to damage as an irreversible change of the structure caused by exceeding the elastic load bearing capacity of the material which leads to cracking. So far a classification of detected damage in terms of e.g. crack size is difficult. For a reliable permanent monitoring, a good calibration of the equipment is essential. This is complicated by varying stresses in different regions of a structure. This study compares CWI measurements to stress computations on a structural analysis model to evaluate the possibility of a computation based measurement calibration.

2 METHODOLOGY

The CWI is a relative measurement technology that always needs a reference measurement. This means that the technology can only detect additional damage compared to the reference. Existing damage is only detectable if e.g. a crack is increasing. Also it is of major importance that the ultrasonic signal is scattered multiple times on the way from a source to a receiver. Thus, concrete with its heterogeneous mix of cement, aggregates, pores and reinforcement is an ideal material for the technology. The scattering not only extends the sensing area but also increases the sensitivity to small changes in the medium. A good review on the basics of CWI in concrete can be found in Planès & Larose (2013). The present study is based on an experiment that is further described in Grabke et al. (2021, 2022).

The central element in CWI is a cross-correlation (CC) evaluation of the measurements. Changes in the medium e.g. by cracks but also temperature (Wunderlich & Niederleithinger (2011)), moisture (Ju et al. (2015)) and stresses (Larose & Hall (2009); Lillamand et al. (2010))

affect the coda signal. The CC in the signal φ at time t is measured in a time frame of length T with the following formula:

$$CC(t) = \frac{\int_{t-T/2}^{t+T/2} \varphi_{ref}(t)\varphi(t) dt}{\sqrt{\int_{t-T/2}^{t+T/2} \varphi_{ref}^2(t) dt \int_{t-T/2}^{t+T/2} \varphi^2(t) dt}} \quad (1)$$

Depending on the type of monitoring the CC is either evaluated for a time frame with length of the whole signal or several shorter consecutive time frames that measure a development within the signal. The CC can be used directly as a measurement or with a network of several measurements a damage localization can be performed. For the localization, the sensitivities of a coda wave K are computed as follows (Pacheco & Snieder (2005)):

$$K(S, R, x, t) = \frac{\int_0^t I(S, x, u)I(x, R, t - u) du}{I(S, R, t)} \quad (2)$$

In Equation 2, I (*position 1, position 2, t*) stands for the wave intensity at *position 2* after time t of a wave starting from *position 1*. Looking at the numerator of Equation 2 one can see that the integral sums up all the time combinations of a wave going from the source position S to position x to the receiver position R in time t . Since the waves going through position x are just a fraction of all wave paths arriving at the receiver R , the numerator term is normalized by the general possibility of a wave travelling from source S to receiver R in time t .

In order to reduce computational complexity and the possibility to apply a damage localization at large structures, the diffuse coda wave intensities are approximated. Ryzhik et al. (1996) have shown that the spread of a waves energy in a random media as concrete can be approximated with a diffusive spread in a homogeneous medium. This study uses the finite element method (FEM) to solve the diffusion problem. With the coda wave sensitivities an inverse problem can be formulated whose solution is the damage localization. Grabke et al. (2022) gives further insights on the FEM based computation and damage localization that is based on Planès et al. (2015).

The inversion based damage localization has the advantage that it is mapping a localized damage on the structure but without calibration contains no reliable information about the damage size. A calibration is rather tricky because measurements are strongly depending on the given setup and ideally would require a test damage which is impractical. Also the damage localization requires a steady-state for the time it takes to perform all measurements. Depending on the amount of measurement pairs and used equipment this takes several seconds up to minutes. In conclusion, this means that for a practical application with traffic load only a few measurements are active during a critical loading. Thus this study investigates the possibility to calibrate each measurement pair individually based on computed stresses for critical load cases and derive a damage threshold for each measurement pair. In typical applications the stress state is multiaxial and the principal stress directions indicate crack formations. The von Mises stresses $\sigma_{v,M}$ are fictitious equivalent stresses computed for each element from the Cauchy stress tensor and describe the overall material utilization. Important to note here is that von Mises stresses are actually not a good stress measure for concrete because compressive and tensile load bearing capacity differ by a factor of approximately 10. Later the von Mises stresses are thus modified. Further improvements can be achieved by applying a non-linear material model that contains the actual yield criteria of concrete (e.g. Kupfer & Gerstle (1973)) on the simulation. In this study the Cauchy stresses are first transferred to principal stresses $\sigma_{1,2}$:

$$\sigma_{1,2} = \frac{\sigma_x + \sigma_y}{2} \pm \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau_{xy}^2} \quad (3)$$

The von Mises stresses are then computed as follows:

$$\sigma_{v,M} = \sqrt{\frac{1}{2}[(\sigma_1 - \sigma_2)^2 + \sigma_1^2 + \sigma_2^2]} \quad (4)$$

This study uses a simple first order linear structural analysis on the same mesh as the FEM computations for the diffusion problem. In order to classify CC measurements the coda wave sensitivities are superposed with stresses in the medium. With stresses being an element related quantity and coda wave sensitivities being an node related quantity they need to be transferred to a common basis. This study thus interpolates the coda wave sensitivities on the elements. In order to compare measurements among each other a weighting factor w for each pair is introduced. For comparison this weighting factor is later normed with the maximum norm.

$$w(S, R) = \int_{\Omega} \int_T K(S, R, x, t) dt \sigma_{v,M}(x) dx \quad (5)$$

3 EXPERIMENTAL SETUP

The comparison of structural analysis and coda measurements is made at the experiment described in Grabke et al. (2021). The experiment performed by the Institute of Concrete Structures at the Ruhr University Bochum is a four point bending test. Figure 1 gives an overview on the experimental setup. Figure 2 shows the CC development of selected measurement pairs for increasing loading. In the given experimental setup the concretes tensile strength f_{ctm} is

Figure 1. Overview of the four-point bending test conducted at a real reinforced concrete specimen by the Institute of Concrete Structures at the Ruhr University Bochum. Blue dots show the 25 embedded ultrasound transducers used and green marks the reference measurement with Fiber Optic Sensor. Grey lines indicate the evaluated measurement pairs.

Figure 2. Cross-correlation development of selected pairs over the first load steps.

reached around load step 10. This is the load steps where computationally cracks occur. In the CC development one can see that even before cracking, correlation drops can be measured. One can see that depending on the position of measurement pairs within the structure, the CC values are of different magnitude. In general, measurements near the damage zone show the lowest correlation whereas measurements in zones further away from cracks are comparable little. For the investigated four point bending test Figure 3 gives the von Mises stresses $\sigma_{v,M}$.

Figure 3. Normed von Mises stresses $\sigma_{v,M}$ for the investigated four-point bending test.

4 RESULTS

For evaluation load step 8 is closer investigated. This load step is computationally uncracked and thus the used computations are applicable. On the other hand the measured CC for some measurements are already comparably large. Figure 4 shows the CC measurements at load step 8 mapped onto the structure. One can see that the CC values for each measurement are of very

Figure 4. CC measurements at load step 8 mapped onto the structure.

different magnitudes. The weights from Equation 5 that superpose coda wave sensitivities and stresses in the specimen should help explain these differences. They are shown in Figure 5. One can see that due to the formation of an arch under pressure for the four point bending test,

Figure 5. Weights computed with Equation 5.

especially the measurement pairs in the middle on the top have larger weights, whereas the CC on the bottom in the tensile zone are that lowest. The CC values are most probably due to the fact that concrete works well under pressure but cracks comparably early under tension. Concluding the comparison one can say that a comparison of the measurements in Figure 4 and the weights in Figure 5 is not satisfying. With the CWI as a technology that especially measures cracks with a high sensitivity, the focus is now put on the principle tensile stresses in the specimen. Therefore the compressive principle stresses from Equation 3 are neglected for the von Mises stress computation of Equation 4. The resulting von Mises stresses are shown in

Figure 6. Normed von Mises stresses $\sigma_{v,M}$ with compressive principal stresses neglected.

Figure 7. Weights computed with Equation 5 with neglected compressive principle stresses for the von Mises stress computation of Figure 6.

Figure 6 and the resulting computation of weights is shown in Figure 7. One can see that overall there is a correlation of the value distribution between Figures 4 and 7. Further investigations will deal with the question of how to use the weights to calibrate the CC measurements in order to have an overall damage threshold. Out of the box the results were not satisfying. A big role play selected measurements with over-proportionally little CC. These unusual measurements can come from cracks very close to transducer positions. The weights of Figure 7 however, are an ideal tool to find malfunctioning of measurement equipment.

5 CONCLUSIONS

Concluding one can say that structural analysis can help explain and understand CWI measurements. The study has shown that especially changes in the specimen due to tensile stresses are measured. As mentioned earlier the used modified von Mises stresses are a simple technique and further improvements can be achieved by applying a non-linear material model that contains the actual yield criteria of concrete on the simulation. With a model that can approximate expected measurement values there is immense potential for the future. Future research will try to classify CC measurements based on the structural analysis results.

About the separation of impacts on coda waves in concrete

F. Diewald

Centre for Building Materials, Technical University of Munich, Munich, Germany

ABSTRACT: Our built environment during the last 100 years has expanded more than ever referring to material consumption of the construction industry. Especially for engineering structures, the most common building material is reinforced concrete due to its performance, cost-efficiency and availability. However, this material poses special challenges regarding non-destructive monitoring of both the condition and integrity of civil engineering structures, which is an increasingly important part within life cycle analysis. Ultrasound-based Coda Wave Interferometry (CWI) is one of the most promising monitoring techniques as it can detect and localize even weak changes in the microstructure of heterogeneous materials. Recent research has shown that this technique is also applicable for identifying precursors of deterioration processes.

One of the challenges for concrete monitoring using CWI is the separation of reversible changes due to temperature and moisture as well as mechanical stresses from irreversible changes such as damage in the structure. Previous studies investigated these impacts in the framework of ‘one-dimensional’ experiments at the specimen scale under laboratory conditions. From each experiment, we derived calibration curves for the relation between the individual external impact and the Coda Waves’ velocity variations, which are consistent for one concrete mix. In this contribution, we summarize these relations and propose equations, allowing us to distinguish between the causes of velocity variations of Coda Waves propagating in concrete. With this research, we aim at generating a model that will enable the separation of reversible and irreversible changes in concrete using Coda Wave Interferometry. Our results will contribute to establishing CWI as an early-warning-system for engineering structures made from reinforced concrete and therefore increasing the safety of large parts of our infrastructure.

1 INTRODUCTION

Using Germany as an example, the largest proportion of our infrastructural buildings is raised from structural concrete and the majority of the over 52,000 bridges have been constructed between 1960 and 1990 (BASt 2021). Amongst novel reliability models (Gehlen 2000; Breit et al. 2011; von Greve-Dierfeld & Gehlen 2016a; von Greve-Dierfeld & Gehlen 2016b; von Greve-Dierfeld & Gehlen 2016c) and updated building codes, the scientific community addresses the safety needs of the ageing infrastructure, which has to deal with a steadily increasing traffic volume at the same time, by developing new monitoring methods for damage detection. Structural concrete poses a special challenge to monitoring techniques, mainly because of its distinctive heterogeneity and complex microstructure. One of the most promising techniques to detect even weak changes in the microstructure of concrete is ultrasound-based coda wave interferometry.

A most discussed process of damage development is corrosion-induced deterioration. Figure 1 (Gehlen 2000) illustrates that microstructural changes, or in other words micro-scale damage formation, starts after depassivation of the reinforcement. The damage level becomes critical after exceeding a limit state for the crack width (Gehlen et al. 2010) as

self-reinforcing effects occur due to facilitated gas and liquid transport mechanisms until the structure reaches the Ultimate Limit State, which is equal to its failure. Within this process, detection of mechanical damage is desired as early as possible for safety and economical reasons. It is realized by either inspection at discrete points in time or by a continuous monitoring system. Due to its extraordinary sensitivity in heterogeneous media like concrete, CWI is suitable for damage detection at an unprecedented early stage in comparison with conventional NDT techniques.

Figure 1. Time-depending progress of corrosion-induced deterioration and damaging of reinforced concrete structures and their limit state, adapted from (Gehlen 2000), characterized by the initiation period and the damaging period, during which mechanical damage occurs. In comparison with many conventional non-destructive testing methods in heterogeneous media, coda wave interferometry is more sensitive and has the potential to detect damage before other techniques.

The research presented in this study summarizes the main findings of a doctoral thesis (Diewald 2023), where the content in this article is taken nearly verbatim from the thesis. The results will contribute to establishing CWI for its application as an early-warning monitoring system for integrity assessment of structures made from reinforced concrete. The research is motivated by the need for a general safety increase of our built environment.

2 METHODS

The potential sensitivity of coda waves to weak changes in heterogeneous media has been recognized much before its application to concrete structures. Early studies from the geophysical community investigated the seismic source, attenuation and scattering effects of coda waves from small local earthquakes already in 1969 (Aki 1969; Aki & Chouet 1975). Finite difference and finite element methods have already been suggested for the case of known model parameters to interpret the seismograms regarding the geometrical localization of any change. The model parameters were typically unknown for the earth's crust, however, they may be well-known in static models for engineering structures today. Later in 2002, CWI was introduced by revealing the relationship between the seismic velocity in granite and temperature changes together with the associated acoustic emissions (Snieder et al. 2002). Furthermore, the at first sight chaotically and noisily appearing coda waves were found to be highly repeatable as no change in the medium appears (Snieder 2006).

Multiple methods for CWI analysis are based on the calculation of a stretching factor $\varepsilon = dt/t = -dv/v$ (Snieder et al. 2002; Sens-Schönfelder & Wegler 2006; Hadziioannou et al. 2009), using a maximum signal correlation coefficient CC between a reference signal $u(t)$ and a perturbed signal $\tilde{u}(t)$, where t_1 and t_2 mark the time window in which the velocity change is derived. Equation (1) states the basic equation of the stretching technique (Sens-Schönfelder & Wegler 2006) to determine relative velocity changes dv/v .

$$CC(\varepsilon) = \frac{\int_{t_1}^{t_2} u(t)\tilde{u}(t(1-\varepsilon))dt}{\sqrt{\int_{t_1}^{t_2} u^2(t)dt \int_{t_1}^{t_2} \tilde{u}^2(t(1-\varepsilon))dt}} \quad (1)$$

The exceptional sensitivity, together with the signal repeatability, led to a large number of studies about detecting and locating weak changes in concrete using CWI dealing with the ultrasonic wave speed, affected by thermal, mechanical and chemical damage (Planès & Larose 2013). However, these impacts may affect a structure at the same time and add various terms to the total velocity change. This superimposition is a big challenge regarding the interpretation of the velocity variation as their exact separation into the single effects is unknown. Irreversible changes are of particular interest because they are generally synonymous to occurring damage in the structure. Therefore, another aspect of interpreting the velocity variation is the separation between changes that are reversible and the irreversible ones that indicate damage. Figure 2 shows different impacts on engineering structures that affect the properties of coda waves.

Figure 2. Summarized effects on the velocity variation dv/v between two ultrasonic signals propagating in a structure at a reference state and at the evaluated state. The term long-term phenomena aggregates further concrete-specific phenomena, e.g., shrinkage, creep, carbonation, and corrosion, whereas the remaining effects act on a short-term scale.

3 RESULTS

For each sender-receiver pair in a structure, we can collect one ultrasonic signal at a time and determine the total velocity change between the measurements at a reference state and the evaluated state. The measured velocity variation can be expressed as a sum of three terms that change at different rates over time as in Equation (2). The transient term covers the impacts from state changes due to temperature, stress, or moisture, where the changes in dv/v are expected immediately, e.g., for stress, or over a few hours up to days, e.g., for temperature and moisture in large structures. A second stationary term includes velocity variations that steadily develop over longer periods, in the range of over months or years. This term is affected by long-term strain or chemical changes of the phase composition. In this formulation, the first two terms are considered reversible, whereas a third term includes changes that are induced by any irreversible material change. Therefore, any value greater than zero is an indicator for damage in the structure.

$$\left(\frac{dv}{v}\right)_{measured} = \left(\frac{dv}{v}\right)_{transient} + \left(\frac{dv}{v}\right)_{stationary} + \left(\frac{dv}{v}\right)_{irreversible} \quad (2)$$

The individual effects on Equation (2), coming from the structural system, are presented in greater detail in Figure 3.

The left side of Equation (2) is the result of ultrasonic measurements followed by the calculation of dv/v , while the irreversible term on the right side is usually the critical one that should be determined to identify any damage in the structure. To solve the equation, both the remaining terms must be evaluated in detail. Equation (3) further breaks down the transient term of dv/v , where individual effects of temperature T , saturation degree S of the material, i.e., the pore space, and stress σ are included. In this notation, x_0 refers to the value of each variable at the reference state, while Δx refers to its change.

$$\left(\frac{dv}{v}\right)_{transient} = \frac{dv}{v}(T_0, \Delta T) + \frac{dv}{v}(S_0, \Delta S) + \frac{dv}{v}(\sigma_0, \Delta\sigma) \tag{3}$$

Figure 3. Summarized effects on the velocity variation dv/v refined from Figure 2. Originating from the measured total velocity variation, dv/v splits into three terms according to Equation (2). Transient changes occur on a short time scale, whereas stationary changes are only visible over a long period. Assuming that these two terms can be predicted, any remainder can be considered an irreversible change that indicates damage in the structure.

Both temperature ($T_0, \Delta T$) and saturation degree ($S_0, \Delta S$) are variables that must be considered together, as they affect each other due to the temperature-affected moisture content of the structure’s environment and the moisture gradient that arises in the material. It is important to note that the saturation degree of the pore space affects the anelastic seismic properties of concrete. However, S is usually not directly measurable and must be expressed by external variables, e.g., relative humidity RH or electric resistance of the electrolyte Ω . Equation (3) emphasizes the impact on dv/v as a result of the state change of the material due to the saturation degree rather than using an external variable, for which a delayed system response should be considered.

The relationship between temperature and dv/v is quasi-linear for the same water-to-cement ratio (Larose et al. 2006; Wunderlich & Niederleithinger 2012). For relative humidity variation, a steady decrease of dv/v develops for an increase of water in the pore system between 35%RH up to 80%RH at a reference temperature of 20°C (Diewald 2023). Furthermore, a saturation degree above this value can disrupt the trend, where dv/v increases compared to the lower values of RH . Combining all observations and the additional consideration of the water-to-cement ratio, which influences the pore space, leads to a third order polynomial model that covers the variation of the three variables and their effect on the velocity variation dv/v at a high degree of confidence.

The saturation degree exposes particularly well the fact that any relationship stated for the individual arguments depends on the material composition as the amount of water in the pore space is also affected by the volume of the pore space which again depends on the water-to-cement ratio w/c . We showed this in the polynomial model that had dominant terms depending on w/c . Furthermore, also elastic, anelastic and scattering properties may change for different material mixes. This implies that any experimentally determined relationship for both the transient and the stationary terms is only valid for the particular material. The relationships between the transient and stationary impacts on the velocity variation can either be

experimentally determined for the particular case, for which Equation (2) should be solved, or predicted by material models in combination with wave propagation simulations (Vu et al. 2021a; Vu et al. 2021b; Saenger et al. 2021; Holla et al. 2021). Such models can be calibrated by means of the physical relationships and the data from experimental studies with the objective to be transferable for arbitrary material mixes. Nevertheless to compensate for velocity changes due to temperature and the saturation degree, the T and S of the structure must be known and measured on a continuous basis, e.g., in the same grid as ultrasonic transducers are embedded.

The relationship between stress ($\sigma_0, \Delta\sigma$) and the velocity variation is also affected by the material mix as the crack formation process changes for different material mixes. A stress increase can be approximated by a linear relationship in the elastic range up to 30% of the material strength for both compression and tension, while an irreversible velocity decrease occurs above this load level (Diewald, Epple, Kraenkel, Gehlen, & Niederleithinger 2022).

The influence of the cross correlation value CC on the calculation of dv/v must also be considered and its computation should be standardized during the entire evaluation cycle (Diewald et al. 2022). This becomes especially important for major changes in the structural system, i.e., irreversible ones or long-term changes with a great effect on the ultrasonic waveforms. Equation (4) provides the arguments of the long-term stationary term, where the effects of strain ε and chemical phase changes Ψ are included.

$$\left(\frac{dv}{v}\right)_{stationary} = \frac{dv}{v}(\varepsilon_0, \Delta\varepsilon) + \frac{dv}{v}(\Psi_0, \Delta\Psi) \quad (4)$$

Typical phenomena that induce long-term strain ($\varepsilon_0, \Delta\varepsilon$) in concrete are shrinkage and creep, where the resulting strains have an impact on the velocity variation in addition to immediate change of dv/v due to stress. It was shown that the characteristic shrinkage and creep behavior of concrete can be measured for several load levels using CWI (Diewald et al. 2022). Consequently, these changes must be considered especially for long-term state comparisons using CWI and, thus, appear in in the stationary term.

Furthermore, the velocity variation is affected by chemical phase changes ($\Psi_0, \Delta\Psi$). Phase changes are a continuous process in cementitious materials, whereas two types of phase changes should be distinguished here. First, early hydration is the most extreme case, during which cement and water react, develop strength, and develop to the solid form cement paste. It was shown that the velocity variation development using stepwisely compared ultrasonic signals correlates with the dissolution of the main clinker phases over time (Diewald et al. 2022). CWI shows similarly high accuracy in detecting characteristic hydration periods compared to conventional techniques, e.g., heat flow calorimetry and Vicat test, but also to a thermodynamic model of early-age phase formation using CemGEMS. Although the study showed that ultrasonic velocity changes can detect the early-age strength development of concrete during the early hydration, CWI is usually designed to detect weak changes in a structural concrete system as expressed by Equation (2). Hence, phase changes addressed in Equation 4 are rather long-term and must be considered as a source for velocity changes.

4 CONCLUSIONS

In order to make Equation (2) fully interpretable, we will need material models that can cover all the summarized effects for individual material mixes with arbitrary scattering properties. In turn, the scattering properties should be defined by material parameters, e.g., elasticity, pore and aggregate size, which can be easily determined for each concrete. As soon as the individual arguments for the transient and the stationary terms can be predicted by concrete models, the total measured velocity variation may be evaluated regarding any remaining value that can be assigned to the irreversible term as an indicator for damage.

However, this requirement only exists, when a full interpretation becomes necessary. This is mostly the case regarding the identification of long-term damage development together with the separation from other long-term phenomena that are non-destructive. For the identification of spontaneous or short-term damage development in general, CWI is a suitable technology due to its sensitivity to changes in the microstructure, even if the transient and the stationary terms or the scattering properties are not fully known. In this case, even without an exact interpretation of the causes for velocity changes, CWI is applicable as an early-warning system.

ABSTRACT: Identifying and preventing damage in concrete structures at an early stage of material degradation can significantly reduce costs associated with the maintenance and repair of concrete infrastructure. Weak material degradation, such as load-induced initiation and propagation of microcracks, is a precursor of localized damage (macrocracking) in concrete structures and can be detected by means of multiple-scattered late arriving ultrasonic signals, also called coda waves. In order to reliably identify and quantify damage initiation and propagation using coda waves, a systematic tool that translates ultrasonic coda signals into the state of damage is required. To this end, we systematically investigate the effect of material degradation on the coda variations at the specimen level using a combination of multiscale computational modeling, forward wave propagation simulations and feature extraction. At the specimen scale, damage initiation and propagation in realistic mesoscale concrete models is simulated using a virtual lab and a novel reduced order multiscale method. The concrete specimens subjected to specific level of damage in the virtual lab are subsequently analyzed by wave propagation simulations. Finally, a strategy for using specimen scale information for predicting the state of damage at the structural scale will be presented.

1 INTRODUCTION

Throughout their service life, concrete structures undergo a gradual degradation process as they are constantly exposed to a wide spectrum of environmental and mechanical loads. These influences promote the growth of pre-existing defects in concrete. Without appropriate maintenance of the structure, microcrack growth might lead to microcrack coalescence and crack localization and ultimately to complete loss of load bearing capacity of a concrete structure. In this regard, detection of early stage degradation of concrete structures can help reduce costs associated with maintenance and repair of concrete structures (Gharehbaghi et al., 2021, Inaudi 2009). This can be potentially achieved by the use of coda wave based monitoring system as it is highly sensitive to weak changes.

Coda Wave Interferometry (CWI) (Snieder et al. 2002) is a technique used in seismology that utilizes the late arrival part of an recorded ultrasonic signal (typically called coda waves). On one hand, this part of the signal contains rich information of concrete microstructure thanks to the multiple sampling process within the concrete medium. By analyzing the evolution of coda features, information of subtle material changes can be extracted. On the other hand, the high sensitivity of the coda wave constitutes a challenge in reliably translating the variation of coda waves into the corresponding level of damage in concrete structures. Various experimental

investigations have been conducted to explore the potential of CWI to quantify load induced damage in concrete. Yet, under laboratory environment, two underlying issues arise: damage quantification and effect discrimination.

Therefore, numerical simulations can provide insights regarding the physical phenomena and consequently help establish the relationship of damage and coda variations quantitatively. In this contribution, we present a computational framework that simulates 1) load induced distributed damage in concrete, and 2) wave propagation process in an affected concrete specimen. The usefulness of the proposed framework is demonstrated through data generation for ultrasonic waves based investigation of damage.

2 CONCEPT OF CODA BASED VIRTUAL LAB FOR DAMAGE IDENTIFICATION IN CONCRETE

The design of a coda based virtual lab is analogous to a standard setup for non-destructive evaluation of concrete specimens in laboratory condition (see, e.g., Diewald et al. 2022, Stähler et al. 2011). We designed our simulation workflow as follows: the first step is called Data Generation, in which simulated coda signals are generated for various damage conditions of a concrete specimen by means of mechanical and wave propagation simulations. Here, the uniaxial compression load case is considered. In the second step–Feature Extraction, the feature of simulated signals at increasing damage levels obtained from the CWI operation is further validated with the experimental data. See Figure 1 for a schematic illustration of the workflow.

Figure 1. Schematic illustration of the virtual concrete laboratory.

3 UNIAXIAL COMPRESSION SIMULATION OF LOAD INDUCED DISTRIBUTED DAMAGE IN CONCRETE

Under uniaxial compression, damage process in concrete involves various complex mechanisms taking place simultaneously across scales (Van Mier 1998). The complex behavior originates from the heterogeneous nature of concrete ranging from nanometer scale to decimeter scale. Particularly, at microscopic scale (approx. 10^{-3} m), mortar consists of hardened cement matrix hosting sand particles, pores, as well as defects known as microcracks. At the meso-level, concrete consists of irregular coarse aggregates randomly distributed in a mortar matrix. As a result, concrete under loading exhibits a highly perturbed stress field. Such stress fluctuation causes microcracks to first deform and subsequently propagate, playing a governing role in the pre-peak behavior of concrete.

In this regard, from the modeling viewpoint, it is important to consider these microstructure details and its evolution induced by the external load. Therefore, to simulate distributed damage in concrete, we adopted the reduced order multiscale modeling strategy proposed in Vu et al. 2021a. The schematic illustration of the multiscale model is presented in Figure 2.

Figure 2. Schematic illustration of the multiscale model showing distributed penny-shaped microcracks and coarse aggregates embedded in the mortar matrix made of hardened cement paste and sand.

3.1 Methodology

In general, a multiscale modeling framework requires two primary operations to efficiently transfer information across scales: *Localization* and *Homogenization*. This approach mitigates the need of relying on conventional empirical constitutive models and enables the generation of microstructure-property relationships (Matouš et al. 2016). If the microstructure is explicitly resolved, such a multiscale modeling scheme is generally computationally demanding as one has to solve a large number of sub-problems at each material point. Thus, it is often appropriate to employ a model order reduction technique. In the proposed multiscale approach for modeling concrete, we use a K-means clustering based model reduction (Liu et al. 2016) to group material points (voxels) that have a similar mechanical behavior into a finite number of groups denoted as clusters. Subsequently, a microscopic continuum micromechanics based sub-problem is incorporated to each cluster during numerical simulation. In the *Localization* step, given the applied macroscopic strain, the mesoscopic strain field is computed by means of the Fast Fourier Transform (FFT) based computational homogenization method (Moulinec & Suquet 1994). This information (mesoscopic strain tensor) is transferred to the microscopic scale, where the evolution of microcrack topology is modeled using a damage law based on the framework of Linear Elastic Fracture Mechanics (LEFM) (Pichler et al. 2007, Iskhakov et al. 2021). In the *Homogenization* step, the effect of evolving microcracks results in the change of the effective secant stiffness tensor, computed using the modified Interaction Direct Derivative (IDD).

3.2 Mesomodel of concrete

One of the important simulation inputs is the mesoscopic description of concrete. To generate a highly realistic virtual specimen, we used the computational tool developed by co-authors. Input of the mentioned tool includes the measured size distribution of coarse aggregates and geometrical description of each aggregate family (e.g., size, aspect ratio, smoothness, concave surface parameters). The generated mesomodel is also periodic, which shows clear advantage in computational homogenization and in the forward wave simulations. Further details regarding the algorithmic implementations can be found at (Holla et al. 2021).

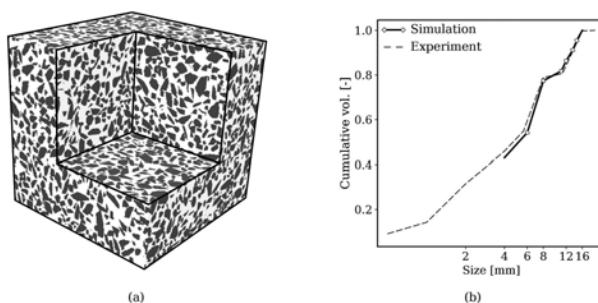

Figure 3. Visualization of the simulated concrete specimen of standard AB16 (a) and its corresponding grain size distribution.

Concrete specimens of size 10 cm, standard AB16 were considered for the analysis. The high-fidelity concrete specimen is discretized using 201^3 voxels of size 0.5 mm (Figures 3 a, b). Moreover, via k-means based model reduction procedure, the information of the meso-model is compressed into 72 clusters: 64 clusters of mortar matrix, and 8 clusters of quartzitic aggregates. Also, the material parameters for each constituent at this scale are listed in Table 1.

Table 1. Material parameters of quartzitic aggregate, mortar matrix ($\varphi_{quartz}=43.95\%$), and concrete standard AB16.

Material parameter	Quartzitic aggregate	Mortar matrix	Concrete
Young's Modulus E [GPa]	84.6	30.1	48.03
Poisson's ratio ν [-]	0.12	0.19	0.15
Density ρ [kg/m^3]	2650	2104	2364

3.3 Micro-parameters of mortar cementitious material

Regarding the material and numerical parameters, we used parameters provided in (Vu et al. 2021a). It is to be noted that, the model has been validated with the experimental data. The microcrack parameters and the corresponding mechanical properties of mortar matrix used in the numerical simulations are summarized in Table 2.

Table 2. Microcrack geometrical parameters.

Microcrack radius	a	0.023	mm
Microcrack half thickness	c	0.001	mm
Total microcrack volume fraction	φ_{crack}	8.3	%
Solid mortar's fracture energy	g_f	0.661	N/mm

3.4 Uniaxial compression

Figure 4. Stress-strain response obtained from the numerical simulation (a), and the evolution of secant stiffnesses (b).

The clustered virtual sample is then subjected to the uniaxial compression test with the strain increment of 10^{-5} . The stress-strain curve obtained from the simulation is presented in Figure 4 a. From the simulation, one can specify 3 pre-peak regimes: elastic deformation, microcrack growth, and microcrack coalescence. The elastic regime is characterized by the elastic relation between global stress and strain. The microcracking regime starts at 15.89 MPa (20.4% f_c). At this stage, microcracks whose plane parallel to major stress axis grows, resulting in a steady reduction of the axial secant stiffness. At the near peak regime (45-55 MPa), concrete undergoes a rapid reduction in stiffness. This can be attributed to the coalescence of microcracks and crack localization. Also from Figure 4b, it can be seen that, the lateral secant stiffnesses reduce at much faster rate than the longitudinal one due to the selective direction of propagation of the microcracks.

At a given load step, local information of the degraded secant stiffness tensor is exported and serves as input for the forward wave propagation simulations.

4 SIMULATION OF ULTRASONIC WAVES IN CONCRETE MEDIUM

In this section, we demonstrate the use of the wave propagation simulation for generating simulated coda signals. These simulated signals, once validated with measured ones, can be utilized for coda wave based investigations and help the development of a data-driven damage classifier, especially when measured data are not often available for training. Moreover, another advantage of numerical modeling is that damage information is known at each simulation step and therefore reliable damage labeling is possible.

4.1 Simulation setup

The simulation setup is analogous to the setup for ultrasonic investigation of concrete under uniaxial compression described in Diewald et al. 2022. The test subjects are prism concrete samples of $10 \times 10 \times 40$ cm. Two transducers are embedded at the center axis, located at 30 cm away from each others and at 5 cm distance to the nearest boundary. The high slenderness ratio is desired to keep the distance between the transducers longer than the wave length of the excitation source (60 kHz).

This setup can be realized by stacking 4 periodic cubic concrete samples from previous simulation in the vertical direction. It is important to note that, the frictionless boundary condition can be applied to impose the true uniaxial compression stress state. As such, the pre peak behavior of concrete is then independent of the specimen slenderness (Van Vliet & Van Mier 1996, Van Mier et al. 1997).

Ultrasonic 3D wave simulations are performed using a rotated staggered-grid finite-difference scheme (Saenger et al. 2000) over 40,000 time steps (2 ms duration), with the gridsize of 0.5 mm and the time step size of 5×10^{-8} s. The mentioned scheme is ideal for simulating the wave field in heterogeneous medium and has been successfully applied to concrete as demonstrated in Kocur et al. (2010). To simulate the attenuation phenomenon observed in ultrasonic measurement, a specific viscoelastic model is used and thus 4 additional parameters are introduced. Frequency-dependent attenuation is simulated with 2 Maxwell bodies with $\gamma_1 = 0.04$, $\gamma_2 = 0.1$ (defining $\bar{Y}_m^{ijkl} = c_{ijkl} \gamma_m$) at frequencies $\omega_1 = 2\pi 20$ kHz, $\omega_2 = 2\pi 1$ MHz, respectively. See Equation (4) of Saenger et al. (2005) for further details regarding the parameters. In addition, to simulate reflective boundary, additional vacuum layers have been added to all sides of the concrete model. For the simulation of concrete at the initial condition, the material parameters for each phase are taken from Table 1. In the remaining 12 damaged cases, the stiffness is computed by taking the average of lateral and longitudinal stiffnesses. Whereas, the stiffness and Poisson's ratio of vacuum are set to zero and its density is set to 10^{-5} kg/m^3 .

Following the approach outlined in (Finger et al. 2021), the excitation source is a moment tensor source with 2 non-zero components (xx and zz). The wavelet form was also taken from (Finger et al. 2021) with a central frequency of 60 kHz. This is within the recommended frequency range for ultrasonic testing in concrete (Fröjd & Ulriksen 2017).

Multiple receivers are considered in the analysis. Here, a total of 27 receivers positioned at 3 zz-planes of 27.5, 30.0, 32.5 cm distance to the source, respectively. The spacing between receivers on the same planes is 2.5 cm. The simulated signals are the average of temporal displacement in x, y, and z directions. An exemplary numerical setup is illustrated in Figure 5.

5 CODA WAVE INTERFEROMETRY (CWI) ANALYSIS

5.1 The CWI-method

Given 2 ultrasonic signals recorded from a fixed source and a fixed receiver, CWI can be applied on their coda parts to evaluate the similarity of two signals. In this process, changes in

Figure 5. Summary of a 3D simulation setup. a) Visualization of the model at mid-plane ($y = 5$ cm), aggregate phase and mortar phase are marked in black and grey, respectively, red circle denotes source location ($z = 5$ cm), white triangles denote receiver locations. b) Displacement (z) snapshot at 0.04 ms. c, d) Visualization of the pulse signal used to induce a seismic wavefield in concrete medium, and the recorded signal at location $x = y = 5$ cm, $z = 35$ cm.

the examined medium can be detected. Various CWI methods have been proposed in recent decades. In most methods, velocity variation and cross correlation features are calculated. In our analysis, the stretching technique (Niederleithinger et al. 2018) is adopted as the method is stable regardless of the choice of the time-window. Given two signals $u_u(t)$, $u_p(t)$, evaluated within the time window $[t_1, t_2]$, the relative velocity change $\frac{dv}{v}$ is the value of the stretch factor ε that maximizes the cross correlation of two signals and is calculated as:

$$\frac{dv}{v} = \operatorname{argmax}_{\varepsilon \in \mathbb{R}} CC(\varepsilon) = \operatorname{argmax}_{\varepsilon \in \mathbb{R}} \frac{\int_{t_1}^{t_2} u_u(t) u_p(t(1 + \varepsilon)) dt}{\sqrt{\int_{t_1}^{t_2} u_u^2(t) dt \int_{t_1}^{t_2} u_p^2(t(1 + \varepsilon)) dt}}, \quad (1)$$

Here u_u and u_p denotes signals travelling through unperturbed and perturbed medium, respectively.

5.2 Numerical results

The stretching method has been applied for all 27 sender-receiver pairs over 13 load steps (1 intact, and 12 affected conditions). The time window $[0, 1]$ ms was selected for the evaluation, this includes both direct and coda parts of the ultrasonic signal.

Figure 6 shows the correlation of $\frac{dv}{v}$ and the applied stress. Three stages can be identified, marked in Figure 6. In the elastic stage, the simulation could not reproduce the typical increase in wave velocity typically seen in the experiment, this is because the current model is not yet accounting for microcrack closure. In stage 2 (18–32 MPa), we see a reduction of $\frac{dv}{v}$ at the rate of 0.0041 MPa^{-1} due to diffuse microcracking. At stage 3, measurement at different receiver locations shows a higher deviation as compared to stage 2. This could imply an uncertainty and robustness of CWI technique at higher load level, which should no longer be considered a weak change. Overall, the trend reproduced from the simulation is similar to the experimental range reported in He et al. 2022. Moreover, an almost linear correlation between $\frac{dv}{v}$ and the global stiffness reduction can be seen in Figure 6 b. The rate of change is 0.799 with maximum standard deviation of 0.988.

Figure 6. a) The relative velocity change $\frac{dv}{v}$ in relation with the applied stress. Each mark ‘x’ represents measurement from one transducer-receiver pair. In total, 351 $\frac{dv}{v}$ measurements were calculated. b) Correlation of reduction in velocity and the reduction in average stiffness.

6 CONCLUSIONS

In this contribution, we demonstrated the use of a computational framework for damage evaluation of concrete using ultrasonic waves. First, mechanical simulations were performed using a multiscale reduced order modeling methodology. It was followed by performing wave propagation simulation in the concrete specimen at different damage levels. The recorded signals were analyzed by means of the CWI method and a relation between the relative velocity change and global stiffness change was derived. Based on the numerical results, the following remarks can be drawn:

- A virtual environment for ultrasonic testing has been established. The proposed methodology is able to reproduce experimentally observed phenomena and can be used to generate a large synthetic dataset for data-driven damage classification.
- From the structural health monitoring viewpoint, one can evaluate the level of global material degradation in concrete using CWI method, provided that the type of damage is known a-priori. In general, concrete is highly resistant to compression loads and can sustain a prolonged microcracking stage. While under uniaxial tension, concrete fails at much lower threshold of microcracking (see Diewald et al. 2022).

To realize a robust tool for structural health monitoring at the structural level, the following aspects should be taken into account:

- Material uncertainty has to be introduced into the numerical model, for instance, by simulating more concrete samples with varied grain size distribution, strength, and stiffness.
- Damage in tension should also be considered, and a strategy to distinguish critical damage threshold in tension and compression has to be formulated.
- It is important to analyze the effect of the geometrical condition on the signals features. This can be achieved by using absorbing boundary condition in the wave simulations.

ABSTRACT: Concrete is produced by mixing hydraulic cement and aggregates with water. In contact with water, the cement particles first dissolve and subsequently hydrates form through various chemical reactions determining the overall mechanical material properties. Modeling, simulation, and monitoring of the cement hydration provide insights into the processes involved and allow prediction of overall material properties. Thereby, linking the underlying chemical processes to macroscopic material properties remains a key challenge. In this contribution, thermodynamic simulation and a multi-scale modeling approach were employed for Young's modulus development prediction for an ordinary Portland cement paste during the first 24^h of hydration. Further, ultrasound based Coda Wave Interferometry (CWI) methods were applied for monitoring of corresponding cement paste specimens. Coinciding trends were found for model and monitoring based results: Initial small alterations are followed by a period of strong material changes with an accelerated stiffness development and a strong increase in wave velocity.

1 INTRODUCTION

Reinforced concrete is used extensively for the construction of infrastructure around the globe. To produce concrete, cement, and aggregates are mixed with water. Through various reactions of the cement with the water, a cement paste matrix is formed, binding the aggregates together and leading to the overall solidification and strength development of the material. This process is referred to as hydration. The hydration determines the short- and long-term strength of concrete and is therefore an essential part of holistic durability assessment. Previous researchers have focused on understanding and predicting the chemical processes (e.g., Ouzia & Scrivener 2019; Lothenbach & Zajac 2019), strength and stiffness development (e.g., Pichler et al. 2009), as well as the development of new monitoring methods (e.g., Diewald et al. 2022b). Nevertheless, it remains challenging to link the complex microstructural changes to macroscopic material properties. Advances have been made in thermodynamic simulation of the chemical reactions, including the development of a web application (CemGEMS) for thermodynamic simulations by Kulik et al. (2021). Using existing concepts of multi-scale modeling for macroscopic material properties there is potential to predict stiffness development during hydration based on thermodynamic simulation results. Such predictions need to be validated by experimental information. Therefore, in-situ monitoring of material changes is required. Recently, ultrasound (US) based Coda Wave Interferometry (CWI) is extensively

investigated for low-cost, in-situ monitoring of concrete structures (Diewald et al. 2022a). Diewald et al. (2022b) applied CWI methods for investigating early hydration and compared the respective results to conventional hydration monitoring techniques.

2 THEORETICAL BACKGROUND

2.1 *Microstructure development during cement hydration*

Cement is a multi-phase material, which is comprised of the cement clinker, calcium sulfates such as gypsum and anhydrite, and optional mineral additives. In ordinary Portland cement (OPC), the cement clinker is the main component (Taylor 1997). Within the clinker, grains of alite (C_3S) and belite (C_2S) are bound together by aluminates (C_3A) and ferrite (C_4AF) (Stutzman 2004). When the cement is mixed with water, it dissolves and hydrates form out of the aqueous solution, which build the solid cement paste matrix. The main hydrates during early hydration up to 24 h are needle shaped calcium silicate hydrates (C-S-H), plate-like portlandite (CH), and ettringite needles (AFt) (Scrivener 1984). Other phases might occur in smaller quantities (Scrivener 1984; Li et al. 2022), including plates of monocarbonate, flake-like hydrotalcite, or spherical hydrogarnet. The hydrates precipitate mainly on or near the cement grain surface and grow, leading to the connection of individual cement grains, when a certain hydration degree (percolation threshold) is reached (Garboczi & Bentz 1998; Torrenti & Benboudjema 2005). The development of the microstructure through hydrate formation and percolation causes the transition of the initial workable, liquid mixture to a solid material. The related development of elastic properties, such as the Young's modulus is therefore intrinsically linked to the underlying chemical reactions.

2.2 *Thermodynamic simulation*

Thermodynamic modeling and simulation provide information on the thermodynamically stable phase assemblage at a certain degree of reaction of the cement and therefore indicate microstructural changes. It predicts hydrate formation based on cement consumption and thermodynamic information. Appropriate thermodynamic data for cement based systems is available through databases (Lothenbach et al. 2019). For predictions, the hydration process is typically depicted in two steps (Lothenbach & Zajac 2019): (I) Modeling of cement dissolution. (II) Thermodynamic simulation of hydrate formation. Forecasts on cement dissolution are usually based on empirically derived models, e.g., by Parrott & Killoh (1984). As their model was developed using long-term data, it has been reported by Kulik et al. (2021) to insufficiently describe cement dissolution during early hydration. Alternatively, they propose to use the five-parameter logistic (5PL) function fitted to experimentally obtained dissolution data. Given the dissolution information, thermodynamic calculations predict the phase assemblage as the most stable composition at the temperature and pressure stated, while simultaneously considering all aqueous, solid, and gaseous phases. Therefore, thermodynamic equilibrium is assumed, i.e., that the system has reached its most stable state under the given external conditions. However, during hydration, the system changes extensively, especially within the first hours. Thus, the equilibrium condition is not met during early hydration and calculations need to be restrained to mirror experimental observations. Therefore, the formation of certain phases is suppressed, as their formation is kinetically hindered.

Common software solutions for thermodynamic calculation, such as GEMS (Kulik et al. 2012), use the Gibbs free energy minimization approach to predict hydrate formation. Methods and software are under continuous improvement. Recently Kulik et al. (2021) developed the web application CemGEMS based on the GEMS-Selektor code and thermodynamic information from established databases for facilitated thermodynamic simulations. Customizable templates enable individual adjustments for the cement paste mixture and hydration conditions. They further provide simulation options including dissolution modeling according to the 5PL function.

2.3 Microstructure modeling

As discussed above, the microstructure of hydrating cement is heterogeneous. The properties of such a heterogeneous material can be described using the concept of a representative elementary volume (REV). An REV describes a volume (length scale L) containing heterogeneities (length scale l). The size of the REV is chosen such that $l \ll L$. The REV represents the effective behavior of a heterogeneous structure. If the properties of the individual constituents in the REV are given, the corresponding overall property can be obtained by homogenization using analytical or computational methods. If multiple geometries over a wide range of scales are involved, REV's are specified at each scale and homogenization is performed sequentially. In general, the stiffness (henceforth, the fourth order tensor of elasticity will be called the stiffness) of an REV with n different components with n different stiffness can be estimated using the following expression (Timothy & Meschke 2016):

$$\mathbb{C}_{REV} = \sum_{i=1}^n \phi_i \mathbb{C}_i : \mathbb{A}_i \quad (1)$$

In the above equation, \mathbb{C}_{REV} is the homogenized and effective stiffness of the REV; \mathbb{C}_i is the stiffness and ϕ_i the volume fraction of the i^{th} component. The fourth order tensor \mathbb{A}_i is the localization tensor that downscales an applied strain at the REV level to the phase level. It also specifies geometrical information corresponding to the i^{th} material component. The localization tensor can be approximated by several methods depending on the material morphology (i.e. spatial distribution of the phases in an REV). For a material with a clear matrix-inclusion morphology, the Mori-Tanaka (MT) method can be used (Timothy & Meschke 2016):

$$\mathbb{C}_{REV}^{MT} = \mathbb{C}_h + \sum_{i=1}^n \phi_i (\mathbb{C}_i - \mathbb{C}_h) : \mathbb{A}_i : \left[\phi_h \mathbb{I} + \sum_{i=1}^n \phi_i \mathbb{A}_i \right]^{-1} \quad (2)$$

$$\mathbb{A}_i = \left[\mathbb{I} + \mathbb{S} : \mathbb{C}_h^{-1} : (\mathbb{C}_i - \mathbb{C}_h) \right]^{-1} \quad (3)$$

In the above expression, \mathbb{S} is the Eshelby tensor and \mathbb{C}_h is the elastic tensor of the matrix (host) phase. In case there is no clear matrix-inclusion morphology, but the phases are mixed together, the cascade micromechanics model (CCM) can be applied.

$$\mathbb{C}_{REV}^{CCM}(n+1) = \sum_{i=1}^n \phi_i \mathbb{C}_i : \mathbb{A}_i(n) : \left[\sum_{i=1}^n \phi_i \mathbb{A}_i(n) \right]^{-1} \quad (4)$$

$$\mathbb{A}_i(n) = \left[\mathbb{I} + \mathbb{S} : \mathbb{C}_{REV}^{-1}(n) : (\mathbb{C}_i - \mathbb{C}_{REV}^{-1}(n)) \right]^{-1} \quad (5)$$

At $n \rightarrow \infty$ the self-consistent scheme is recovered. In this paper the Mori-Tanaka scheme and the CCM model (Timothy & Meschke 2016) at the regularized self-consistent limit is used.

2.4 Ultrasound based monitoring with CWI methods

State-of-the-art transmission techniques for US based hydration monitoring assess the development of wave velocity. A concise overview of these methods is given by Gabrijel et al. (2020). Currently, a new US approach is under investigation for monitoring reinforced concrete structures: Coda Wave Interferometry (CWI) uses multiply scattered waves for the detection of even marginal material changes. The term coda thereby refers to the tail of the US signal (Aki 1985), which contains information from these waves. Multiply scattered waves sample the material extensively, and therefore the coda is more sensitive to material changes than the direct wave.

Numerically, two waves recorded at different times $u(t')$ and $\tilde{u}(t')$ can be compared by a time-shifted correlation coefficient with a center-time t , and a window length from t_1 to t_2 (Snieder 2006). The stretching technique (Lobkis & Weaver 2003) describes the change in the waveform via stretching or compression such that the correlation coefficient $CC(\varepsilon)$ is maximized:

$$CC(\varepsilon) = \frac{\int_{t_1}^{t_2} u(t')\tilde{u}(t'(1-\varepsilon)) dt'}{\sqrt{\int_{t_1}^{t_2} u^2(t') dt \int_{t_1}^{t_2} \tilde{u}^2(t'(1-\varepsilon)) dt'}} \quad (6)$$

The stretching factor ε thereby corresponds to the velocity variation dv/v :

$$\varepsilon = \frac{dv}{v} \quad (7)$$

Signals can be compared stepwise, or relative to a fixed reference signal. When using a stepwise reference, the cumulated velocity variation ε_c for the n^{th} signal can be calculated as well:

$$\varepsilon_c = \begin{cases} \varepsilon_n, & n = 1 \\ (\varepsilon_{n-1} + 1)(\varepsilon_n + 1) - 1, & n > 1 \end{cases} \quad (8)$$

CWI is usually applied for the detection of subtle material alterations. Cement hydration, however, is associated with major changes in the material structure and properties. Nevertheless, the application of CWI methods with stepwise comparison enables tracing of time-dependent modifications. The ability of stepwise CWI to capture trends during early hydration was shown by Diebold et al. (2022b) by comparing CWI results for repeated US measurements for OPC concrete to corresponding information from conventional monitoring and thermodynamic simulation.

3 METHODS

3.1 Thermodynamic simulation

CemGEMS (Kulik et al. 2021) was used for the thermodynamic simulation of the cement phase assemblage during the first 24 h of hydration. Therefore, the phase assemblage of the anhydrous cement used for the US experiments as determined by quantitative X-ray diffraction, the water-to-cement ratio of 0.45, and conditions of 20 °C and 1 bar were implemented. For hydration simulation, the 5PL dissolution modeling approach was selected, setting the process parameters as proposed by CemGEMS. The calculation was performed for 24 h with 101 linear steps. To prohibit the formation of corresponding, kinetically hindered phases, the formation of specified phases, e.g., gibbsite and dolomite, were disabled as proposed by CemGEMS, and phosphorus, titanium, and manganese containing oxides were removed from the cement composition.

3.2 Multi-scale modeling

In order to model the evolution of the elastic properties of hydrating cement paste, a multi-level micromechanics homogenization model that uses the Mori-Tanaka and the CCM model was employed. The temporal evolution of the volume content of the material phases was obtained from the CemGEMS thermodynamic simulation. The corresponding elastic properties were obtained from literature (Haecker et al. 2005). To use Equation 1 and 2 also the geometry of the phases had to be specified. The hydrate phases C-S-H and ettringite are assumed to be needle-shaped (prolate spheroidal) while portlandite and monocarbonate are assumed to be disc shaped (oblate spheroidal). All other phases are assumed to be spherical in shape. All phases are assumed to be isotropically distributed. In total 6 REV's are used to upscale the elastic properties of hydrating cement paste. The REV's used in the homogenization procedure are shown in Figure 1.

REV-1 is modeled as a mixture of aluminat and ferrite without a clear matrix-inclusion morphology. Here the CCM model is applied. REV-2 corresponds to alite and belite embedded in a material mixture whose properties are obtained by homogenization of REV-1. The Mori-Tanaka scheme is applied for the homogenization of REV-2. REV-3 represents a heterogeneous

Figure 1. Schematic representation of the multi-scale model for stiffness development based on thermodynamically predicted phase assemblage by volume. All geometries represent 3-dimensional objects. For the representative elementary volumes REV-1 to REV-5 the material properties are homogenized and used as input for the larger scale REV. Through homogenization of REV-6 the overall material stiffness is obtained.

mixture of particles such as gypsum, anhydrite, calcite and the material phase whose properties have been obtained from homogenization of REV-2. As no clear matrix-inclusion morphology can be specified, the CCM model is used for homogenization of REV-3. The cement phase, i.e., REV-3 surrounded by REV-4 that represents the hydrates, is homogenized using the Mori-Tanaka scheme. This morphology refers to REV-5. REV-5 is finally embedded in the aqueous solution. REV-5 together with the aqueous solution is homogenized using the CCM model to obtain the effective elastic properties of REV-6. The evolution of the elastic properties using multi-scale homogenization was simulated using PyMatSim a Python based research software for materials simulation currently developed by the authors.

3.3 Ultrasound based monitoring with CWI methods

Cement paste with a water-to-cement ratio of 0.45 was produced using a CEM I 42.5 R with a density of 3.12 g/cm^3 and a Blaine specific surface of $3,400 \text{ cm}^2/\text{g}$. The raw materials were equilibrated at $20 \text{ }^\circ\text{C}$ and 37.619 kg of CEM I 42.5 R and 16.928 kg of tap water were mixed using a compulsory mixer with a capacity of 75 L for a total of 150 s . Each specimen was prepared with two piezoelectrical US transducers symmetrically embedded at a distance of 300 mm . Figure 2 shows (A) one US transducer (ACSYS S0807) with a center frequency of 60 kHz , (B) the transducer positioning within the specimen, and (C) one specimen with embedded transducers after solidification and demolding. After casting, the specimens were covered with a moist jute cloth and stored in a climate chamber at $20 \text{ }^\circ\text{C}$ and 65% relative humidity.

The US transducers were connected to the measuring system, which transmits pulses with a frequency of 60 kHz to the selected transducer and records the signal at the corresponding

Figure 2. (A) New piezoelectrical US transducer. (B) Symmetrical transducer positioning within $400 \times 100 \times 100 \text{ mm}^3$ specimen for US monitoring. (C) Solidified CEM I 42.5 R pure cement paste specimen after demolding with two embedded US transducers as illustrated in (B). The mean temperature of the sample during the first 24 h of hydration was determined as approximately $30 \text{ }^\circ\text{C}$.

receiver with a sampling rate of 2 MHz and 10,000 samples. Signals were collected every 5 min for the first 22 h with both embedded transducers acting as a sender and receiver once.

The recorded signals were processed by performing offset compensation, pretrigger, and crosstalk removal as well as frequency filtering as described by Niederleithinger et al. (2018). Further, the signals were clipped to the length of 4,500 μs and faulty signals were removed for which the maximum amplitude was less than 0.1 times the amplitude of the previous signal or with a maximum tail amplitude exceeding half the maximum amplitude of the early signal and maximum amplitudes greater than the noise.

4 RESULTS AND DISCUSSION

The simulated cement phase assemblage for the first 24 h of cement hydration in terms of volume fractions is shown in Figure 3(A). The thermodynamic simulation predicts a continuous decline in clinker content and an increase in hydrate volumes with increasing hydration time. Thereby, the total volume loss of solid and liquid phases was compensated artificially by the addition of air. The volume loss appears as a linear trend over time. However, the alterations of phase assemblage of cement phases and hydrates follow a non-linear behavior with striking events occurring between 6 h and 9 h: After about 7 h of hydration, gypsum disappears and at about 8 h the slope of volume increase in solid phases decreases. Moreover, from 8 h onwards, less ettringite is formed. The associated evolution of the material structure, expressed using the Young's modulus predicted by the multi-scale model is shown in Figure 3(B). Within the first hours, the Young's modulus increases only marginally below 0.1 GPa until the increase becomes visible at approximately 5 h of hydration and further accelerates after about 6 h. From this point on, the Young's modulus increases monotonously. After 24 h a maximum value of 8.65 GPa is reached.

The results of the CWI-based monitoring are shown in Figure 3(C)-(E). The entire processed signals were used to calculate the velocity variation dv/v , the correlation coefficient CC and the cumulated velocity variation ε_c by stepwise comparison according to Equations 6-8. The general trends are consistent with those reported by Diewald et al. (2022b). Initially, a 4 h long period of stagnating values is observed for all CWI parameter. Subsequently, strong changes occur between 4 h and 12 h, and a transition to minor parameter changes takes place from 12 h onwards. Within the first hours, the velocity variation fluctuates around zero due to noise dominating signal alterations. A switching process in the early signal leads to stabilization of the corresponding correlation coefficient within this period. During the second period, the velocity variation drops to negative values, indicating a velocity increase. Meanwhile, the correlation coefficient first deviates from and subsequently converges again to 1 as the US signals initially develop and later stabilize. Corresponding to the velocity variation, the cumulative velocity variation decreases to negative values within the second period and merges into a trend of smaller slope in the last hours.

The development of the cumulated velocity variation and the Young's modulus correlate, as both exhibit an initial period of no alteration, followed by a monotonous trend of declining or increasing values. This compliance can be explained by the underlying microstructure development: At first, the fluid suspension of solid particles in water does not yield significant stiffness. This remains unchanged until a certain hydration degree is reached, at which point the hydrates have grown so that the individual particles are bonded together. Progressing connectivity leads to the development of a continuous solid matrix and its densification. Consequently, the stiffness and the wave velocity increase, whereby the increase in velocity is reflected in an increasingly negative cumulated velocity variation. However, the transition time from the initial to the second phase differs between the model based prediction and experimental observations by about 2 h. This discrepancy is assumed to be mainly attributed to the difference in temperature, which is 20 °C for the model based results and 30 °C for the experimental data. The temperature has a major influence on the hydration progress and can enhance the hydration in the range of hours.

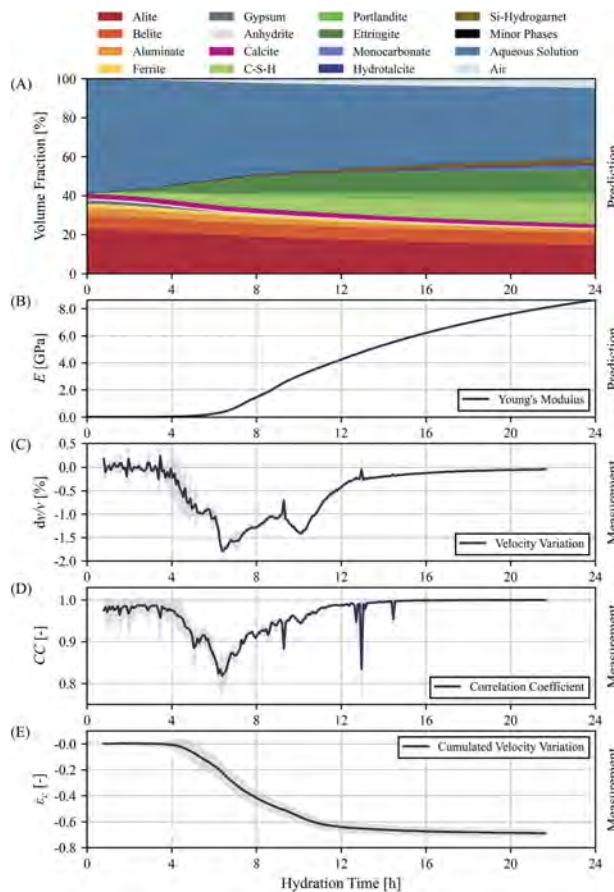

Figure 3. Thermodynamically predicted cement paste phase assemblage over hydration time at 20 °C (A). Composition as volume fractions relative to initial cement paste volume. Volume loss due to chemical shrinkage is compensated by air. (B) Young's modulus E , predicted by multi-scale modeling based on the thermodynamic prediction at 20 °C. Velocity variation dv/v (C), correlation coefficient CC (D), and cumulative velocity variation ϵ_c (E) retrieved by CWI with a stepwise comparison. Average values (solid blue lines) and standard deviation (grey shadowed areas) from two specimens and two measurement directions each. Specimens for US monitoring exhibited an average temperature of approximately 30 °C during the observed period.

5 CONCLUSIONS

In this study, thermodynamic simulation of cement paste phase assemblage was combined with a multi-scale model for stiffness prediction. The development of the Young's modulus retrieved was compared to experimental results of US monitoring using CWI methods. The validity of the model was indicated by correlation of the Young's modulus and the cumulated velocity variation. A period of major microstructural change was observed within the predicted phase assemblage, Young's modulus development, and the CWI parameter at about 4 to 8 hours of hydration. Agreement of results is limited by the thermodynamic equilibrium assumption and a hydration temperature of 20 °C, which underlie the thermodynamic simulation and the idealized stiffness model.

The feasibility and potential of an integrated approach, combining thermodynamic simulation, multi-scale modeling, and CWI monitoring was demonstrated. Further refinement of the models and simulations, as well as the evaluation by means of corresponding experimental data, is required for improved predictions. A deepened understanding of CWI parameter

development during hydration seems further promising for the linkage of microstructural developments to macroscopic material properties.

ACKNOWLEDGEMENTS

We thank the German Research Foundation (DFG) for the funding of the Research Unit FOR 2825 (project number 398216472). This research was enabled in the framework of Subprojects TUM1 and RUB1 with the provided measurement devices of BAM. We thank Sara Niedenzu, Felix Bachl, Manuel Gebhart and Karin Hartlieb-Pfüller for their valuable contribution.

Financial risk assessment of flexible infrastructure systems

N. Acuña-Coll & M. Sánchez-Silva

Department of Civil and Environmental Engineering, Universidad de Los Andes, Bogotá, Colombia

ABSTRACT: Extreme natural hazards impact infrastructure systems, causing economic losses and environmental problems, affecting well-being and quality of life. During the last decades, the public and private sectors have focused on developing approaches to manage infrastructure capable of accommodating changes in demand and responding efficiently to uncertain damaging events. This paper presents a new strategy to assess the financial value of incorporating flexibility. First, the paper describes infrastructure systems as processes and briefly describes how to incorporate flexibility in design and management. Afterward, the paper reviews traditional approaches for the financial evaluation of infrastructure throughout its lifetime and offers a proposal based on the Decoupled Net Present Value (DNPV). Finally, the proposed method is illustrated by three different infrastructure management approaches. The results indicate that the DNPV is a better indicator of the system's financial performance. Besides, financial validation strengthens the value of flexible systems over standard design and construction strategies.

1 INTRODUCTION

It is estimated that urbanization in developing countries will reach values above 90% between 2012 and 2032 (Baker, 2012). Rapid urbanization is a challenge to all sectors of society since it demands the adaptation and rapid growth of new sustainable infrastructure. In addition, in most developing countries, the growth of urban areas leads low-income people to relocate to areas with high exposure to risk (e.g. landslides and flooding). Furthermore, the increasing number of high-intensity hazard events due to climate change will significantly impact communities, especially in the most vulnerable sectors. The World Bank calculates that natural hazards cost the global economy about \$ 520 billion annually. Within this context, governments and worldwide institutions seek to develop approaches to manage complex infrastructure systems capable of adapting to events in an uncertain future.

The main task behind hazard management is managing large uncertainties. Currently, it is possible to create models that support managing under deep uncertainty, such as decision trees, roadmaps, and stochastic programming, among other planning approaches. More recently, the idea of flexible design and management of infrastructure systems has emerged as an alternative in this direction. Flexible systems can easily respond to or change operational parameters, or their design, to keep or add value to the system when subjected to external or internal demands. Furthermore, flexible systems change their state by modifying their internal structure, thus moving to a new state defined by a continuous or discrete set of options (e.g. Adaptation Pathways). Overall, introducing flexibility in the development of infrastructure contributes to better management of planned/unplanned events, taking advantage of investment/business opportunities, reducing possible cost overruns, and handling the perceptions and interests of stakeholders. The most common method for evaluating infrastructure performance over time is a Life Cycle Cost Analysis (LCCA). Most studies support this evaluation by a financial assessment that includes the Net Present Value (NPV). Several authors have shown that, financially, incorporating flexibility in infrastructure management is much better than the implementation of traditional designs. (Cardin et al., 2015; De Neufville & Scholtes, 2011; Sánchez-Silva & Calderón-Guevara, 2022). The objective of this paper is to compare the traditional LCCA that uses the NPV as the fundamental financial strategy with

a new financial tool called Decoupled NPV (DNPV) proposed by Espinoza and Morris (Espinoza & Morris, 2013). This comparison is carried out within the context of systems that evolve and change with time. In addition, this comparison provides new insights into project performance in relation to risk management.

2 MODELING INFRASTRUCTURE SYSTEMS

2.1 *System thinking approach*

Large infrastructures could be modeled as *systems* based on the ideas of systems theory (Checkland, 1999). Systems are an organized assembly of elements with a purpose (Meadows & Wright, 2008). Mainly, the three pillars for system thinking are (Blockley & Godfrey, 2017): i) structuring information hierarchically, ii) identifying and recognizing the importance of loops, and iii) understanding the system as a set of processes. Similarly, Ackoff (2010) considers that system thinking focuses on connectivity, relationship, process, patterns, and context. Many researchers have identified the importance of analyzing systems as processes over the life cycle, especially in the area known as project management. For example, Lean construction, which is currently widely used, is a broad practice and philosophy that is key to controlling and improving the processes in the construction industry (Babalola, Ibem & Ezema, 2019). Overall, systems are a set of interacting processes that are organized hierarchically and exhibit emergent properties. This last element is the key to the so-called holistic view of projects. Understanding systems from this perspective requires recognizing the continuously changing nature of infrastructure and the importance of focusing on the interactions of components (subsystems) and emerging properties at different levels.

2.2 *Flexible and adaptable infrastructure systems*

Flexibility is “the ability of a system to respond or change some of its design or operational parameters easily to keep or add value to the system when subjected to either internal or external demands.” (Sánchez-Silva, 2021; Torres-Rincón, Sánchez-Silva & Bastidas-Arteaga, 2021). Flexible systems are designed with specific features that facilitate future changes in system parameters, such as the implementation of new technology or the expansion or contraction of the system according to demand (Cardin et al., 2015). Likewise, adaptability describes the system’s ability to change its functionality or structure when required (Chester & Allenby, 2019). Flexibility and adaptability are sometimes used as synonyms; however, in most cases, flexible systems are also adaptable, but the contrary is not always true.

There is a distinction between fully flexible systems and systems whose flexibility is defined by the so-called Adaptation Pathways (AP). In form, the system can change its state at any time to any value; this is, actions that modify system parameters can take values in a continuous space. However, in the case of Adaptation Pathways, possible actions (system interventions) are limited by a finite set of actions that can only initiate after a particular point in time and that limit the system to take specific state values. In a way, Adaptation Pathways are a specific case of fully flexible systems. Note that incorporating flexibility in infrastructure is linked with the design and management strategies, which define the type and nature of changes (interventions) that are executed over time. In this context, we do not consider systems that can change their internal structure autonomously. Note also that at the heart of Infrastructure management, there is the need for sequential decision-making to guarantee that the systems operate as planned.

3 FINANCIAL PERFORMANCE

3.1 *Life cycle cost analysis*

Life cycle cost analysis (LCCA) is a technique to evaluate the financial performance of projects. Many institutions, such as the FIB or the Federal Highway Administration (FHWA) in the U.S., have established a guide to carry out LCCA. This paper uses the basic LCCA approach to evaluate the performance of three design and management system types:

standard, fully flexible, and Adaptation Pathways. The paper focuses mainly on their financial performance when carrying out a discounted cash flow analysis.

3.2 Net present value and the role of risk in discounting

There are different economic indicators for the economic assessment of infrastructure projects, such as Net Present Value (NPV), Benefit/Cost Ratio (B/C), and Internal Rate of Return (IRR). NPV is the most widely used method to analyze the profitability of projects. Not only infrastructure projects but any investment projects. Net Present Value is calculated as the total discounted difference between the expected cash inflows or benefits (\bar{B}) and the expected cash outflows or investments (\bar{I}). The benefits result from the fulfillment of the purpose of the system. They are usually calculated from the demand met or payments agreed upon by contract. In contrast, the investments are an outcome of the operation, maintenance, or modification of the design or operation parameters of the infrastructure. Then NPV is computed as:

$$NPV = \sum_{t=0}^N \left[\frac{\bar{B}_t - \bar{I}_t}{(1 + \delta)^t} \right] \quad (1)$$

where t is a specific time, N is the finite time window and δ is the discount rate. Projects are profitable if the NPV value exceeds zero ($NPV > 0$). Large NPV values imply better financial performance. The NPV is extensively used, mainly due to its simplicity. However, the main implementation problem is the choice of the discount rate, δ . This parameter is not standard; it depends on the type of project, the economic, social, and environmental conditions and perceptions, the risk of the investment, and the funds' origin, among others. In a nutshell, this rate should reflect the time value of money (time preference) and the uncertainty of the project.

Selecting a particular discount rate, δ , have important implications on the feasibility of the project and the decisions that follow. Note that if all the benefits and costs of an infrastructure project were certain, the project should be evaluated with a *risk-free rate*. The risk-free rate is the theoretical rate of return of an investment with zero risk. In practice, cash flows include some degree of uncertainty; therefore, the risk-free rate of return does not truly exist. For example, there is uncertainty coming from the randomness in the operation's income or the size of interventions throughout the project's lifetime. This variability imposes some risks on investors and stakeholders. In infrastructure, the risk is often quantified as the expected value of the losses. However, quantifying the cash flow's risk is challenging when defining the project's financial structure. Loss metrics are generally based on property conservation, public safety, economic losses, or business continuity (Lounis & McAllister, 2016).

In traditional financial assessments, risks are frequently considered within the discount rate. Then, in this setting, the discount rate is called *risk-adjusted discount rate*. This rate is increased according to the project's risk profile, i.e. larger uncertainty means larger discounting. Experts often select the rate for the specific conditions of a project based on the project location and the origin of funds.

Espinoza and Morris (2013) identified several problems with selecting risk-adjusted discount rates when making traditional NPV evaluations. These are: 1) the use of a single discount rate throughout the project's entire life cycle is not consistent with the fact that risks may increase or decrease over time; 2) discounting benefits and costs at the same rate fail to recognize that they have different risk profiles; and 3) the NPV method substantially minimizes future cash flows in high-risk projects. Based on these observations, Espinoza and Morris (2013) proposed an alternative approach to performing the financial assessment of projects in which the risks are explicitly considered, called Decoupled Net Present Value (DNPV).

3.3 Decoupled net present value

Espinoza and Morris (2013) proposed an alternative method to the NPV based on separating the risky part from both benefits and costs in the cash flow. This solution allows discounting the "known" cash flow part at a risk-free rate while risks are transferred to a third party via some premium. As a result, the DNPV formula can be written as follows:

$$DNPV = \sum_{t=0}^N \left[\frac{\bar{B}_t - \bar{I}_t - \bar{R}_t}{(1+r)^t} \right] \quad (2)$$

where N is the number of cash flows occurring during the project's lifetime (known and finite). The term \bar{R}_t is the expected risk premium paid at time t , and r is the risk-free rate.

Figure 1. Distribution of benefits at a specific time and potential loss distribution at that time due to benefit shortfall (adapted from Espinoza & Morris, 2013).

The expected risk premium is obtained by identifying all the sources of risk in the specific period or stage. Since the DNPV differentiates between risks associated with the outflow or the inflow, $\bar{R}_t = \bar{R}_{B_t} + \bar{R}_{I_t}$. The premiums are calculated as a percentage of profits ($\eta_B B_t$) or investments ($\eta_I I_t$). The specific values of η_B or η_I can be obtained using various methods, including a probabilistic approach and option pricing (Espinoza & Morris, 2013). In the probabilistic approach, it is necessary estimating the probability distribution of benefits and investments at each time. Consider, for example, the distribution of the project's benefits at time t , as shown in Figure 1. In this case, the premium of the cash inflows at time t is related to the mean shortfall (\bar{L}_{B_t}), i.e. the mean value of the distribution of potential losses (Espinoza & Morris, 2013). The premium of the cash inputs at time t is computed as follows:

$$\bar{R}_{B_t} = \bar{L}_{B_t} \times P(\bar{B}_t > B_t) \quad (3)$$

Similarly, for the case of costs, it is possible to calculate the investment mean excess cost (\bar{L}_{I_t}). In this case, the premium of the cash outflows at time t is calculated as:

$$\bar{R}_{I_t} = \bar{L}_{I_t} \times P(\bar{I}_t < I_t) \quad (4)$$

Equations 3 and 4 associate the risk premium with the possibility of obtaining lower benefits or higher costs than expected. The larger the average drop in benefits or cost overruns, the larger the risk premium.

3.4 Value of the DNPV in dynamic adaptable management

The project's risk profile often changes with time; therefore, the DNPV methodology requires computing the premium at every time. However, this way of calculating the discounted values has two drawbacks when modelling dynamic adaptable systems. First, the distributions of costs could be skewed because the costs in adaptive problems do not occur at fixed times; they will depend on a prediction of future demands, in particular of extreme events, which add large uncertainties to cost estimations. Second, the distribution of costs or benefits is not easy to obtain, given the lack of data and demand variability.

Based on the previous discussion, a proposal to approximate the solution is as follows. First, the time mission of the project can be divided into a set of time intervals with similar lengths. Then, the percentage of profits or investment, i.e. η_B or η_I , could be computed and kept constant for every interval. For example, for a time horizon of 60 years, it might be

reasonable to have intervals of 15 years. Finally, the mean shortfall or mean excess cost is calculated by simulation. Equations 2 y 3 could be rewritten as:

$$\bar{R}_{B_t} = \frac{1}{K} \left[\sum_{k=0}^k \mathbf{1}_{B_t,k} (\bar{B}_t - B_{t,k}) \right] \quad (5)$$

$$\bar{R}_{I_t} = \frac{1}{K} \left[\sum_{k=0}^k \mathbf{1}_{I_t,k} (I_{t,k} - \bar{I}_t) \right] \quad (6)$$

where K is the number of simulations, $B_{t,k}$ represents the benefits at time t in simulation k , $\mathbf{1}_{B_t,k}$ is an indicator function that is 1 if $\bar{B}_t > B_{t,k}$ and 0 otherwise. Similarly, $I_{t,k}$ is the investment at time t in simulation k , $\mathbf{1}_{I_t,k}$ is an indicator function that is 1 if $\bar{I}_t < I_{t,k}$ and 0 otherwise.

Equation 5 illustrates the mean shortfall (\bar{L}_{B_t}). Each shortfall value is subtracted from the benefit \bar{B}_t to build the cash flow in the DNPV. The probability distribution of the benefits is calculated from simulations; and the number of simulations where we find a shortfall over the number of simulations. With this simplification, we find that the number of times we observe shortfalls is trivial. Similarly, Equation 6 shows the \bar{L}_{I_t} as the average of overruns. In this case, the expected investment is subtracted from each excess value to make the potential overruns distribution. The probability of the cost overruns is computed as the number of simulations where we find overruns over the number of simulations. Then, the number of times we find overruns results irrelevant to the estimation.

4 ILLUSTRATIVE EXAMPLE

4.1 Case description

Let us consider a system with a vector of parameters that depends on time, $X(t)$. The system state $X(t)$ moves to a new state $X(t + \Delta t)$ by choosing an action a from a set of possible actions \mathbf{A} . This system has some emergent properties, such as capacity, resistance, or safety, which conform to a vector of system performance indicators $V(t)$. For simplicity, in this paper, we will consider $V(t)$ as the system's capacity (single parameter). Furthermore, let us consider that the system is subjected to a time-variant demand $D(t)$. The system is designed to withstand the demand for some specific time τ , $0 \leq \tau \leq t_m$, with t_m the expected service life (i.e. time mission). Then, the system initial state $V(0)$ satisfies $P(V(0) \leq D(\tau)) = \zeta$. The acceptable failure probability is $\zeta = 10^{-3}$. Finally, it was assumed that the project's lifetime is 60 years.

In this example, three design and management system types were considered: a fully flexible system, a flexible system subjected to changes constrained by adaptation pathways, and the standard (traditional) design. The illustrative case also considers that if the system fails (sudden drop in capacity), it will recover its initial capacity almost instantly. In the first two cases in which flexibility plays an important role, the system is equipped with some flexibility features that are part of the management and operation. In other words, the system's capacity can be modified when required to accommodate changes in demand. These changes respond to specific intervention strategies (policies) that follow certain rules, such as when to make changes and the size of those changes. In addition, a strategy also considers aspects such as the critical capacity v , the time window t_q used for recurrent predictions, the restriction between capacity expansions t_k ; and the flexibility range h . The basic parameters that define the performance of the three systems: fully flexible, Adaptation Pathways and standard are, respectively: $V(0) = \{93.17, 93.17, 197.28\}$, $v = \{52.20, 52.20, 112.42\}$, $t_p = 8$, $t_q = 5$, $t_k = 5$ and $h = 3 \times V(0)$.

Figure 2a shows a sample path of the standard and flexible strategies subjected to extreme events and specific demand. Likewise, Figure 2b presents the standard case and Adaptation Pathway strategies under the same conditions. In Figure 2b we can observe the discretized set of actions or paths $\mathbf{A} = \{a_1, a_2, a_3, a_4\}$ adopted in this illustrative example. In these realizations, it was assumed that extreme events occur with a return period of 40 years, which causes most failures to occur towards the end of the project's lifetime.

Figure 2. Realization of flexible, Adaptation Pathways and standard strategies under a random demand.

Figure 3. Distribution of the Net Present Value for the three strategies with a discount rate of 6%.

4.2 Financial risk assessment

Selecting the best design and management strategy depends on many factors. This paper focuses on a financial assessment based on evaluating discounted cash flows. Because the system response depends on the demand, which is unknown, the financial response of the three system types was evaluated statistically using simulation. Then, for every policy, every system was subjected to 2000 different demand paths. Initially, the NPV for every simulation was computed with a risk-adjusted discount rate of 6%. The histograms of the NPV for the three system types are shown in Figure 3. It can be observed that the best performance, i.e. the largest expected NPV, corresponds to the fully flexible strategy with $\mathbb{E}[\text{NPV}] = 113.04$, followed by the Adaptation Pathways and the standard cases with expected NPV 15.28% and 76.27% smaller than the flexible strategy respectively. The probability that the project is not feasible tends to zero in the flexible and Adaptation Pathways strategies, while this value is 0.7% for the standard case. To assess the sensitivity of the risk-adjusted discount rate, we calculated the expected value of the NPV for various discount rates. The results are reported in Table 1. It can be observed that the standard strategy is the most sensitive to the risk-adjusted discount rate. This result is consistent with the systems dynamic because the main cost in the standard case occurs in the initial year or early stages, which means that only the total benefits

Table 1. Expected NPV for different discount rates.

Strategy	Discount rate [%]			
	2	4	6	8
Flexible	311.34	177.66	113.04	77.70
Adaptation pathways	258.60	148.11	95.77	67.51
Standard	154.47	66.00	26.82	7.78

Figure 4. Difference between DNPV and Expected NPV vs discount rate with a risk-free rate of 3%.

vary significantly with the discount rate. In contrast, the discount rate influences adaptable systems in both total benefits and costs, achieving a less variable difference in the NPV method.

The NPV financial evaluations were compared with DNPV. In the latter, the risk-free rate was chosen as $r = 3\%$. Repeating the analysis performed to assess the NPV, the DNPV was also evaluated for the three system types. As in the NPV analysis, the best option for DNPV is the flexible strategy with a DNPV of 212.2, followed by the Adaptation Pathways and the standard case. Note that by using the DNPV strategy, the expected discounted value almost doubles for the flexible case, which has implications when defining the project's feasibility. The value of the discounted risk premiums (\bar{R}) for the fully flexible, Adaptation Pathways and standard cases were 21.04, 19.36, and 20.79, respectively. However, if the risk is expressed as a percentage of the expected profitability, the riskiest strategy is the standard, then the Adaptation Pathways, and finally, the fully flexible strategy. The standard case has a larger risk since the expected profitability is highly uncertain; it depends significantly on the evolution of the demand. On the contrary, for adaptable systems, there is less uncertainty in profitability, and the risks of cost overruns are transferred to future years. Furthermore, the fully flexible case manages risks better than the Adaptation Pathways approach because the adaptations are made in a continuous space; that is, better adaptability and greater certainty of profits.

To compare the DNPV and the NPV, the indicator $W = \text{DNPV} - \mathbb{E}[\text{NPV}]$ for each system type was calculated for various discount rates δ (see Figure 4). A value of W closer to 0 indicates that the discount rate used in the NPV analysis approaches the most accurate risk-adjusted discount rate based on the understanding of the system dynamic. The risk-adjusted discount rate, δ_m for which $\text{DNPV}(r) - \text{NPV}(\delta_m) = 0$. The value of δ_m for flexible and Adaptation Pathways strategies is 3.32% and 3.40%, respectively, while this rate reaches 3.50% for the standard approach. Note that for the three system types, the value of $\delta_m - r$ is the inherent risk derived from the system performance and management.

This analysis might be an important tool for a financial institution considering funding an infrastructure project. In this case, the minimum discount rate on loans may be conditioned on the management strategy (policy) used to operate the system. Any value above δ_m depends on other factors such as credit history, the country's risk, the exchange rate, and political stability, among others. In most cases, these factors dominate the ultimate selection of the final rate. Funding institutions using discounting rates above δ_m have the possibility of larger profitability margins. Note that it does not make much sense to use values of $\delta < \delta_m$; this clearly underestimates risk.

In Figure 4, different discount rates can be selected to keep the index W constant. For example, to establish a margin of $W = \text{DNPV} - \mathbb{E}[\text{NPV}] = 50$ units, the standard management strategy will require a risk-adjusted discount rate of $\delta = 5.8\%$, while this value will be $\delta = 4.75\%$ and $\delta = 4.45\%$ for the Adaptation Pathways and the fully flexible cases, respectively. These results are consistent, given that the flexible strategy is the least risky, followed by the Adaptation Pathways. Finally, note that if the three project types are evaluated with the same discount rate (larger than any δ_m), the flexible case will always render the largest W due to its risk profile.

5 CONCLUSION

Infrastructure systems are subjected to a large variety of external and internal demands, which include social, environmental, and economic pressures, as well as operational and extreme natural events. The traditional approach to managing the uncertainties derived from these demands consists of designing for solicitations expected to occur at the end of the project's lifetime. This approach yields over designs for most of the project's lifetime. In this context, flexible strategies emerge as a new paradigm. This paper aims to compare the LCCA of three systems types, i.e. fully flexible systems, systems whose evolution is defined by a set of adaptation pathways, and the standard design. Specifically, the comparison is based on two different strategies to assess the financial value of incorporating flexibility: Net Present Value (NPV) and Decoupled Net Present Value (DNPV). Despite being widely used, the NPV has important drawbacks, among which is the difficulty of estimating the risk-adjusted discount rate. Then, the DNPV is presented as an alternative indicator that addresses the problems of the NPV. The results indicated that the NPV does not account properly for the project risk, especially in the fully flexible design strategy. The results also showed that when the LCCA is based on the NPV only, the flexible system is the most efficient, with a high Net Present Value and a low variance. Furthermore, the flexible management strategy has the lowest financial risk, while the standard strategy has the highest risk due to the large uncertainties that it involves.

Time-dependent assessment of corrosion impact on R/C members

M. Calò & G. Gabbianelli

Department of Civil Engineering and Architecture, University of Pavia, Pavia, Italy

ABSTRACT: The assessment of structures subject to deterioration is a non-negligible aspect that engineers must deal with to correctly estimate the structural response, retrofit strategies as well as maintenance plans. In fact, inaccurate estimation could result in an inappropriate design or require premature and additional interventions that were not initially planned, thus increasing the maintenance costs of the structure. Consider in this regard that in the United States alone, investment in the replacement and rehabilitation of reinforced concrete structures and infrastructures can be estimated at around \$20 billion annually. Thus, accurate estimation of structural response can result in resource savings. To this end, a simplified approach to consider the impact of corrosion on reinforced concrete structural elements is proposed here. Material deterioration, in terms of reduced area and spatial and temporal concrete degradation with a reduction in strength and deformation capacity, is numerically incorporated through a fibre approach with the advantage of not increasing the computational cost of analysis. The technique is validated by comparing numerical results with experimental tests available in the literature considering nonlinear static and dynamic analyses due to corrosive attack. The results demonstrate the ease and efficiency of the proposed technique to capture the impact of deterioration in the response of structural elements during the nominal life period.

1 INTRODUCTION

1.1 *Rationale, literature review and research objectives*

Ageing of structures is a problem that our society must be able to deal with both for new construction as well as for those buildings that have reached the end of their nominal design life. The influence of environmental exposure (i.e. variation in atmospheric temperatures and humidity), carbon dioxide concentration levels and the infiltration of harmful substances such as chloride ingress have an effect on the entire lifecycle of a construction, in addition to the materials used and the construction processes. Recent studies, in fact, focused on understanding the impact of climate change and the implications of rising CO₂ levels and temperatures on corrosion (Rianna et al. 2020). On the other hand, in developed countries, chloride attack appears to be the major environmental stressor capable of affecting the structural capacity of elements and producing a significant economic impact. Indeed, considering only the United Kingdom and Scotland, the corrosion damage to infrastructure can be estimated at around £1 billion (Wall-bank 1989). In the U.S., on the other hand, the Federal Highway Administration (FHWA) estimates a direct annual cost of corrosion on infrastructure (i.e. highway bridges, gas and liquid transmission pipelines, waterways and ports, hazardous materials storage, airports and railroads) at \$22.6 billion, of which \$8.3 billion is due to highway bridges (Koch et al. 2002).

To this end, in the previous decades, several efforts have been made both to assess the impact of corrosion on the behavior of structural components through accelerated degradation procedures in the laboratory (Val and Melchers 1997, Stewart 2004) as well as individual reinforcing steel rebars (Du et al. 2005a, Kashani et al. 2013), or, in a more comprehensive

approach, de-tecting the overall dynamic characteristics of the building or structural and non-structural elements (Gara et al. 2021, Nicoletti et al. 2022a, 2022b).

From a phenomenological point of view, degradation is induced by a kinetic process of diffusion of chemical components, such as sulphates and chlorides, caused by concentration gradients within the volume of the material (Mehrer 2007). Chlorides, which are critical in the marine environment but also result from the application of de-icing salts, penetrate through the concrete cover, locally breaking the passive film of the reinforcement and producing oxidation. Corrosion of reinforcement steel induces concrete cracking and produces rusting at the inter-face, delamination and potential cover expulsion (Vidal et al. 2004). Furthermore, at a local material level, with regard to individual reinforcing bars, experimental studies show premature buckling, low-cycle fatigue, and loss of ductility and strength. Consequently, the foremost effects of deterioration on the response of structural elements are loss of adherence and cross-sectional area of the reinforcement, change of mechanical properties of the degraded materials, as well as of the overall ductility of the members due to the variation in flexural stiffness and shear capacity (Vu et al. 2016). Localised embrittlement can seriously compromise the capacity of an element and cause abrupt failure with nefarious consequences.

The evaluation of the influence of corrosion has not only been observed experimentally, but several researchers have adopted analytical and numerical criteria. From what emerges in the literature, efforts placed to capture the degradation by structural analysis are diverse (Kashani et al. 2019). For example, through 3D finite element analysis (di Carlo et al. 2017) but given the high computational burden, it is not yet extendable for large-scale analysis. Alternatively, through sophisticated methods such as implementing nonlinear mechanical bonds to simulate the effects of deterioration on the reinforcing bars (Kashani et al. 2015, Dizaj et al. 2018) or, globally, by means of damage indices (Ghosh and Padgett 2010, Berto et al. 2020) while, in other cases, this is taken into account through the reduction of reinforcing bars alone (Rao et al. 2017). In the case of structural elements subject to corrosive attack, the mechanical properties of materials and the effects of confinement of transverse stirrups should be updated, thereby capturing both the spatial extent and the accumulation of damage during the propagation of the phenomenon. Therefore, the present study aims to provide a numerical approach considering spatial and temporal deterioration. Thus, in this study, the effect of deterioration is explicitly considered at the local material level without increasing the computational onus. The intent is to propose a model that is easy to implement in commercial finite element software so that practitioners may address structural assessments while also considering the actual durability of structures.

2 STRUCTURAL MODELING OF DEGRADATION DUE TO CORROSION IMPACT

As reported in the previous section, the intent of the framework presented in this study is to develop a refined procedure for encompassing the corrosion degradation in finite element software - that employ beam-column elements - without increasing the computational burden; in this way, it would be possible to perform vulnerability analyses with the traditional tools currently adopted by practitioners. Although fibre beam-column elements are particularly efficient from a computational viewpoint and in terms of accuracy (Spacone *et al.* 1996a, 1996b), simulation of reinforced concrete elements is primarily appropriate when the response is flexural-dominant. Where the response is brittle-type, thus marked by shear failure, these models are not so accurate because they do not capture the coupling of the complete stress state, i.e. the axial-shear-flexural interaction. Some researchers (Jeon *et al.* 2015), in order to overcome this obstacle, have set up shear springs to account for shear strain, but in any case, this strategy does not account for the complete interaction, as previously recalled. To overcome this issue, future work could improve the proposed methodology by evaluating, for each individual member, the minimal value of shear capacity corresponding to the stirrup yielding, bonding failure and flexural-bonding failure (Belletti *et al.* 2013, Walraven *et al.* 2013) and so the possible violation of the member shear capacity in order to be removed from the analysis.

The modelling approach proposed here can account for the actual state and extent of damage across the distributed integration point sections (IPs) by pointwise variation of the

fibres at the sectional level. The idea stems from the usual in situ inspections, aiming to recreate the structure's actual condition, as depicted in Figure 1. In this way, following the inspection of an artefact, it is possible to tackle the future structural behaviour hypothesising extensions and the progressive deterioration thus performing temporal analysis.

In the following, the methodology employed will be presented and validated by experimental case studies.

Figure 1. Conceptual depiction of the proposed approach: material-level degradation is accounted for by means pointwise variation of the fibres at the sectional level.

2.1 Description of corrosion modelling

Corrosion is a phenomenon that alters the mechanical properties of materials over the nominal life of a structure. All of this, as is well-known, can have effects on the reduction of steel in reinforcing bars, or strands in the case of prestressed concrete structures, affecting the strength and ductility of the concrete due to cracking and altering the adherence. In the case of chloride attack, pitting is the typical corrosion mechanism that occurs in reinforcement embedded in concrete. Unlike uniform corrosion that spreads uniformly over metal surfaces, pitting corrosion is a highly localised type of corrosion where a break in the protective film of the reinforcement results in a crater or pit. To explain the model, in the literature, a representation of the phenomenon has been proposed through geometric considerations (Stewart 2004). For what concerns the modelling of degradation as a spatial and temporal phenomenon, the evaluation procedure begins with the notion of the chloride profile in structural elements so that appropriate time-decay relationships of physical properties of materials can be considered. Therefore, given the environmental conditions, the following steps can be performed to assess the capacity of a concrete member (Imperatore et al. 2016):

1. Evaluation of the chloride distribution and content in time.
2. Definition of the critical corrosion content related to the corrosion initiation period.
3. Evaluation of the corrosion rate.
4. Evaluation of the rebar mass loss in time.
5. Definition of the strength decay laws of the corroded rebars versus the mass loss (or the time).
6. Structural analysis and check of corroded elements.

Regarding steps 1-2, we can refer to the diffusive models known in the literature (Chatterji 1994, 1995). Typically, unlike experimental tests with accelerated corrosion, the chloride content on the surface is about 0.4 % (by concrete weight), with a critical content of 0.05 % (by concrete weight). The evaluation of the pit depth over time can be expressed as (Stewart 2004):

$$P_x \left(\frac{\text{mm}}{\text{yr}} \right) = 0.0116 \cdot i_{\text{corr}} \cdot R \cdot t \quad (1)$$

Where the corrosion rate i_{corr} is measured as a current density $\mu\text{A}/\text{cm}^2$ (Otieno et al. 2011), R is the ratio between the maximum localised attack on steel and the average attack along the rebar surface, and it can be estimated between 4 and 8, finally, t is the time since initiation of corrosion. Focusing then on step 3, the corrosion rate, i_{corr} , should not be assumed constant

since it reduces over time due to rust which decreases the irons of steel surface. An expression of corrosion rate is:

$$i_{\text{corr}}(t) = 0.85 \cdot i_{\text{corr}}(1) \cdot t^{-0.29} \quad (2)$$

where $i_{\text{corr}}(1)$ is the corrosion rate at the beginning of propagation:

$$i_{\text{corr}}(1) = \frac{3.78 \cdot \left(1 - \frac{w}{c}\right)^{-1.64}}{c} \quad (3)$$

with c the concrete cover expressed in centimetres.

Starting from relations Equations 1-3, it is possible to evaluate the corrosion loss of the cross-sectional area of individual reinforcing steel rebars relative to the uncorroded configuration (step 4). In what follows, $X(t)$ will denote this relative reduction. In this study, the model used to predict the loss of cross-sectional area of reinforcing bar due to pitting is that proposed by Val & Melchers (1997). Then, in conjunction with the adoption of empirical factors, the constitutive laws of materials account for the spread of the spatial and temporal decay of the phenomenon (step 5) and so the structural analysis (step 6).

2.2 Impact of corrosion on mechanical behavior

A model for reducing the strength of reinforcing steel rebars was investigated by Du et al., conducting accelerated corrosion tests on reinforcing rebars embedded in concrete (Du et al. 2005b). The relationship that the authors proposed to determine the time loss of yield strength, $f_{y,\text{corr}}$ relative to the initial condition, $f_{y,\text{uncorr}}$, is:

$$f_{y,\text{corr}}(t) = (1 - 0.005 \cdot X(t)) \cdot f_{y,\text{uncorr}} \quad (4)$$

In addition, the change in strengths is interrelated with strain; therefore, the material's ductility reduction appears evident for the same modulus of elasticity. This type of corrosive process changes the expected failure from ductile to brittle.

The corrosive process of steel produces rust that expands, causing splitting stresses in the concrete and affecting the concrete's mechanical properties around the deteriorated reinforcing bar. Shayanfar *et al.* investigated the reduction of concrete strength as a function of the degree of corrosion through an experimental accelerated corrosion test (Shayanfar et al. 2016), proposing the relation:

$$f_{c,\text{corr}}(t) = (1 - \lambda(t)) \cdot f_{c,\text{uncorr}} \quad (5)$$

The percentage of loss strength compared to the initial configuration, $f_{c,\text{uncorr}}$, is related by empirical factors that consider the water/cement ratio (w/c). For instance, the reduced compressive strength due to reinforcement corrosion, Equation 5, for a specimen with a w/c equal to 0.5, can be assumed as: $\lambda(t) = 2.576 \cdot X(t) - 1.876$. The relationships Equations 4-5 make it possible to differentiate not only the individual reinforcing rebars of a section subject to degradation but also the stirrups, reflecting the loss of confinement in the mechanical property of the concrete.

3 CASE STUDIES

3.1 Experimental test of a simply supported beam subjected to a monotonic load

A laboratory test conducted by Rodriguez *et al.* in 1997 was carried out to investigate the effect of reinforcing bar corrosion on the service limit state and ultimate capacity of reinforced concrete beams (Rodriguez *et al.* 1997). The study also sought to investigate the influence of different variables, such as the level of degradation, reinforcement detailing, and interaction

versus load. The beams had a length of 2.3 m, with a cross-section of 200 x 150 mm². The diameter of the rebar used was distinguished between lower ($\Phi 10$, $\Phi 12$) and upper ($\Phi 8$) rebars, while the brackets had a diameter of 6 mm, spaced every 170 mm. Regarding the mechanical properties of the concrete, the compressive strength value is assessed around 34-37 MPa, with a water/cement ratio of 0.5. The concrete used to induct corrosion, is featured by 3% calcium chloride. The steel had a yield strength of 585 and 628 MPa, with an ultimate strength equal to 655 MPa. The accelerated corrosion process occurred for about 200 days, and the steel was subjected to a current intensity of about 0.1 mA/cm². When the corrosion process was completed, the simply supported beam was subjected to a four-point bending test loading scheme.

In Table 1, the specific values of test named 114 are reported and considered for the analysis performed. Values of numerical steel and concrete corroded reported in the mentioned table refer to the rebars $\Phi 10$. The structural analysis conducted in this study was performed using the OpenSees software framework (McKenna et al. 2010), while the deteriorated mechanical properties over time were computed by means of a set of specific subroutines written in MATLAB (The MathWorks Inc. n.d.). The user can specify the duration of corrosion, the environmental conditions, the structural configuration of a specific member and the selected rebars subjected to a deterioration process. The output files are constituted by the pointwise fibres of the section and the materials. In this way, the accurate extension of the damage around the reinforcing steel rebars is captured. The depth of crack propagation and the concrete cracked around the rebars are taken as twice the concrete cover of the section. The constitutive relations of concrete and steel material were adequately scaled. In Figure 1, a depiction of the deteriorated section after 130 days of accelerated corrosion and the comparison of the numerical-experimental test considered is represented.

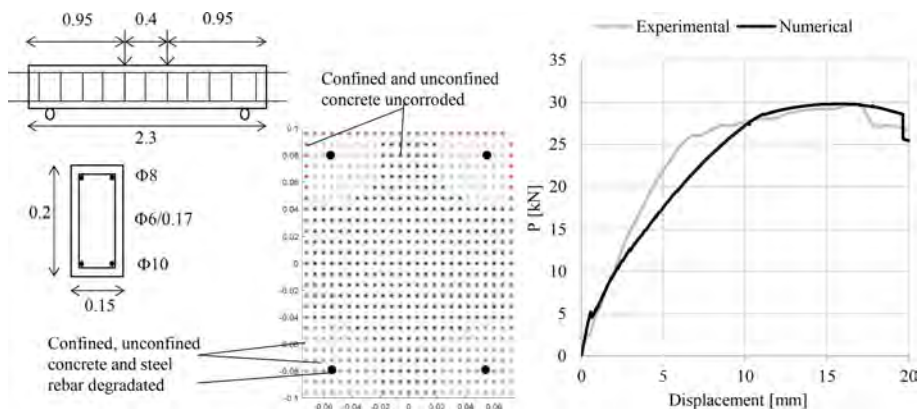

Figure 2. A) Experimental test readapted from literature (Rodriguez et al. 1997); b) section deteriorated and c) numerical response.

In the present study, five uniform nonlinear beam-column elements, with a force-based formulation and five Gauss-Lobatto integration sections, are adopted. Moreover, to capture geometric nonlinearities, the co-rotational formulation is adopted. A displacement control with an adaptive solution of the algorithm is implemented through scripts in the usual tcl programming language. In fact, the analysis is carried out through the Newton-Raphson iterative solution, and if convergence is not achieved, the displacement increment is reduced. The convergence criterion adopted is the norm of displacements, with a tolerance of 1×10^{-6} obtained through, at most, 50 iterations.

3.2 Experimental test of a pier in dynamic conditions

To the authors' knowledge, the unique available experimental test in the literature on corroded RC columns under dynamic earthquake loading is the one performed by Yuan et al.

Table 1. Properties of the test specimen 114. Unit of measure: MPa unless otherwise specified.

Uncorroded	f_c	f_{ct}	E_c	$f_{sy-su}(\Phi 10)$			
Experimental	34	3.1	27405	575-655			
Corroded	$f_{c,corr.}$	$f_{ct,corr.}$	$E_{c,corr.}$	$f_{sy,corr}(\Phi 10)$	R [-]	$p_{130 \text{ days}}(\text{mm/year})$	$X_{130 \text{ days}}(\text{mm}^2/\text{mm}^2)$
Numerical*	17.24	1.7	19515	518	7.75	4.2	0.3

* Symbols here of last three columns, refer to Equations (1-5).

(Yuan et al. 2018). In this study, the results of shaking table tests conducted for coastal bridge piers by considering the effect of a non-uniform corrosion are described. Four structural specimens with different degrees of corrosion at the designed splash and tidal zone are first fabricated by the electrochemical accelerated corrosion method and then subjected to incrementally increasing ground motions. For the complete experimental campaign, the reader may refer to the literature (Yuan et al. 2018); here, for the sake of simplicity, only a few pieces of information are reported. The diameter of the column is 200 mm with a 15 mm concrete cover and an effective height of 1.66 m. Figure 3a shows a scheme of the test as well as the time-relative displacement relationship of the specimen.

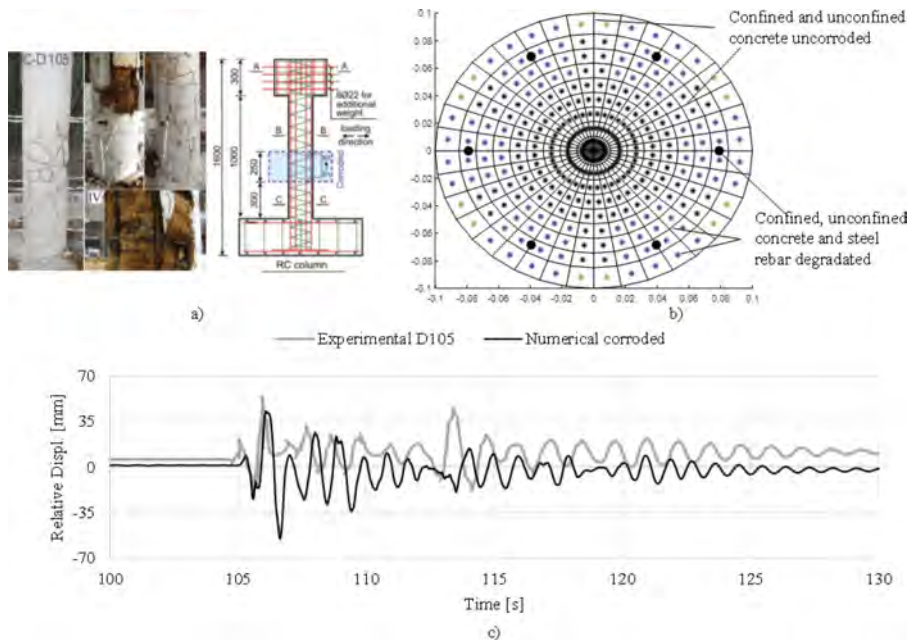

Figure 3. A) Schematic of test specimen readapted from literature (Yuan et al. 2018); b) section deteriorated and c) numerical response of the four time history.

The section consisted of 6Φ10 reinforcing steel rebars with a yield and ultimate strength of 662 MPa and 422 MPa, respectively, while the stirrups had a diameter Φ6 mm. The water-cement ratio of the concrete was equal to 0.38. The 28-day average compressive strength and modulus of elasticity were tested to be 36.27 MPa and 19.5 GPa, respectively. A mass of about 7.86 tons was placed at the head, while the extent of the zone subjected to accelerated corrosion with a current density of 300 $\mu\text{A}/\text{cm}^2$ for 105 days was 250 mm and 300 mm above the footing as represented in Figure 3. The corrosion region was immersed in a 4.0 % NaCl solution before the current was applied with the purpose to allow enough chloride ions to penetrate. The Imperial Valley “El-Centro” 1940 recording set was chosen by scaling the motion to investigate the damage process (eight-time histories were applied to the specimen with a peak-table acceleration of: 0.112 g, 0.32 g, 0.64 g, 0.85 g, 1.10 g, 1.35 g, 1.6 g and 1.85 g). The numerical degraded

section considered in the analysis is shown in Figure 3b, where the explicit representation of the deterioration can be appreciated around the rebars through the integration points, here taken as twice the concrete cover of the section. As mentioned before, even in this case the model used to predict the loss of cross-sectional area of reinforcing bars is that proposed by Val & Melchers (1997). In this study, four force-based beam-column elements are used to reproduce the specimen with five Gauss-Lobatto integration point sections. For the top node, a lumped transverse mass and an axial load were applied. In addition, the “Bond_SP01” model was used to capture the bond-slip phenomenon of the fully anchored bars at the column-to-footing in conjunction with the adoption of a single zero-length section to consider the strain penetration effects.

OpenSees model was created to perform the transient analysis of the corroded specimen using an implicit response integration scheme, namely the HHT method. Figure 3c shows the test and simulation results of the time histories of the relative displacement (between the mass block and shaking table) under the excitation of earthquake number four according to the test campaign (E4). From the figure, it can be observed that the simulated responses of the displacement match reasonably well, even though the model does not fully capture the accumulated residual displacement.

4 CONCLUSIONS

In the present study, the spreading of material’s degradation subjected to corrosion by means of the pointwise modification of fibres at the sectional level of beam-column elements was validated through the results of experimental tests. A specific subroutine developed in MATLAB has been developed to conceive this aim. Firstly, a simply supported beam subjected to a monotonic load was considered, while subsequently, the only test currently available in the literature of a column subjected to accelerated corrosion and subjected to a series of dynamic incremental loads was examined. In both cases, nonlinear beam-column type elements with diffuse plasticity were used, subjected to spatial and temporal updating of the fibres around the reinforcing bars. Specifically, the reduction of steel area and change of mechanical properties of concrete due to cracking were considered in the volume of material affected by the degradation.

One of the main advantages of the presented approach is its accuracy and feasibility; as a matter of fact, practitioners can accurately reproduce the geometry of the degradation by means of in-situ inspection and then assess the elements’ capacity without adopting more sophisticated tools. Further studies will allow the model to include brittle failure modes and additional local detailing exploring the use for large-scale analyses.

University of Tehran, Tehran, Iran

ABSTRACT: This paper presents a mathematical framework for optimal management of aging bridge networks subjected to mainshock-aftershock sequences. The pre- and post-earthquake management of the highway systems is addressed considering performance objectives based on seismic resilience and life-cycle costs. Structural capacity of vulnerable bridges and traffic performance of the transportation network are investigated accounting for the effects of aftershocks by state-dependent fragility curves informing cumulative damage scenarios, and the effects of aging and deterioration process by time-dependent fragility curves. Optimal intervention sequences are identified under uncertainties involved related to bridge damage levels and mainshock-aftershock sequences based on a bi-objective optimization problem aiming at maximizing network resilience and minimizing costs associated with pre-event maintenance and retrofit interventions as well as post-repair restoration activities.

1 INTRODUCTION

Community seismic resilience has been defined as the ability of social units (e.g. organizations and communities) to mitigate hazards, contain the effects of disasters when they occur, and carry out recovery activities in ways that minimize social disruption and mitigate the effects of future earthquakes (Bruneau et al. 2003). An outstanding example of seismic event is the 1989 Loma Prieta earthquake on California's Central Coast, hitting the Bay Area in San Francisco, which caused numerous fatalities and injuries besides serious damage to physical facilities. The 1994 Northridge earthquake in Los Angeles was another major event that led to severe social and economic losses, especially concerning electric power outage and disruptions in the water system. In 1995, the Hyogo-ken Nanbu earthquake in Japan induced thousands of deaths and injuries along with prolonged downtime of integral lifelines such as electric, gas, water, telecommunication and transportation system. In addition to the disruptive effects of mainshocks, major seismic events such as 1994 Northridge, 2008 Wenchuan, and 2012 Emilia were followed by noticeable aftershocks, which may exacerbate the damage scenarios on mainshock-damaged structures and bridges leading to functional issues up to collapse.

Transportation networks play a significant role in the resilience of communities after extreme events such as earthquakes, by providing communication service to critical units (e.g. hospitals, fire stations, among others) and transition to damaged areas. Bridges are among the most vulnerable components of transportation networks and their damage can disrupt the emergency response (Bocchini & Frangopol 2011a, 2012a, Capacci et al. 2022). The vulnerability of bridges depends on its resistance to earthquakes which is also affected by its damage state due to aging and deterioration process (Capacci & Biondini 2020, Capacci et al. 2020a, 2020b). Retrofitting and maintenance activities as well as restoration interventions would

enhance the seismic capacity of bridges, but existing limitations for available manpower, equipment or financial resources requires an optimal management. Nonetheless, priorities are largely influenced by uncertainties in seismic hazard (e.g. ground motion variability) and structural vulnerability as well as, subsequently, bridge damage conditions and their consequence at the network scale. Optimization can aid the decision-making process defining prioritization patterns for these activities aimed at enhancing the resilience of networks accounting for the related uncertainties and constraints.

Based on this background, this paper is devoted to plan management strategies for resilient bridge networks by jointly considering pre-event management to enhance emergency response and post-event management to promote the recovery procedure by considering mainshock-aftershock sequences affecting aging bridges. A multi-objective optimization process is proposed to find Pareto-Front of optimal solutions representing optimal retrofit methods and prioritized start time of restoration activities to maximize the network resilience exposed to mainshock-aftershock sequences and minimize costs related to these strategies. The vulnerability of bridges is estimated based on fragility curves taking into account the effect of retrofitting, aging and deterioration processes and damage accumulation caused by previous shocks. A congestion-based functionality metric is used to evaluate travel time delay and distance increase due to using detours when bridges traffic capacities decrease due to damage. The proposed methodology is applied to a small-scale six-bridge transportation network exposed to a seismic scenario considering the effect of mainshock and aftershocks. The results show that one can enhance seismic resilience of transportation network with the lowest cost by selection of critical bridges to be properly retrofitted before extreme events and prioritization of bridges to start restoration activities after extreme events based on their effectiveness in functionality, their proximity to epicenters and aging or deterioration condition.

2 SEISMIC VULNERABILITY

Seismic vulnerability of bridges can be evaluated by fragility analysis. Fragility curves represent the cumulative probability of being in or exceeding each damage state for a given seismic intensity. Seismic demands i_b at bridge sites exposed to given mainshock-aftershocks sequences are evaluated by seismic hazard analysis for spatially distributed networks (Jayaram & Baker, 2009). If a bridge gets damaged with a mainshock and not recovered at the occurrence time of aftershock, its seismic capacity decreases and a state-dependent fragility curve considering damage accumulation is needed to assess seismic vulnerability. The detrimental effects of deterioration processes, such as chloride-induced corrosion, may be exacerbated by climate change and lead to increase over time the seismic vulnerability of bridges. Therefore time-dependent fragility curves are required to evaluate damage states. Retrofitting is a solution to improve seismic resistance of bridges and decrease vulnerability. Proper retrofit methods can be based on bridge type and structural damage condition.

Vulnerable elements of bridges include piers, bearings, cap beams, and joints, among others. Different retrofit methods can be applied to decrease the vulnerabilities of these components. Seismic isolator bearings and seismic restrainers are retrofit methods to decrease vulnerability related to bearings. Seat extender and reinforced concrete jacketing are effective to reduce the damage in cap beams and concrete joints. Shear keys or traverse bumpers are used to restrain traversal movement of bridges. Different kinds of jacketing such as concrete, steel, fiber reinforced polymer (FRP), engineered cementitious composite (ECC), and fabric reinforced cementitious matrix (FRCM) jacketing are used to increase the ductility and shear capacity of bridge piers. In addition, FRCM confinement may decrease the vulnerability related to environmental deterioration caused by dioxide emission or chloride diffusion, and preserve its functionality under high temperatures (Padgett & DesRoches 2009, Billah et al. 2013, Zanini et al. 2020, Skokandić et al. 2022). According to literature, retrofit, pre-existing damage condition, and deterioration may lead to considerable changes in median values, but slight changes in dispersion of fragility curves (Padgett & DesRoches 2009, Iervolino et al. 2020, Capacci et al. 2020, Ghosh & Padgett 2010).

A general formulation for fragility curves considering possible conditions leading to as-built, retrofitted, state-dependent, and time-dependent fragility curves, can be formulated as follows:

$$P[S_b \geq s_b | \hat{s}_b, r_b, i_b, t_b] = \Phi \left[\frac{\ln(i_b) - \ln(MF_a(s_b, t_b) \cdot MF(s_b, \hat{s}_b, r_b) \cdot i_{b,m}(s_b))}{\zeta_{s,b}(s_b)} \right], \quad s_b > \hat{s}_b \quad (1)$$

where S_b = variable representing the damage state of the b -th bridge in the network with values $s_b = 0, 1, 2, 3, 4$ associated with no damage, slight, moderate, extensive, and complete damage state, respectively; \hat{s}_b = pre-existing damage state; r_b = retrofit method and takes the value 1 for a non-retrofitted bridge, and values 2, 3, ... for different types of retrofit interventions; i_b = seismic intensity at b -th bridge site; $i_{b,m}(s_b)$ = median intensity measure leading to the exceedance of a given damage state s_b ; $\zeta_{s,b}(s_b)$ = standard deviation of the natural logarithm of the intensity measure leading to the exceedance of a given damage state s_b ; t_b = bridge age; $MF(s_b, \hat{s}_b, r_b)$ = modification factor for median values of fragility curves for damage state s_b considering retrofit measure r_b and pre-existing damage state \hat{s}_b ; $MF_a(s_b, t_b)$ = modification factor for median values of fragility curves for damage state s_b considering the bridge age t_b at occurrence time of shocks, with $MF_a(s_b, t_b) \leq 1$. Figure 1 shows typical trends of modification factors.

Figure 1. Typical trends for modification factors: (a) $MF(s_b, \hat{s}_b, r_b)$; (b) $MF_a(s_b, t_b)$.

For $s_b = \hat{s}_b$, $P[S_b \geq s_b | \hat{s}_b, r_b, i_b, t_b] = 1$, and for $s_b = 5$, $P[S_b \geq s_b | \hat{s}_b, r_b, i_b, t_b] = 0$. The occurrence probability of damage state s_b on bridge b is hence evaluated based on fragility curves as follow:

$$P[S_b = s_b | \hat{s}_b, r_b, i_b, t_b] = P[S_b \geq s_b | \hat{s}_b, r_b, i_b, t_b] - P[S_b \geq s_b + 1 | \hat{s}_b, r_b, i_b, t_b], \quad s_b \geq \hat{s}_b \quad (2)$$

It is worth noting that for $s_b < \hat{s}_b$, the probability of being in damage state s_b is equal to zero ($P[S_b = s_b | \hat{s}_b, r_b, i_b, t_b] = 0$). An average of occurrence probabilities of different damage states can be used to quantify damage level l_b of each bridge affected by an earthquake (Bocchini & Frangopol 2011a):

$$l_b = E(S_b) = \sum_{s_b \geq \hat{s}_b}^4 s_b \cdot P[S_b = s_b | \hat{s}_b, r_b, i_b, t_b] \quad (3)$$

The damage level l_b is bounded within the interval $[0, 5) \subset \mathbb{R}$.

3 RESILIENCE FRAMEWORK

Spatially distributed bridges in a transportation network exposed to earthquakes might experience different damage levels. These damage levels combination is representative of bridge network damage state. Since damage level l_b takes values in the interval $[0, 5)$, the total number of possible network damage level combinations are discretized by rounding the damage level

l_b to the nearest smaller integer to define the expected damage state for each bridge (i.e. 0, 1, 2, 3, 4). The expected damage state combinations can be collected in a vector s representing the bridge network damage state, with N_b columns denoting the number of bridges and N_s rows denoting the total number of possible network damage combinations. The damage levels l_b can be evaluated by using fragility curves, explained in seismic vulnerability section.

To quantify resilience, a proper performance metric representing the network functionality for each damage state combination s caused by shocks is required. In this paper, a performance metric based on total travel time $TTT(s)$ and total travel distance $TTD(s)$ is used (Bocchini & Frangopol 2012a, b). These functionality indicators are computed by combined traffic assignment and distribution problem (Bocchini & Frangopol 2011b) for each damage state combination s . Damage states of bridges are taken into account by considering the time delay and distance increase caused by using detours when bridges are partially or completely closed. In this case, it is considered that for expected damage states 0, 1, 2, 3, and 4, the bridge traffic capacity is respectively 100, 75, 50, 25, and 0 percentage of the undamaged bridge. Considering different factors such as bridge type, available resources affect the restoration process of damaged bridges. It is assumed that each bridge will restore from a damage level to the next one over a definite time interval.

Therefore, by selecting proper retrofit method and start time of restoration activities for each bridge, network functionality can be evaluated at each time step based on the current damage state. In this way, the network resilience can be computed as follow (Capacci & Biondini 2020):

$$R = \frac{1}{\Delta t_h} \sum_{i=0}^{N_t} Q_i(s) \cdot \Delta T_i \quad (4)$$

where Δt_h = time horizon; ΔT_i = time step; N_t = total number of time steps in the network recovery process; and $Q_i(s)$ = network functionality at i -th time step with respect to the damage state combination s .

Resilience R to be maximized and cost C to be minimized are considered as targets in a bi-objective optimization problem to inform the decision-making process addressing the retrofitting and restoring interventions. Decision variables are retrofit methods and start time of restoration activities selected from a time horizon, for each bridge. Constraints on the maximum number of simultaneous restoration activities and maximum time duration for simultaneous restoration activities that can be done on different bridges, are applied due to limited resources. This multi-objective constrained problem is solved by NSGA-II (Deb et al. 2002) meta-heuristic algorithm using penalty functions. Decision makers can select optimal solutions from Pareto-Front obtained by solving the optimization problem, based on their required resilience, budgets and available resources. Further details can be found in Jafari et al. (2023).

4 APPLICATION

The proposed methodology is applied to the small-scale six-bridge network shown in Figure 2a, exposed to a mainshock- aftershocks scenario at times 0, 3, and 7 months with magnitudes m equal to 7.0, 6.8, and 7.5, respectively. The ages of bridges are 50, 20, 40, 100, 70, and 80 years at the occurrence time of mainshock. Modification Factors $MF_a(s_b, t_b)$ are based on Figure 1. The seismic demands i_b obtained by attenuation law (Bindi et al. 2011) are shown in Figure 2b. The bridge network functionality for each damage state combination $Q(s)$ is computed by the combined traffic assignment and distribution problem.

It is assumed that B1 is a multi-span continuous (MSC) steel girder bridge, B2 and B5 are multi-span simply supported (MSSS) concrete girder bridges, B3 is MSSS steel girder bridge, and B4 and B6 are MSC concrete girder bridges. The details of these four types of bridges and their as-built fragility curves parameters can be found in Padgett (2007) and Padgett & DesRoches (2009). The optimal retrofit methods are selected from those listed in Table 1 and 2. Modification factors $MF(s_b, \hat{s}_b=0, r_b)$ and costs of these retrofit methods are supported by engineering judgments and based on literature (Padgett 2007, Raza et al. 2019, Zanini et al. 2020). It is assumed

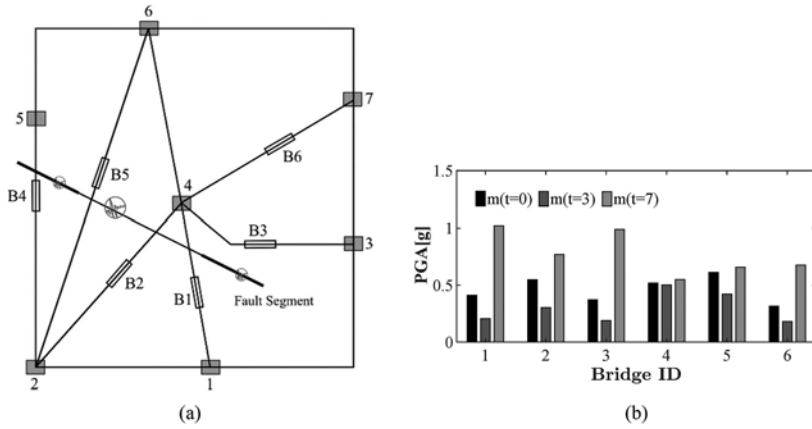

Figure 2. (a) Bridge network layout and fault segment. (b) Seismic demands at bridge sites associated with mainshock and aftershocks.

that the modification factor $MF(s_b, \hat{s}_b, r_b)$ for each s_b and $\hat{s}_b = 1, 2,$ and 3 is $0.9, 0.8,$ and 0.7 times the corresponding modification factor $MF(s_b, \hat{s}_b=0, r_b)$ for each s_b , respectively. A detour of 30 km is assumed for each bridge. Restoration cost for one month time unit is considered 250 k\$. More details about bridge network traffic characteristics, as well as the required recovery time for each damage state of each bridge type, can be found in Jafari et al. (2023).

6	Shear Keys	0.99	0.98	0.98	0.97	1.08	1.14	1.13	1.09	12.0
7	Restrainer Cables & Shear Keys	1.02	1.02	1.04	1.09	1.09	1.17	1.21	1.21	28.5
8	Seat Extenders & Shear Keys	0.99	0.98	0.99	1.23	1.09	1.15	1.15	1.41	24.0
9	Concrete Jacketing	1.05	1.03	1.04	1.11	1.03	1.07	1.09	1.15	100.0
10	ECC Jacketing	1.08	1.12	1.12	1.16	1.05	1.29	1.23	1.22	120.0
11	CFRP Jacketing	1.07	1.10	1.11	1.17	1.05	1.23	1.22	1.23	32.0
12	FRCM Jacketing	1.07	1.20	1.30	1.50	1.05	1.26	1.37	1.58	70.0

The solution of the bi-objective optimization problem involves several computational steps. The damage level of bridges is firstly evaluated at each time step (0.2 month), based on recovery process and fragility curves, for restoration and retrofit strategies selected by NSGA-II algorithm, to obtain the bridge network damage state s at each time step of selected time horizon $\Delta t_h = 2$ years. Therefore, the bridge network functionality at each time step $Q_\lambda(s)$ is determined. Then the bridge network resilience R and cost C of selected retrofit and restoration strategies are quantified. Start times of restoration intervention are selected from a time horizon $\Delta t_h = 2$ years and it is assumed that maximum three simultaneous restoration activities with maximum time interface of 12 months can be done on different bridges. The optimal Pareto-Front solutions obtained by solving the optimization process are shown in Figure 3. Several optimal solutions are selected from the Pareto-Front and reported in Table 3. The outputs extracted from these solutions include network functionality (Figure 4) and bridge damage profile with the corresponding recovery schedule charts (Figure 5) that provide essential information for decision makers.

5 CONCLUSIONS

A resilient transportation network is an integral part of a resilient community, and bridges as the most susceptible components to extreme events such as earthquakes, should be the center of attention. The seismic performance of existing aged bridges might decrease due to deterioration process such as chloride induced corrosion or climate changes. Also, most of these bridges were not designed based on seismic design codes. As pre-event interventions, different retrofit methods based on bridge type and structural condition can be applied. Also, effective post-event activities are needed to recover rapidly the bridge network functionality after an extreme earthquake. After a mainshock, corresponding aftershocks might also strictly affect the bridge network resilience. Optimal resource allocation is the priority of managers and decision makers to improve the resilience of infrastructures. This paper presented an optimization methodology to find optimal interventions for applying to bridges taking into account all possible factors affecting resilience. The vulnerability of bridges has been calculated based on time-dependent, state-dependent, retrofitted and pristine bridge fragility curves. The objectives are maximizing resilience and minimizing cost of rehabilitation interventions, considering retrofit methods and start time of restoration activities as decision variables. The optimization

problem has been applied to a small-scale bridge network. Decision makers could select optimal solutions of Pareto-Front obtained from optimization process based on their budget and available resources. Further research is needed to extend the proposed approach to large scale networks and to account for a wider spectrum of retrofitting interventions and maintenance strategies.

Risk-based optimal life-cycle maintenance of post-tensioned concrete bridges considering accuracy of inspection methods in structural model updating

M. Taeb, A.B. Mehrabi & K. Lau
Florida International University, Miami, USA

ABSTRACT: This paper recommends a procedure for risk-based lifetime cost optimization of maintenance for PT bridges. To demonstrate the procedure, an actual segmental post-tensioned bridge is used for which the inspection results are available. Hands-on and nondestructive tests were performed on several external PT tendons to verify the accuracy. The results showed that non-destructive evaluation (NDE) and hands-on inspection results are correlated, as such, the level of accuracy for the selected methods to be used for the inspection was determined to be acceptable for the inspection to continue in large scale. External tendons of the bridge were then inspected using the selected NDE method. The inspection results were used to calculate the reduction in the cross section of post tensioning elements. Investigation is underway to optimize the lifetime risk of the bridge, simplified reliability analysis associated with updated finite element model subjected to deterioration of the external post tensioning elements.

1 INTRODUCTION

Considerable number of Post-Tensioned (PT) bridges have been constructed because PT systems enable them to carry significant traffic loads and have an aesthetical structure at the same time. However, corrosion has been a long-standing issue for PT tendon that leads to the weakening and failure of tendons and deterioration of the structural performance. In the case of external PT tendons, the limited interaction points between the post-tensioning elements and the main structure increases the redundancy and reliability concerns for the PT elements in terms of deterioration. Because of this, the inspection of post-tensioning system, updating structural model, and reliability analysis of deteriorating PT bridges are of great importance. To address this need, a risk-based decision support system for maintenance of post tensioned concrete bridges (Taeb & Mehrabi 2019) can be adopted. Figure 1 shows the modules of the corresponding decision support system, research modules completed, and ongoing research modules. This paper aims to demonstrate the application of such decision support system on a bridge, called here the bridge of case study. The first module of the decision support system is the selection of inspection method which is developed in the independent paper (Taeb & Mehrabi 2022). Normally, the inspection results are used deterministically to estimate the existing condition of the bridge ignoring the probability of false results. To address this shortcoming, the second module is the stochastic condition assessment covers the applicable condition ratings and probability of true and false condition diagnostic during the inspection, and proposes a new approach in considering inspection results. The third Module is the inspection of external post tensioning elements of the bridge of case study and discussion on the inspection results. The fourth Module focuses on the available maintenance scenario for the post tensioning elements which include “No action”, “Repair”, and “Replacement” of the external tendons. The fifth module proposes a deterioration model for the post tensioning elements which will be used in the structural simulation of maintenance scenarios in time and the

lifetime risk analysis of the bridge of case study. Ongoing research modules include finite element modeling, updating structural model based on the inspection results, structural simulation of the maintenance scenarios, reliability analysis, and scenario-based lifetime risk analysis that are under investigation and will be presented in future works.

Figure 1. Risk-based decision support system for maintenance of post-tensioned concrete bridges.

2 STOCHASTIC CONDITION ASSESSMENT

Structural condition assessment is based on condition rating, and the post-tensioning system is not an exception. A variety of condition rating methods are available in the literature (AASHTO 2018). The purpose of this module is determination of stochastic parameters of the rating diagnosis in NDE test, which will be used in modules to follow. An arrangement of condition rating for post tensioning elements is used in this study which was developed by Taebay and Mehrabi (Taebay & Mehrabi 2022) based on comparable SNBI rating.

To determine the actual accuracy and the analysis of rating diagnostic, twenty tendons among more than one thousand were randomly selected. Figure 2 is the sketch showing the cross-section of the bridge of the case study in the bridge span.

True rating diagnosis are the cases where the result of the NDE and destructive test are the same. False diagnosis refers to cases where the result of the impact testing is not the same as the dissection inspection method, however, the result of the NDE method in this case could have indicate a condition worse or better than the result of the dissection test which assumed to be as the inspection method with zero false diagnostic. Overrated false diagnosis is the case that NDE reports the condition rating better than the condition assessed by the dissection test, which can be considered as non-conservative. Underrated false diagnosis is the case that NDE reflects the condition rating more than the condition assessed by the dissection test, which can be considered as conservative.

Based on the results of investigation among the twenty cases investigated, fourteen true diagnosis (70%), three (15%) underrated false diagnosis, and three (15%) Overrated false diagnosis were reported. Figure 3 shows the results of the investigation on stochastic parameters of condition assessment in the bridge of case study.

Figure 2. Typical cross section of the approach viaduct.

Figure 3. Stochastic parameters of condition assessment in the bridge of case.

3 INSPECTION OF EXTERNAL POST TENSIONING ELEMENTS AND THE RESULTS

The bridge of case study is one span of the approaches which is constructed as a post-tensioned segmental bridge. The bridge is simply supported and is spanned 35 meter with 10 external post-tensioned tendons along the entire span. There are three deviators inside the box and the external tendons were passed through pipes embedded in these deviators. There are two holes in the deviators and diaphragms anticipated by the designer to accommodate additional PT tendons if necessary. There are 5 tendons at the left side of the section (from L1 to L5) and there are 5 tendons at the right side of the section (from R1 to R5). The inspection results based on SNBI rating for corresponding tendons are concluded in Table 1. Figure 4 shows one of the anchorage caps in the bridge of case study which strands are exposed to the environment. Figure 5 shows one of the tendons in the critical condition (Condition Rating 2).

Table 1. Inspection results for the ramp bridge of the case study.

Tendon	L1	L2	L3	L4	L5	R1	R2	R3	R4	R5
Condition	7	6	0	6	8	3	7	5	5	4

Figure 4. One of the anchorages without proper cap.

Figure 5. Critical condition of a tendon.

4 MAINTENANCE SCENARIO IDENTIFICATION

Three scenarios considered for maintenance of external post tensioning elements are, “no action”, “repair”, and “replacement”. “No action” means that there is no need to change the current condition of the tendon and the tendon will be kept in the same condition as it is.

In the case of “repair,” there are actions that needed for the free length of the tendons as well as the anchorages. These actions cannot change the structural condition of the tendons, however nonstructural parts of the tendons which are the corrosion protection barriers will be repaired.

To address the issues in anchorage zones activities such as cleaning and brushing the anchor plate/wedge plate, and installation of new galvanized steel caps on the anchorage zone will also be needed.

In the case of “Replacement”, that is removing the existing tendon and installing a new tendon, both structural and nonstructural conditions will be changed to “excellent” condition. The replacement procedure includes the steps of structural safety determination, submittal of theoretical elongations and jacking forces, cutting the old tendon, new strands and HDPE pipe installation, stressing of the new strands, grouting, and quality control check.

5 DETERIORATION MODEL FOR POST-TENSIONING ELEMENTS

In this research, the authors considered the localized corrosion in addition to uniform corrosion. Localized corrosion is normally one of the serious side effects of excess bleed water and

usually appears within ten years from construction (Permeh, Samanbar & Lau 2022; Carsana & Bertolini 2015). The slope and height of the tendons in post tensioning system influences the chance of grout segregation and probability of the localized corrosion. Uniform corrosion is characterized by corrosive attack progressing evenly over the entire surface area. Corrosion protection barriers prevent the uniform corrosion to occur on strands. Proposed deterioration model includes parameters involved in both local and uniform corrosion.

To follow the risk-based decision support system for maintenance of post tensioned concrete bridges, the probability of failure in a deteriorating PT tendon is needed. Equation (1) is introduced to represent the probability of failure of a tendon due to local and uniform corrosion.

$$P_f(t) = \omega P_f^L(t) + (1 - \omega) P_f^U(t) \quad (1)$$

P_f is the probability of failure of a tendon, ω is the percentage of the tendons impacted by localized corrosion, P_f^L is the probability of failure of the tendon due to localized corrosion and P_f^U is the probability of failure of the tendon due to uniform corrosion. It is assumed that the chance of occurrence of severe local and uniform corrosion at the same time is zero. This assumption supports the thinking that the bleeding is within the corrosion protection system while uniform corrosion occurs when the protection system fails. Since the research on the corrosion speed due to bleed water is still ongoing, the probability of the failure caused by localized corrosion should be considered stochastic. Suitable distribution to demonstrate the failure of the tendon due to localized corrosion is an exponential distribution. The exponential distribution is frequently used for reliability calculations as a first cut based on its simplicity to generate the first estimate of reliability when more details failure modes are not described (Ott/Longnecker 2015). If the expected service life of a tendon attacked by bleed water is assumed t_L , the corresponding coefficient of the exponential distribution and the probability then will be determined using Equation (2).

$$P_f^L(t) = 1 - e^{-\lambda t}; \lambda_L = \frac{1}{t_L} \quad (2)$$

The probability of failure due to uniform corrosion, however, needs further assumptions. It can be assumed that the rate of corrosion in protected tendon by corrosion protection barriers is diminished. Nonetheless there is a chance for the protection system to fail. Therefore, the probability of failure of a tendon due to uniform corrosion includes the failure of the corrosion protection system and probability of structural failure of the tendon considering the time for tendon to be corroded. Penetration time for external ions and moisture content needed for the corrosion to occur is considered at the time to failure of the corrosion protection system (t_1).

$$P_f^U(t) = P_f^P(t = t_1) \times P_f^S(t = t) \quad (3)$$

In Equation (3) P_f^P is the probability of failure of the corrosion-protection system, P_f^S is the probability of structural failure of the tendon due to uniform corrosion, t_1 is the time which the protection system fails, and t is the time. The probability of failure of the corrosion protection barriers can be estimated by exponential distribution based on expected remaining lifetime of the protection system (t_0). It is based on the condition of the corrosion protection system. The probability of failure of the corrosion protection system is determined by Equation (4).

$$P_f^P(t) = 1 - e^{-\lambda_P t}; \lambda_P = \frac{1}{t_0} \quad (4)$$

Equations (5) to (8) are to determine the probability of structural failure of a tendon.

$$P_f^S(t) = P(Y < 1) \quad (5)$$

$$Y = \frac{\text{Capacity}}{\text{Demand}} = \frac{R}{Q} \quad (6)$$

$$R = \varphi_c f_y A_0 (1 - \omega) g_U \quad (7)$$

$$Q = \frac{f_y A_0}{S} \quad (8)$$

In Equations (5) to (8), Y is the capacity to demand ratio, R is the capacity of the tendon based on the corresponding condition and Q is the demanding design load which the tendon should carry. It is assumed that the distribution for both R and Q are lognormal (Nowak & Collins 2000), hence the distribution for Y is also lognormal. It is also assumed that the tensile stress is uniformly distributed across the cross section.

φ_c is the condition factor, f_y is the yielding stress of high stress steel, A_0 is the intact cross section of the strand, ω is the percentage of the tendons attacked by the localized corrosion, g_U is the deterioration function, and S is the design safety factor.

Equation (9) represents the parameters involved in the deterioration function.

$$g_U(t) = \begin{cases} 1, & t < t_1 \\ (1 - R_U(t - t_1))^2, & t \geq t_1 \end{cases} \quad (9)$$

R_U is the corrosion rate which is selected based on the environmental condition of the bridge location. Table 2 summarizes the recommended corrosion rates for variety of environments based on literature (Sivakumar et al. 2011; Ghosn et al. 2013). Corrosion rates are dependent on variety of parameters as discussed in the last section of this paper, therefore, the rates in the Table 2 should be considered as rough estimates for the decision support system and are subject to change on case-by-case basis. The time which corrosion protection system fails is t_1 . In Equation (9) it is assumed that the corrosion reduces the radius of the strand. It is also assumed that the residual materials caused by the corrosion does not influence the corrosion rate. It is also assumed that the corrosion is uniformly distributed along the free length of the tendon.

Table 2. Uniform corrosion rates based on the environmental condition of the bridge.

Climate type	$I_{\text{corr}} \left(\frac{\mu\text{A}}{\text{mm}^2} \right)$	Metal Loss (mmpy)
Dry	$<1.2 \times 10^{-4}$	5.817×10^{-3}
Temperate/Continental	$1.2 \times 10^{-4} - 2.4 \times 10^{-4}$	$5.817 \times 10^{-3} - 11.61 \times 10^{-3}$
Tropical	$2.4 \times 10^{-4} - 24 \times 10^{-4}$	$11.61 \times 10^{-3} - 116 \times 10^{-3}$

For determination of the structural failure of the tendon, since Y is lognormally distributed, coefficient of variance and mean value of the parameters involved in corrosion are needed. In the proposed deterioration model, it is recommended to estimate t_0 based on the condition of the corrosion protection system, therefore, Table 3 includes the recommended coefficient of variance for the deterioration function (g_U) with respect to t_0 .

5.1 Case study

The bridge of case study (Figure 2) is one of the spans in a 6-km long bridge for which damages to the external tendons was found during a routine inspection. Inspection results for all 10 external tendons for this span were available. In this paper, the deterioration of one tendon with poor condition of corrosion protection barrier is investigated ($t_0=25$ year). Design safety factor is considered $S=1.45$. The structural condition of the tendon is satisfactory $\varphi_c = 1$. Coefficient of variance for the condition factor φ_c is 15% and for safety factor, S, is diminished. Inspection

Table 3. Estimated t_0 and coefficient of variance for g_U based on condition of corrosion protection system.

Condition	Explanation	Recommended t_0 (year)	COV g_U
Good	No defect is observed in the corrosion protection system. Few defects such as small voids are observed through the free length of the tendon. Anchorage cap has some minor defects. Defects are not correlated together. There is no clue for sever environmental interaction for the strand.	75	0.2
Fair	Significant voids in the grout are observable. Initial clues of fatigue in the HDPE layer are observable. The chance of environmental interaction for the strand is not significant. The anchorage zone is not properly sealed. No evidence for the environmental interaction.	50	0.3
Poor		25	0.4

results 8 years after the operation of the bridge shows that 10% of the external tendons are impacted by local corrosion and almost in the failed condition ($\omega=10\%$, $t_L=8$ year). It is worth noting that the true and false probability of diagnosis for the inspection is 0.7 and 0.3, respectively. The bridge of case study is located in the region with tropical climate, therefore, the inspection team decided to consider uniform corrosion rate of $R_U=0.075$ mmpy.

Effective percentage of the tendons impacted by local corrosion based on the stochastic parameters of condition assessment will be determined using Bayesian updating.

$$\omega' = P(\text{local}|\text{true}) + P(\text{uniform}|\text{false}) = 0.1 \times 0.7 + 0.9 \times 0.3$$

$$\omega' = 0.34, 1 - \omega' = 0.66$$

By substitution of corresponding values in the Equations (1) to (9) for different values of t_1 (time to failure of corrosion protection barrier), Figures 6a and 6b show the probability of failure (P_f) of the tendon which was described in the bridge of case study associated with probability of failure due to local corrosion (P^L) and probability of failure due to uniform corrosion (P^U).

Figure 6a. Probability of failure of a tendon in the bridge of case study in poor condition $t_0=25$, $t_1=10$.

Figure 6b. Probability of failure of a tendon in the bridge of case study in poor condition $t_0=25$, $t_1=25$.

Proposed probabilistic deterioration model is a simplified probabilistic model to estimate the time dependent reliability of the post tensioning elements. Proposed deterioration model will be used in the ongoing research modules to determine the time dependent reliability of the bridge of case study.

6 ONGOING RESEARCH MODULES

The overall goal of this research is to obtain the optimum total risk among available maintenance scenarios while the probability of failure of the bridge meets the minimum threshold

during remaining service life. The previous sections described the tasks and modules completed to date. In the following, the approach for conducting the remaining tasks as described.

Equation (10) demonstrates the optimization goal, while Equation (11) defines the parameters involved. In Equations (10) and (11), R_T is the total risk, C_M is the maintenance cost, C_B is the value of the bridge, and P_f is the probability of the failure of the bridge. There are three identified scenarios ($i=3$) in this study including “no action”, “repair”, and “replace” which each has two different scenarios of deterioration ($j=2$).

$$\text{Min}(R_T); P_f(t) \leq P_{\text{threshold}} \quad (10)$$

$$R_{Ti}(t) = C_{Mi}(t) + P_{ij}(t)C_B \quad (11)$$

The limit state of study which is illustrated in Equation (12) is based on Strength I of AASHTO LRFD bridge design specification (AASHTO 2021) and AASHTO manual for bridge evaluation (AASHTO 2018).

$$R_n \geq 1.25DC + 1.5DW + 1.75LL \quad (12)$$

In Equation (12), R_n is nominal resistance capacity, DC is dead load, DW is the load associated with wearing surface, and LL is the live load.

To investigate the limit state for the flexural capacity of the bridge due to compression crushing of concrete, finite element modelling of the bridge of case study is developed and verified for intact structure. The finite element modelling simulates 11 segments, 3 deviators, and 2 diaphragms at both ends. Ten (10) external PT tendons are connected to the segments via deviators and diaphragms properly to model the behavior of the segmental post tensioned (PT) bridge. Figures 7 shows the corresponding finite element model.

Figure 7. Finite element model for the bridge of case study (3D).

The live load data for the bridge of case study is gathered from Florida department of transportation reports and converted to HS-20 truck. HS-20 is the truck that used by NCHRP 368 during the calibration of the AASHTO LRFD as design truck and associated calibration parameters and factors then used in literatures to simplify the reliability evaluation of the bridges. One of the realistic representations of live load effects on bridges would take the form of Equation (13) (Sivakumar et al. 2011).

$$LL_T = L_{\text{max}} \times L_{\text{HS20}} \times IM_{\text{fact}} \times \lambda_T \quad (13)$$

Where LL_T = total live load effect on the bridge member or on the bridge system, L_{max} = maximum projected load due to the random trucks on the bridge presented in the function of the number of HS-20 equivalent trucks, $L_{\text{HS-20}}$ is the load effect of the HS-20 truck used as the base line for analysis, IM_{fact} = dynamic amplification factor of the total load effect, and λ_T

is the adjacent data parameter. Hence, in this study, HS-20 truck represents the live load of the bridge and the capacity of the bridge will be presented as the number of HS-20 trucks.

Updating of the finite element modeling is based on inspection results for the external post tensioned tendons. Based on condition factor (ϕ_c) reported by the inspection, the cross sections of the strands will be updated and adjusted. Future deteriorating updated models associated with corresponding maintenance and deterioration scenarios then will be used to determine the capacity of the structure for each scenario.

Simplified reliability analysis then will be used to calculate the reliability of the structure using nominal capacity achieved by finite element modeling and the equivalent HS-20 trucks. The method is called simplified since it assumes that both the demand and capacity, have the lognormal distribution (like Equation (5)). The results then will be used in equation (11) with associated costs to determine the cost of the scenarios to give the owner the options to choose.

7 CONCLUSION

Post-tensioning elements play a critical role in the structural integrity of post-tensioned bridges and their maintenance is important for the asset managers and bridge owners. A risk-based decision support system (DSS) for maintenance of post tensioned concrete bridges was introduced in this study and implemented to investigate the safety of a bridge of case study. Some of the research modules are complete and some are ongoing. Among subjects covered in this paper is a unified and reliable risk-based methodology for selecting the inspection method with minimum risk as the subsystem of DSS. Normally, the inspection results are used deterministically to estimate the existing condition of the bridge ignoring the probability of false results. In the proposed method, the true and false diagnostics probability of condition assessment using a variety of available inspection methods was investigated in the module of stochastic condition assessment. Accordingly, the optimum inspection method was selected for the bridge of case study and inspection on the external post tensioning system of the bridge was carried out. Maintenance scenarios were presented and elaborated in detailed steps. The parameters which influence the deterioration of post tensioning elements were discussed and a deterioration model was introduced. Finite element modeling is ongoing to investigate the capacity, safety, and reliability of the structure. The FE model will be used to determine the capacity of the structure in each maintenance scenario and to calculate the reliability index and probability of failure accordingly. Determined probabilities of failure then will be used with associated costs to have the optimal scenario.

Seismic safety assessment of “Palácio do Itamaraty” at Brasília reliability-based

P.Q. Rodrigues & J.C. Pantoja

University of Brasilia, Brasilia, Federal District, Brazil

P.S.T. Miranda

Federal Institute of Education, Science and Technology of Ceará - IFCE, Ceará, Brazil

ABSTRACT: In Brasilia (Brazil) heritage buildings have been designed without considering seismic loads. The aim of the paper is to assess seismic behavior of reinforced concrete structure of “Palácio do Itamaraty”. In this study, Monte Carlo simulation technique is implemented in Hirosawa method to examine structural level of safety. Reliability indexes for each floor are estimated and comparisons to target reliability indexes are made. The sensitivity of different input variables is also studied. Seismic indexes of structure for each floor remained greater than seismic demand indexes in all Brazilian seismic zones through Hirosawa method. Despite of, inadequate reliability indexes is noticed in all floor, which implies that structure is not enough to guarantee an adequate performance. Sensitivity analysis shows the influence of irregularity of structure in seismic response. The results highlight the importance of a probabilistic approach by Hirosawa Method to assertive decisions of conservation and rehabilitation of architectural heritage subject to seismic hazards.

1 INTRODUCTION

The “Palácio do Itamaraty” in Brasilia is a symbol of modern architecture designed by the architect Oscar Niemeyer. The headquarter of Ministry of Foreign Affairs of Brazil was opened in 1970 and from a structural point of view the building is carried by a sequence of reinforced concrete frames with floors and the span of the slab is quite large. Once this historic heritage owns architectural and historic relevance it must be preserved and conserved (ICCOMOS, 2013).

Due to low seismicity in Brazil, “Palácio do Itamaraty” was not designed to withstand seismic loads and few researchers have evaluated seismic vulnerability of Brazilian buildings. Nevertheless, increasing of seismic hazard in localized areas have been recorded (Petersen et al. 2018). Miranda (2021) developed an exhausted study of structures from Brazilian city with high seismicity. In this context, the purpose of the present work is to evaluate the seismic performance of “Palácio do Itamaraty” in a probabilistic approach. Assessment is carried out by Hirosawa method adopted by Japan Building Disaster Prevention Association (JBDPA) and adapted to Brazilian reality (Miranda, 2013). The uncertainties involved in the problem are taken into account by Monte Carlo simulation implemented in Hirosawa Method.

Japanese Seismic Index Method or Hirosawa Method has been used to evaluate seismic performance of existing reinforced concrete buildings with less than six stories (Calvi et al, 2009). Pan American Health Organization adjusted this methodology and have implemented in Latin America, mainly in Chile, Peru, Mexico and Ecuador (PAHO, 2000). Ozdemir et al (2005) proposed an adaptation and calibration to Turkish buildings using nonlinear static analyses of 12 buildings. Letelier & Parodi (2021) analyzed a sample of 116 buildings in Chile comparing their real behavior during the 2010 earthquake with seismic performance specified by Hirosawa method.

2 SEISMIC ASSESSMENT

In first level of procedure, Hirosawa method seeks to evaluate the strength of a story on the basis of average stresses and the cross-sectional area of columns without demanding for ductility (Hiroyuki, 1981). The seismic index I_S for the total earthquake resisting capacity of a story is defined by the product of three indices (1): basic seismic index E_0 , irregularity index S_D and time index T_D .

$$I_S = E_0 \cdot S_D \cdot T_D \quad (1)$$

and E_0 :

$$E_0 = \left(\frac{n+1}{n+i} \right) \cdot a_1 \left[\frac{f_c}{20} \cdot \frac{\tau_c \cdot A_c}{W} \right] \cdot F_c \quad (2)$$

where n = number of stories of a building, i = number of the story for evaluation, W = total weight, A_c = total cross-sectional area of columns in the story studied, τ_c = average shear stress at the ultimate state of columns, which may be taken as 7 kgf/cm² and F_c = ductility index of columns which may be taken as 1.0, a_1 = effective strength factor of the columns and should be taken as 1.0. The influence of the deterioration is taken into account in the index T_D varying from 0.7 to 0.8 according to inspection of the building (Hirosawa, 1992). For more advanced model see Biondini & Bianchi (2019). The methodology also estimates another index: seismic demand index of structure I_{S0} and should be calculated by eq. 3 regardless of the story building.

$$I_{S0} = E_S \cdot Z \cdot G \cdot U \quad (3)$$

where E_S = basic seismic demand index of structure, Z = zone index namely factor accounting for the seismic activities in the region of the site, G = ground index and considers the effects of the amplification of the surface soil and geological conditions and usage index (U) contemplates the use of the building. Seismic safety of structure shall be judged by $I_S > I_{S0}$. If this inequation is satisfied the building possess the seismic capacity required against the considered earthquake motions (JBDPA, 2001).

3 RELIABILITY ANALYSIS

3.1 Probability of failure and reliability index

According to Holicý & Vruouwenvelder (2005) one of the most important term in the theory of structural reliability is the probability of failure p_f . Structural behavior may be defined as the set of basic variables $\mathbf{X} = [X_1, X_2, \dots, X_n]$ and limit state is given by the limit state function and It is defined as $g(\mathbf{X}) = \mathbf{0}$. In general, probability of failure p_f (4) remains below a given target probability. The failure is defined when a limit state is reached i.e. solicitation S exceeds resistance R . Probability of violation of limit state may be expressed as:

$$p_f = P\{g(X) \leq 0\} = \int \dots \int_{g(X) \leq 0} f_X(x) dx < p_{target} \quad (4)$$

where $f_X(x)$ is the probability density function for the randomic variable X . Commonly reliability is quantified in terms of index of reliability:

$$\beta = -\Phi^{(-1)}(p_f) \quad (5)$$

where $\Phi^{-1}(\cdot)$ = inverse normal distribution. For system in series involving multiples mode of failure, Equation 6 demonstrates failure probability of system composed of m members and then probability of survivor in Equation 7:

$$p_f = P(F_1 \cup F_2 \cup F_3 \cup \dots \cup F_m) \tag{6}$$

$$p_s = P\left(\bigcap_{i=1}^m G_i(X) \geq 0\right) = \int_{\bar{D}} \dots \int f_X(x) dx \tag{7}$$

where $\bar{D} : \bar{F}_1 \cap \bar{F}_2 \cap \bar{F}_3 \cap \dots \cap \bar{F}_m$ is the region or mode of survivor. A numerical approach is required and reliability analysis can be performed by Monte Carlo simulation (Melchers, 2001) where repeated analyses are carried out with random outcomes of the basic variables X generated in accordance to their marginal density function $f_{X_i}(x_i)$, $i = 1, \dots, n$.

3.2 Target reliability level

The Probabilistic Model Code (2001) suggests target reliabilities for the ultimate limit state considering several consequence classes and cost of safety measures (Table 1).

Table 1. Target reliabilities considering one year reference period according to JCSS (2001).

Relative cost of safety measure	Consequences of failure		
	Minor	Moderate	Large
Large	$\beta = 3.1$	$\beta = 3.3$	$\beta = 3.7$
Normal	$\beta = 3.7$	$\beta = 4.2$	$\beta = 4.4$
Small	$\beta = 4.2$	$\beta = 4.4$	$B = 4.7$

4 SENSITIVITY ANALYSIS

In order to determine the most contributing input variable to an output behavior in Hiroswawa Method or even ascertain some interactions effects within the model Sensitivity Analysis are need (Ioss & Lemaitre, 2015). SA allows to verify how the model responses varies when the input parameters of the model vary (Marelli et al, 2017). Also, how the uncertainty in the input of a model can be apportioned to different sources of uncertainty in the model input (Saltelli et al. 2000). There are several methods to evaluate sensitivity, the most complete and most costly is Morris Method that consists in discretizing input space for each variable and then performing a giving number of one at a time design allowing to classifying inputs in groups of having negligible effects, inputs having large linear effects without interactions and. Morris method offers two sensitivity measures for each factor (8, 9): μ estimates the overall effect of the factor on the output and σ that measures nonlinearity and interaction effects of the input factor.

$$\mu_j = \frac{1}{r} \sum_{i=1}^r |E_j^{(i)}| \tag{8}$$

$$\sigma_j = \sqrt{\frac{1}{r} \sum_{i=1}^r \left(E_j^{(i)} - \frac{1}{r} \sum_{i=1}^r E_j^{(i)} \right)^2} \tag{9}$$

5 APPLICATION

5.1 Structural model

The building is characterized by a squared plan with sides measuring about 84 m (Figure 1). The overall building height is about 14 meters. The three-story RC structure is composed of

beam span of 6.0 m, 18.0 m and 36.0 m. The nominal material strength is $f_c = 40\text{MPa}$ for concrete in compression. Beams depth varies depending on the floor between 40 cm to 120 cm and width also varies between 8 cm to 400 cm. The free interstory height differs in each story. For first floor height is 2.88 m, the second one is 3.50 m and the last one is 4.82 m. The geometry of cross-section varies in both shapes: trapezoid and rectangular. The structural modelling of “Palácio do Itamaraty” is exhibited in Figure 2.

Figure 1. The external view of the “Palácio do Itamaraty”.

Figure 2. Structural model of the “Palácio do Itamaraty”.

5.2 Deterministic assessment

Analysis of the seismic behavior of the structure were developed first in a deterministic approach of Hirosawa Method. The period of the structure is about 0.4765 second. Seismic index of each floor was estimated and a summary of information are presented in Table 2 and Table 3.

Table 2. Summary of input variables related to the floor 1 and 2 of “Palácio do Itamaraty”.

	Floor 1	Floor 2
Level of floor	+0.00	+3.60
Weight of the building upper the story (W) in kgf	18298435.02	14646983.91
Floor area in m ²	5774.30	4424.28
Sum of cross-sectional area of column (Ac) in cm ²	380800.00	418200.00
Fundamental Period (Ta) in seconds	0.4765	0.4765
Basic seismic index of structure E_0	0.6474	0.7448
Irregularity Index S_D	1.2	1.14
Time Index T_D	0.7	0.7
Seismic index of Structure I_S	0.6215	0.6792

Note that seismic indices of first, second and fourth are increasing owing to basic seismic index E_0 . This index takes in account cross sectional area of column and as the weight of the building upper the story decreases, the index E_0 increases. As presented in Table 3 cross sectional area reduces in third floor and impacts in index E_0 . The lower value of seismic index $I_S = 0.6215$ is applied to all structure. Even though detailed inspection indicated the time index $T = 0.8$ due to the fact the age of building is upper to 30 years, it was considered the minimum

Table 3. Summary of input variables related to the floor 3 and 4 of “Palácio do Itamaraty”.

	Floor 1	Floor 2
Level of floor	+7.82	+13.24
Weight of the building upper the story (W) in kgf	11002432.15	773435.97
Floor area in m ²	5342.28	6649
Sum of cross-sectional area of column (Ac) in cm ²	401200.00	326200.00
Fundamental Period (Ta) in seconds	0.4765	0.4765
Basic seismic index of structure E_0	0.8154	0.8254
Irregularity Index S_D	1.14	1.14
Time Index T_D	0.7	0.7
Seismic index of Structure I_S	0.7436	0.7527

value in method T = 0.7. A class E soil is considered in this study. The seismic demand index of “Palácio do Itamaraty” concerning seismic activities in the Brasilia is estimated about $I_{S0} = 0.08$. Regarding the region with moderate seismic activity in Brazil (State of Ceará) the seismic demand index $I_{S0} = 0.3922$ still satisfies inequation $I_S > I_{S0}$. To describe the seismic index I_S for every floor, surfaces of seismic response are developed. Figure 3 presents seismic index I_S versus Irregularity Index S_D and Time Index T_D related to first floor.

Figure 3. Surface of seismic index I_S .

5.3 Numerical simulation and reliability assessment

The assessment of seismic performance is based on probabilistic model assuming W, dead load, as normally distributed random variable (Ellingwood et al. 1982) and concrete compressive strength f_c is considered lognormal distributed random variable (Table 4). The time index (T_D) and irregularity index (S_D) is taken as random variable uniformly distributed between the values $\lambda_{min} = 0.7$ and $\lambda_{max} = 1.0$ and values $\lambda_{min} = 0.4$ and $\lambda_{max} = 1.2$, respectively.

Figure 4 exhibits reliability indices $\beta = -\Phi^{-1}(p_f)$ for each floor (SC 00 – Scenario 00). It is worth noting that lower probability of failure is detected in fourth floor $P_F \approx 0.0133$ and the elevated failure probability is found in first floor. The relation between dead load of structure and cross-sectional area of floor influences in reliability index. The number of simulation (n = 300.000) has been properly chosen in order to detect probability of failure. Comparing every single floor reliability index these values are lower than the recommended limits provided by JCSS (Table 5). Even regarding three different scenarios (SC 01, SC 02 and SC 03) where time index T_D was set constant for each floor (Table 6) structure of “Palacio do Itamaraty” depicts

inadequate probability of failure. For the scenario 01, β decreased when T_D was reduced to the minimum.

Table 4. Probability distribution and their parameters (mean value μ and standard deviation σ).

Random variables	Distribution type	μ	σ
Concrete Strength f_c	Lognormal	6.0998	0.0998
Dead Load W	Normal	1.05W	0.10 μ
Cross-Sectional Area A_c	Normal	381600	39972.99

Table 5. Reliability indices for each floor.

β	Floor	Probability of Failure
1.6955	1 st	0.0450
1.9885	2 nd	0.0234
2.1596	3 rd	0.0154
2.2179	4 th	0.0133

Figure 4. β versus floor of building.

Table 6. Reliability indices with T_D for each floor set constant.

Floor	Scenario 01		Scenario 02		Scenario 03	
	Time index T_D	β	Time index T_D	β	Time index T_D	β
1 st	0.95	1.9784	0.85	1.7474	0.7	1.3590
2 nd	0.7	1.6167	1.0	2.4035	0.8	1.8874
3 rd	0.8	2.1072	0.7	1.7886	1.0	2.7075
4 th	0.75	1.9834	0.95	2.5814	1.0	2.7370

The sensitivity of seismic behavior obtained from the model with respect to the uncertain input variables are presented in Figure 5. It can be seen that the most influential basic variable in this analysis is the irregularity index (S_D) that quantifies the effect of the shape, complexity and the stiffness unbalance distribution and also followed by the concrete strength (f_c),

cross-sectional area (A_c), weight (dead load W), Time Index (T_D). It is also observed that model linearly depends on the inputs and there is no input interaction once $\sigma_j \ll \mu_j^* \forall j$.

Figure 5. Sensitivity of seismic index.

6 CONCLUSIONS

A probability-based approach to qualitative assessment of seismic behavior of existing building has been presented. This approach considering uncertainties related to the materials and load was implemented in Hirosawa Method. Furthermore, the sensitivity of seismic behavior of structure regarding the basic variables was studied. It has been showed that “Palácio do Itamaraty” do not possess the seismic capacity required against the considered earthquake motions once seismic index of structure is lower to seismic demand index.

The unacceptable failure probability is noticed in all floor, which implies that the structure is not enough to guarantee an adequate performance. Moreover, Sensitivity analysis showed the influence of irregularity of building in the seismic response of structure by Hirosawa Method followed by cross-sectional area, deterioration, total weight of structure and concrete strength.

The results showed that small contraction in total cross section area columns of third floor did not affect reliability index. In contrast constant time index modified directly probability of failure and since the level of deterioration was low, the reliability expanded but still remained below JCSS target reliabilities. Though Hirosawa Method structure of “Palácio do Itamaraty” has acceptable performance against seismic load because was established the lower importance factor and risk category of building (category I) referring to buildings that represent a low risk to human life in the event of failure. Thereby if it alters category of risk the seismic demand index will be upper than seismic index of structure and meet the reliability indices.

Bridge weigh-in-motion to support SHM

D. Cantero

NTNU Norwegian University of Science and Technology, Trondheim, Norway

ABSTRACT: Bridge Weigh-in-motion (BWIM) is an established technology that allows estimating the wheel weights, axle spacing and velocity of travelling vehicles moving at full speed. It relies on the structural response of a bridge to infer the desired vehicle properties. These systems provide an enormous amount of information on the traffic's characteristics that can be used to develop accurate site-specific road traffic models. However, BWIM technology has matured sufficiently and there is a trend to find additional uses, not only for the traffic data obtained, but also for existing instrumentation on the bridge. In particular, various recent publications suggest that the information extracted from such systems can also be used for the purpose of SHM. The integration of the vehicle loading characteristics should further extend the capabilities and reduce the cost of SHM systems.

1 INTRODUCTION

Weight-in-Motion (WIM) is a group of technologies and methods that allow the weighing of passing road traffic at full speed, without having to stop or divert the vehicles. Originally, the aim of WIM technology was to enforce axle weight limits on freight vehicles. However, the information gathered by WIM systems can be used to elaborate more precise site-specific traffic models for improved infrastructure design, assessment and management (van Loo and Žnidarič, 2019). Yet a more recent application has been found as possible Structural Health Monitoring (SHM) technique. More precisely, the recorded signals and estimated information about individual vehicles can be used to evaluate the structural integrity of bridges.

This paper gives an overview of WIM technology, a description of some recent results and an exploratory discussion on the potential usage for SHM. First, the paper provides a brief introduction of the technology in order to introduce WIM to a broader audience. Secondly, a summarized description of some of the latest published ideas by the author is presented. Amongst others, a level I damage detection method (i.e. capable of detecting the existence of damage) for short- to medium-span bridges is outlined, that combines information from pavement-based and bridge-based WIM systems. In addition, the Virtual Axle concept is introduced. This theoretical finding shows that it is possible to assess damages in certain types of bridges by introducing a fictitious weightless axle in the WIM algorithm. Finally, this paper wants to put forward a discussion on the potential and applicability of WIM technology (hardware, methods, measurements and inferred data) for SHM, based on published experiences and the author's own view.

2 WIM TECHNOLOGY

WIM systems consist of a wide range of technologies that weight road vehicles moving at full speed and are able to estimate their wheel weights and axle spacing. Two main categories of WIM systems exist, namely pavement-based and bridge-based.

In Pavement-based WIM systems, sensors are located on the road surface or embedded in the pavement, which can be pressure cells, bending plates and inductive loops, among others. Adequate processing of the recorded signals will provide the sought information about the passing vehicles (axle weights, spacing and speed). The accuracy of the weight estimates is affected by the road unevenness that increases the variability of the axle forces due to the vehicle's dynamic response. Because the sensor in a pavement-based WIM system is only able to weigh the axle for a very short period of time, the estimated axle weight might be corrupted by the vehicle dynamics. However, its accuracy has been enhanced, since its appearance in the 1950's and is nowadays a technology used worldwide (van Loo and Žnidarič, 2019).

On the other hand, Bridge-based WIM systems (BWIM) utilize measured bridge responses (generally strain) during a vehicle passage to infer the axle weights by means of the approach introduced by Moses in 1979 (Moses, 1979) and can be summarized as follows. To estimate each individual axle weight $\{P_i\}$ for a vehicle with N axles it is necessary to calibrate the system and obtain the corresponding influence line $\{I_i\}$ for every sensor location. For every vehicle-crossing event, the system measures the strain $\{\epsilon_i^{me}\}$ and extracts information about the vehicle's speed, number of axles and distance between them. This is in practice achieved in modern BWIM systems utilizing various strain gauges along the bridge with the so-called Nothing-on-Road strategy (Kalin et al., 2006). With this information it is possible to describe the theoretical strain $\{\epsilon_i^{th}\}$ and compare it to the measured strain. The minimization of the squared difference between measured and theoretical responses can be expressed in matrix form reducing the problem to a system of linear equations (OBrien et al., 2009).

$$\{P_i\} = \frac{[I_{t,i}]^T \{\epsilon_i^{me}\}}{[I_{t,i}]^T [I_{t,i}]} \quad (1)$$

The solution of this linear system provides the weight estimates for each individual axle of a passing vehicle. In Equation (1), the term $[I_{t,i}]$ is the matrix of influence line's ordinates of dimension $(T \times N)$ where T is the total number of sampling points. The matrix $[I_{t,i}]$ is composed of multiple copies of the influence $\{I_i\}$ line for the particular sensor location considered and shifted accordingly to the axle spacings of the vehicle. The accuracy of the BWIM system depends on the bridge span and the vehicle's axle spacing, where stiff short straight spans are best suited for BWIM purposes (Gonzalez, 2010). However, over the past decades (Yu et al., 2016) many improvements have been incorporated to this technology. This has increased the applicability of BWIM and allowed to successfully implement it in other bridge sites.

During the installation of a BWIM system, the structure's influence line $\{I_i\}$ must be obtained and calibrated on-site using a vehicle of known speed, axle spacing and weights. However, over time, the structural behaviour of the bridge might change due to damage. As a result, the influence line $\{\tilde{I}_i\}$ at a sensor of the BWIM system has changed with respect to the influence line obtained during calibration. The axle weight estimates provided by the system have an inherent error for any subsequent event since the influence line has not been recalibrated. This is, the predicted axle weights are computed using the original influence line $\{I_i\}$ whereas the actual measured strain is related to the new influence line $\{\tilde{I}_i\}$. Therefore, the estimated axle weights $\{\tilde{P}_i\}$ are different from the actual axle weights of the traversing vehicle $\{P_i\}$. In the remaining of the document the influence line obtained during calibration is termed healthy influence line, whereas the modified one is termed damaged influence line.

3 COMBINATION OF WIM AND BWIM

In (Cantero and González, 2015) a level I damage detection technique is proposed for short to medium span road bridges using the input provided by two different WIM systems: a pavement-based WIM station located in the same route as the bridge and a bridge-based WIM system. If the bridge suffers some local or global damage, the structure's response will change and as a result, the BWIM system will provide incorrect GVW estimations.

This idea can be further elaborated following the notation in Section 2. Consider that the actual axle loads of a passing vehicle $\{P_i\}$ are correctly obtained from a nearby pavement-based WIM station, while the BWIM provides the estimates $\{\tilde{P}_i\}$ based on the current bridge responses. If both weight estimates are available their relationship can potentially be used for SHM of the bridge. More specifically, it is proposed to study the error in total vehicle weight estimation of the BWIM system (E_{BWIM}) defined as:

$$E_{BWIM} = \frac{\sum_{i=1}^N \tilde{P}_i - \sum_{i=1}^N P_i}{\sum_{i=1}^N P_i} \times 100 \quad (2)$$

When the bridge is undamaged, the error is close to zero, but not exactly zero because of the influence of the inherent system inaccuracies (dynamics, noise, inaccurate truck location). However, significant changes of E_{BWIM} over time indicates that the structural response to traffic has changed. Incorrect axle weight predictions by the BWIM system indicate changes in the structure's influence line and that probably damage has occurred.

This indicator E_{BWIM} can be used as an indicator of structural integrity and it can be periodically updated with additional frequent vehicle crossing events. Furthermore, it can be shown that this indicator is more sensitive to damage than a frequency-based indicator. Figure 1 shows the relative variation of the beam's natural frequencies compared to the variation of E_{BWIM} for a range of degrees of global damage. For the same amount of global damage, the BWIM error-based indicator approximately doubles the sensitivity to damage of a frequency-based approach.

Figure 1. Theoretical relative changes (in absolute value) in E_{BWIM} (solid) and natural frequency (dashed) due to global damage.

The identification of local damage on the bridge is more complex than for global damage. The results and sensitivities depend on the damage location, severity and bridge boundary conditions and sensor locations. However, the proposed indicator E_{BWIM} provides some indication of damage. To evaluate this, in (Cantero and González, 2015) a numerical investigation is performed by simulating one month of traffic within a Monte Carlo scheme to vary the passing vehicle properties. Different damage locations are explored for a local stiffness reduction of 50% using the signals from strain sensors located at three different positions along the damaged beam. The results are summarized in Figure 2. Even though the average E_{BWIM} due to local damage are smaller than for global damage, the stiffness loss is still identifiable. For a given damage, the average E_{BWIM} is different for each sensor location. This information could be used to roughly estimate the location of the damage.

Figure 2. One-month average EBWIM for sensor located at $\frac{1}{4}L$ (dashed); $\frac{1}{2}L$ (solid); $\frac{3}{4}L$ (dash-dot) and a 50% local damage at seven different locations (dots).

This idea could be applied to a road network with multiple critical bridges, as schematically represented in Figure 3. Each bridge should have a monitoring system capable of performing BWIM that calculate axle weight estimates. A pavement-based WIM station along the network would provide the reference weight estimates. The information can be correlated to identify the corresponding reference values to the estimated values considering the expected arrival time of the vehicle to each bridge. Traffic congestions, vehicle delays or even vehicles abandoning the road network at some exit, would difficult or reduce the number of correlated vehicles. However, because this idea is not based on the results of one single vehicle crossing but rather on the aggregate results of multiple events, with time sufficient correlated events can be found.

Figure 3. Weigh-In-Motion based damage identification concept for structural health monitoring of bridges.

4 THE VIRTUAL AXLE CONCEPT

In (Cantero et al., 2015), the authors introduce a level I damage identification method for statically indeterminate bridges using the information provided by a BWIM system. It is theoretically shown that for damage detection it is useful to assume the presence of an additional weightless axle, which has been termed ‘Virtual Axle’ (VA). A change in structural behavior will lead to weight estimates different from zero for this fictitious VA load by the BWIM system. It is possible to identify even small changes in influence lines by applying the VA concept. The proposed idea can be used to define a new robust output-only model-free level 1 SHM technique.

To illustrate this idea, the linear system in Equation (1) is solved for the particular case of a vehicle with only two axles. The linear system can be solved, resulting in expressions for the estimated axle weights as seen in Equation (3).

$$\begin{Bmatrix} \tilde{P}_1 \\ \tilde{P}_2 \end{Bmatrix} = \begin{bmatrix} \frac{(P_1 D_{1,1} + P_2 D_{1,2}) H_{2,2} - (P_1 D_{2,1} + P_2 D_{2,2}) H_{2,1}}{H_{1,1} H_{2,2} - H_{1,2}^2} \\ \frac{(P_1 D_{2,1} + P_2 D_{2,2}) H_{1,1} - (P_1 D_{1,1} + P_2 D_{1,2}) H_{1,2}}{H_{1,1} H_{2,2} - H_{1,2}^2} \end{bmatrix} \quad (3)$$

where matrix $[H]$ derives from the matrix product of healthy influence lines, and matrix $[D]$ is the result of the matrix product of healthy $\{I_i\}$ and damaged $\{\tilde{I}_i\}$ influence lines. (It is acknowledged that this text does not provide a full description of the terms in Equation (3). Refer to (Cantero et al., 2015) for a complete description of the formulation.) Furthermore, if we assume that one of the traversing axles is weightless ($P_2 = 0$) it reduces to Equation (4).

$$\begin{Bmatrix} \tilde{P}_1 \\ \tilde{P}_2 \end{Bmatrix} = \begin{bmatrix} \frac{P_1 D_{1,1} H_{2,2} - P_1 D_{2,1} H_{2,1}}{H_{1,1} H_{2,2} - H_{1,2}^2} \\ \frac{P_1 D_{2,1} H_{1,1} - P_1 D_{1,1} H_{1,2}}{H_{1,1} H_{2,2} - H_{1,2}^2} \end{bmatrix} \quad (4)$$

Equation (4) shows that the installed BWIM system provides an estimate for both axles, even though one of the axles traversing the system is known to have no weight. This weightless axle has been termed Virtual Axle (VA) and its properties are listed below:

- The VA is zero if there is no damage, i.e. when $\{\tilde{I}_i\} = \{I_i\}$.
- The VA is zero if the axle distance d is greater than the length of the influence line L . This result sets the limits of possible axle distances to consider in any VA calculation to the interval $[-L, +L]$.
- The VA is zero if the damaged influence line is a linear transformation of the healthy one, i.e. when $\{\tilde{I}_i\} = \lambda\{I_i\}$ for λ a constant.
- A value of VA different to zero indicates that the influence line obtained during calibration is different in shape to the current influence line of the structure.

Figure 4 shows a schematic representation of the concept of Virtual Axle. An existing BWIM system would render an actual weight estimate for a fictitious weightless axle if the current influence line has changed in shape with respect to the one obtained during calibration. The derivation of VA was presented for the case of a hypothetical 2-axle vehicle (one real and one virtual). However, it is possible to extend the expressions to vehicles with more axles obtaining the same properties listed above.

Figure 4. Schematic Description of Virtual Axle Concept.

The location of this additional weightless axle with respect to the other two is a key parameter. In fact, it can be located either in front or to the back of the vehicle. The maximum distance between the virtual axle and the vehicle is limited by the length of the influence line L . Therefore, it is possible to obtain weight estimates for virtual axles located between $-L$ (back of vehicle) and $+L$ (front of vehicle).

This idea is checked numerically in (Cantero et al., 2015) using the results from a Vehicle-Bridge interaction model for a 2-axle vehicle traversing a fixed beam. The generated strain signals are corrupted with additional noise and an example reproduced in Figure 5. This signal is used to calculate weight estimates including the additional weightless axle at different distances from the vehicle. Figure 6 shows the VA estimates within the valid distance range and compares the results between healthy and damaged bridges. The VA values are given as a percentage of the Gross Vehicle Weight (GVW). Because this example also includes the dynamic behavior of the bridge the VA results are not exactly zero even for the healthy bridge case. However, Figure 6 shows some clear differences in VA estimates between healthy and damaged cases.

Figure 5. Strain signal with noise for a sensor located at $\frac{1}{4}$ span.

An inherent limitation of the BWIM algorithm is related to closely spaced axles, which renders an ill-conditioned linear system to solve. Small perturbations in the signal (e.g. noise), produce unreliable and unrealistic results. Therefore, in order to avoid ill-conditioning of the system, the location of the virtual axle is placed at a minimum distance L_0 (equal to $\pm 10\%$ of L) away from the vehicle. The assumed range of ill-conditioned virtual axle distances correspond to the shaded area shown in Figure 6.

Figure 6. Virtual axle results for healthy (dashed) and damaged (solid) bridge with a 30% stiffness reduction at mid-span. Sensor location $\frac{1}{4}L$.

As shown in (Cantero et al., 2015) it is possible to derive a damage index from the results of VA analysis. The repeated calculation of this index for several vehicle crossing events can be used to detect small local damages in statically indeterminate structures. The method is applicable to a wide range of road conditions, while it shows very little sensitivity to noise. The numerical results show that the sensitivity of the proposed method is good enough to compensate for the variability in results due to: difference in vehicle properties, bridge dynamics and signal noise. Therefore, the method could be classified as a level I SHM technique. The VA methodology could also provide some indication on damage location.

The VA concept is applicable to standard BWIM systems that are already installed since no changes in hardware are required. It is only necessary to update the software to include the calculations of a fictitious load. However, its scope is limited to identification of local damages in statically indeterminate structures. It is important to note that in general BWIM systems provide more reliable results the shorter the length of the influence line. This is why most of currently operational installations are on short span bridges. However, BWIM systems can also be used in longer multiple-span continuous bridges locating the sensors in members that feature local responses. In those cases, the effective length of the influence line can be small and good accuracies can be achieved too.

Nevertheless, the proposed idea has inherent limitations. The sensitivity to local damages greatly depends on the actual location of the damage. In addition, the idea relies on the use of extracted influence lines, which are known to be dependent on environmental conditions. These factors will affect the damage detection effectiveness. The proposed idea can be considered as one possible strategy for damage detection, that should be supplemented with other methods. Further investigations are necessary to confirm the practical potential of the proposed idea.

5 DISCUSSION

SHM of bridges and its ultimate goal of correct assessment of existing structures is not an easy task. In recent decades multiple approaches and ideas have been proposed. Many research groups continue exploring this topic because of its scientific interest and potential cost reduction capabilities on infrastructure management. However, the reality of the bridge assessment problem is very broad because of the heterogeneity in structural solutions, construction materials, loading and environmental conditions. It is unlikely that there will ever be a single method or technology for the correct structural integrity evaluation. Most likely, any relevant progress in this field will emerge from the combination of multiple methods and sources of information.

In this regard, BWIM technology should be considered as one important technology that can contribute positively to SHM. Standard BWIM installations provide information about the passing traffic and the recorded structural responses can be further processed to infer additional information on the structural integrity. On the other hand, existing long-term monitoring systems can be adapted or improved to estimate traffic loading based on the BWIM algorithm. However, future long-term monitoring systems should ideally include sensors and algorithms that maximize the information that can be extracted. The author believes those systems should also include BWIM capabilities.

As shown in this article, the direct analysis of the predicted vehicle weights and their change in time gives an indication of the structural integrity. Also, the processing of the signals gathered for the BWIM problem can be analysed with the novel Virtual Axle concept to infer additional indications of possible structural changes. Furthermore, the information gathered by such BWIM systems can be used to elaborate more precise site-specific traffic models for improved infrastructure design, assessment and management. Together with other sources of information, this data constitutes a valuable source of information to be used as input in data-driven bridge model updating procedures. Furthermore, there is a large potential when combining the supplementary information provided by ITS (Intelligent Transport Systems). The real-time data flow should allow to move forward from BIM (Building information modelling) models towards the desirable goal of having digital twins of existing bridges, which in turn would facilitate the predictive maintenance of the infrastructure.

It is worth mentioning that this article has only discussed two recent developments on BWIM for SHM that the author has been part of. However, there are more developments in BWIM technology led by other research groups internationally. A non-exhaustive list of recent advances includes: sensing technology (fibre sensors, wireless, energy harvesting, . . .), measured response (acceleration, shear strain, displacements, . . .), processing techniques (machine learning, signal processing, . . .), system calibration methods (influence line extraction . . .), information management (data compression, . . .) and extension to other bridge types (railway). Therefore, the potential applications of BWIM have not been exhausted yet and many more might arise in the coming future to support SHM.

6 CONCLUSIONS

This paper has provided a short overview of WIM technology with more emphasis on bridge-based solution. Then it presented the idea of combining the information from different WIM systems (one pavement-based and one bridge-based). The error in weight estimates has been reported to be a reliable and robust indicator of structural integrity, more sensitive to damage than the traditional method based on variation in natural frequencies. Secondly, a qualitative description of the Virtual Axle concept was provided. The addition of a weightless axle in the BWIM algorithm can be used to derive a damage index in certain structures. This novel idea can readily be tested on existing BWIM installations since it does not require any physical modification. To apply the VA concept, only modifications on the calculation algorithm are required. In summary two different level I SHM methods based on WIM technology that can be integrated into a broader SHM strategy in road network.

I. Yoshida & H. Sekiya

Department of Urban and Civil Engineering, Tokyo City University, Tokyo, Japan

ABSTRACT: Being a unique characteristic of a structure, the identification of an accurate bridge influence line from real measurement of bridge response under moving loads is on high demand for new structural design, model calibration, structural condition assessment and bridge weigh-in-motion. Despite its uniqueness, the identified influence lines from different measured signals tend to differ due to perturbations owing to the dynamic effect, road surface roughness, difference in calibration trucks and so on. This paper proposes a robust method using Bayesian framework for the identification of a single influence line by considering multiple measured signals. The effectiveness of the proposed method is demonstrated through a field experiment on a simply-supported steel girder bridge using three calibration trucks with different axle numbers and axle configurations. Using Bayesian framework, the uncertainties associated with the identified influence lines are also estimated which are useful for knowing the accuracy of predicted signals and estimated axle weights using a particular influence line.

1 INTRODUCTION

Over the last few decades, a large number of civil infrastructures, such as bridges, have emerged worldwide as a part of social-economic development. They are considered as important asset of every society. However, many of the existing bridges have already crossed a significant amount of their service life. On the other hand, there is a rapid increase of demands on these infrastructures because of the ever-increasing nature of traffic loads and operational speeds. Consequently, various types of damage, such as corrosion and fatigue, have been discovered. The combined effects of aging and increasing load conditions has prompted the needs to intensify maintenance and implementation monitoring of these assets. Therefore, it is becoming increasingly important to know the actual in-service condition of bridges for the evaluation of their remaining service life and performances so that appropriate countermeasures be taken to ensure their safety and operation.

The above goals can be achieved by analyzing the load-deformation characteristics of a bridge and obtaining an accurate information about the past, present and future traffic conditions. Among these two, the former can be achieved by simply looking into the bridge influence line which represents a unique characteristic of a bridge that shows the variation of response at a certain location when a unit concentrated load traverses the bridge (Timoshenko & Goodier 1934). The later can be achieved by implementing a bridge weigh-in-motion (BWIM) system that gives information about traffic loads by utilizing the measured response and bridge influence line (O'Brien et al. 1999, Cardini & DeWolf 2009, Mustafa et al. 2021). Therefore, bridge influence line plays a crucial role in achieving both the goals. Moreover, because it gives a direct relationship between the load and the response, it is also used for other applications such as improving structural design (Fiorillo & Ghosn 2015), finite-element model updating (Lin et al. 2022, Xiao et al. 2015), structural condition assessment and damage detection (Chen et al. 2015, He et al. 2017).

Due to the practical significance of bridge influence line in many important applications, the accurate identification of it from real measurements on the bridge is becoming an important research topic.

For instance, the backbone of BWIM algorithms is bridge influence line and their accuracy is highly governed by the accuracy of identified influence line. Accordingly, many methods have been developed to extract the bridge influence line from measured responses induced by a calibration truck. The measured responses can be either measured displacements, strains or bending moments, depending on the measurement system and their intended purpose. Depending on the analysis domain, the influence line identification methods can be categorized into two: time-domain method and frequency-domain method, although both uses the same mathematical framework (Mustafa et al. 2021). McNulty & O'Brien (2003) first developed a crude way of estimating bridge influence line using a point-by-point graphical method. An improved method was developed later by O'Brien et al. (2006) in time-domain using a linear least-squares method. It is basically an inverse approach where the influence line is identified by minimizing the residual norm between the measured and theoretical bridge responses. However, this method is often ill-posed due to the fact that a slight change in the measured response leads to a considerable change in the identified influence line. To overcome this issue, regularization methods (Chen et al. 2015, Zheng et al. 2019) and base function method (Wang et al. 2017), that are commonly used to solve an ill-posed problem, have been introduced recently. In case of frequency-domain analysis, the response equation is first converted to frequency-domain by using the Fourier transformation and then, the influence line is obtained by dividing the response function by a quantity that is a product of axle weights and complex exponential (Mustafa et al. 2021). Finally, the influence line in original domain can be obtained by applying the inverse Fourier transform. Alternatively, the convolution theorem can be applied to extract the influence line in frequency-domain as done by Frøseth et al. (2017). The main issue with frequency-domain analysis is that it makes the solution unstable for shorter length of measured data due to the inherent assumptions involved in discrete Fourier transform (Mustafa et al. 2021). A comprehensive review and comparison among different influence line identification methods can be found in Zheng et al. (2019).

In all the methods described above, the bridge influence line was extracted from a single measured signal induced by a single calibration truck. Clearly, such methods are not robust to perturbations, and they may produce different influence lines for different measured signals. The measured signals induced by the same calibration truck in different test runs could also be different due to many factors such as bridge vibration, road roughness, measurement noise, disturbances from other loadings and so on (O'Brien et al. 2009). Thus, the variations in the measured signals are inevitable. Hence, the influence line identification method should be robust against such perturbations. For this reason, it would be worthy to know the underlying uncertainty associated with the identified influence line. One of the ways to address this issue is by simultaneously considering multiple signals, either induced by the same or several different calibration trucks. The goal is to determine a single influence line that is capable to predict all bridge responses induced by different calibration trucks. Only one example of addressing this issue is found in Ieng (2015) where the author used the maximum likelihood estimation and considered many signals for the estimation of influence line numerically. The limitation of this method is that the uncertainty associated with the identified influence line was not calculated.

This paper presents a new method for the identification of bridge influence line using Bayesian framework that addresses the aforementioned issues. The advantages of using a Bayesian method are that it allows to take into account all types of available information along with their associated uncertainties by modelling them probabilistically. At first, the mathematical model for influence line identification using conventional time-domain formulation is provided. Then, a Bayesian framework with consideration of multiple measured signals is introduced. The proposed method is then validated through field tests on a simply-supported steel girder bridge and measuring the bridge displacement responses. Three calibration trucks with different axle numbers and axle configurations are used for investigating the variability in the measured bridge response and their effect on the influence line identification process.

2 CONVENTIONAL FORMULATION OF INFLUENCE LINE

In conventional formulation, the bridge influence line is identified from measured response induced by a single passage of a calibration truck. It assumes that the measured response due

to a traversing vehicle is a summation of contributions from individual axles plus an additive noise term that represents a combined effect of bridge and vehicle dynamics, road roughness, measurement noise and so on (Obrien et al. 2006, Yoshida et al. 2021). This is a valid assumption when the response is linear and axle-load effects are independent. Subsequently, for a calibration truck with known axle weights w_i , and axle distance d_i with respect to the first axle, the observation equation for bridge response $z_t(t_k)$, at k th scan of time, is given by

$$z_t(t_k) = \sum_{i=1}^N w_i x_s(s_i(t_k)) + \varepsilon \cdots \cdots; s_i(t_k) = k\Delta t v - d_i \quad (1)$$

where N is the total number of axles of a calibration truck, $x_s(s)$ is the influence line coefficients corresponding to the i th axle, ε is the observation error, Δt is the sampling time of measurement, and v is the speed of calibration truck. The above expression in Eq. (1) can be conveniently written in matrix form as

$$\mathbf{z} = \mathbf{H}\mathbf{x} + \varepsilon \quad (2)$$

where $\mathbf{z} \in \mathbb{R}^{N_m \times 1}$ is the measured bridge response vector with N_m sampling points, $\mathbf{x} \in \mathbb{R}^{N_m \times 1}$ is the influence line vector to be determined with N_l number of coefficients, and $\mathbf{H} \in \mathbb{R}^{N_m \times N_l}$ is the vehicle information matrix. The \mathbf{H} matrix is constructed based on the information of a calibration truck such as its axle weights and axle spacings, as given below.

$$\mathbf{H} = \begin{bmatrix} w_1 & 0 & \dots & \dots & 0 \\ 0 & w_1 & 0 & \dots & \vdots \\ \vdots & \vdots & \ddots & \dots & \vdots \\ w_2 & 0 & \dots & \ddots & \vdots \\ 0 & w_2 & 0 & \dots & w_1 \\ \vdots & \vdots & \ddots & \dots & \vdots \\ w_N & 0 & \dots & \ddots & \vdots \\ 0 & w_N & 0 & \dots & w_2 \\ \vdots & 0 & \ddots & \dots & \vdots \\ \vdots & \vdots & \dots & \ddots & 0 \\ 0 & 0 & \dots & \dots & w_N \end{bmatrix} \quad (3)$$

The \mathbf{H} matrix defined above is a constant matrix with known axle weights that are separated according to their sampling point difference. It should also be noted that the \mathbf{H} matrix is a non-square matrix due to the consideration of presence of only the first (last) axle at the time entry (exist) on the bridge. For this reason, the identified influence line has a shorter length than the measured response vector by a number C_N , where C_N represents the sampling point difference between the first and the last axles. The significance of \mathbf{H} matrix is that each row of this matrix represents a relationship between one bridge response and N_l influence coefficients. For a non-square \mathbf{H} matrix, Eq. (2) is solved by ordinary least-square method using the following objective function J of sum of squared residuals

$$J = (\mathbf{z} - \mathbf{H}\mathbf{x})^T (\mathbf{z} - \mathbf{H}\mathbf{x}) \quad (4)$$

The solution for unknown influence line \mathbf{x} is obtained by minimizing J

$$\mathbf{x} = (\mathbf{H}^T \mathbf{H})^{-1} \mathbf{H}^T \mathbf{z} \quad (5)$$

Clearly, the conventional method of influence line identification using ordinary least-squares does not consider the measurement noise and associated uncertainty explicitly. Moreover, as the influence line is identified from a single measured signal, it can't include the variability of measured

responses due to different calibration trucks and different test conditions, such as road roughness, driving lane of calibration trucks and travelling speeds.

3 BAYESIAN FRAMEWORK CONSIDERING MULTIPLE SIGNALS

3.1 Basic Bayesian framework

A probabilistic framework incorporating multiple signals and various uncertainties is introduced in this section. In Bayesian method, the posterior probability of uncertain model parameters \mathbf{x} given some measured data \mathbf{D} can be obtained using Bayes' theorem (Beck & Katafygiotis 1998)

$$p(\mathbf{x}|\mathbf{D}) = \frac{p(\mathbf{D}|\mathbf{x})p(\mathbf{x})}{p(\mathbf{D})} \quad (6)$$

where $p(\mathbf{D}|\mathbf{x})$ is the probability density function (PDF) of observed data based on a model specified by the model parameters \mathbf{x} . It reflects a probability model for the prediction error between the actual measured response \mathbf{D} and model prediction specified by \mathbf{x} . The term $p(\mathbf{x})$ represents the prior PDF of \mathbf{x} which is based on previous knowledge or user's judgement, and $p(\mathbf{D})$ is the normalizing constant.

3.2 Posterior PDF considering multiple signals

A probability model is first developed for $p(\mathbf{D}|\mathbf{x})$. If there are N_s number of measured signals available resulting from N_s test runs of one or several different calibration trucks on the bridge, then the observed data set will be $\mathbf{D}_{N_s} = \{z_1, \dots, z_{N_s}\}$. Using the axioms of probability, we can write

$$p(\mathbf{D}_{N_s}|\mathbf{x}) = \prod_{n=1}^{N_s} p(z_n|\mathbf{D}_{n-1}, \mathbf{x}) = \prod_{n=1}^{N_s} p(z_n|\mathbf{x}) \quad (7)$$

where $p(z_n|\mathbf{D}_{n-1}, \mathbf{x})$ can be written as $p(z_n|\mathbf{x})$ when the user's uncertainty in the n th measured signal specified by model parameter \mathbf{x} is not influenced by the previous measured signals. Moreover, in the problem of influence line identification, only the measured response is used to identify it. Therefore, in the absence of any prior knowledge, $p(\mathbf{x})$ can be treated as a constant i.e., non-informative prior (Yuen et al. 2002). Hence, the expression for posterior PDF in Eq. (6) can be simplified as

$$p(\mathbf{x}|\mathbf{D}_{N_s}) = c \prod_{n=1}^{N_s} p(z_n|\mathbf{x}) \quad (8)$$

where c is a constant term incorporating normalizing constant and non-informative prior that do not include \mathbf{x} . Therefore, by simply extending the product by one term, new measured data can be incorporated in a systematic and consistent fashion for the estimation of posterior PDF of model parameters \mathbf{x} . This is an important feature of Bayesian framework.

3.3 Identification of influence line using Bayesian framework

For a linear response, the probabilistic forward model for predicting the observation $z_n \in \mathbb{R}^{N_n \times 1}$ from \mathbf{x} is expressed by

$$\mathbf{z}_n = \mathbf{H}_n \mathbf{x} + \varepsilon_n \quad (9)$$

where $\varepsilon_n \in \mathbb{R}^{N_n \times 1}$, is the prediction or observation error between the measured and predicted response for the n th test. If the PDF model for ε_n is a zero-mean Gaussian with covariance matrix $\mathbf{R}_n \in \mathbb{R}^{N_n \times N_n}$, then the posterior PDF in Eq. (8) can be written as

$$p(\mathbf{x}|\mathbf{D}_{N_s}) = c \prod_{n=1}^{N_s} \frac{1}{(2\pi)^{N_n/2} |\mathbf{R}_n|^{1/2}} \exp \left[-\frac{1}{2} (\mathbf{z}_n - \mathbf{H}_n \mathbf{x})^T \mathbf{R}_n^{-1} (\mathbf{z}_n - \mathbf{H}_n \mathbf{x}) \right] \quad (10)$$

The most probable value of \mathbf{x} is obtained by maximizing the above posterior PDF. Using asymptotic approximation for Gaussian distribution, a maximum-a-posteriori (MAP) is estimated for optimal value of \mathbf{x} by minimizing the negative of logarithm of posterior PDF i.e., $\hat{\mathbf{x}} = \arg \min[-\ln p(\mathbf{x}|\mathbf{D}_{N_s})]$. Therefore, the MAP estimate is obtained by minimizing the following objective function and ignoring the constant terms

$$J = \frac{1}{2} \sum_{n=1}^{N_s} (\mathbf{z}_n - \mathbf{H}_n \mathbf{x})^T \mathbf{R}_n^{-1} (\mathbf{z}_n - \mathbf{H}_n \mathbf{x}) \quad (11)$$

The MAP estimate can be obtained analytically by performing $\partial J / \partial \mathbf{x} = 0$

$$\hat{\mathbf{x}} = \mathbf{P} \sum_{n=1}^{N_s} \mathbf{H}_n^T \mathbf{R}_n^{-1} \mathbf{z}_n \quad (12)$$

$$\mathbf{P} = \left(\sum_{n=1}^{N_s} \mathbf{H}_n^T \mathbf{R}_n^{-1} \mathbf{H}_n \right)^{-1} \quad (13)$$

where $\hat{\mathbf{x}}$, \mathbf{P} represents the mean and covariance matrix of posterior PDF, respectively. The influence line calculated using Eq. (12) takes into account multiple measured signals. If the observation error is independent, then the covariance matrix for observation noise can be simplified as $\mathbf{R}_n = \sigma_n^2 \mathbf{I}$ where σ_n is the standard deviation of observation error in n th test and \mathbf{I} is the unit matrix.

4 VALIDATION OF PROPOSED METHOD

4.1 Description of test bridge and field experiment

The test bridge is a single-span slab-on-girder steel girder bridge consisting of three main girders with two traffic lanes (Yoshida et al. 2021). It has a span length of 33.65 m and a width of 6.25 m. As a part of the BWIM system for the target bridge, a displacement gauge was installed at the longitudinal center of girder no. 2 (G2) for measuring the bridge displacement responses induced by the travelling vehicles. The schematic views of the test bridge along with sensor layout is shown in Figure 1.

Figure 1. Schematic diagrams of the test bridge with sensor layout: (a) Plan view; (b) Sectional view.

Table 1 shows the specifications of the contact displacement gauge used in this study. Multiple test runs were conducted using three different calibration trucks to consider the variability in the measured bridge responses. The specifications of three calibration trucks are listed in Table 2. A total of ten calibration runs involving different test conditions, listed in Table 3, were considered in this study. The measured bridge responses corresponding to these calibration runs are shown in Figure 2. As can be seen, a lot of variability exists in the measured bridge responses owing to the perturbation in the dynamic component. Due to this variability in the measured responses, the calculated bridge influence lines will also vary from one to another. Therefore, it would be difficult to judge the actual influence line of the bridge calculated using the single measured signal corresponding to anyone of the calibration trucks. Hence, incorporating multiple measured signals corresponding to different calibration trucks

and test conditions (mainly driving lanes and travelling speeds) would make the influence line identification process a lot more robust. This can be done easily using Bayesian framework as discussed in the preceding section, namely by using Eq. (12).

Table 1. Specifications of contact displacement gauge.

Model	Sampling Frequency (Hz)	Capacity (mm)	Nonlinearity (mm)	Sensitivity ($\times 10^{-6}$ strain/mm)
CDP-25 (Tokyo Sokki Kenkyujo Co., Ltd.)	100	0–25	0.1% of rated output	500

Table 2. Specifications of three calibration trucks.

Axle type	Axle weights and GVW (kN)					Axle spacing (m)		
	1st axle	2nd axle	3rd axle	4th axle	GVW	1st-2nd	2nd-3rd	3rd-4th
4-axle	44.7	44.2	53.8	52.5	195.2	1.85	4.18	1.2
3-axle	53.6	34.9	35.0	-	123.5	3.23	1.31	-
2-axle	22.8	24.1	-	-	46.9	2.87	-	-

Table 3. Description about calibration runs on the test bridge.

Run No.	Driving lane	Types of calibration truck used	Travelling speed (m/s)
1	Travelling	4-axle	10.87
2	Passing	4-axle	12.94
3	Travelling	4-axle	12.74
4	Passing	4-axle	13.71
5	Passing	3-axle	14.29
6	Travelling	3-axle	13.92
7	Passing	3-axle	14.04
8	Passing	2-axle	13.88
9	Travelling	2-axle	13.52
10	Travelling	2-axle	12.23

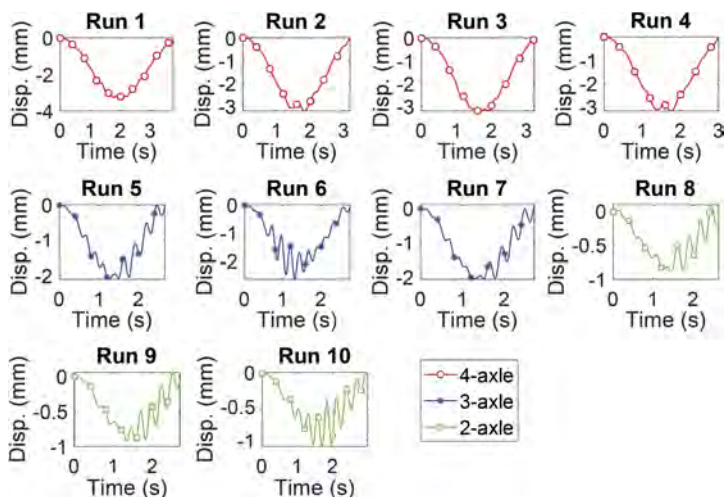

Figure 2. Measured displacement responses under three different calibration trucks.

4.2 Bayesian-based influence line identification considering multiple signals

At first the influence lines were identified by the conventional method (using Eq. (5)) which considers only one signal at a time and treat the observation error as the white noise (uncorrelated). Figure 3 shows the identified influence line from each measured signal using conventional method. Clearly, the conventional method could not identify a unique influence line since it is very sensitive to perturbations. Hence, the influence line identified using the measured signal of one type of calibration truck cannot predict well the measured response due to another type of calibration truck.

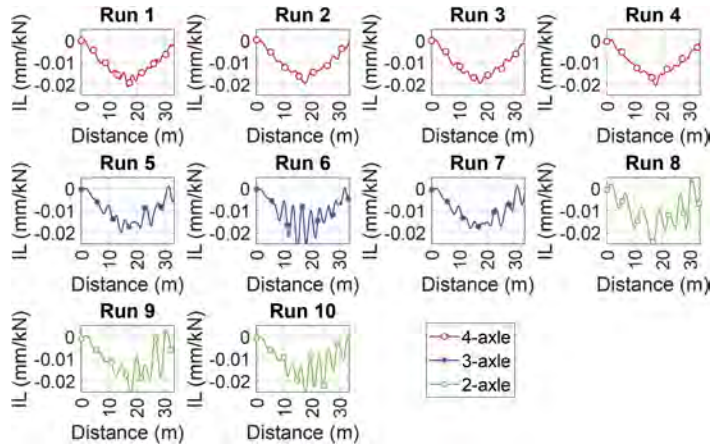

Figure 3. Identified influence line for each measured signal using conventional method.

To address these issues, the influence line was identified using the proposed Bayesian method considering multiple measured signals simultaneously, namely by using Eq. (12). Figure 4(a) shows the identified influence lines using the proposed method. A single influence line was identified accounting all measurement signals collected during the ten passages of calibration runs. The uncertainties associated with the identified influence lines were estimated using the proposed method. Figure 4(b) shows the standard deviations of identified influence lines. Since the standard deviation of identified influence line is very small, it could be considered as accurate. Hence, the identified influence line considering multiple signals could be used for the accurate prediction of the theoretical bridge responses due to any vehicle types or the estimation of axle weights of unknown vehicles traversing the test bridge.

Figure 4. (a) Identified influence lines using the proposed method considering multiple signals; (b) Standard deviation of identified influence lines using Bayesian method.

5 CONCLUSIONS

It is important to calculate an accurate and robust influence line due to its wide range of applications. The conventional methods of influence line identification are limited to the use a single

measured signal which is why it is not so robust against the various perturbations in the measured signals. In this work, an accurate and robust influence line was identified using the Bayesian method and considering multiple measured signals of different types of calibration trucks. The proposed method makes it possible to estimate a single influence line using as many measured signals as desired. Moreover, using proposed Bayesian framework, the uncertainty in the identified influence line could be quantified which provides a valuable information for predicting the theoretical responses due to any vehicles and axle weights estimation of unknown vehicles.

Bridge weigh-in-motion: Feedback on various types of bridges

F.B. Cartiaux, V. Le Corvec & J. Semiao
OSMOS Group SA, Paris, France

A. Brouste
Laboratoire Manceau de Mathématiques, Le Mans Université, Le Mans, France

ABSTRACT: Bridge Weigh-in-Motion (B-WIM) systems use the bridge deck itself as a scale for the estimation of the vehicle gross weight and axle loads. This implies that the performance of a B-WIM is strongly dependent on the bridge structure, even more than on the quality of the sensors used for collecting the raw data necessary to derive the WIM results. This paper describes the feedback of the use of B-WIM systems by OSMOS Group since 2018, focusing on the incidence of the bridge deck material and geometry on the WIM results. The feedback relies on a sample of fifteen different bridges of various types, including reinforced concrete slab or beam girder decks, steel truss bridges, composite decks with steel beam girders, and prestressed concrete beam or box girders. The incidence of geometrical parameters is discussed, with span length from 10 m to 50 m, a number of main beam girders from two to ten, and also some bridges with a significant skew angle. The examples are located mainly in France and Italy, but also in Asia and the Middle East. Based on this feedback, some general guidelines are given for the applicability of B-WIM on different types of bridges, and cases for which the expected performance is the best are pointed out. Further improvements of the B-WIM system are finally discussed, to deal with the conditions which still induce some difficulties for an efficient B-WIM.

1 INTRODUCTION

Road infrastructure owners and managers can get significant benefit from an accurate knowledge of the real traffic level, in terms of asset management (Dolcemascolo et al., 2015), road and truck safety including overweight detection (Jacob et al., 2010), and assessment of the impact of the traffic in terms of damages to optimize the maintenance operations (Schmidt et al., 2013). To get this knowledge, Weigh-in-Motion (WIM) solutions allow to estimate the gross vehicle weight (GVW) of each individual vehicle, sometimes along with its silhouette and load by axle, without interrupting the traffic flow.

Usual WIM solutions use devices that must be installed inside the pavement, which implies works with road closures, sensitivity to the pavement condition, and inconvenience when the road must undergo pavement maintenance works. Bridge-WIM (B-WIM) solutions offer a way to remedy to the above-mentioned issues, by using a bridge located anywhere along the road as a scale. Sensors are installed on the bridge deck, on well-chosen locations, usually under the main girders, thus avoiding works on the road itself and allowing a high robustness of the WIM system, insensitive to pavement condition.

As a counterpart, the performance of a B-WIM system in terms of accuracy for GVW and axle load estimation is strongly dependent on the bridge deck itself and may highly vary from one bridge to another. This issue is discussed in this paper by analyzing the feedback of OSMOS Group, which developed and used a specific B-WIM system called “WIM+D” in the last years. Fifteen different bridges have been instrumented with this system since 2018, covering a large variety of typologies and materials.

2 DESCRIPTION OF THE BRIDGE-WIM SYSTEM

2.1 General principle for the Bridge-WIM

B-WIM systems use strain sensors on critical parts of the bridge deck, where the variations of the strain are the most significant under the effect of the traffic loads: for example, on the lowest member of main girders at the middle of one span, where the bending of the deck is maximal.

The WIM+D system specifically uses Optical Strand (OS) strain sensors, which measure the average longitudinal strain over a length of one meter, to smooth the potential effects of the heterogeneity of the material, especially for reinforced concrete bridges which may present microcracks.

The set of sensors is divided into three categories, according to the purpose of each measurement:

- “Gross Weight Sensors” are set on main girders of one span, if possible, on all girders, or a selection of them equally distributed along the deck width, if there are more than six girders,
- “Speed Sensors” are similarly set on the next span if the bridge has more than one span. The speed of the vehicle is computed and then used to calculate the GVW. For single span bridges, the speed may be deduced from the gross weight sensors, but with a lower accuracy.
- “Axle Load Sensors” are optional. They are set on locations subject to a local strain while axles are crossing the bridge. One axle load sensor per traffic lane is enough. Not all types of bridge structures are suitable for axle weighting: some bridges do not have sensitive enough local strain.

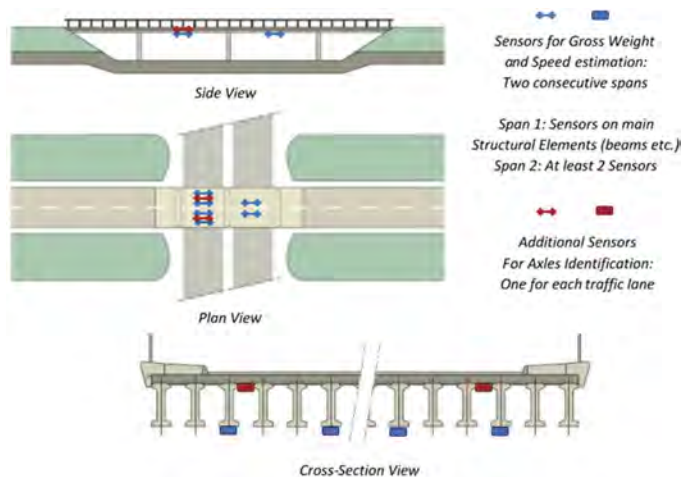

Figure 1. A typical WIM+D sensors layout.

The usual set-up of the WIM+D system comprises six to twelve sensors, depending on the bridge deck structure (Figure 1), incl. two to six gross weight sensors, two speed sensors and two to four axle load sensors, if applicable. All sensors are connected to an Expert Data Acquisition System (EDAS), allowing a continuous recording at a sampling rate of 100 Hz. The records are automatically triggered by thresholds applied to the strain variations, to associate each record to one – or a few successive – passages of vehicles on the bridge.

2.2 The Optical Strand technology

The strain sensors used by the WIM+D system are Optical Strands (OS). They are using the principle of the modulation of the intensity of light in fiber optics through micro-bending: three fiber optics are braided together inside a common one-meter-long coating duct which

ensures their protection, and the intensity of the light returned by the device to its interrogator directly depends on the elongation (or shortening) of the braided part.

Thus, it is possible to measure an average strain over the one-meter length of the sensor, at a high sampling rate (here, 100 Hz), and without the need of complex optoelectronics and specific light sources, unlike other fiber optic sensing technologies. Due to their easy and robust installation (Figure 2), OS have been widely used for Structural Health Monitoring (SHM) purpose, but they are also convenient for B-WIM (Cartiaux et al., 2019).

Figure 2. Optical Strand set under one of the main beam girders of a prestressed concrete viaduct.

2.3 Data flow, processing, and release of the results

The raw strain measurements are acquired by the system at the sampling rate of 100 points every second. The EDAS ensures the synchronicity of the data on all the different sensors set on the bridge deck and carries out a first data selection: only the data which correspond to significant strain variations on any of the OS are kept for further analysis, with a few seconds (usually, five) of pre- and post-trigger buffer. After this first step of recording and preprocessing, the data is organized as a succession of dynamic records of a few seconds, each one of them gathering the effects of one heavy vehicle on the bridge as they are recorded by all the synchronized OS.

After this first step, the strain data are sent through the 4G network to a cloud, which will keep them for further analysis, including the WIM but also SHM-dedicated ones like spectral decomposition or rainfall counting. For the WIM feature, a dedicated algorithm identifies the results related to the truck, like GVW and axle loads, from the response of the bridge deck as recorded by the OS. Indeed, heavier vehicles induce a stronger mechanical response with higher strain. The algorithm is also able to distinguish vehicles driving on the bridge at the same time in opposite directions, or vehicles which follow each other at short distance and triggered the same dynamic record.

The final WIM results are released after one to two minutes delay on a web interface, on which they are available for any user interested in the traffic data on the monitored bridge. The results available are time of passage, gross vehicle weight, direction, and speed. On specific types of bridges, it is also possible to release the vehicle length, number of axles, silhouette, and load of each axle. In addition, the system can be coupled with a video camera to get images and even plate numbers of the vehicles.

3 BRIDGE-WIM IMPLEMENTATION AND ACCURACY ASSESSMENT

3.1 Description of the bridges

The WIM+D system has been in use on fifteen different bridges since its first release in Italy in 2018. Some of these individual experiments have been documented more in detail already (Cartiaux et al., 2021 and 2023). In this paper, we present a general overview of all the fifteen cases: it is interesting that the bridges have a high variety of typologies, span length, and number of girders. This allows a discussion on the incidence of these characteristics on the performance of B-WIM.

Table 1 gives the brief description of each bridge with the main characteristics: number of spans and span length, number of main girders, type of material and typology, along with a geographical indication and the year of installation of the WIM+D system. The span length ranges from 10 m to 59 m, and the typologies from historical iron truss beams to prestressed concrete or composite decks. It is also indicated whether the spans are isostatic (6 cases among 15).

Table 1. Brief description of the bridges, sorted by chronological order of WIM+D installation.

Bridge	Country	Date	Typology	Nb of spans	Span length (m)	Nb of girders	Nb of sensors
1	Italy	2018	Composite deck	3	32	4 steel beams	8
2	Italy	2018	Concrete slab	2	19	None (slab)	8
3	Italy	2018	Composite deck	2	28	2 steel beams	6
4	France	2018	Reinforced concrete (RC)	15	17	3 RC beams	4
5*	France	2019	Prestressed precast concrete beams (PPCB)	4	15	10 PPCB	12
6	Italy	2019	Prestressed concrete (PC) box girder (isostatic)	1	16	1 box girder	6
7	Kuwait	2020	Concrete slab	2	18	None (slab)	12
8	France	2021	PC beams (isostatic)	1	26	4 PC beams	6
9	Taiwan	2021	PC beams (isostatic)	1	35	5 PC beams	8
10	France	2021	Composite deck (isostatic)	1	10	3 iron beams	3
11	France	2021	PC beams	5	59	2 PC beams	6
12*	Italy	2021	PC beams (isostatic)	9	32	4 PC beams	8
13	Ukraine	2021	RC beams (isostatic)	4	33	8 RC beams	10
14	France	2021	Iron truss, historical	5	45	2 truss beams	4
15	France	2022	Iron truss, historical	11	45	2 truss beams	6

* Bridges 5 and 12 have been documented more in detail, see resp. Cartiaux et al., 2021, and 2023.

3.2 Methods for the accuracy assessment

Assessing the accuracy of an on-site WIM system requires a dedicated verification procedure, which implies to use a sample of vehicles as reference loads and let them drive on the bridge at various speeds, in all available traffic lanes (and even out of lane). The GVW of each one of the test vehicles is measured on a homologated weighbridge just before and after each test day. If the silhouette and axle load results are assessed as well, their reference value are measured at the same occasion.

The accuracy assessment is carried out by comparing the results given by the B-WIM as the vehicles are driven on the bridge to these reference values. It implies a statistical analysis of the difference between reference values of GVW or axle load and values given by the B-WIM. Thus, a significant number of test passages is required. A usual accuracy assessment of the WIM+D system implies two or three different vehicles, each one of them running at least 10 to 20 times back-and-forth on the bridge.

Once all the measured weights of the B-WIM are recorded for the whole test, the relative error with respect to the reference values of GVW and – if required – axle load is analyzed to eventually accept the system into an accuracy class. A few different standards define such classes. For this study, we have chosen to give the estimation of the 95% quantile of the absolute value of the relative errors, which means that 5% (or less) of the measured absolute value of relative errors are above this quantile (percentage of accuracy).

In a second step, for some of the bridges only, a more robust statistical analysis of the percentage of accuracy has been carried out, according to the COST 323 methodology, which considers the uncertainty related to the number of runs and the environmental conditions of the test through categories of reproducibility and repeatability (Jacob et al., 2002, Brouste, 2021). The COST 323 defines accuracy classes ranking from A to E: the class A (best one) means that the percentage of accuracy (for GVW) is less than 5%, and the class E (worst one) that it is above 25%.

In the case of the bridge 12, an additional accuracy assessment according to the OIML standard has been carried out, for information only, as the OIML requirements are technically not applicable to such a B-WIM system, not used for legal metrology (OIML, 2006). This methodology simply considers the maximal measured relative errors.

3.3 Test plans

The fifteen bridges have been tested for accuracy assessment of the WIM+D system according to the plans summarized in Table 2 (in which “-” means “not tested”). In some cases, two of the test vehicles happen to have the same GVW (rounded at tons) but they had different silhouettes and number of axles.

Table 2. Test plans.

Bridge	Nb of vehicles	GVW (t)	Nb of runs (total)	Axle load test	COST 323	OIML
1	2	36 and 56	22	-	-	-
2	2	35 and 57	27	-	-	-
3*/Test 1:	2	35 and 57	31	-	-	-
3*/Test 2:	3	19, 39, and 50	30	Yes	-	-
4	3	12, 16, and 19	18	-	-	-
5*/Test 1:	3	19, 32, and 44	33	Inconclusive	Yes	-
5*/Test 2:	3	19, 40, and 40	194	Inconclusive	Yes	-
6	3	20, 35, and 50	9	Yes	-	-
7	3	20, 25, and 30	26	-	-	-
8	3	19, 32, and 40	36	Yes	-	-
9	2	21 and 36	27	Yes	-	-
10	3	19, 32, and 40	36	-	-	-
11	3	19, 32, and 38	36	-	-	-
12*/Test 1:	3	24, 42, and 42	75	Inconclusive	Yes	Yes
12*/Test 2:	3	17, 29, and 34	42	Inconclusive	Yes	Yes
13	6	13, 21, 29, 32, 44, 45	67	Inconclusive	Yes	-
14	1	10	20	-	Yes	-
15	2	10 and 12	36	Yes	Yes	-

* Bridges 3, 5 and 12 have been tested twice at different dates, with different vehicles.

The design of the WIM+D system allows an accurate estimation for the GVW in any case, but the axle identification is strongly dependent on the possibility of measuring some local bending effect, typically the local bending of a thin slab between two main girders. Not all bridge deck types allow this possibility. Concrete slabs (bridges 2 and 7) are not suited to this feature, for example. Thus, one third only of the fifteen cases were tested for the axle identification and axle load estimation. Moreover, in some cases there was no demand for axle load estimation from the asset manager, so the system was optimized for GVW only, which enabled to use less sensors.

In the case of bridges 3, 6, 8, 9, and 15, the accuracy assessment of the system for the axle load estimation was successful. In the case of bridges 5, 12, and 13, some axle load sensors were set up to investigate whether these bridge types would fit the requirements for axle detection by the WIM+D system, but without acceptable accuracy. This gives valuable feedback for further improvement of the system.

In any case, the estimation of the GVW is totally independent of the one of the axle loads, unlike classical WIM devices installed inside the pavement.

4 MAIN RESULTS OF THE FEEDBACK

4.1 Accuracy assessment for the Gross Vehicle Weight (GVW)

The results of the accuracy assessment for GVW are released in Table 3. The bridge typology is reminded, and the tolerance is given as the percentage of accuracy, which corresponds to

the 95% quantile of absolute values of all measured relative errors during each test. That means that (less than) 5% of the measured relative errors are above this percentage of accuracy. The equivalent absolute error is also given, in tons.

Whenever it is applicable, the COST 323 and OIML classes in which the WIM+D system is accepted are released as well.

Table 3. Accuracy assessment for the Gross Vehicle Weight.

Bridge	Typology	Tolerance (%)	Tolerance (t)	COST 323	OIML
1	Composite deck	8	4.5		
2	Concrete slab	12	5.2		
3*/Test 1:	Composite deck	7	3.1		
3*/Test 2:	Composite deck	10	5.1		
4	RC beams	7	1.3		
5*/Test 1:	PPCB	9	3.6	C(15)	
5*/Test 2:	PPCB	14	4.7	C(15)	
6	PC box girder (isostatic)	15	5.7		
7	Concrete slab	15	3.8		
8	PC beams (isostatic)	12	3.9		
9	PC beams (isostatic)	14	3.3		
10	Composite deck (isostatic)	12	3.7		
11	PC beams	15	3.4		
12*/Test 1:	PC beams (isostatic)	4	1.0	A(5)	5
12*/Test 2:	PC beams (isostatic)	5	1.0	B+(7)	10
13	RC beams (isostatic)	6	2.1	B+(7)	
14	Iron truss, historical	9	0.9	C(15)	
15	Iron truss, historical	7	0.9	B(10)	

* Bridges 3, 5 and 12 have been tested twice at different dates, with different vehicles.

The WIM+D system shows good performances for a WIM device, with no tolerance above 15% whatever the bridge and test conditions. When the assessment according to COST 323 is released, the accepted class is always C(15) or better for the GVW. In one case (bridge 12) the class A(5), which is the best possible one, is even reached.

The bridges 3, 5, and 12 have been tested twice, and the difference in the assessment results depending on the test deserves some explanation:

In the case of bridge 3, the second test was carried out three months after the first one, after adding two additional sensors for the axle detection. For bridge 5, it was even twenty months between the two tests. In both cases, the environment conditions were very different, and the second test was carried out without re-adjusting the system, so we have an insight on the evolution of the performance without maintenance actions. In the case of bridge 5, it is shown that even after almost two years, the accuracy class C(15) assessed initially remains valid.

In the case of bridge 12, the second test was carried out the day after the first one, with the same vehicles, but they were half-loaded. So, the results of the first test, with accuracy class A(5) and even OIML class 5, are valid for full-loaded vehicles – the most interesting ones in regard to overweight detection, and the results of the second test are valid for half-loaded vehicles only.

The best performance is reached by PC or RC beams isostatic bridges, at the condition that they have more than one span (bridges 4, 12, and 13). Indeed, bridges 6, 8, 9 and 10 have only one span, which induces some uncertainty for the estimation of the speed, a result not only useful for the asset manager but also mandatory to compute the GVW. Iron truss and composite decks, even hyperstatic, give also good results (bridges 1, 3, 14, and 15). The concrete slabs (bridges 2 and 7) are the least performant, however both bridges have a significant skew angle, which also induces some difficulties.

The case of bridge 11 is specific: it is a long hyperstatic PC beams bridge of 200 m, with a central span of 59 m, on which the length of the influence lines and the density of the traffic poorly allows to separate properly the strain measurements due to successive vehicles, thus inducing a poor performance compared to other PC beams bridges.

4.2 Accuracy assessment for the silhouette and axle loads

The silhouette and axle loads are detected on five among the fifteen bridges, with results released in Table 4:

Table 4. Accuracy assessment for the axle load.

Bridge	Typology	Tolerance (%)		COST 323
		Single axles	Groups of axles	
3 (Test 2)	Composite deck	30	28	
6	PC box girder (isostatic)	19	22	
8	PC beams (isostatic)	24	15	
9	PC beams (isostatic)	39	22	
15	Iron truss, historical	10	not tested*	B(10)

* Due to weight limitation, the test vehicles for bridge 15 were 2-axles vehicles without groups of axles.

On the few cases on which the test for axle load is available, the results reflect the difficulty of analyzing a relevant local bending effect, which strongly depends on the bridge type. Moreover, in the case of bridges 6, 8, and 9, the single-span configuration already mentioned has an incidence on the axle load results, which are speed-dependent as well.

In the case of bridge 15 however, the axle load estimation gives good results, consistent with the results for the GVW. This is due to a favorable configuration of the bridge deck, with a thin ultra-high-performance fiber reinforced concrete (UHPFRC) slab located between the two lateral historical iron truss girders, used as “axle detector” with a very clear local bending effect under traffic loads.

5 GUIDELINES FOR THE APPLICATION OF BRIDGE-WIM

5.1 Best suitable types of bridge deck structures

The feedback on various types of bridges and the results in terms of tolerance for the GVW estimation allow to formulate guidelines as follows for the expected performance of the WIM +D system, depending on the characteristics of the bridges. We classify the performance in three main categories, each one gathering one third of the fifteen tested bridges:

Table 5. Performance categories.

Category	Tolerance (%)	Bridges	Number of girders	Span length
Very good	8% or less	1, 4, 12, 13, 15	4, 3, 4, 8, 2	32, 17, 32, 33, 45
Good	8% to 12%	2, 3, 8, 10, 14	0 (slab), 2, 4, 3, 2	19, 28, 26, 10, 45
Acceptable	12% to 15%	5, 6, 7, 9, 11	10, 1 (box), 0 (slab), 5, 2	15, 16, 18, 35, 59

To expect a very good performance, the bridge for the application of the WIM+D system should be chosen as follows:

- Number of main girders ideally between 2 and 4, and up to 8,
- Span length ideally between 30 m and 45 m,
- Isostatic decks with more than one span give the best results (bridges 12 and 13).

The type of material, whether reinforced or prestressed concrete, composite deck with steel main girders or even historical iron truss, has no significant incidence on the performance.

5.2 Additional conditions for axle detection

The previous considerations apply for the GVW estimation only. The axle detection and axle load estimation come as an option and are not possible for every bridge. The technical

condition to ensure an efficient axle detection is to be able to measure, on some locations on the bridge deck, a significant local bending effect, the influence line of which is shorter than the usual spacing between successive axles (around 2 m, for example).

This is achieved on thin slab structures which carry the pavement between girders. However, the slab must be thin enough to present sufficient bending under the effect of a single wheel, and the usual transverse location of the wheels needs to be somewhere on the slab, ideally just above the dedicated axle load sensors, and not right on the main girders.

These constraints leave only few possibilities among the fifteen tested bridges. The only one with good performance for the axle detection is bridge 15, with a very thin UHPFRC slab spanning the two lateral girders, and thus ensuring that we have both always the wheels on the slab, and the slab itself flexible enough.

6 CONCLUSIONS

With fifteen very different bridges monitored since 2018, the WIM+D system by OSMOS Group has significant feedback to get conclusions about its applicability depending on the type of bridge.

For the gross vehicle weight (GVW) estimation, the ideal bridge would be a reinforced or pre-stressed concrete beams, or composite bridge deck, with few main girders (2 to 4) and a span length between 30 m and 45 m, with more than one span, and, for the best performance, isostatic. This case allows to expect a percentage of accuracy of 5% or less, and one of the tested bridges was accepted in class A(5) of COST 323. At the opposite, thick concrete slabs with significant skew angle, and very long highly hyperstatic bridge decks, give less accurate results. Interestingly, very good performance has been achieved on historical iron truss bridges, despite of hyperstaticity.

Axle load detection through the WIM+D process still deserves some improvements. One of the tested bridges was accepted in class B(10) of COST 323 for the axle load estimation, with a very favorable configuration comprising an UHPFRC thin slab for measuring local bending effects. Research is currently going on for that specific point, to allow axle detection through a better identification of superimposed influence lines inside the measured signal, involving advanced regression and regularization methods.

Estimation of remaining fatigue life of railway bridges using measurements from the WIM system

M. Zakharenko, G.T. Frøseth & A. Rönquist

Norwegian University of Science and Technology (NTNU), Trondheim, Norway

ABSTRACT: This study presents an approach to estimate the remaining fatigue life of railway bridges using the fatigue load model and its calibration with the data from a Weigh-in-Motion (WIM) System. The basement of the model is an assumption that damage caused to the infrastructure by each train passage equals the damage of the most damaging train of the traffic at the site. The calibration of the model is performed using the measurements of strains on rails of the Sokna bridge (Dovreline), Norway. The idea of calibration is to guarantee that the load model induces the same fatigue damage as actual traffic. To simplify and unify the analysis influence lines (IL) approach, the standard method for predicting the stress histories of railway bridges, is used in the load model. Correction factors for calibration the model estimations are obtained for the fifteen most common IL for five main groups of trains.

1 INTRODUCTION

Railway infrastructure is an essential part of every country, and its degradation is an important question. Railway infrastructure, especially in Norway, includes a lot of bridges. For example, Norwegian railway system includes more than 2300 bridges. About 40% of all bridges are steel bridges, and they have material fatigue as a primary damage mechanism (Sustainable Bridges, 2007). Collapses of bridges lead to catastrophic consequences such as loss of human lives and high expenses to renovation. The above facts make fatigue of railway bridges a significant topic to study.

There are two approaches to estimate remaining fatigue life. In the case of a crack that has already been detected, the fracture mechanics approach is applicable for the estimation of the remaining fatigue life (Lovejoy, 2003). When the initial crack size is not available, the combination of a fatigue endurance model (Taras & Greiner, 2010) and a damage accumulation model is used (Fatemi, & Yang, 1998). The description of loading cycles experienced by the material is necessary for both approaches, and a fatigue load model is required. Fatigue load model represents traffic conditions at the bridge and usually it consists of a reference load and a set of calibrating the damage from reference load to the actual damage in the bridge (Hirt, 1982). Based on rolling stock data, statistics, and operational rules the Norwegian load model was established (Frøseth & Rönquist, 2019a). The measurement station collecting loads and geometries of trains was presented (Zakharenko et al., 2022a). The calibration coefficients for the Norwegian fatigue load model were calculated (Zakharenko et al., 2022b).

This paper is organized as follows. First, the theoretical background behind the fatigue load model is presented at Section 2.1. Next, the measurement station that was used to obtain traffic conditions is described at Section 2.2. Methodology to calculate correction factors for the calibration of the fatigue load model is described at Section 2.3. Section 3.1 presents measured traffic conditions and defines five main groups of trains. Section 3.2 demonstrates the level of conservatism of the load model and represents obtained correction factors. Finally, conclusions regarding the estimation of fatigue life using weigh-in-motion system are drawn.

2 METHODS

2.1 Fatigue damage and load model

Fatigue is a damage mechanism characterized by the initiation and propagation of the crack under cyclic loading of the material. Fatigue endurance curve (Wagener & Melz, 2018), S-N curve, is a dependency defining the number of loading cycles N with a stress range S that material can resist before failure. The classical and simple fatigue endurance curve is defined by Basquin's relation (Taras & Greiner, 2010):

$$N(S) = CS^{-m} \quad (1)$$

where C and m are experimentally obtained fatigue resistance parameters.

Miner's damage accumulation rule is used to consider different stress ranges induced by varying loads. It states that the cumulative fatigue damage D is equal to the sum of damages induced by each stress range individually (Fatemi & Yang, 1998):

$$D = \sum_i \frac{1}{N(S_i)} = \frac{1}{C} \sum_i S_i^m \quad (2)$$

where stress ranges S_i can be obtained from stress history by rainflow cycle counting (Amzlag et al., 1994).

The stress histories are usually described with static load function $f(x)$. The function can be defined through sum of influences of train axles:

$$f(x) = \sum_{i=1}^{n_p} p_i \delta(x - x_i) \quad (3)$$

where n_p is the number of the axles in train, p_i is axle load of the axle i , $\delta(x)$ is the Dirac delta function, x_i is coordinate of axle i .

Influence lines (IL) approach to static analysis is a common approach to predict stress histories in studying of railway bridges (Imam & Righiniotis, 2010). Influence line is a representation of a fatigue component in the form of the response of a structure to a unit load located at horizontal line. Table 1 shows IL representing the majority of critical components of railway bridges. IL can be obtained from measurements (OBrien et al., 2006) on real structures as well as from numerical modeling (Jepsen & Damkilde, 2018).

The response of a structure consists of two parts: static and dynamic. The static response $z_0(s)$ is a convolution of the load function and the IL (4), where $*$ is a convolution operator, s is a distance that the train has passed along the load path of the IL.

$$z_0(s) = (f * l)(s) \quad (4)$$

The dynamic part is defined through dynamic amplification factor (Liu et al., 2013):

$$\Phi = \Phi(v, L_\Phi) \quad (5)$$

where v is a train speed, L_Φ is length of IL.

The total response of a structure $z(s)$ than:

$$z(s) = \Phi(v, L) \cdot \sum_{i=1}^{n_p} p_i l(s - x_i) \quad (6)$$

The damage caused to the infrastructure by the train passage can be calculated using formulas above. To estimate the remaining fatigue life the first step is to establish a load model of past traffic at the site. Taking the assumption that each train passing a bridge causes to the infrastructure damage that is equal to the damage from the most damaging train at the site the fatigue load model was established for Norway. The traffic conditions of Norwegian railway system were collected (Frøseth & Rönquist, 2019a). Most damaging trains were identified with the help of the late acceptance hill climbing method for four time periods (1900–1930,

1930–1960, 1960–1985 and 1985–present) and two train types (Frøseth & Rönnquist, 2019b). The load functions of identified passenger and freight trains for the last period are presented in Figure 1. Then the load model was established on the rolling stock data, operational rules, and statistics (Frøseth & Rönnquist, 2019c).

However, fatigue load model includes load model as well as its calibration. To calibrate the model to actual traffic real loads were measured, see details in next section.

Table 1. Influence lines representing the majority of critical components of railway bridges. The table is adopted from Zakharenko et al. (2022b).

IL	Shape	Base system	Description
1		-	Total load effect
2			M_{AB}
3			V_{AB}
4			M_{AB}
5, 5r			M_A, M_B
6, 6r			M_{AB}, M_{BC}
7			M_B
8			M_{BC}
9, 9r			M_B, M_C
10, 10r			M_{AB}, M_{CD}

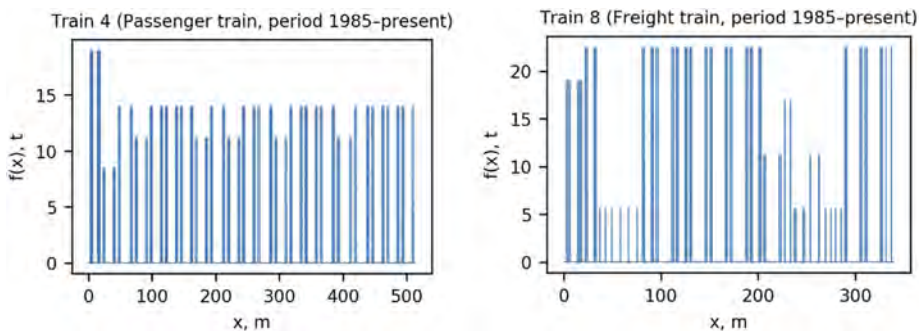

Figure 1. Load functions of the most damaging trains (last time period) from Norwegian fatigue load model. Figures are adopted from Zakharenko et al. (2022b).

2.2 Measurements

The measurement station is placed at one of the Norwegian railway lines, Dovreline, that connects Oslo and Trondheim. The Sokna bridge (Lundamo station) has low permissible speed (50 km/h) which helps the measurements to represent static part of the loading mostly (the dynamic part is negligible). The station uses for measurements six strain gauges placed at rails (three channels are at right rail, three are at left rail) and one temperature sensor. A photo of strain gauges of one channel is depicted in Figure 2. Every strain gauge forms one of the six strain channels.

The signal from one channel is filtered with the help of the moving average filter that removes random noise and smooths the signal. Next, the bias is removed from the smooth signal (Figure 3). Figure 4 shows the example of the final result (output of the strain channel) of measurement of the passage of one passenger train (one locomotive, six wagons).

The wheel loads are obtained from the output of the strain channels with Equation (7):

$$F(t) = V \cdot \frac{G}{4} \cdot C \cdot \varepsilon \tag{7}$$

where $F(t)$ is a vertical force from the wheel that the rail is subjected to in the middle between gauge pair, V is the input excitation voltage, G is a gauge factor, C is a calibration factor converting the voltage output of the system to tonnes, ε is an output signal of one channel.

To obtain the axle load p_{axle} of the train passing the measurement station the Equation (8) is used:

$$p_{axle} = median(w_{L1}, w_{L2}, w_{L3}) + median(w_{R1}, w_{R2}, w_{R3}) \tag{8}$$

where w_i is the final load obtained from channel i (the wheel load since gauges placed on the rails). The examples of load functions that are the goal of measurements can be found in Table 2.

Figure 2. Placement of strain gauges of one channel on the rail.

Figure 3. Processing of the signal from the strain gauge.

The details regarding the measurement station, the thorough description of an approach to proceed raw measured data and question of the measurement errors can be found at Zakharenko et al. (2022a).

2.3 Model calibration

The fundamental idea of the calibration is to adjust damage induced by the load model to the damage of the actual traffic. To achieve this goal the damage D_{model} caused by the model train (the most damaging train) and damage D_i caused by the real measured train are compared. The relationship γ_i between these damages (9) shows the level of conservatism of the model.

Figure 4. Example of output of one channel after passage of the passenger train consisting of one locomotive and six wagons.

$$\gamma_i = \frac{D_{model}}{D_i} \quad (9)$$

The total damage of n trains passed measurement station should cause to the infrastructure the same damage that induced by the model (n passages of the model train corrected by the correction factor γ_m).

$$\sum_{i=1}^n D_i = n \frac{D_{model}}{\gamma_m} \quad (10)$$

Finally, plugging D_{model} from (9) we obtain a formula for the calculation of the correction factor γ_m that calibrates the model to the actual traffic:

$$\gamma_m = \frac{n}{\sum_{i=1}^n 1/\gamma_i} \quad (11)$$

3 RESULTS AND DISCUSSION

3.1 Main train groups

The measurement station has registered more than 10,500 passages of trains. The main groups of trains are presented in Table 2, the algorithm to filter trains by types is published in Zakharenko et al. (2022a). There are two train types in Norway, passenger and freight. Passenger trains can be categorized in a sense of moving force, passenger trains moving by the locomotive and passenger Multiple Units (one of the wagons is motorized, locomotive is absent).

The distribution of percentage of measured trains by types is next: the passenger trains with locomotives consists about 6% of measured traffic, freight trains is 24%, MU Class 93 is 5%, MU Class 92 is the greatest part, and it composes about 49% of traffic, MU Class 73 is 10%. The remaining trains are service trains, single or double locomotives that do not have great damage potential and consequently can be excluded from the analysis. There are also MU compositions consisting of two or three MU of one type attached together, they are extremely limited in number and included in the main MU groups.

3.2 Calibration factors

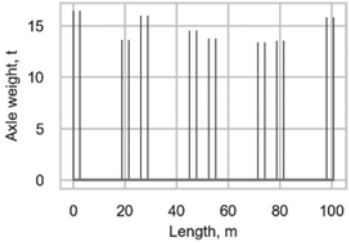

To study the level of conservatism and to obtain calibration coefficients for the model all announced trains were compared with the model trains (the most damaging trains) in a sense of damage that a train causes to the infrastructure. In different words, γ_i were calculated individually for every single train (passenger trains were compared with the most damaging passenger train, freight trains with the most damaging freight train), γ_m were calculated for each train group. γ_m are presented in Figure 5.

Table 2. Main groups of trains. Illustrations are adopted from Zakharenko et al. (2022a), Zakharenko et al. (2022b).

Train type	Load function	Photo
Passenger (with locomotive) 6%		
Freight (with locomotive) 24%		
MU Class 935%

The chart displays several vertical bars representing axle weights at various positions along the train length.</p>	 <p>A photograph of a high-speed train, likely a Shinkansen, stopped at a station platform. The train is white with red and blue accents.</p>

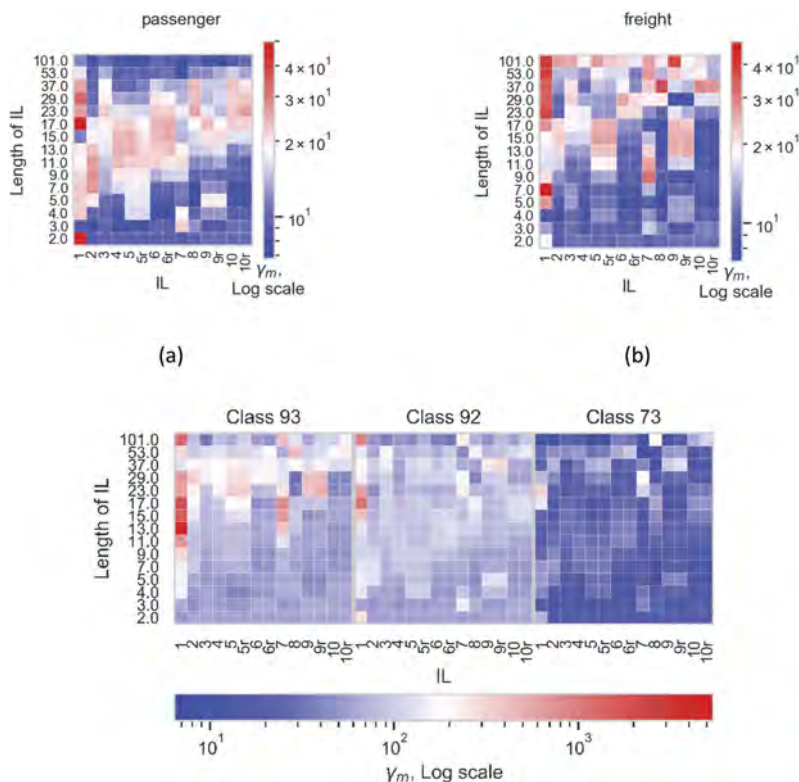

Figure 5. Correction coefficient γ_m for a) passenger trains, b) freight trains with locomotive and MU c) Class 93, Class 92, Class 73. The red lines are γ_m for studied cases.

The most conservative estimations the model gives for MU Class 92 since the train is much lighter than the model train and has a smaller number of axles. The closest to reality estimations the model gives for passenger trains. However, estimations are too conservative.

As the result, the calibration must be done since the level of conservatism of the model is excessive. The tables with exact numbers for the model calibration are presented in Zakharenko et al. (2022b). For quick estimations the minimum correction coefficients among all damage cases (IL length with the type of IL) can be used. According to Zakharenko et al. (2022b) the calibration can be performed with $\gamma_m=6.4$ for freight, passenger with locomotive and Class 73 trains, and $\gamma_m=32.7$ for Class 92 and Class 93.

4 CONCLUSIONS

The question of accurate estimation of the remaining fatigue life, and consequently maintenance, of railway bridges is essential for countries around the world because of a high importance of railways and catastrophic consequences of bridge collapses. The fatigue load model for estimation of residual life of railway bridge consists of artificial load and calibration coefficients.

At current work the Norwegian load model plays the role of the artificial load. The basic assumption of the model is that each train that passes the bridge is equal to the most damaging train at the site in a sense of damage causing to the infrastructure. The load model incorporated the influence lines (IL) approach to represent most critical details in the structure of the railway bridge. The model distinguishes two types of trains, passenger trains, and freight trains.

The calibration of the model is suggested to be made with the help of the weigh-in-motion (WIM) system having the six strain gauges. The method to proceed raw data from the measurement system is described. The main train groups are defined: freight train with locomotive, passenger train with locomotive, Multiple Units of three classes (Class 93, Class 92, Class 73).

The calibration coefficients (correction factors) for the fatigue load model are defined and discussed. The correction factors for the individual trains were calculated, the correction factors for each of the main group of trains were obtained. The load model is acknowledged to be too conservative. The suggestion is to use correction coefficients. The quick estimations can be performed with calibration of model with the coefficient 6.4 for freight, passenger with locomotive and Class 73 trains, and $\gamma_m = 32.7$ for Class 92 and Class 93.

Bridge-weigh-in-motion by strain of transverse stiffener and heavy-truck traffic characteristics in Fukuoka area, Japan

E. Yamaguchi, Y. Furusato, R. Nakamura & K. Horiuchi
Kyushu Institute of Technology, Kitakyushu, Japan

ABSTRACT: Information on actual traffic loads travelling along highways is valuable to determine maintenance scheme of bridges. The techniques that weigh trucks in motion, known as weigh-in-motion have attracted many highway engineers and researchers. One of such techniques is based on the deformation of a bridge and is called bridge-weigh-in-motion (BWIM). Although relatively inexpensive, the conventional BWIM requires the strains of transverse stiffeners for supplemental information in addition to the strains of main girders. Effort has been made to conduct BWIM only by the strains of transverse stiffeners. It was successful for truck-load estimation and then extended to estimate axle loads. By this economical axle-load estimation method, the axle loads are evaluated and analyzed. The susceptibility of the lane to fatigue is then discussed.

1 INTRODUCTION

Needless to say, the road infrastructure is of vital importance for the society. However, in many countries their deterioration due to age is now a big concern, and a good maintenance scheme is urgently needed to balance maintenance cost and the serviceability of road infrastructure. A factor that deteriorates the road infrastructure is traffic load. The information on actual traffic loads travelling along highways is therefore valuable to determine maintenance scheme of bridges. Because of that, the techniques that weigh trucks in motion without disturbing traffic flow have attracted many highway engineers and researchers. Those techniques are called collectively weigh-in-motion.

One of the weigh-in-motion techniques is based on the deformation of a bridge and is called bridge-weigh-in-motion (BWIM). The technique was first explored by Moses (1979). Because of its lower cost than pavement scales, much attention has been drawn to BWIM in Japanese bridge engineering community (Matsui & El-Hkim 1989, Ojio et al. 2001, 2018, 2019, Miki et al. 1987, 2001, Ishio et al 2002), as maintenance work is getting very important in recent years in Japan.

A group of the authors has applied BWIM to a regional project in 2002 (Yamaguchi et al. 2004, 2009). It was to find out actual truck loads on National Route 201. A problem encountered in this project was that a two-span continuous bridge with skew was the only bridge available to the project while a short, simply-supported steel bridge with no skew is ideal for BWIM. Therefore, a careful preliminary field test with known truck loads was conducted, having shown that even this type of bridge could be used for BWIM. The method for this BWIM is based on that employed by Miki et al. (1987, 2001). The estimates of truck loads are obtained by the strains of main girders. Those strains are however insufficient to conduct BWIM. The supplemental information such as truck velocity is required, for which the strains of transverse stiffeners are also needed.

After the project, the possibility of estimating truck loads solely by the strains of transverse stiffeners was explored (Yamaguchi et al. 2010). It was successful, showing that the proposed approach can give a good estimate of the truck load, provided that the transverse stiffeners

are chosen carefully. The method is economical, reducing the BWIM cost, since the required strain measurements are much less.

Figure 1. Illustration of variables in Equations (2) and (3).

The renewal project of intercity expressway is now underway in Japan. This is a big project, the cost of which is estimated at JPY 3 trillion (about USD 231 billion). Much of the cost would be spent for the replacement/repair of the bridge deck. For the damage of the bridge deck, axle load is known to be more responsible than truck load. Against this background, the method of estimating axle load by using the strains of transverse stiffeners only has been explored successful (Yamaguchi et al. 2021, 2022) which is economical and of much help for the maintenance of the bridge deck and thus the bridge itself. In Japan, a large number of bridges, 71% of them, belong to municipal governments that suffer budget deficit constantly. The proposed method should be able to help those bridge owners assess the influence of traffic loads and construct efficient maintenance scheme with affordable cost.

The axle-load estimation method is given first in this paper. Solving a set of simultaneous equations each of which is associated with a different lane, the approach is mathematically more consistent than that in the past approach. The axle loads are evaluated and analyzed by this approach, based on which the susceptibility of the lane to fatigue is discussed.

2 AXLE-LOAD ESTIMATION

The axle load of a truck is estimated from the strain in the transverse stiffener induced by the truck running on the bridge.

Suppose that at time t , an n -th axle of a truck in Lane l is located at a position x_{nl} . The strain ε_i induced in the transverse stiffener S_i in Lane i is expressed as

$$\varepsilon_i(t) = \sum_{l=1}^{N_l} \sum_{n=1}^{N_k} I_{il}(x_{nl}(t)) A_{nl} \quad (1)$$

where N_l = the total number of lanes of the highway; N_k = the total number of axles of the truck; A_{nl} = the axle load of the n -th axle of a truck in Lane l ; and I_{il} = the influence line function, giving the normal strain in the vertical direction in S_i induced by the unit load of 1 kN at the position x_{nl} . I_{il} is therefore a function of x_{nl} . The influence line function is obtained by the 3-D finite element analysis.

In the case of a two-lane bridge, $N_l = 2$, as illustrated in Figure 1, Equation (1) is written explicitly as

$$\varepsilon_1(t) = \sum_{n=1}^{N_1} I_{11}(x_{n1}(t)) A_{n1} + \sum_{n=1}^{N_2} I_{12}(x_{n2}(t)) A_{n2} \quad (2)$$

$$\varepsilon_2(t) = \sum_{n=1}^{N_1} I_{21}(x_{n1}(t)) A_{n1} + \sum_{n=1}^{N_2} I_{22}(x_{n2}(t)) A_{n2} \quad (3)$$

If the estimated axle loads are good, $\varepsilon_f(t)$ should be close to the measured strain ε_f^* . Therefore, the axle loads should be estimated by minimizing D defined by the following equation:

$$D = \sum_{m=1}^M \{\varepsilon_1^*(t_m) - \varepsilon_1(t_m)\}^2 + \sum_{m=1}^M \{\varepsilon_2^*(t_m) - \varepsilon_2(t_m)\}^2 \quad (4)$$

where M = the number of strain measurements; and t_m = the time at the strain measurement. The axle load A_{nl} is to be obtained by solving the following set of simultaneous equations:

Figure 2. Plans of Sasaguri Bridge.

$$\frac{\partial}{\partial A_{n1}} \left[\sum_{m=1}^M \{\varepsilon_1^*(t_m) - \varepsilon_1(t_m)\}^2 \right] + \frac{\partial}{\partial A_{n1}} \left[\sum_{m=1}^M \{\varepsilon_2^*(t_m) - \varepsilon_2(t_m)\}^2 \right] = 0 \quad (5)$$

$$\frac{\partial}{\partial A_{n2}} \left[\sum_{m=1}^M \{\varepsilon_1^*(t_m) - \varepsilon_1(t_m)\}^2 \right] + \frac{\partial}{\partial A_{n2}} \left[\sum_{m=1}^M \{\varepsilon_2^*(t_m) - \varepsilon_2(t_m)\}^2 \right] = 0 \quad (6)$$

As discussed in Yamaguchi et al. (2010, 2021), depending on the layout of the lateral members of the bridge such as a cross girder between main girders, the influence of axle loads of the truck traveling on an adjacent lane would be negligible. In that case,

$$I_{il} = 0 \text{ for } i \neq l \quad (7)$$

The equations would be simpler and easier to solve.

The truck velocity is obtained by measuring the strains of two transverse stiffeners under each traffic lane. To that end, the identification of the strain responses due to the same truck is required. This has been done by using the auto-correlation function. (Yamaguchi et al. 2004). Once the axle loads are obtained, the truck load can be computed by simply taking the sum of the axle loads.

3 VALIDITY

3.1 Field test

The validity of the proposed method is studied by using the field test data with Sasaguri Bridge. The field test was conducted in 2003. Sasaguri Bridge is located on National Route

201 and consists of two parallel bridges, the up-lane bridge and the down-lane bridge. Each bridge has two lanes, and each bridge is for traffic in one specific direction, up or down. The up-lane bridge is about 70 m long while the down-lane bridge is about 80 m long. Otherwise, they are very similar to each other. Both are a two-span continuous plate-girder steel bridge with five main girders. The plans are presented in Figures 2.

The circles in Figure 2 show the locations of the transverse stiffeners whose strains were measured in the field test. The strain measurement was carried out using two transverse stiffeners in each lane to evaluate the truck velocity. The strains measured at U1A, U4B, D3A and D5A are made use of also for the axle-load estimation. Therefore, the strain influence line at each of these four transverse stiffeners is obtained by the three-dimensional finite element analysis of Sasaguri Bridge with the single axle load travelling on the lane. The magnitude of the axle load for the analysis is 1 kN. Nastran (MSC 2014) is used for the analysis.

	AXLE WEIGHT			GROSS WEIGHT
	a ₁	a ₂	a ₃	
TRUCK A	48.1	77.1	74.2	199.4
TRUCK B	58.7	71.1	66.2	196.0
TRUCK C	52.6	58.4	49.6	160.6

UNIT : kN

Figure 3. Calibration trucks.

The field test was conducted with three calibration trucks shown in Figure 3. The following four patterns of traffic situation were considered in the field test:

- Pattern 1: Only one truck runs
- Pattern 2: Two trucks run in the same lane
- Pattern 3: Two trucks run side by side
- Pattern 4: Two trucks run in the same lane while the other runs in the other lane

Figure 4 illustrates the four traffic patterns. For each pattern, various combinations of the three trucks were considered and the same truck-running test was repeated three times since variation in the measurement is expected. The number of the truck-running tests amounted to 60. It is noted that to enhance the reliability of the field test data, traffic was controlled so that no public vehicles would run on the bridge during each truck-running test. The same test data were used previously and more details of the test are available in there (Yamaguchi et al. 2004, 2009).

3.2 Estimation result

First, the axle loads are estimated, assuming that the influence of axle loads of the truck traveling on the adjacent lane is negligible. In short, Equation (7) is applied, which then requires much less computational cost.

For all the patterns in the up-lane bridge and Patterns 1 and 2 in the down-lane bridge, the average errors are smaller than 10%. Some of the maximum errors are a slightly larger than 20%, which are still considered acceptable for practical purpose. This result ensures that the influence line function obtained by the 3-D finite element analysis is good. On the other hand, much larger

error is observed for Patterns 3 and 4 in the down-lane bridge, the patterns where trucks run on both the cruising and passing lanes. Which suggests that the influence of the truck on the adjacent lane cannot be ignored in the down-lane bridge.

The axle loads for Patterns 3 and 4 in the down-lane bridge are re-estimated without applying Equation (7). The estimations are improved considerably with the average error of up to 7.2%, and the estimate accuracy is now considered acceptable for practical purpose. Besides, these traffic patterns are seldom observed, little influencing the overall result of axle loads on this highway anyway. The improvement is more discussed by Yamaguchi et al. (2022).

It is therefore concluded that the estimation of axle loads solely by the strains of transverse stiffeners is possible.

4 AXLE LOADS OF HEAVY TRUCKS

Strain measurement was carried out from March 3, 2004 to November 30, 2004. Because of the trouble of the measurement device, no data were taken for 44 days and hence the total number of the measurement days is 229.

Figure 4. Traffic situations in field test.

The legal limit on the truck load is 245 kN in Japan. For a truck heavier than the limit to run, permission must be obtained. Yet it is generally believed that quite a few heavy trucks run on highways. In the present research, the characteristics of the traffic flow of those heavy trucks is focused on, because the information on the traffic flow of those heavy trucks is very scarce if available. The strain measurement was 18 years ago, yet the traffic volume on this highway hasn't changed much: the traffic volume per day is 35363 in 2005, 35235 in 2010 and 36289 in 2015 (because of the COVID-19, the survey hasn't been conducted in recent years). Hence, the data to be used can be considered still good. In what follows, a truck heavier than 245 kN is simply referred to as a heavy truck or merely a truck for the sake of simplicity. Photos of heavy trucks were also taken. The heaviest truck found in the project is shown below. The truck didn't run in the way that a heavy truck is supposed to run: it should be accompanied by two cars, one in front and the other behind, but no such cars were observed. The truck weight was estimated as 97 metric tons (951 kN), which is about 3.9 times larger than the legal limit.

The damage due to traffic load is greatly influenced by the magnitude of the load and the number of loads. The influence on the fatigue damage is not simply proportional to the magnitude of the load. The welding is one of the most susceptible parts to fatigue damage in a steel bridge, and it is known that the damage would be in proportion to the cube of the applied load. In short, the axle load of 200 kN gives the damage 8 times larger than 100 kN-axle-load, for example. Based on that, Figure 6 shows how many axle loads effectively equivalent to 98 kN-axle-load, the legal limit, passed on each lane during the period of the measurements for the project UL and DL

Figure 5. The heaviest truck observed in the project.

Figure 6. 98 kN-axle-loads travelling on each lane.

stand for the up-lane bridge and the down-lane bridge, respectively, and the subscripts of c and p stand for the cruising lane and the passing lane, respectively.

As observed, since 45% of the 98 kN-equivalent axle loads traveled on UL_C , the members that support UL_C are most susceptible to fatigue damage. The members that support DL_C are also susceptible to fatigue damage since 35% are passing on DL_C . On the other hand, fatigue damage is much less expected in in the members that support UL_P or those that support DL_P . The possibility of fatigue crack development in the members that support UL_C is 7 times larger than that in the members supporting UL_P . The possibility of fatigue crack development in the members that support DL_C is 4 times larger than that in the members supporting DL_P . Members related to the cruising lane should be inspected very carefully.

Figure 7 presents the rate of heavy trucks in terms of the number passing on each lane. Obviously much more heavy trucks run on the cruising lanes than on the passing lanes. To be interesting, the proportions in Figures 5 and 6 are not much different. They are indeed very similar to each other, as can be seen in Figure 8, although the truck weight varies widely. The similarity of the two figures implies that a heavy truck tends to have more axles so as to reduce the axle load. Which is indeed confirmed by the result of Yamaguchi et al. (2022).

By estimating axle loads travelling on various bridges in a region, it can be figured out which lane of a bridge is the most susceptible to damage, which lane follows it and so forth. Such data on axle loads should then be able to help construct an effective scheme for the maintenance of the bridges in the region.

5 CONCLUDING REMARKS

An economical BWIM to estimate axle loads was briefly reviewed. Only strains in two transverse stiffeners per lane are needed for the method. It is therefore much inexpensive to evaluate the influence of traffic loads. In this paper, an application of the method to bridge maintenance was demonstrated: in Sasaguri Bridge the cruising lanes are 4 to 7 times more susceptible to fatigue crack development than the passing lanes, suggesting that cruising lanes and the members that support cruising lanes should be taken care of much more in maintenance work. The estimation and analysis of traffic loads should thus help construct a good maintenance scheme.

ABSTRACT: Bridge weighing in motion (BWIM) detects heavy vehicles passing a sensor or multiple sensors. Sensor technology with rapid development enables us to monitor bridges with multiple types of sensors and cameras. These sensors are installed at different positions and require synchronization. In this paper, we propose a novel vehicle detection framework for the multiple strain sensors BWIM systems based on a novel deep sensor-fusion approach. The proposed framework is composed of three components. The first component collects and denoises the strain sensor signal. Then, the cleaning signals are processed by the Wavelet transform in the second component to obtain the corresponding coefficient matrices. Finally, the third component feeds the coefficient results into an improved deep neural network. It extracts complex features through multiple neural layers and can detect vehicle properties from multi-view signals. The performance of the proposed framework is evaluated on real-world bridge health monitoring datasets. The results of the experiments show that the proposed framework is reliable and effective for vehicle detection in the BWIM system.

1 INTRODUCTION

Advanced technology in the fields of sensors, data collection and communication, signal analysis, and data processing have brought great benefits to structural health monitoring. Bridge Health Monitoring System (BHMS) usually deploys surveillance cameras to visually identify passing vehicles. BHMS also set up multiple types of sensors at different positions to measure its changes over time. The sensor signal data provide meaningful information on passing vehicles. There are two main types of sensors, such as accelerometers and strain meters, for using vehicle detection task (Alegre-Sanahuja et al. 2016, Doan and Takasu 2017, Doan and Takasu 2020). The accelerometer sensor senses the vibration, while the strain meters measure the strain of the bridge induced by passing vehicles. However, the authors in (Alegre-Sanahuja et al. 2016) only use one strain signal view to detect spikes for vehicle passing, whereas (Doan and Takasu 2017, Doan and Takasu 2020) only use accelerometers signal data to detect oscillations for vehicle crossing in a bridge. According to (Alegre-Sanahuja et al. 2016), the Wavelet method transforms each signal into scale-time space before searching for spikes in the originals signals. In (Doan and Takasu 2017), the acceleration signal is denoised using morphological component analysis with the tunable Q-factor wavelet transform to reveal oscillations that indicate events of passing vehicles in the signal. These researchers only focus on spike-by-spike sequences after applying wavelet transform to identify passing vehicles for a strain sensor or an accelerometer. There are two main vehicle-weighing aims. The first proposal is that the BWIM system detects overloaded vehicles to enforce laws. Then, the BMHS system can estimate the damage progression of bridges. Many researchers have been interested in the heavy vehicles detection task, which is an important component of the BWIM system. For BWIM, we consider the problem of vehicle detection in terms of multiple strain sensing.

(Kawakatsu et al. 2017, Kawakatsu et al. 2018, Kawakatsu et al. 2020) proposed the deep neural networks (DNNs)-based techniques for detecting overloaded vehicles crossing a bridge. These systems can help us to alert the serious damage caused by vehicle overloading to the bridge. The authors built a Traffic Surveillance System (TSS) that interacts with a surveillance camera. The system identifies a vehicle from the collected video by combining a moving-object detector. More specifically, the authors exploited a deep Convolutional Neural Network (CNN) (Ren et al. 2015) to recognize the individual passing vehicles. Their main aim is to extract free oscillations from the observed vibration data following vehicle-passing events. They observed that the extracted oscillations from sensor signals data caused by a large, heavy vehicle are preferred. However, the research projects only consider detecting vehicle passing based on CNN from image data. On the other hand, multiple strain meters provide the speed of the vehicles as well as their weight. Combining the multiple strain sensors from different views enables us to obtain the same information like vehicle speed and vehicle weight, which can be improved the performance of the system. Therefore, we consider how to use the rich information from sensor signals to support image-based TSS for the vehicle detection task. Deep multi-view representation learning methods aim to exploit consistency and complementary information between these views to learn new representations for the data. Therefore, these methods often have better generalization ability. Specifically, in our previous work (Vuong et al. 2022), we proposed an improved sensor signal alignment framework that combined dynamic time warping and the objective function of DNNs to align multiple sensor signals. It employs the generalized sequentially correlated autoencoders (GSCAE) model (Doan & Takasu 2020) for multiple sensor signal alignment. In this paper, we propose an improved vehicle detection framework based on a deep sensor-fusion approach. Firstly, the difference with the previous research, we process the original sensor signals by Wavelet transform methods to get the coefficients matrix. The signal processing can make rich information for the system instead of only using raw sensor signals. Based on exploiting DCCA method (Andrew et al. 2013), we propose deep sensor-fusion learning by using two autoencoders instead of feed-forward neural networks as in DCCA. It extracts complex features through multiple neural layers and can detect vehicle properties from the multi-view sensor signals.

The paper is organized as follows. Section 2 describes the problem settings for BWIM system. In section 3, we briefly present some background for the methods proposed in this article. The proposed framework and its main components are described in section 4. Section 5 empirically evaluates the performance of the proposed framework, and section 6 concludes the paper.

2 PROBLEM SETTINGS

Many researchers have been interested in the heavy vehicles detection task which is an important component of the BWIM system. A simple approach is to install an axle load meter on the road surface. It is difficult to retrofit existing bridges because paving requirements and meters can be fragile and require frequent repair. To solve the problems, BWIM systems address them by treating the bridge structure itself as a large weighing scale. The system uses data from strain sensors. These sensors are installed at different positions of the bridge, such as deck, girder, beam, and flange. Figure 1 (a) shows a typical BWIM, which installed multiple strain sensors at different positions on the bridge. Note that signal sensor datasets are synchronous and require alignment. Figure 1 (b) describes a strain signal sequence example with two spikes corresponding to the events that the wheels of vehicles pass over the sensor. Based on strain sensors analysis, we use multiple strain signals for vehicle detection to improve the performance of BWIM systems.

3 BACKGROUND

3.1 Continuous Wavelet Transform (CWT)

With the capability to provide both time and frequency domain information, wavelet analysis is mainly a technique for time-frequency analysis of signals, signal compression, signal denoising, and feature extraction. Wavelet transform decomposes a signal into a linear combination of basic functions, which are derived from one mother wavelet by means of dilation and translation. More specifically, given a 1D signal $f(t)$ that is a function w.r.t time t , CWT (Rhif et al. 2019) computes a 2D scale-time representation as follows:

$$C(a, b) = |a|^{-\frac{1}{2}} \int_{-\infty}^{\infty} f(t) \psi^* \left(\frac{t-b}{a} \right) dt, \quad (1)$$

where $C(a, b)$ represents the coefficients of CWT, (*) denotes the complex conjugate, ψ is the wavelet mother, a denotes the scaling parameter, and b is the time shifting parameter or translation.

For effectively representing patterns in the signal, the selection of the wavelet mother is crucial. According to (Ngui et al. 2013), the main challenge of using Wavelet transform is to select the most optimal mother for the different problems. Because the different mother Wavelets applied on the same signal may produce different results. The different Wavelets in scales and time are shifted along the entire movement and multiplied by its sampling interval to obtain significant physical, resulting in coefficients. This enables better characterizing oscillated behavior in signals.

3.2 Deep sensor-fusion learning
